Title: Decreased neurogenesis and abnormal development of ventricular zone and lateral ganglionic eminence in the embryonic brain of BTBR T+ tf/J mice: correlation between embryonic neuroanatomy and idiopathic autism spectrum disorder

Authors: *J. LEE, S. CHENG;
Dept. of Biol., William Paterson Univ., Wayne, NJ

Abstract: Autism spectrum disorder (ASD) is a developmental disorder, where genetic abnormalities and exposure to environmental agents during embryonic development have been suggested as possible causes. Using BTBR T+ tf/J (BTBR) mouse, an animal model for idiopathic ASD, we examined the pattern of neocortex development that may be associated with expression of ASD-like behaviors. In first experiment, to examine the pattern and location of embryonic neurogenesis, EdU (50mg/kg, IP) was injected to timed-pregnant BTBR and C57 dams, and embryos (E16 and E18) were removed 12hrs later. Brains were frozen-sectioned and processed for Click reaction. In second experiment, to examine the development and rate of maturation of cortical radial glial and intermediate progenitor cells, embryonic brains (E16 and E18) of BTBR and C57 mice were frozen-sectioned and double-labeled for TBR-2 and Sox-2 immunoreactivity. In C57 embryonic cortex, dense EdU-labeled cells were observed around the ventricular zone (VZ), with subventricular zone (SVZ) displaying moderate EdU-expression. Both the LGE and MGE expressed dense EdU-labeled cells. In autistic BTBR (E16 and E18), the VZ was thinner (~50%) and expressed fewer/diffuse EdU-labeling in VZ, SVZ and IMZ. The size of LGE and MGE were also smaller in BTBR and had significantly fewer EdU-labeled cells. Interestingly, these EdU-IR cells did not display the mediolateral migratory pattern. In C57 (E16 and E18), the Sox-2- and TBR-2-immunoreactive (IR) cells were observed in VZ and SVZ, respectively. In autistic BTBR, the VZ was thinner (~50%) and had fewer Sox-2-IR radial glial cells compared to C57. However, these radial glial cells were observed dispersed from VZ to IMZ indicating high migratory pattern towards cortical layer. The TBR-2-IR SVZ layer was also thinner in BTBR and had fewer intermediate progenitor cells compared to C57.The abnormal development of E16/E18 embryonic cortex seen in BTBR (1. decreased rate of neurogenesis in VZ, LGE, MGE; 2. decreased size of LGE and MGE; 3. decreased number of intermediate progenitor cells derived from radial glial cells; 4. increased rate of migration of radial glial cells

from VZ to IMZ) may be contributing factors that may predispose the BTBR with expression of ASD-like behaviors.

Title: Alterations in connectivity in the deeper layers of the developing in motor cortex in an ASD model of mouse

Authors: H. K. SRIVASTAVA[1], Y. SELVARAJAN[2], *S. BANDYOPADHYAY[2];
[1]Advanced Technol. Develop. Ctr., Indian Inst. of Technol. Kharagpur, Kharagpur, India; [2]IIT Kharagpur, Kharagpur, India

Abstract: Autism spectrum disorders (ASD) is a set of neurodevelopmental disorders are characterized by atypical repetitive behavior and motor movements along with impairments in speech and reciprocal communication skills as its core symptoms. Meaningful motor movements require correlated and sequential neural activity patterns in the motor cortex. Recurrent neural connections are critical in generation of correlated and sequential activity patterns in a network. Developmental aberrations in these recurrent connections within the motor cortex leading to an altered network structure could underlie atypical motor movements observed in ASD. We investigated the intra-laminar and extra-laminar excitatory connections of the deeper layers of the mouse motor cortex using simultaneous 2-photon MNI-caged glutamate uncaging and Ca^{2+} imaging based circuit mapping, *in vitro*. Typically developing (P1-P10) motor cortex circuitry was compared with that of *in utero* Valproic Acid (VPA) exposed ASD model mice. We found that the targeted (uncaged) neurons responded with similar reliability across trials to MNI-glutamate stimulation suggesting an intact neuronal firing thresholds but the response strengths of the connected neurons were significantly different (lower) in the VPA treated P1-P5 group as compared to control group. However, the probability of connections between neurons was significantly higher in the VPA treated P1-P5 age group as compared to control. Further, in the control groups, the connection probability increased with age whereas in the VPA treated groups, the connection probability decreased with age indicating an altered circuit development and

network architecture in the motor cortex in ASD. Such alterations within motor cortex circuitry in ASD could form the basis of atypical motor behaviour and also altered vocalization sequence generation in the pup isolation calls of the mouse model of ASD.

Title: Improved learning and increased sensory sensitivity in a cerebellar mouse model of autism

Authors: *M. OOSTLAND[1], M. KISLIN[1], Y. CHEN[1], T. CHEN[2], B. DEVERETT[3], S. S.-H. WANG[1];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Dept. of Neurolog. Surgery, Univ. of California, San Fransisco, CA; [3]Dept. of Anesthesiol., Stanford Univ., Palo Alto, CA

Abstract: Autism is associated with an increased sensory sensitivity with occasional islands of enhanced function. Here we report that a cerebellum-specific mouse autism model with progressive Purkinje cell degeneration, L7-Tsc1, shows enhanced learning on a sensory evidence-accumulation task (Deverett et al., 2018, eLife; Deverett et al., 2019, Nat Comm; L7-Tsc1 wildtype mice: median number of trials to reach final level of the task: 5106, n=23 mice; L7-Tsc1 mutant mice: 3410 trials, n=8 mice; $p < 0.01$). L7-Tsc1 mutant mice also had more eye blinks in response to air puffs to their whiskers (L7-Tsc1 wildtype mice: median number of eye blinks in response to an air puff of 25 psi, 15 ms: 2, n=15 mice; L7-Tsc1 mutant mice: 9 eye blinks, n=7 mice; $p<0.01$), suggesting increased sensory sensitivity. Faster learning was emulated in wildtype mice by increasing stimulus intensity (C57BL/6J mice, air puffs at 10 psi (normal intensity): 4275 trials, n=9 mice; C57BL/6J mice, air puffs at 20 psi: 2225 trials, n=9 mice; $p < 0.01$) or by pairing stimuli with cerebellar optogenetic activation (*Pcp2-Cre x Ai27D* wildtype mice: 3311 trials, n=5 mice; *Pcp2-Cre x Ai27D* transgenic mice: 2512 trials, n=6 mice; $p < 0.01$). Enhanced learning was accompanied by delays in complex-spike firing in Purkinje cells (n=12 cells from 5 L7-Tsc1 wildtype mice and n=8 cells from 4 L7-Tsc1 mutant mice; as well as n=13 cells from 4 *Pcp2-Cre x Ai27D* transgenic mice) whose time course was similar to that of increased activity in the anterior cingulate cortex (n=262 cells from 5 L7-Tsc1 wildtype

mice and n=312 cells from 6 L7-Tsc1 mutant mice; as well as n=260 cells from 4 *Pcp2-Cre x Ai27D* transgenic mice), a prefrontal region known to express evidence- and choice-related activity. Two cerebellum-specific forms of learning, delay eyeblink conditioning and delay tactile startle conditioning, were still impaired in L7-Tsc1 mutant mice compared with wildtype littermates. These results show that a brain-region-specific alteration that leads to cognitive and social endophenotypes can also selectively improve specific domains of function.

Title: Developmental progression of prefrontal circuit dysfunction in a SHANK3$^{-/-}$ mouse model of Autism Spectrum Disorder

Authors: *G. DEVIENNE, J. R. HUGUENARD;
Wu Tsai Neurosciences Inst., Stanford Univ., Palo Alto, CA

Abstract: Autism Spectrum Disorders (ASDs) are phenotypically and genetically heterogeneous behavioral disorders of neural development. A leading candidate gene is Shank3, with mutations occurring in 1 - 2% of affected individuals. Shank genes encode scaffolding proteins located at the postsynaptic density of glutamatergic synapses. Shank3 complete knockout mice (Shank3$^{-/-}$) exhibit phenotypes of neurodevelopmental disorders such as ASD. Despite numerous studies focusing on ASD Shank3-/- related pathophysiological circuit mechanisms in mature mice, little is known regarding ASD onset and its evolution through the development. Our team aims to fill this knowledge gap by studying the effect of Shank3$^{-/-}$ genetic mutation at different stages of postnatal development in a murine Shank3 model. We performed our study in the medial prefrontal cortex (mPFC), which plays an important role in social and cognitive behavior and

displays a critical period of development that coincides with the onset of ASD behaviors. We used local field potential (LFP) analysis in acute brain slices of adult wild type (WT) and Shank3$^{-/-}$ mice. We used linear silicon arrays, which allowed us to characterize mPFC function across the entire cortical column. Intracortical stimulation resulted in a distinct LFP laminar profile, which was deconstructed via current source density (CSD) analysis to identify local sources and sinks of neuronal signals. Pharmacological dissection isolated distinct presynaptic (fiber volley) and postsynaptic (excitatory and inhibitory) sources/sinks, each with a specific spatiotemporal profile. We identified a global mPFC hyperfunction, affecting pre- and post-synaptic (by ~1.5x at maximum stimulus) components, with greatest deficits seen in deeper neocortical layers (by ~2x). Such hyperexcitability is coherent with other studies and might explain a comorbid epileptic disorder. We began to investigate early time points; a first screening at P10 showed no significant difference suggesting that mPFC circuit dysfunctions appear later. P14 time point was next tested, as the Shank3 isoforms reach their maximal expression at this age. Interestingly, our preliminary data show a transient hypofunction of the mPFC at P14, suggesting that mPFC dysfunction may result from reduced early circuit activity that could disrupt normal circuit formation contributing to the acquisition of ASD features in adults. This project will reveal how postnatal circuit alteration is involved in ASD and, through ultimate identification of specific circuit elements/synapses responsible for early developmental changes, may help to identify possible therapeutic targets or windows.

Title: Brainstem white matter microstructure predicts sensory features in autistic adolescents

Authors: *O. SURGENT[1], D. DEAN, III[2], K. AUSDERAU[3], A. ALEXANDER[4], B. TRAVERS[3];
[1]Neurosci. Training Program, [2]Dept. of Pediatrics, [3]Occup. Therapy Program in the Dept. of Kinesiology, [4]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Autistic youth often demonstrate differences in sensory features that impact adaptive behaviors and quality of life (Baranek et al., 2006; Ismael et al., 2018). Recent work has demonstrated associations between sensory features and brainstem white matter in both autistic children and autistic infants (Surgent et al., in prep; Wolff et al., 2017). Specifically, more prominent sensory features have been associated with higher white matter structural coherence (higher fractional anisotropy [FA], lower mean diffusivity [MD]) in the middle cerebellar peduncle (MCP) and pontine white crossing tract (PCT). However, it is unclear whether these relationships remain throughout adolescence, a time of white matter maturation and development. Therefore, the present study investigated the relationship between brainstem white matter and sensory features in autistic adolescents. We collected information about sensory features via the Sensory Experience Questionnaire 3.0 and diffusion weighted imaging brain scans from a pilot sample of 26 autistic adolescents (ages 13-17 years). In addition to analyzing the relationship between sensory features and MCP and PCT using classical diffusion tensor imaging metrics (FA and MD), we implemented multi-compartmental modeling to extract neurite-specific measures of orientation dispersion index (ODI) and intracellular volume fraction (ICVF). The PCT was the only white matter area to show relationships with sensory features. Sensory features were negatively associated with MD (r=-.49, p=.01; Fig A) and positively associated with both ODI (r=.47, p=.02; Fig B) and ICVF (r=.48, p=.01; Fig C). Results indicate that the relationship between sensory features and brainstem white matter in autistic youth remains consistent throughout adolescence. Further, results suggest that increased white matter coherence in addition to increased neurite density and dispersion in the brainstem underlies sensory features. Future analyses will seek to further evaluate these relationships in a larger sample of autistic adolescents.

Title: Atypical emotional modulation of cognitive control in children with anxiety and high autistic traits

Authors: *T. S. MULLINS, J. HOGEVEEN;
Univ. of New Mexico, Albuquerque, NM

Abstract: Autism and anxiety independently affect a large number of children and children with autism are at increased risk for anxiety disorders. Yet, the degree to which anxiety's underlying neural mechanisms and clinical symptoms are transdiagnostic, or distinct in youths with comorbid autism, remains unclear. Here, we determined whether a classic finding in the cognitive neuroscience of anxiety—increased salience and attention to negative emotional stimuli—varies across children who do or do not also have elevated autistic traits. Specifically, we used the *Adolescent Brain Cognitive Development* (ABCD) study dataset to compare threat or negative emotion bias across 4 well-matched subgroups of 9-10 year old children: 1) high anxiety and low autistic traits (ANX; *N*=54), 2) high autistic traits and low anxiety (AUT; *N*=54), 3) high anxiety *and* autistic traits (ANX+AUT; *N*=54), and 4) low anxiety and low autistic traits (CTRL; *N*=54). This enabled us to isolate the effects of anxiety, autistic traits, and their interaction on the behavioral and neural correlates of emotional modulation of cognitive control using the ABCD study's emotional *n*-back (EN-Back) fMRI paradigm. Behavioral data indicated that fearful faces enhanced cognitive control performance specifically within the ANX group, but not in the ANX+AUT group, suggesting that the attention to threat bias often found in the anxiety literature may not be a characteristic of comorbid autism and anxiety. Neuroimaging analyses are ongoing and will hypothesize differential recruitment of prefrontal-amygdala circuitry in response to negative emotional faces in ANX relative to CTRL groups, and a lack of differences in these circuits between ANX+AUT and AUT. Our preliminary findings indicate that the attention to threat bias may be unique to children with anxiety and low levels of autistic traits, and may not be a mechanism driving anxiety in children with comorbid autism. This

would indicate a need for more transdiagnostic mechanistic studies to develop novel precision medicine approaches for treating children with anxiety and comorbid autistic traits.

Title: Dose-dependent effects of oxytocin on brain function during an interactive social game in Autism Spectrum Disorder

Authors: *E. ANDARI[1], A. S. COTTON[2], J. F. CUBELLS, JR[3], J. K. RILLING[4], L. J. YOUNG[5];
[1]Univ. of Toledo, Ruppert Hlth. Ctr., Toledo, OH; [2]Univ. of Toledo, Toledo, OH; [3]Dept. of Psychiatry and Beh. Sci., Emory Univ. Sch. Med., Dept. of Human Genetics, Emory Univ. Sch. Med., Atlanta, GA; [4]Dept. of Anthropology, Emory Univ., Atlanta, GA; [5]Ctr. for Translational Social Neurosci., Emory Univ., Atlanta, GA

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that is characterized by deficits in social interaction and communication. Oxytocin is a key modulator of social behavior. Acute administration of intranasal oxytocin (IN-OT) enhances social functioning in autism. However, long-term trials with IN-OT have yielded some inconsistent findings. Here, we conducted a dose-dependent study with IN-OT to examine target engagement for this treatment on the brain activity of adults with ASD. A total of 31 ASD participants were recruited from the Emory Autism Center in Atlanta. ASD subjects underwent four fMRI scanning sessions in which they completed an interactive social ball game. The social ball game consisted of playing with groups of individuals who gave either positive or negative feedback during the game. Participants also played the same game with computers. All patients received 4 doses of IN-OT (8IU, 24IU and 48IU) and IN-placebo in a randomized, double-blind, within-subject, placebo-controlled design. Visits were separated by a one-week interval. Participants played the ball game inside the MRI scanner (3T, Siemens) 60 minutes after receiving IN spray.ROI analysis on the basolateral amygdala, ventral anterior insula and ACC yielded a significant dose-dependent effect for oxytocin in response to social feedback, as compared to

computer feedback. Specifically, higher doses of IN-OT (48IU) enhanced the activity of these areas in response to negative and positive social feedback, compared to placebo and smaller doses. These findings show promising effects of IN-OT on brain function in Autism Spectrum Disorder in key brain areas known to be involved in social and emotional processes.

Title: Contrastive AI reveals the structure of individual variation in Autism Spectrum Disorder

Authors: *A. AGLINSKAS, J. HARTSHORNE, S. ANZELLOTTI;
Boston Col., Boston, MA

Abstract: Autism Spectrum Disorder is highly heterogeneous. Individuals with ASD differ in the severity of social and behavioral symptoms, and in their cognitive abilities. Most of the work done in this area focuses on comparisons between ASD and typically developing (TD) controls. Individual variation within ASD is less studied, but it is likely key to inform diagnosis and personalized interventions. However, ASD-specific neuroanatomical variation is entangled with variation due to other causes (e.g. age and gender), making it challenging to tell apart anatomical dimensions that are due to ASD, from those that are shared with the TD population. In this work we trained a novel deep neural network architecture to disentangle ASD-specific neuroanatomical variation from variability shared with typically developing (TD) participants. We trained a contrastive variational autoencoder (CVAE) on the ABIDE dataset (N=539 TD and N=470 ASD subjects) using brains extracted from anatomical T1w scans. For each subject, the CVAE separately learned a set of anatomical features that are common to both TD and ASD participants (like age and gender), and a set that are unique to ASD. Representational similarity analyses revealed that ASD-specific neuroanatomical features identified in this way capture individual differences in autism severity (ADOS) and symptoms (DSM-IV behavioral subtypes) irrespective of confounding variability in age, gender and scanner-type (these confounding variables were better captured by the CVAE's shared features).Next, to identify interpretable anatomical loci of individual variation - we reconstructed the anatomy of ASD participants only using shared features, generating “synthetic twin” brains without autism. Thanks to this

procedure, we identified two continuous dimensions of variation among ASD participants: one associated with structural changes in the thalamus; and second affecting the right somatosensory cortex and right superior longitudinal fasciculus.

Title: Specific Loss of Thalamic Modulation of Cerebellum-Neocortex Codevelopment in Autism Spectrum Disorder

Authors: *B. LI[1], F. D'OLEIRE UQUILLAS[1], E. BUEICHEKÚ[2], J. SEIDLITZ[3], H.-J. BOELE[1], J. VERPEUT[4], M. LATIF[1], R. GESUE[1], K. STEELE[1], M. TROTTER[1], T. FASULO[1], J. YAO[1], J. SEPULCRE[2], S. S.-H. WANG[1], J. GOMEZ[1];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Dept. of Radiology, Gordon Ctr. for Med. Imaging, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [3]Children's Hosp. of Philadelphia, Univ. of Pennsylvania, Philadelphia, PA; [4]Dept. of Psychology, Arizona State Univ., Tempe, AZ

Abstract: A diaschisis in cerebellar-neocortical pathways, related to Autism Spectrum Disorder (ASD), may be modulated by thalamic structural integrity. Previous tract-tracing work in mice has found that cerebellar-fugal pathways traverse specific thalamic nuclei. These pathways emerge from the coordinated development of multiple brain regions subserving a common functional specialization. Using structural MRI, we investigate the relationship between morphometric covariance in typically developing (TD) and ASD children amongst specific cerebellar lobules, thalamic nuclei, and somatosensory cortex.
Methods: T1w MRI data from 69 children from ABIDE (94% males, 40% controls, median age=8±2;range:5-17 years) were used to compute volume density (mm3) at every brain region of

the HCP-180, SUIT-Cerebellar-13, and Iglesias-Thalamic-25 atlases. Separately in TD and ASD, we assessed the following lateralized pathways based on covariation of brain volumes: Cerebellar Lobule I-IV, Crus I, and Lobule VI structural volume values were modeled as independent variables in predicting somatosensory cortex (SSC) volume, with thalamic nuclei volumes modeled as moderators: ventral-posterolateral (VPL), ventromedial (VM), medial-ventral reuniens (MvR), mediodorsal medial magnocellular (MDm), mediodorsal lateral parvocellular (MDl), laterodorsal (LD), medial geniculate (MGN), lateral geniculate (LGN), and anteroventral (AV). Results were corrected for multiple comparisons (FDRq < 0.05).
Results: In TD children, we found that the covariation between left/right cerebellar Lobules I-IV and contralateral SSC was moderated by contralateral thalamic MvR nuclei values ($p < 0.05$, Cohen's effects > 0.4). Covariation between left/right Crus I and contralateral SSC was moderated by contralateral MvR ($p < 0.05$, Cohen's effects > 0.4) and LGN values ($p < 0.05$, Cohen's effects > 0.5). We found similar relationships between Lobule VI and SSC with thalamic MDm and MGN ($p < 0.05$, Cohen's effects > 0.5). These relationships were not evident in ASD children ($p > 0.05$). Further, right SSC volume in ASD was significantly greater relative to TD ($p < 0.05$, cohen's effects = 0.48).
Conclusions: Consistent with the rodent literature, we show that the somatosensory cortex is a significant downstream target of the cerebellar-cortical pathway, and reveal for the first time that thalamic nuclei moderate volumetric trajectories between these distal brain regions. Disruptions in these pathways may result in social and cognitive impairment during development, such as in ASD. The ASD connectome across childhood may be leveraged as a biomarker of change in intervention studies.

Title: Neurophysiological and neurobiochemical alterations in cerebellar granule cells in kindled mice

Authors: *M. AGUERO MEDINA[1], J. ACOSTA MAGALLANES[1], C. RUBIO OSORNIO[1], L. HERNÁNDEZ LÓPEZ[1], J. BRITTO BRITTO[1], N. RIVERA SOTELO[2], V. CUSTODIO RAMÍREZ[1];

[1]Neurofisiología, [2]Neurocirugía, Inst. Nacional de Neurología y Neurocirugía MVS, Ciudad de México, Mexico

Abstract: The cerebellum plays a major role in the control of epilepsy. Epileptic patients have shown activation of the neocortical-pontocerebellar pathway, evidencing extensive participation of the cerebellum and the middle cerebellar peduncle in the neuropathophysiology of epilepsy. Afferent fibers of the cerebellum pass through the mossy fibers, exciting the granule and Golgi cells, both cell types are part of the cerebellar cortex. The aim of this study was to identify and analyze the neurophysiology and neurobiochemical changes produced after the kindling model in granule cells of the cerebellum in mice. In order to test this, we carried out calcium imaging and immunohistochemistry. The kindling model was carried out placing bipolar electrodes in the left basal lateral amygdala. Subsequently, the mice received a daily electric stimulus until each mice presented generalized tonic-clonic seizures. Two groups of mice cerebellum slices were used for calcium imaging. The cerebellum slices were incubated in (Flou 4-AM) a fluorescent calcium indicator. Thus, active cells were quantified by increased fluorescence. The second group of control and kindled mice were sacrificed by intracardiac perfusion to carry out an immunohistochemistry essay to quantify the expression of glutamate, GABA, c-Fos, GFAP, nNOS, iNOS, and the GABAA receptor in the cerebellum and cortex. All procedures followed the International Guide for the Care and Use of Laboratory Animals (NIH publication No. 86-23, revised 1987). Our results showed increased activity in cerebellar granule cells in kindled mice compared to the control group. Additionally, we also found significant increases in the immunopositivity expression of glutamate, GFAP, and GABAA receptor in granular cells of the cerebellum in addition an increasing trend was found of nNOS and iNOS. Moreover, a significant decrease in GABA and c-Fos was observed. In the cerebral cortex, we found a significant increase in the expression of GABA, c-fos, GFAP, and GABA receptors and also a positive trend of increased nNOS and iNOS, while glutamate concentration did not present significant changes. The cerebellar granular hyper-synchronization is explained by the increase in neuronal coactivity as a result of the imbalance of neurotransmitters for excitation and inhibition of granule cells. These results suggest that changes in the frequency of potential actions and the coactivity in the granule cells of kindled mice, lead to neurophysiological and neurochemical changes.

Authors: F. A. CONCEPCION, M. N. KHAN, N. A. EKSTROM, *N. P. POOLOS; Neurol., Univ. of Washington, Seattle, WA

Abstract: Studies have shown altered tau expression and phosphorylation in human epilepsy. We investigated in a pilocarpine status epilepticus (SE) rat model of acquired epilepsy the changes in total tau expression and tau phosphorylation at the S202/T205 human locus, known to be hyperphosphorylated in Alzheimer's disease. We used western blotting to analyze tau expression within the hippocampus at two time points of chronic epilepsy: 6-9 weeks post-SE and 14-17 weeks post-SE. We also used mass spectrometry (MS) to identify tau phosphosites in both rat model and brain tissue from human epilepsy patients to determine the correspondence between the two species. In the whole hippocampus at 6-9 weeks post-SE, we observed reduced total tau levels (82.1 ± 3.2% of naïve control; n=8; p=0.0008) and S202/T205 phosphorylated tau (p-tau) levels (72.2 ± 11.2% of controls, n=8; p=0.043). In 14-17 weeks post-SE, we noticed a loss of p-tau levels (67.9 ± 13.2% of control, n=4; p=0.094) that was not significant, but no changes in total tau amounts (93.3 ± 8.0% of control, n=4; p=0.47). Investigating hippocampal subregions of 6-9 week post-SE rats, we observed a loss in total tau expression in CA1 (79.1 ± 5.2% of naïve levels; n=4; p=0.027), and although nonsignificant, reduced p-tau levels (65.7 ± 14.3% of naïve levels; n=4; p=0.096). In CA3 there was a greater loss of p-tau (57.7 ± 14.8% of naïve; n=5; p=0.046), and a trend towards a drop in total tau (80.2 ± 10.7% of controls; n=5; p=0.14). With MS, we identified 29 rat tau phosphosites (p-sites) and 23 human tau p-sites (n=2 samples for both rat and human). Of the 26 rat p-sites that had corresponding potential p-sites in humans, 17 (65%) showed phosphorylation in their human counterparts. Conversely, of the 21 human p-sites that had corresponding potential p-sites in rats, we observed phosphorylation in their rat counterparts in 17 (81%) of these human p-sites. We conclude that tau expression is dysregulated in our rat epilepsy model, with differing changes in expression in hippocampal subregions. Tau dysregulation persists at two time points of chronic epilepsy. Identification of 29 rat tau phosphosites and 23 human tau phosphosites indicates a high degree of correspondence in tau phosphosite patterns between rats and humans. These data indicate that a rat model of acquired epilepsy will enable future correlation of changes in tau expression and phosphorylation with the development of epilepsy after a brain insult.

Title: Loss of hippocampal efferent projections in the mouse intrahippocampal kainic acid model

Authors: *A. M. FERNANDEZ[1], C.-A. N. GUTEKUNST[2], D. P. GROGAN[3], N. P. PEDERSEN[4], R. E. GROSS[5];

Abstract: Unilateral intrahippocampal injection of kainic acid is used as a model of medial temporal lobe epilepsy and provides a platform to study the mechanisms of epilepsy. Here, we used an AAV-9 EYFP-tagged viral vector as an anterograde tracer to map out the efferent hippocampal projections after the development of spontaneous seizures in this model in C57BL/6J male mice. The purpose of the study was to identify the extent of changes in hippocampal efferent system in several brain regions that receive significant inputs from the hippocampus. Loss of efferent hippocampal fibers was greatest in the retrosplenial cortex where neuronal loss was also observed. Loss of fibers was also observed in the fornix without any specific effect in the lateral mammillary nuclei. Although expected, these observations provide further evidence of the broader network effects as a result of hippocampal cell loss.

Title: O-glcnac transferase ogt-1 and the ubiquitin ligase eel-1 modulate seizure susceptibility in c. elegans

Authors: *N. SUTHAKARAN[1], J. WIGGINS[1], A. GILES[2], K. OPPERMAN[3], B. GRILL[4], K. DAWSON-SCULLY[1];

[1]Biol. Sci., Florida Atlantic Univ., Boca Raton, FL; [2]Neurosci., The Scripps Res. Inst., Jupiter, FL; [3]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; [4]Pediatrics, Univ. of Washington Sch. of Med., Seattle, WA

Abstract: Neurodevelopmental disorders such as epilepsy and autism have been linked to an imbalance of excitation and inhibition (E/I) in the central nervous system. The simplicity and tractability of *C. elegans* allows our electroconvulsive seizure (ES) assay to be used as a behavioral readout of the locomotor circuit and neuronal function. *C. elegans* possess conserved nervous system features such as gamma-aminobutyric acid (GABA) and GABA receptors in inhibitory neurotransmission, and acetylcholine (Ach) and acetylcholine receptors in excitatory neurotransmission. Our previously published data has shown that decreasing inhibition in the motor circuit, via GABAergic manipulation, will extend the time of locomotor recovery following electroshock. Similarly, mutations in a HECT E3 ubiquitin ligase called EEL-1 leads to impaired GABAergic transmission, E/I imbalance and altered sensitivity to electroshock. Mutations in the human ortholog of EEL-1, called HUWE1, are associated with both syndromic and non-syndromic intellectual disability. Both EEL-1 and its previously established binding protein, OGT-1, are expressed in GABAergic motor neurons, localize to GABAergic presynaptic terminals, and function in parallel to regulate GABA neuron function. In this study, we tested behavioral responses to electroshock in wildtype, *ogt-1*, *eel-1* and *ogt-1; eel-1* double mutants. Both *ogt-1* and *eel-1* null mutants have decreased inhibitory GABAergic neuron function and increased electroshock sensitivity. Consistent with EEL-1 and OGT-1 functioning in parallel pathways, *ogt-1; eel-1* double mutants showed enhanced electroshock susceptibility. Expression of OGT-1 in the *C. elegans* nervous system rescued enhanced electroshock defects in *ogt-1; eel-1* double mutants. Our *C. elegans* electroconvulsive seizure assay was the first to model a human X-linked Intellectual Disability (XLID) associated with epilepsy and suggests a potential novel role for the OGT-1/EEL-1 complex in seizure susceptibility.

Title: Respiratory alkalosis as a tool to interrogate absence seizure-generating neural circuits

Authors: K. A. SALVATI[1], R. J. SKYBERG[2], I. P. LESMANA[1], ***M. BEENHAKKER**[1]; [1]Univ. of Virginia Sch. of Med., Charlottesvle, VA; [2]Uva, Charlottesville, VA

Abstract: Hyperventilation reliably provokes seizures in patients with absence epilepsy. To understand the physiological parameters that drive hyperventilation-provoked absence seizures we developed rat and mouse models that recapitulate the predictable human seizure response. We now use these models to both (1) resolve the cellular mechanisms that contribute to hyperventilation-provoked seizures, and (2) resolve neural circuits that initiate and propagate absence seizures. In seizure-prone rats (WAG/Rij) and mice (*Gria4* mutant), absence seizures are primarily sensitive to the respiratory alkalosis that accompanies hyperventilation. In both rodent models, hypoxia-induced hyperventilation provokes a burst of spike-wave discharges (SWDs), electrographic correlates of absence seizures, that is also associated with arterial alkalization. Consistent with the hypothesis that SWDs are specifically provoked by alkalosis, supplementing hypoxic conditions with high CO_2 suppresses the SWD response; high CO_2 alone is also sufficient to reduce SWDs in the rodents. Activity-dependent labeling approaches (i.e., cFos) suggest that hyperventilation activates neurons in the intralaminar thalamic nuclei to provoke SWD-generating neural circuits. Using multielectrode silicone recording probes in head-fixed *Gria4* mutants, we are leveraging the predictability of hyperventilation-provoked SWDs to identify neural circuit activity patterns that precipitate seizures. Our recordings show that spontaneous (i.e., during normal breathing conditions) and hyperventilation-provoked SWDs follow a stereotyped temporal progression of activity. Also, preliminary recordings indicate that the midline thalamic nuclei, including some intralaminar nuclei, produce SWDs before the laterally-situated sensory nuclei. Collectively, our data support a model wherein pH sensitive neurons of midline thalamic structures precipitate hyperventilation-provoked absence seizures.

Title: Entorhinal-hippocampal desynchronization in chronically epileptic mice

Authors: *S. Y. FENG, L. PAGE-HARLEY, K. DIEGO, S. LAMSIFER, T. SHUMAN; Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Temporal lobe epilepsy is one of the most common types of epilepsy in adults and causes pervasive memory impairments that significantly impact the quality of life. Pilocarpine-treated epileptic mice show altered hippocampal synchronization with reduced theta coherence and abnormal interneuron firing between the CA1 and dentate gyrus (DG) region of the hippocampus (HPC). However, it remains unclear whether synchronization deficits in HPC reflect impaired inputs from the entorhinal cortex and when these deficits emerge following epileptogenesis. The medial entorhinal cortex (MEC) is the upstream region sending direct spatial inputs into HPC, which shows severe cell death and cell hyperexcitability in epilepsy. Cognitive processes require precise communication between circuits, suggesting that altered timing between HPC and MEC may contribute to epilepsy-associated cognitive deficits. We have performed acute in vivo electrophysiology with silicon probes to simultaneously record from 512 channels in HPC and MEC of epileptic and control mice running in virtual reality. Wireless EEG devices were implanted in all animals to monitor chronic seizure activity. Two time points (3 weeks and 8 weeks post pilocarpine) were chosen to capture the early and late stages of epilepsy. Preliminary analysis using local field potentials (LFPs), multiunit activity, and coherence measures revealed that epileptic mice had altered LFP power and synchronization between the MEC and HPC. In the hippocampus, theta power deficits were progressive, with significant changes found only at the 8-week time point. Gamma power, on the other hand, was reduced in CA1 and DG by 3 weeks post-pilocarpine, likely reflecting interneuron death early after pilocarpine. At 8 weeks post pilocarpine, we also found reduced theta phase coherence between MEC layers II/III (MECII, MECIII) and CA1, and reduced phase locking of MECII spiking to CA1 theta oscillations. Together, these data indicate a significant impairment in the timing of MEC inputs into HPC, which may contribute to the reduced coherence and altered spike timing we have previously found in epileptic mice. Future analysis will focus on single-unit analysis to determine whether excitatory and inhibitory neurons are specifically altered, and whether spatial coding in MEC is disrupted in epileptic mice.

Title: Spontaneous seizure and memory loss in mice expressing an epileptic encephalopathy variant in the calmodulin-binding domain of Kv7.2

Authors: *E. KIM, H. CHUNG;
Dept. of Mol. and Integrative Physiol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Epileptic encephalopathy (EE) is characterized by seizures that respond poorly to antiseizure drugs, psychomotor delay, and cognitive and behavioral impairments. One of the frequently mutated genes in EE is KCNQ2, which encodes the Kv7.2 subunit of voltage-gated Kv7 potassium channel. Kv7 channels composed of Kv7.2 and Kv7.3 are enriched at the axonal surface where they potently suppress neuronal excitability. Previously, we reported that de novo dominant EE mutation M546V in human Kv7.2 blocks calmodulin binding to Kv7.2 and axonal surface expression of Kv7 channels via their intracellular retention. However, whether these pathogenic mechanisms underlie epileptic seizures and behavioral comorbidities remains unknown. Here, we report conditional transgenic cKcnq2+/M547V mice, in which expression of mouse Kv7.2-M547V (equivalent to human Kv7.2-M546V) is induced in forebrain excitatory pyramidal neurons. These mice display early mortality, spontaneous seizures, enhanced seizure susceptibility, memory impairment, and repetitive behaviors. Furthermore, hippocampal pathology shows widespread intraneuronal aggregation of mutant Kv7.2-M547V proteins, neurodegeneration and reactive astrocytes. This study is the first to demonstrate that the impairment in axonal surface expression of Kv7 channels is associated with epileptic seizures, cognitive and behavioral deficits, and neuronal loss in KCNQ2-related EE.

Title: Reduced hippocampal inhibition and enhanced autism-epilepsy comorbidity in mice lacking neuropilin 2

Authors: *C. EISENBERG[1], D. SUBRAMANIAN[3], M. AFRASIABI[4], J. DELUCIA[1], M. SHIFLETT[2], V. SANTHAKUMAR[3], T. TRAN[1];

Abstract: The neuropilin receptors and their semaphorin ligands play key roles in brain circuit development by regulating numerous crucial neuronal processes, including synapse maturation and migration of GABAergic interneurons. Consistent with its developmental roles, the neuropilin 2 (Nrp2) locus contains polymorphisms in patients with autism spectrum disorder (ASD). Nrp2 deficient mice show autism-like behavioral deficits and propensity to develop seizures. In order to determine the pathophysiology in Nrp2 deficiency, we examined the hippocampal interneuron subtypes and inhibitory regulation of CA1 pyramidal neurons in mice lacking one or both copies of Nrp2. Immunostaining for interneurons revealed that Nrp2-/- mice have reduced number of parvalbumin, somatostatin and neuropeptide Y cells, mainly in CA1. Whole cell recordings identified reduced firing and hyperpolarized shift in resting membrane potential in CA1 pyramidal neurons from Nrp2+/- and Nrp2-/- mice compared to Nrp2+/+ indicating decrease in intrinsic excitability. Simultaneously, the frequency and amplitude of spontaneous inhibitory postsynaptic currents (sIPSCs) are reduced in Nrp2 deficient mice. A convulsive dose of kainic acid evoked electrographic and behavioral seizures with significantly shorter latency, longer duration and higher severity in Nrp2-/- compared to Nrp2+/+ animals. Finally, Nrp2+/- and Nrp2-/-, but not Nrp2+/+, mice have impaired cognitive flexibility demonstrated by reward-based reversal learning, a task associated with hippocampal function. Together these results demonstrate a broad reduction in interneuron subtypes and compromised inhibition in CA1 of Nrp2-/- mice, which could contribute to the heightened seizure susceptibility and behavioral deficits consistent with an ASD/epilepsy phenotype.

Title: Information processing dynamics in hippocampus and cortex and their alterations in experimental pathology

Authors: *W. CLAWSON, N. PEDRESCHI, T. MADEC, A. GHESTEM, P. QUILICHINI, D. BATTAGLIA, C. BERNARD;
Inst. de Neurosciences des Systèmes, Marseille, France

Abstract: Neurological disorders share common high-level alterations, such as cognitive deficits, anxiety, and depression. This raises the possibility of fundamental alterations in the way information conveyed by neural firing is maintained and dispatched in the diseased brain. Using experimental epilepsy as a model of neurological disorder we tested the hypothesis of altered information processing, analyzing how neurons in the hippocampus and the entorhinal cortex store and exchange information during slow and theta oscillations. We equate the storage and sharing of information to low level, or primitive, information processing at the algorithmic level, the theoretical intermediate level between structure and function. We find that these low-level processes are organized into substates during brain states marked by theta and slow oscillations. Their internal composition and organization through time are disrupted in epilepsy, loosing brain state-specificity, and shifting towards a regime of disorder in a brain region dependent manner. We propose that the alteration of information processing at an algorithmic level may be a mechanism behind the emergent and widespread co-morbidities associated with epilepsy, and perhaps other disorders.

Title: Dynamic multiplex network analysis of human intracranial recordings during postictal aphasia

Authors: *N. PEDRESCHI[1,2], A. TREBUCHON[1,3], A. BARRAT[2], D. BATTAGLIA[1,3];
[1]Aix Marseille Univ, Inserm, INS, Inst. de Neurosciences des Systèmes, Marseille, France; [2]Ctr. de Physique Théorique, CNRS, Aix-Marseille Univ., Marseille, France; [3]Assistance Publicque Hopitaux APHM, Marseille, France

Abstract: Lesion related aphasia in humans has been widely investigated, while much remains unknown about the mechanisms that cause aphasia as a transient post-seizure symptom in epileptic patients. We analyse very long intracranial EEG recordings of a few patients suffering from pharmaco-resistant epilepsy and postictal aphasia, whose language capabilities are tested after a seizure until their full recovery. We study the functional connectivity between different cortical sites in a time and frequency resolved manner, to capture how the flexible dynamics of inter-regional interactions is affected by the seizure. Specifically, for each recording, we compute the wavelet coherence, in 5 frequency bands peaked around 1, 5, 10, 20 and 40 Hz, of each pair of electrodes at each time stamp, thus representing each recording as a time-varying, multilayer network (dynamic multiplex). Within each layer of each dynamic multiplex, we then compute the time series of various graph theoretical metrics, such as the instantaneous strength and modularity along with the instantaneous partition of the nodes into different modules. A wide increase in strength, and corresponding decrease in modularity, in all bands from seizure onset to offset is then followed by a phase of gradual recovery to baseline activity, whose duration increases with the frequency and can extend well beyond the disappearance of reported aphasia symptoms. We also characterized the flow between consecutive network frames, identifying and comparing different types of network dynamics. We studied in particular: the rate of overall reconfiguration of links from one frame to the next, or dynamic Functional Connectivity (dFC) speed; and the flexibility or crystallization of network modules through time, by means of a dynamic Allegiance matrix (dAm) analysis. A large variability, combined with a structured allegiance dynamics characterize the baseline "liquid" dynamics, while other dynamics types, more "gaseous" or "crystallized", appear during the seizure and recovery. Importantly, we recover a pathological state whose occurrence is correlated with the reported language-test fallacies. This state is characterized by a loss of allegiance (more evident in gamma and beta layers) between the temporal and parietal regions, which thus leave and enter different modules in an independent and not integrated manner. This state also corresponds to momentary drops of dFC-speed during the recovery phase. In conclusion, in our work we devise a data driven pipeline that can help both shed light on general mechanisms underlying postictal aphasia and address patient specific issues.

Title: Effect of prolactin on absence seizures in the taiep rat: an animal model of H-ABC leukodystrophy

Authors: *C. CORTES[1], E. S. HERNANDEZ[1], J. R. EGUIBAR[1,2];
[1]Inst. of Physiol., B. Univ. Autonoma de Puebla, Puebla, Mexico; [2]Res. Office, Vice-rectory of Res. and Postgraduate Studies, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: The taiep rat, is a spontaneous myelin mutant from Sprague-Dawley strain obtained at the Benemérita Universidad Autónoma de Puebla, with an initial hypomyelination followed by a progressive demyelination in the central nervous system. This mutant is equal of human leukodystrophy hypomyelination with atrophy of the basal ganglia and cerebellum (ABC). We have already reported that taiep rats had spike-wave discharges, with a mean frequency of 6.25 Hz, like human absence seizures. Absence seizures are a generalized type of epilepsy characterized by sudden loss of consciousness and abnormal cortical electrical activity in both cerebral hemispheres with a mean frequency around 6 Hz. Absence seizures have been shown to be sexually dimorphic in humans, but the underlying mechanisms are not discerning until now. The aim of this study was to analyze the possible role of central administration of prolactin on spike-wave discharges in adult female taiep rats. We used 6-month-old female taiep rats with an implant of stainless-steel screw electrodes in the cerebral cortices using stereotaxic surgery. One week later, they were bilateral oophorectomized and maintain in permanent estrous using 17-β estradiol through s.c. injections in the neck region. EEG recordings of 8 h duration under control conditions and after i.c.v. injection of 0.5, 1 and 2 µg of prolactin/2 µL of artificial cerebrospinal fluid. All Ss were maintained under standard conditions and the experimental protocol was approved by IACUC. The results showed that prolactin did not increase the frequency of the absence seizures with the 3 doses tested ($P>0.05$). But prolactin increased the mean duration with 210% and 189%, with 0.5 and 1 µg doses, respectively ($P<0.001$). In fact, 2 µg of prolactin produced the highest increase in the duration of absence seizures 205% ($P<0.001$). In conclusion, prolactin is capable to change the activity of the thalamo-cortical circuit to sustain absence seizures in estrogenized female taiep rats.

Title: Ido2 deficiency is protective against acute seizures and hyperactivity in a kainic acid model of ictogenesis

Authors: *Z. A. MACDOWELL KASWAN, M. HURTADO, E. Y. CHEN, R. H. MCCUSKER;
Univ. of Illinois At Urbana-Champaign, Champaign, IL

Abstract: Neuronal hyperexcitability, particularly in association with neuroinflammation, can trigger the development of acute seizures (ictogenesis), putting patients at risk of subsequent pathologies such as epilepsy and chronic behavioral changes. Neuroinflammation induces expression of indoleamine 2,3-dioxygenase (Ido) 1 and 2 within the central nervous system. The Ido's are the first and rate limiting enzymes of the kynurenine pathway, by which tryptophan is converted into kynurenine and subsequently into neuroactive metabolites. Kynurenine metabolites, some of which are ictogenic, directly interact with glutamate receptors in the brain to modulate neural activity. Ido1 and Ido2, therefore, may provide a mechanistic link between neuroinflammation and ictogenesis. In the kainic acid (KainA) model of ictogenesis, systemically administered KainA crosses the blood brain barrier to activate glutamate receptors and cause seizures. We used this model to explore the effect of Ido1 and Ido2 deficiencies on acute seizure susceptibility. Mice were injected intraperitoneally with five doses of 4.5-5 mg/kg KainA or saline control at intervals of 30 minutes and observed for seizures throughout the injection period and for an additional 30 minutes after the final dose. We found that mice deficient for Ido2 ($Ido2^{KO}$) are less likely to experience seizures following injection of KainA compared to wild-type (WT) C57BL/6 mice. In contrast, mice deficient for Ido1 ($Ido1^{KO}$) have equivalent seizure incidence compared to WT mice. $Ido2^{KO}$ mice are also protected from KainA-induced hyperactivity assessed 8 days post-injection. Gene expression was quantified in hippocampi collected 30 min after the final injection. Unexpectedly, hippocampal Ido1 and Ido2 expression is reduced by KainA treatment regardless of seizure incidence. However, KainA increased expression of the proinflammatory cytokines TNFα and IL-1β. Cytokine expression is higher in the hippocampi of mice that experienced seizures relative to those that did not, indicating higher levels of hippocampal neuroinflammation. Surprisingly, TNFα expression is higher in $Ido2^{KO}$ mice compared to WT or $Ido1^{KO}$ mice despite their lower seizure incidence. Our data indicate that the low seizure incidence of $Ido2^{KO}$ mice makes Ido2 a putative candidate for new anti-seizure therapeutics.

Title: Developmental breathing abnormalities in a Scn1a haploinsuffient model of DS

Authors: *B. MILLA[1], D. K. MULKEY[2];
[1]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT; [2]Dept. of Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: Dravet Syndrome (DS) is a severe form of epilepsy with a high rate of sudden unexpected death in epilepsy (SUDEP). Respiratory failure is a leading cause of SUDEP, despite this it is unclear how DS-associated genetic variants or seizure activity in general disrupts respiratory control. Most DS cases are caused by mutations in the Scn1a gene, which encodes a voltage gated Na+ channel that preferentially regulates activity of inhibitory neurons. Consistent with this, we showed that loss of Scn1a function in inhibitory neurons disrupted CO2/H+-dependent regulation of breathing by the retrotrapezoid nucleus (i.e., RTN chemoreception), caused seizures and premature death. However, Scn1a is also expressed by excitatory neurons particularly later in development indicating loss of Scn1a function in excitatory neurons contributes to progression of DS symptoms. Therefore, the goal of this work is to determine whether and how respiratory function is perturbed across development in a global Scn1a haploinsuficient (Scn1a+/-) mouse model of DS. Scn1a+/- and littermate controls were maintained on 50:50 background of 129S1/SvlmJ::C57BL6/J. Respiratory activity was measured in the same animals at 13 and 21 days of age by whole-body plethysmography during exposure to room air, high CO2 (3-7% CO2) or low O2 (10% O2). At the cellular level, baseline activity and CO2/H+-sensitivity of RTN neurons in brain slices obtained from each genotype was characterized in cell-attached voltage clamp mode. Neonatal Scn1a+/- mice breathe normally in room air but show a blunted ventilatory response to graded increases in CO2. At the cellular level, RTN neurons in slices from Scn1a+/- mice show increased baseline activity compared to RTN neurons from control tissue. We also found the ventilatory response to CO2 improved in these same mice at a later developmental time point. However, breathing problems persisted in juvenile Scn1a+/- as a blunted ventilatory response to hypoxia and importantly this respiratory deficit positively correlated with mortality; mice that died by 24 days of age had a diminished hypoxic ventilatory response compared to Scn1a+/- that survived. Loss of Scn1a preferentially disrupts the CO2 ventilatory response at the cellular and whole animal levels early in development. These results are similar to the phenotype of mice with inhibitory neuron specific

Scn1a disruption, suggesting a dominate role of Scn1a in inhibitory neurons at this developmental time point. We also show that a blunted hypoxic ventilatory response correlates with premature death in juvenile Scn1a+/-. These results suggest multiple aspects of respiratory control are compromised in DS.

Title: Tissue oxygenation dynamics in spontaneous seizure and seizure/spreading depolarization (SD) events in a rodent model of temporal lobe epilepsy

Authors: *J. LIU[1], B. J. GLUCKMAN[2];
[1]The Pennsylvania State Univ., University Park, PA; [2]Ctr. for Neural Engin., Penn State Univ., University Pk, PA

Abstract: Oxygen is critical in maintianing neuronal transmembrane ion gradients, and local deficits in oxygenation are known to be able to initiate spreading depolarization (SD). We demonstrated that SD frequently occurs associated with the seizures in the tetanus toxin rodent model of temporal lobe epilepsy (Bahari F 2020, https://doi.org/10.1101/455519). Here we investigate with continuous recordings if tissue oxygenation changes lead or follow the onset of seizures and the onset of seizure-associated SD.
Methods: We implemented long-term home-cage continuous tissue oxygenation and biopotential measurements on freely moving rats prepared under the tetanus toxin (TeTX) model of temporal lobe epilepsy (TLE) and applied both the constant potential amperometry (CPA) and long-term pulse voltammetry (LPV). Ideally, these methods yield measures of average tissue oxygen concentration C_0. CPA methods depend on both C_0 and average diffusion constant D_{eff} through tissue. In LPV, the initial peak current reflects the local C_0 while its tail is comparable to the mixed CPA measure. We introduce a method to estimate relative changes of D_{eff} from the LPV. We studied tissue oxygenation dynamics during the normal state of vigilance (SOV) transitions, peri-seizure transitions without SD (N=704/412 events), and peri-seizure transitions with SD (N=190/68 events) in (N=9/5) animals using (CPA/LPV) methods. Critically, these measures were done chronically during multi-day homecage recordings in freely behaving non-anesthetized animals.
Results: Across all events, we find comparable dynamics from both CPA and the tail portion of

LPV. For transitions between non-seizure SOV states, these dynamics are consistent with the peak LPV value, which best measures local C_0. This implies that D_{eff} doesn't change appreciably for transitions between non-seizures SOV states. Likewise, neither tissue oxygenation nor Deff changed appreciably ahead of seizure onset. Tissue oxygenation did change of order 5% during seizures and 20% during SD events. But no overt decreases were observed either during the pre-seizure period nor ahead of SD onset during seizures. Instead during seizures C_0 typically increased. In contrast, D_{eff} did decrease as much as 80% during SD events. Oxygen dynamics appear to follow seizure and SD onset transitions rather than precede and potentially cause them. Increases in tissue oxygenation during seizures indicate a robust neurovascular response. In addition, oxygen diffusion rates through tissue during SD are significantly decreased, presumably correlated with cell swelling and decreases extracellular space.

Title: Increased slow gamma power across behavioral states correlates with seizure phenotype severity in the Ank3-1b mouse model of epilepsy

Authors: J. E. VILLACRES PEREZ, N. J. RIVEIRA, S. KIM, L. L. COLGIN, *A. Y. LOPEZ;
Neurosci., Univ. of Texas At Austin, Austin, TX

Abstract: Absence epilepsy is characterized by spike-and-wave discharges (SWD) in electroencephalographic (EEG) signals that correspond to cognitive and behavioral arrest in patients. Many studies have identified various physiological effects of absence epilepsy on human development, and pharmaceutical intervention has significantly improved the treatment of absence seizures. Despite these advances, there remains little understanding of mood and behavioral comorbidities commonly present in pediatric and adult patients with childhood-onset absence epilepsy. The *Ank3* gene provides a unique opportunity to study these comorbidities, as it has been linked to mood disorders in human genetic studies and more recently to absence epilepsy in rodents. Thus, this study aims to identify unique event-related behavioral correlates in EEG signals of *Ank3-1b* knockout (KO) mice. Here, we take advantage of two supervised

learning algorithms to identify seizure events from EEG recordings and track animal movements from video recordings. Pose estimates were extracted from the video recordings to distinguish moving from nonmoving bouts. Then a binary classifier was developed to identify sleep states. Manually scored behaviors were used to generate the classifier's receiver operating characteristic curve and guide the choice of classification threshold. EEG signal power during these behavioral states was estimated for signal frequencies between 1 and 50 Hz using a Morlet wavelet transform. Preliminary results suggest that *Ank3-1b*$^{-/-}$ KO mice exhibit increased slow gamma (~30-40 Hz) power during sleep and moving bouts compared to wildtype controls. *Ank3-1b*$^{-/+}$ KO mice show an intermediate phenotype characterized by a relatively modest increase in slow gamma power. Preliminary results also suggest that these increases in slow gamma power correlated with gene dosage and seizure phenotype severity. These results provide a foundation for exploring gamma oscillations during complex behaviors related to mood disorders in *Ank3* mouse models of epilepsy.

Title: A home-cage monitoring solution for non-invasive seizure screening in rodent models of epilepsy

Authors: D. M. HUFFMAN[1], P. RUKUNDO[2], D. IRADUKUNDA[2], J. PERDEH[3], K. DONOHUE[1], B. F. O'HARA[4], B. BAUER[3], S. SUNDERAM[2];
[1]Signal Solutions, LLC, Lexington, KY; [2]F. Joseph Halcomb III, M.D. Dept. of Biomed. Engin., [3]Dept. of Pharmaceut. Sci., [4]Dept. of Biol., Univ. of Kentucky, Lexington, KY

Abstract: Rationale: There is an urgent need for research into treatment options for epilepsy and other seizure disorders. Animal models are increasingly used to understand disease mechanisms and to screen potential therapeutic approaches. However, such investigations typically require validation via expensive and labor-intensive methods (i.e., EEG measurements), limiting the pace and scale of experimentation. Previously, we have shown that piezoelectric technologies have great utility in non-invasive seizure detection. We present further developments in this effort where monitoring is accomplished through an external sensor

platform located beneath the housing cage.**Methods:** Adult Wistar rats (female; 2 months) were treated with pilocarpine i.p. to induce status epilepticus (SE). Three months after SE, rats were monitored individually in standard cages via piezoelectric *Adapt-a-Base* sensors (Signal Solutions, LLC) alongside a continuous video record for 10 weeks. Weekly recordings were processed to derive a seizure detection statistic time series, to which a threshold was applied to identify the 20 most intense events (20 events/week × 8 cages = 160 events/week). Timestamps of threshold crossings were saved to a spreadsheet for inspection through the video record, and were annotated according to observed behavior (i.e., seizure, grooming, etc). Detection precision was evaluated according to the incidence of true positive detections relative to all detections. **Results:** Piezoelectric sensors captured the essential dynamics of seizures, as well as pre- to post-ictal changes in physiological parameters (i.e., breathing). Derivation of a simple detection statistic was successful in discriminating seizure events, albeit with variable precision (5-65%); likely related to the variability in true seizure yield. **Conclusions:** Overall, this approach shows great utility in identifying spontaneous seizures in chronic epilepsy monitoring; saving labor in identifying seizures compared to exhaustive video review. Piezoelectric signals captured tonic-clonic behavior during seizures and other relevant behaviors such as breathing, freezing, and tremor. Moreover, as this technology has been validated for use in discriminating sleep-wake activity, it opens the door to investigating seizures in the context of sleep/circadian rhythms, which may be a key aspect to consider when evaluating potential treatment strategies. Further development of this method will focus on capturing the temporal evolution of the piezo signal during seizures, aimed at increasing detection sensitivity/specificity, as well as discriminating seizure severity.

Title: Locus coeruleus neuronal activity in an awake mouse model of temporal lobe seizures investigated by juxtacellular recordings

Authors: *M. VALCARCE-ASPEGREN, Q. WU, L.-A. SIEU, P. PASZKOWSKI, A. SHARAFELDIN, H. BLUMENFELD;
Dept. of Neurol., Yale Sch. of Med., New Haven, CT

Abstract: Inhibition of brainstem and basal forebrain cholinergic neurons has been identified in previous rat models as a potential driver of decreased arousal during temporal lobe seizures. The subcortical pathways modulating depressed cortical function during focal limbic seizures remains largely unclear. Recording single-cell activity in the locus coeruleus in an awake mouse model may help elucidate these pathways by examining ictal noradrenergic modulation. Additionally, these studies can show the plausibility of ictal juxtacellular recording of individual neurons in the deep brainstems of awake, moving mice, allowing for future study of other specific subcortical regions of interest. Recordings were performed using head-fixed mice running on a wheel. Chronically implanted bipolar electrodes were used to measure local field potentials in the right orbitofrontal cortex and bilateral hippocampi. Focal limbic seizures were induced via the application of current pulses (2s, 60 Hz) into the hippocampus. Noradrenergic neurons in the locus coeruleus were recorded using 1.5mm glass capillaries filled with 4% Neurobiotin. Neuronal identification was histologically achieved through double staining with cy3-streptavidin and anti-tyrosine hydroxylase antibodies. It was possible to both find and maintain a stable signal from single neurons deep in the brainstem of moving animals (n=9). Preliminary data indicate decreased firing frequency and changes in firing patterns of individual neurons in the locus coeruleus during focal hippocampal seizures. Histology successfully identified labeled neurons in the locus coeruleus. In summary, we found that juxtacellular recordings of individual neurons in the deep brainstem is feasible in awake, moving mice during seizures. Additionally, changes in the firing patterns of neurons in the locus coeruleus appear to have a potential role in changing arousal during focal limbic seizures. To further uncover the mechanisms underlying ictal unconsciousness it is critical to continue exploring specific subcortical neurons and neurotransmitters affected during seizures. Increased understanding of these processes may in turn lead to beneficial, novel treatments for people with epilepsy.

Title: Viral activation of the medial septal nucleus improves spatial memory and increases seizure threshold in a pilocarpine model of status epilepticus

Authors: N. C. ZEPEDA, S. MEDVIDOVIC, M. BERGOSH, W. CHOI, *D. J. LEE;
USC, Los Angeles, CA

Abstract: Recently thalamic deep brain stimulation (DBS) and responsive neurostimulation have been approved for the treatment of medically refractory epilepsy; however, the underlying mechanism of electrical stimulation remains largely unknown. We have previously demonstrated that hippocampal theta power is diminished in animal models of epilepsy with concomitant with deficits in spatial learning. Data from our lab, demonstrates that MSN theta DBS can increase hippocampal oscillations and restore cognitive function in a rodent epilepsy model. In this study, we are using a chemogenetic approach to drive the septohippocampal circuit to increase seizure threshold. Methods: 32 male Sprague-Dawley rats were divided into animals undergoing a pilocarpine injection to induced status epilepticus (n=20) or saline vehicle injection (n=12). 13 days after injection, seizure threshold was measured using flurothyl testing. The following day rats underwent unilateral implantation of a hippocampal recording electrodes as well as bilateral AAV8 intracranial injection of either AAV8-CamKIIa-hM3D(Gq)-mcherry or AAV8-CamKIIa-EGFP (sham) into the medial septal nucleus. On post-injection days 21-25, animals underwent the Barnes maze spatial memory task and given an intraperitoneal injection of either clozapine N-oxide to active the receptor or saline 25 minutes prior to the task. On post-injection day 29, animals were again administered clozapine N-oxide or saline. 25-minutes after injection, repeat flurothyl testing was performed. Results: Pilocarpine-injected rats (sham activation) had a longer latency to finding the escape hole compared to saline-injected rats ($p<0.05$). Pilocarpine-injected rats with MSN activation (AAV8-CamKIIa-hM3D(Gq)-mcherry) had a shorter latency than sham activation pilocarpine-injected rats ($p<0.05$). Latency was similar in saline-injected rats and MSN activated pilocarpine rats. Pilocarpine-injected rats (sham activation) had a lower seizure threshold compared to saline-injected rats (299.6±13.8 seconds vs. 405.6±34.0; $p<0.05$). Pilocarpine-injected rats with MSN activation had a higher seizure threshold compared to sham activation pilocarpine-injected rats (400.2±34.0; $p<0.05$). Conclusion: Viral activation of the medial septal nucleus increases seizure threshold and improves spatial memory in pilocarpine-induced status epilepticus rats.

Title: Cortical slow waves and reduced cholinergic arousal in novel mouse model of focal limbic seizures with impaired behavior

Authors: *L.-A. SIEU[1], S. SINGLA[1], A. SHARAFELDIN[1], G. CHANDRASEKARAN[2], M. VALCARCE-ASPEGREN[1], A. NIKNAHAD[3], I. FU[1], N. DOILICHO[1], A. GUMMADAVELLI[1], C. MCCAFFERTY[4], R. B. CROUSE[1], Q. PERRENOUD[1], M. R. PICCIOTTO[1], J. CARDIN[1], H. BLUMENFELD[1];
[1]Yale Sch. of Med., New Haven, CT; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]John Hopkins school of medicine, Baltimore, MD; [4]Univ. Col. Cork, Cork, Ireland

Abstract: Temporal lobe epilepsy (TLE) is often associated with loss of consciousness and therefore reduced patient quality of life. Clinical studies have shown that this loss of consciousness is positively correlated with neocortical slow waves on EEG, similar to the non-REM sleep state. Further investigation in the rat model of focal limbic seizures revealed that subcortical arousal systems are depressed during seizures, including brainstem and basal forebrain cholinergic neurons. To better elucidate underlying circuit and network mechanisms resulting in loss of consciousness, we developed an awake, behaving mouse model of focal limbic seizure to take advantage of the wealth of genetics tools available. Focal limbic seizures were recorded and unilaterally induced by a 2s, 60 Hz hippocampal stimulus via implanted bipolar electrodes in the dorsal hippocampus, while local field potential (LFP) signals were recorded simultaneously from orbitofrontal cortex (OFC). To assess behavioral responses during seizures, water-restricted mice were trained to lick a water dispenser in response to a sound (0-50kHz noise, 12ms) every 10-15s while head-fixed on a running wheel. To characterize cortical slow waves, multiunit activity (MUA) was recorded in left OFC via a tungsten electrode. Cholinergic input to OFC during seizures was investigated by expressing a genetically encoded fluorescent acetylcholine indicator (GACh) in the OFC and signals were detected via an implanted optic fiber into OFC (fiber photometry). Focal seizures were inducible for several weeks and were of 5-30s duration (n=20 animals). Overall responses to sound and running speed decreased during seizures and recovered post-ictally ($p<0.01$, n=20 animals). However, responses to sound were sometimes normal during seizures, similar to TLE in humans. By examining behavioral responses and cortical activity, we showed that behavioral arrest is correlated with amplitude of cortical slow-wave activity. Cortical slow waves followed an Up and Down state firing pattern on MUA recordings, like the slow wave sleep (n=6 animals). Further, cholinergic input to the cortex was reduced during seizures, with larger decreases associated with impaired behavior (n=5 animals). These results suggest this novel mouse model of focal limbic seizures shares characteristics with the rat model and human temporal lobe seizures. Impaired consciousness is associated with depressed cortical arousal facilitated by reduced cholinergic input. Future work with this model will help to uncover fundamental mechanisms for loss of consciousness in focal seizures in hope to lead to innovative treatment.

Title: Maturation of hESC-derived GABAergic interneurons in epileptic rodent hippocampus

Authors: *E. WALOSCHKOVÁ, A. GONZALEZ-RAMOS, A. MIKROULIS, M. LEDRI, M. ANDERSSON, M. KOKAIA;
Epilepsy Ctr., Lund Univ., Lund, Sweden

Abstract: Epilepsy is a complex disorder affecting the central nervous system and is characterised by uncontrollable spontaneously recurring seizures. Patients suffering from epilepsy are treated with various anti-seizure medication, however, this is ineffective in 30%, mostly in patients suffering from temporal lobe epilepsy (TLE). Therefore, there is a need for developing novel treatment strategies. One of these novel approaches is transplantation of cells releasing gamma-aminobutyric acid (GABA) to restore the balance between excitation and inhibition within the neuronal network. We generated optogenetically modified GABAergic interneuron precursors from human embryonic stem cells (hESCs) by overexpressing two transcription factors, *Ascl1* and *Dlx2*, and transplanted them in the hippocampi of a rodent TLE model. For establishing the model, 8-week-old male Rowett Nude (RNU) rats were treated with a titration-based kainic acid injection protocol until reaching status epilepticus (SE) and behavioural seizures were confirmed by video monitoring 3 months later. By performing whole-cell patch-clamp recordings in slices from the transplanted epileptic animals, we thoroughly characterised the maturation of the transplanted cells into functional GABAergic interneurons. Furthermore, by utilising their optogenetic modification and by using picrotoxin (a $GABA_A$ receptor blocker) we confirmed the presence of functional inhibitory synaptic connections from the transplanted cells onto the host neurons both 3 months (n=50 cells, 7 animals) and 6 months post-transplantation (n=78 cells, 8 animals). Moreover, we fixed and sub-sliced the tissue collected after electrophysiological experiments and performed immunohistochemistry on the slices. We confirmed the expression of calbindin and calretinin (two main interneuron markers expressed when using the *in vitro* differentiation protocol) in the transplanted cells as well as release of GABA from their efferent synaptic connections. In addition, we observed a tendency

for reduced seizure frequency in transplanted animals compared to untreated controls at 4 months post-SE. In summary, these data present a proof-of-concept for a cell-based therapeutic approach in treating epilepsy.

Title: Intervention in the Medial Entorhinal Area recues TLE-related pathology in CA1 hippocampus via the temporoammonic pathway.

Authors: *S. BEESLEY[1], T. SULLENBERGER[2], S. S. KUMAR[3];
[1]Florida State Univ., Tallahassee, FL; [2]Florida State Univ., tallahassee, FL; [3]Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Temporal lobe epilepsy (TLE) is the most common form of drug-resistant epilepsy in adults, with an unknown etiology. A hallmark of TLE is the characteristic loss of layer 3 neurons in the medial entorhinal area (MEA) that underlies seizure development. The MEA is known to entrain the hippocampus primarily through the perforant pathway (PP), which connects stellate cells in layer 2 of the MEA with granule cells of the dentate gyrus to drive the hippocampal tri-synaptic circuit. Using immunohistochemistry, high-resolution confocal microscopy, and the rat pilocarpine model of TLE, we show here that the lesser known temporoammonic pathway (TAP) plays a significant role in transferring MEA pathology to the CA1 region of the hippocampus independently of the PP. Our previous studies revealed that daily intracranial infusion of D-serine (100 μM), an antagonist of GluN3-containing triheteromeric N-Methyl D-aspartate receptors (t-NMDARs), into the MEA prevented loss of layer 3 neurons and curtailed subsequent epileptogenesis. This intervention in the MEA also led to the rescue of hippocampal CA1 neurons, and the down regulation of astrocytes and microglia expression, thereby mitigating the effects of neuroinflammation. Interestingly, these changes were not observed to a similar extent in other regions of vulnerability like the hilus, DG or CA3, suggesting that the pathology manifest in CA1 is driven predominantly through the TAP. These findings aid in better

understanding the factors driving hippocampal pathophysiology and are of relevance in seeking therapeutic avenues to mitigate the cognitive co-morbidities associated with this disease.

Title: The effect of antagonism of miR-324-5p on epileptogenesis following intrahippocampal kainic acid injections in mice.

Authors: *A. MCGANN[1,2], D. TIWARI[1,3], C. GROSS[1,3];
[1]Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Neurosci. Grad. Program, Univ. of Cincinnati Col. of Med., Cincinnati, OH; [3]Pediatrics, Cincinnati Children's Hosp., Cincinnati, OH

Abstract: Epilepsy affects over 50 million people worldwide. It is often caused by an initial brain insult, such as traumatic brain injury or infection, that is followed by the development of spontaneous recurrent seizures. The process by which the brain becomes prone to spontaneous recurrent seizures following an initial insult is termed epileptogenesis. The details of this process are still largely unknown, and further elucidation of the molecular and cellular mechanisms turning a healthy brain into an epileptic brain is needed to develop treatment strategies to prevent epileptogenesis. MicroRNAs have emerged as critical regulators of neuronal excitability via regulation of mRNA translation and stability, and are often altered in epilepsy. Our lab has shown that miR-324-5p is a critical regulator of neuronal excitability that acts by inhibiting expression of the A-type potassium-channel Kv4.2. Antagonism of miR-324-5p decreases seizure susceptibility and reduces seizure frequency in chronically seizing mice. It remains unknown, however, whether antagonism of miR-324-5p shortly following a brain insult can inhibit the progression of epileptogenesis. Here, we tested the hypothesis that miR-324-5p contributes to the development of epilepsy following *status epilepticus*. We used the intrahippocampal kainic acid model to induce epileptogenesis in wild type male mice aged 6-8 weeks. Twenty-four hours after kainic acid-induced *status epilepticus*, we administered a miR-324-5p or scrambled antagomir intracerebroventricularly and implanted cortical surface electrodes for EEG monitoring. EEG data was collected for a period of 28 days, during which the majority of mice developed spontaneous seizures. Mouse brain tissue was then perfused for assessment of neuronal cell death. Data was collected for 6 mice per group. Researchers were

blinded to treatment condition during surgery, EEG analysis, and histological analysis. EEG data was assessed for time to seizure onset, frequency, and duration, as well as interictal spike activity. Results indicated high levels of variability within treatment groups requiring larger sample sizes to determine potential effects. Ongoing work in the lab aims to increase sample sizes and clarify the network of mRNAs targeted by miR-324-5p to identify the critical genes controlling epileptogenesis. Many miRNAs have been implicated in brain hyperexcitability and it is likely that antagonism of miR-324-5p alone is insufficient to result in complete inhibition of epileptogenesis. Future work is needed to assess whether combined inhibition of several epileptogenic microRNAs leads to more complete prevention of epileptogenesis.

Title: Bimodal regulation of status epilepticus by hippocampal glucocorticoid receptor deletion

Authors: *K. L. KRAUS[1,3], C. M. GODALE[3], A. CHORDIA[3], N. NAWREEN[2], C. L. LASARGE[3], J. P. HERMAN[2], S. C. DANZER[3];
[1]Med. Scientist Training Program, [2]Dept Pharmacol. and Systems Physiol., Univ. of Cincinnati, Cincinnati, OH; [3]Dept of Anesthesia, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Status epilepticus (SE) is a life-threatening medical emergency defined by sustained seizure activity. Current treatments fail to terminate SE in all patients, highlighting a critical need to better understand the mechanisms driving SE severity and duration. Seizures are associated with a rapid increase in glucocorticoid levels, which can modulate neuronal excitability in the hippocampus through the activation of glucocorticoid (GRs). Previous studies suggest that corticosterone (CORT) exposure can be pro-convulsant and that GR antagonism after SE can reduce hippocampal cell death. However, with widespread expression across the brain and body, the precise role of GRs in the hippocampus during SE is unclear. Here, we tested the hypothesis that GR deletion from ventral hippocampal glutamatergic neurons will decrease SE severity. To delete GRs, adult male and female $GR^{fl/fl}$ (B6.Cg-*Nr3c1*$^{tm1.1Jda}$/J) mice on a C57BL/6 background underwent bilateral stereotaxic injection of AAV9.CaMKII.Cre-mCherry into the ventral hippocampus (GRKO, N = 23). Controls included $GR^{fl/fl}$ mice injected with AAV9.CaMKI-

mCherry and $GR^{wt/wt}$ mice injected with the Cre-mcherry virus (Control, N=25). Two weeks later, mice received pilocarpine (400 mg/kg, s.c.) to induce SE. GR deletion was confirmed with immunohistochemistry and SE severity was determined with modified Racine scale behavioral scores. Survivors received diazepam at 75-min post-pilocarpine and were sacrificed 48hrs post-SE. GR deletion primarily affected hippocampal dentate granule cells, mossy cells, and variable numbers of CA1, CA3 and subicular pyramidal neurons. Latency to Racine class III partial seizures after pilocarpine injection was reduced among GRKO mice. Paradoxically, latencies to both class IV and V convulsive seizures were increased among GRKO mice. Although overall mortality was high in both groups (Con: 85%, GRKO: 65%), GR deletion significantly delayed the onset of death. Baseline morning corticosterone (CORT) concentrations were not impacted by GRKO. Measures of serum CORT revealed a rapid increase after the onset of SE; however, increases were similar between control and GRKO mice. In conclusion, GR deletion from ventral hippocampal glutamatergic neurons had divergent effects on early vs late seizure pathology during SE, which may reflect the state-dependent action of hippocampal GRs. These preclinical data shed light on the seizure mechanisms which are stress-dependent, building the rationale for the exploration of GR-modulating drugs as potential adjunctive treatments for late SE.

Title: Lacosamide decreases seizure-like activity in the neocortex of neonatal mice

Authors: *R. L. LANGTON, J. GLYKYS;
Pediatrics, Univ. of Iowa Carver Col. of Med., Iowa City, IA

Abstract: A high proportion of neonates experiencing seizures fail to respond to first-line anticonvulsant medications. Phenobarbital, a $GABA_A$ receptor allosteric modulator, has low efficacy in a significant number of neonatal seizures, yet it is one of the most used anticonvulsants in this age group. In mice, the poor effectiveness of phenobarbital is due to a higher intraneuronal chloride concentration in the neonatal neocortex compared to the adult one, resulting in more depolarizing actions of GABA. One approach to treat neonatal seizures is to

use anticonvulsants that do not rely on GABAergic modulation. Therefore, we investigated if lacosamide, a non-GABAergic anticonvulsive drug, decreases seizure-like activity in the neonatal neocortex *in vitro*. We tested the effect of different concentrations of lacosamide on seizure-like activity induced by the pro-convulsant drug 4-aminopyridine in adult (1-1.6 month-old) and neonatal (postnatal day 8-11) neocortical slices (layer IV/V) from wild-type C57BL/6J mice. We observed that lacosamide decreased seizure-like events in the neocortex of both adult and neonatal slices in a concentration-dependent manner. The ratio of seizures (events longer than 10 seconds) to total events also significantly decreased with lacosamide in both neonates and adults. We conclude that lacosamide effectively reduces seizure-like activity in neonates with similar efficacy as in adult brain slices. Our results support the rational use of lacosamide in the treatment of neonatal seizures.

Title: Human stem cell-derived interneurons transplanted into a genetic mouse model of cortical dysplasia-focal epilepsy syndrome

Authors: *A. GONZALEZ-RAMOS, F. BERGLIND, A. MIKROULIS, K. LAURIN, D. HATAMIAN, M. HAYATLEH, A. VOMBERGAR, A. BOSIO, M. LEDRI, M. KOKAIA, M. S. ANDERSSON;
Epilepsy Center, Lund Univ., Lund, Sweden

Abstract: Focal cortical dysplasia (FCD) is a group of developmental malformations of the cortex manifesting as confined regions of pathology. It is the most common cause of drug resistant epilepsy in children, with an estimated half of children undergoing epilepsy surgery diagnosed with FCD as well as a fifth of adults, creating a need for new therapeutic strategies. Previous studies have shown that early postnatal transplants of allogenic embryonic medial ganglionic eminence precursor cells or postinduction transplantation of human GABAergic neuronal progenitors enhances inhibition and decreases seizures in diverse rodent models of

temporal lobe epilepsy. Based on these positive results, we have explored a GABAergic cell-based replacement therapy for cortical dysplasia-focal epilepsy syndrome using the *Cntnap2*$^{-/-}$ mouse model, which develops spontaneous reoccurring seizures at six months of age. GABAergic neurons mainly expressing Calretinin and Calbindin were generated from human embryonic stem cells (H1 cell line) using transient expression of *Ascl1* and *Dlx2*. Human embryonic stem cell-derived interneurons (hdIN) were transplanted unilaterally to dorsal hippocampus of postnatal day 2 *Cntnap2*$^{-/-}$ mice and behavioral tests assessing memory function, cognitive flexibility, anxiety, and locomotor activity were performed at 4 and 6 months of age, followed by 2 weeks of continuous video-EEG monitoring (cell group n= 32, and sham group n=26). Histological evaluation confirmed survival of hdIN in all time points studied, up to 9 months, with hdIN migrating to contralateral hippocampus and adjacent structures. Behavioral seizures were significantly reduced in the cell- compared to the sham-treated group suggesting that hdIN transplantation reduces the severity of seizures but does not prevent the development of epilepsy in this model.

Title: Age, APOE and sex modify the bacterial composition of the gut microbiome in EFAD transgenic mice

Authors: *J. E. MALDONADO WENG[1], J. GAWENDA[1], A. AAMIR[1], Z. ISLAM[1], J. YORK[1], S. J. GREEN[2], M. LADU[1];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Rush Univ., Chicago, IL

Abstract: The gut microbiome (GM) is a modifiable metabolic organ composed of gastrointestinal bacteria, emerging as an important component of Alzheimer’s disease (AD) pathology. AD patients exhibit GM dysbiosis, a decrease in beneficial bacteria with an increase

in toxic microbial species. This disrupts the digestion of carbohydrates, lipids and proteins, limiting the production of crucial metabolites. However, it remains unclear how the universal biological variables (UBVs) of AD risk (age, *APOE* genotype, and sex) affect the GM bacterial composition. While age is the greatest risk factor for AD, *APOE4* as the greatest genetic risk factor, and females (♀) exhibit a 2-fold greater risk than males (♂). To study the interactions among UBVs, we utilized the EFAD transgenic mice (5xFAD$^{+/-}$/*APOE*$^{+/+}$), a mouse model that exhibits an age-dependent AD-like phenotype that includes increased behavioral deficits, Aβ deposition and neuroinflammation, with the following hierarchy: ♂E3FAD < ♀E3FAD = ♂E4FAD < ♀E4FAD. Our previous analysis of fecal samples from 4-month (M) ♂ and ♀ E3FAD and E4FAD mice demonstrated dysbiosis, specifically decreased abundance and richness in the GM, that reflected the hierarchy observed with the other measures of pathology, ♂E3FAD < ♀E3FAD = ♂E4FAD < ♀E4FAD. The current study addresses the effects of age by generating and comparing the compositional profiles, across taxonomic levels (amplicon sequence variants; ASVs, Genus, and Family), of the GM in 4M and 8M, ♂ and ♀, E3FAD and E4FAD mice. **Thus, our hypothesis is that the distinct GM compositional profiles will reflect an age-associated increase in AD pathology in EFAD mice.** Using 16S rRNA amplicon sequencing, abundance and richness were compared across samples via permutational analysis of variance (PERMANOVA). Analysis of similarities (ANOSIM) quantified the magnitude of differences in diversity with an R value that ranges 0 - 1, where 1 is complete dissimilarity. The results demonstrated that age increased the *APOE* and sex-driven differences of the compositional profiles. An unbiased heatmap analysis of 60 ASVs, identified by a machine-learning algorithm, distinguished 4M and 8M cohorts and clustered samples following the hierarchy of AD pathology we have established in the EFAD mice. Notably, PERMANOVA demonstrated that sex played a greater role than *APOE* in defining the composition profiles at 8M; inversely, the role of *APOE* was greater at 4M. This indicates that the role of *APOE* and sex in shaping the GM is dependent on age. Overall, distinguishing the GM of ♂E3FAD, ♀E3FAD, ♂E4FAD and ♀E4FAD across age is critical step in establishing the functional metabolic role of the GM in the context of AD pathology.

Title: Emergence of age-specific spatial memory deficits in the Transgenic Fischer 344 rodent model of Alzheimer's Disease (TgF344-AD) following adolescent intermittent ethanol exposure

Authors: *N. L. REITZ, A. J. STANWISE, P. MARSLAND, T. DEAK, L. M. SAVAGE; Behavioral Neurosci. Program, Dept. of Psychology, Binghamton University-SUNY, Binghamton, NY

Abstract: Alcohol-related brain damage (ARBD) and Alzheimer's disease (AD) have considerable overlap in key neuropathologies. One of the most consistent pathologies throughout the progression of AD and ARBD is the loss of cholinergic projections, largely from the basal forebrain to the hippocampus and associated cortices. By utilizing different aging timepoints (3- and 6-months) that encompass prodromal AD in rodent models, we tracked developmental ethanol-induced alterations in disease progression as determined by a cognitive battery that was assessed in a longitudinal design. The current study characterized spatial and social memory deficits in a transgenic rat model of AD (TgF344-AD) following adolescent intermittent ethanol (AIE) exposure. TgF344-AD and wildtype F344 rats (male and female) were exposed to an intragastric gavage of water (control) or 5g/kg of 20% ethanol (AIE) for a 2 day on/off schedule from PD27-57. AIE-exposed rats reached binge-like levels of ethanol intoxication as measured by their blood ethanol concentration (BEC; ~201 mg/dl). There were no differences in BECs between genotype or sex. Rats of both genotype and exposure groups gained weight at similar rates (separated by sex) throughout the AIE-exposure period. Following AIE, all rats completed a spontaneous alternation task on an elevated plus maze at PD90 (3 months) and PD180 (6 months). Overall, TgF344-AD rats had impaired spatial working memory when compared to wildtype rats at both 3- and 6-months of age. At 3- and 6-months of age, AIE-exposed TgF344-AD rats had significantly lower percent alternations when compared to both control and AIE-exposed wildtype rodents. However, AIE-exposed TgF344-AD rats were the only group that showed a further deficit in spatial memory at 6-months, relative to their 3-month scores. This indicates that AIE is accelerating the emergence of memory impairments in a rodent model of AD as early as 6 months of age. Behavioral data from a final aging timepoint (9 months) will be discussed in comparison to the 3- and 6-month data. Despite the lack of sex differences so far, we will continue to monitor sex as a variable through 9 months as AD prevalence and symptom progression has been shown to be sexually dimorphic in both pre-clinical and clinical settings.

Title: Housing Conditions Influence Mouse Fecal Microbiome Composition of C5aR1KO in the Arctic AD mouse model

Authors: *T. PETRISKO[1], S.-H. CHU[1], P. SELVAN[1], K. L. WHITESON[1], A. J. TENNER[2]; [1]Univ. of California, Irvine, CA; [2]Univ. California Irvine, Irvine, CA

Abstract: The complement (C') system, a critical component of the innate immune system, is activated in the context of Alzheimer's disease (AD) pathology. Overactivation of the C' cascade in AD is hypothesized to result in enhanced inflammation, synapse loss and cognitive decline. Previous studies have demonstrated that genetic ablation or pharmacologic inhibition of the downstream C5a receptor C5aR1, provides protection from gliosis and cognitive decline in AD animal models, although the underlying mechanisms remain unclear. The C' system is expressed throughout the body, including in the gut, and as a result may influence the composition of the gut microbiome. Importantly, gut microbes influence an animals' behavior, including cognitive changes via the gut-brain-axis. The objective of this study was to determine if constitutive deletion of C5aR1 (C5aR1KO) alters the fecal microbiome in either WT or the Arctic (Arc) model of AD, and if these changes could contribute to observed changes in AD-associated behavior. Due to the strong effect of microbiome normalization due to the coprophagic activity of mice, we also sought to determine the impact on the microbiome when C5aR1KO and C5aR1-suffcient (C5aR1+/+) were housed separately or together. Fecal samples were collected at 10 mo, and subjected to microbial focused Illumina sequencing.When housed separately from C5aR1+/+ mice, WT C5aR1KO animals had a significantly reduced alpha-diversity, ie. number of species within their microbiome, as measured by the Shannon Diversity Index, compared to C5aR1+/+ mice. Arc C5aR1KO mice had a trending decrease ($p<0.09$) compared to their Arc controls. Beta-diversity, as calculated by Bray-Curtis dissimilarities, indicated significant variation between the genotypes, and further analysis revealed WT C5aR1+/+ mice had increased levels of the genus *Alistipes* compared to both WT/Arc C5aR1KO mice, while WT C5aR1KO had elevated levels of *Turicibacter* compared to WT and Arc animals. In contrast, when all 4 genotypes were housed together, no difference in alpha- or beta- diversity was observe. Cohousing also eliminated differences in *Alistipes* and *Turicibacter* levels. This study demonstrates that deletion of C5aR1 does influence the fecal microbiome, but only when KO mice are housed alone. In Hernandez et al, 2017, in which C5aR1KO mice were housed separately, Arc mice displayed reduced cognition compared to WT. As there was no difference in the microbiome of WT and Arc C5aR1+/+ animals, cognitive changes in these animals were not due to different populations of microbes. However, cohousing between all genotypes is required to fully eliminate microbiome from CNS causal effects.

Title: Expression of sex hormone receptors differs in postmortem brain regions between Alzheimer's Disease subjects with and without prior depression

Authors: *K. PRZYBYL[1], W. LUO[1], E. H. BIGIO[2], S. WEINTRAUB[2], M.-M. MESULAM[2], E. E. REDEI[1];
[1]Psychiatry and Behavioral Sci., [2]Mesulam Ctr. For Cognitive Neurol. and Alzheimer's Dis., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Stress-related disorders, like depression, has been linked to a state of accelerated aging and subsequent pathological cognitive aging. Major depressive disorder (MDD) is a risk factor for the development of dementia, and MDD prevalence rate is up to 37% in dementia. Even moderate depression increases risk of progression from healthy to mild cognitive impairment, and to dementia. Prevalence of both MDD and dementia are higher in women compared to age-matched men. Progression of cognitive decline and its association with MDD shows that females are particularly vulnerable. Men and women with AD exhibit different cognitive and psychiatric symptoms, and women show faster cognitive decline after diagnosis of mild cognitive impairment or AD dementia. We hypothesized that sex differences in the expression of sex hormone receptors and Cytochrome P450 Family 19 Subfamily A Member 1 (CYP19A1), the aromatase enzyme that aromatize testosterone to estradiol, in the hippocampus (Hip) and anterior cingulate cortex (ACC) might be more pronounced between the subpopulation of AD subjects with MDD compared to AD. We examined the differences in transcript levels of estrogen receptor 1 (*ESR1*), *ESR2*, Progestin And AdipoQ Receptor Family Member 7 (*PAQR7*), also named as membrane progesterone receptor alpha, (*mPRα), PAGR8* (*mPRβ*) and *CYP19A1* in post-mortem brain samples from individuals with AD dementia and neuropathologic changes of AD, with (n=15) and without (n=19) prior depression. Hippocampal and ACC tissues were received from the Brain Bank of the Northwestern Cognitive Neurology and Alzheimer Disease Center. Transcript levels were determined by quantitative RT-PCR. Significant comorbidity differences were found in both Hip and ACC of AD+MDD samples compared to those of AD without MDD; *mPRα*, and *mPRβ* expressions were significantly lower in AD+MDD samples.

Expression of *CYP19A1* in the ACC was significantly and dramatically reduced in AD+MDD in both sexes, compared to that of AD without MDD. Expression of both *ESR1* and *ESR2* were significantly higher in the ACC of females with AD without MDD, but reduced in AD+MDD females and all males. These data suggest that sex hormone receptor regulation, and the availability of estradiol in the brain, could be altered by MDD in AD, and that this can lead to identifying novel drug targets in a subgroup of AD patients.

Title: Metabolomic analysis of mouse forebrain reveals that exercise may reverse some effects induced by loss of ovarian function and by an Alzheimer’s disease genotype

Authors: *J. WILLIAMS[1], E. WEN[1], E. A. FINCH[2], C. A. COLTON[3], J. W. THOMPSON[4], K. J. ADAMS[4], C. L. WILLIAMS[1];
[1]Dept. of Psychology & Neurosci., Duke Unviversity, Durham, NC; [2]RLA, Ctr. for Scientific Res., Rockland, MD; [3]Dept. of Neurol., Duke Univ. Med. Ctr., Durham, NC; [4]Duke Proteomics and Metabolomics Core Facility, Duke Univ. Sch. of Med., Durham, NC

Abstract: Alzheimer’s Disease (AD) disproportionately impacts women and the loss of ovarian hormones during perimenopause has been identified as a sex-specific risk factor. Physical exercise has neuroprotective effects for people with cognitive impairment and may be an effective therapeutic intervention for AD. While understanding of AD is limited by lack of biomarkers for diagnosis and treatment, metabolomics is a powerful tool to identify changes in biochemical pathways associated with disease progression and treatment. We sought to identify changes in cognition and forebrain metabolite levels in 36-week-old, CVN-AD mice (APPSwDI/mNos2$^{-/-}$) induced by a gradual loss of ovarian function (mouse model of transitional menopause) and by chronic aerobic exercise. Local immune suppression and arginine deprivation drive AD pathology in CVN-AD mice; by 36 weeks of age sedentary CVN-AD mice normally show memory loss and typical AD neuropathology. In this study, CVN-AD mice and control C57BL/6 and mNos2$^{-/-}$ mice were treated with either oil or 4-vinylcyclohexene diepoxide (VCD) to induce gradual ovarian failure. Half of the CVN-AD mice remained sedentary while the other half were exercised with both voluntary wheel running (access 5 days/wk) and forced

treadmill training (2 days/wk) for 12 wks beginning at 24 WOA, which is after cycling had ceased in the VCD group. All control mice remained sedentary. Novel object recognition tests at 36 WOA revealed that exercise improved short-term memory of CVN-AD mice, especially in mice that were no longer cycling. Following behavioral testing, mice were sacrificed and forebrain homogenates analyzed using the Biocrates MxP Quant 500 kit. As expected, arginine levels were decreased in CVN-AD mice compared to controls. However, exercise prevented this decrease, supporting its neuroprotective effects. Five metabolic pathways diverged between CVN-AD and C57 mice including aminoacyl-tRNA biosynthesis; glycine, serine, and threonine metabolism; arginine biosynthesis; alanine, aspartate, and glutamate metabolism; and glyoxylate and dicarboxylate metabolism. There was little overlap in the metabolites affected by ovarian failure across C57, NOS, and CVN-AD mice, suggesting that transitional menopause has differential effects in the 3 genotypes. Ceramides and sphingolipids increased significantly with exercise, though this effect was less pronounced in VCD mice. Overall, these results suggest that loss of ovarian function has differential effects on brain metabolic profiles in AD and non-AD mice and that exercise training can prevent some of the metabolic changes induced by an AD genotype and transitional menopause.

Title: Aerobic exercise alters the lipidome in mild cognitive impairment

Authors: T. J. GROSS[1], R. MALHAS[1], M. MONTGOMERY[2], F. MACCIARDI[1], A. K. CHEEMA[3], M. ESPELAND[4], S. O'BRYANT[5], C. W. COTMAN[1], L. BAKER[4], *M. MAPSTONE[1];
[1]Univ. of California-Irvine, Irvine, CA; [2]Hobart and William Smith Colleges, Geneva, NY; [3]Georgetown Univ., Washington, DC; [4]Wake Forest Univ., Winston-Salem, NC; [5]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: There is some controversy whether aerobic exercise benefits episodic memory in people with Mild Cognitive Impairment (MCI). The underlying mechanism of putative benefits of aerobic exercise may include alterations to lipid metabolism. The metabolism of polyunsaturated lipids including docosahexaenoic (DHA) and arachidonic (AA) polyunsaturated fatty acids (PUFAs) may impact the pathobiology of early Alzheimer's disease (AD). This disease-associated lipid dyshomeostasis may be improved with a sustained program of aerobic training. In a retrospective analysis of the Piedmont Aging, Cognition, and Exercise (PACE) study we considered 28 participants with MCI (> 50 yrs, 50% female, 18% APOE ε4 carriers) randomly assigned to Aerobic Exercise (n = 18) or Stretching (n = 10) arms. Prior to and following the 24-week study, participants contributed venous peripheral blood plasma specimens. We analyzed blood lipids using the 5500 QTRAP® LC-MS/MS (Sciex) targeted mass spectrometry platform. We modelled changes in PUFA metabolite abundances pre- and post-study as a function of intervention arm using restricted maximum likelihood (REML) regression as evaluated for each lipid. We found that tri-and di-acylglycerols (TAGs and DAGs) comprised the majority of altered DHA and AA PUFA-bearing lipids (89%), of which eight unique glycero-PUFA metabolites were altered (nominal $p < .05$) following active aerobic intervention. Subsequent analyses demonstrated that 33% of TAGs (but not DAGs) which incorporated any fatty acid in the DHA or AA biosynthetic pathway significantly varied due to aerobic exercise (five unique metabolites, nominal $p < .05$). Fatty acyl-glycerol dyshomeostasis has been frequently associated with aging-associated metabolic diseases. In addition, lipid dysmetabolism plays an increasingly studied and important role in early AD. These peripheral dynamics involving PUFAs support the notion of a physiologically extended brain-peripheral metabolic axis that is responsive to exercise intervention. Aerobic exercise may be useful for modifying the pathophysiological trajectory of AD, especially early in the course of the disease.

Inst., [5]Kimmel Ctr. for Biol. and Med. at the Skirball Inst., NYU Grossman Sch. of Med., New York, NY; [6]Program in Chem. Biology, Sloan Kettering Inst., [7]Med., Mem. Sloan Kettering Cancer Ctr., New York, NY

Abstract: The recognition of the importance of complicated stressor-to-phenotype associations in human disease demands a greater understanding of how specific stressors affect interactomes, especially in the context of late onset neurodegenerative disorders such as Alzheimer's disease (AD). Currently untreatable diseases arise due to variations in, and through a combination of, multiple stressors of genetic, epigenetic, and environmental nature. Unfortunately, how these stressors lead to a specific disease phenotype or inflict a vulnerability to some cells and tissues but not others, remains largely unknown and unsatisfactorily addressed. This concept 'selective vulnerability' is especially relevant in AD and related neuropathological conditions, where specific neuronal populations and circuits degenerate while others do not, making treatment a vexing problem. Accordingly, analysis of cell- and tissue-specific interactome networks is posited to shed light on organization of biological systems and subsequently to disease vulnerabilities. To date, deriving human interactomes across different cell- and disease-contexts remains a challenge. We provide evidence linking stressor-induced protein interactome network perturbations to the formation of pathologic scaffolds termed epichaperomes. A specialized 'omics platform, epichaperomics is a viable and reproducible experimental solution to obtaining rigorous context-dependent interactomes. Epichaperomics can be performed as a standalone approach as well as complement and enhance currently available conventional approaches to aid the scientific community in defining, understanding, and ultimately controlling interactome networks of complex diseases such as AD. Ultimately, this approach may aid the transition from a limited single-alteration perspective in disease to a comprehensive network-based mindset, which we posit will provide an evidence based view how these maladaptive changes from stressor to phenotype provide unique precision medicine opportunities for diagnostic and therapeutic development, especially in the context of neurodegenerative disorders such as AD where treatment options are currently limited.

Title: Assessing genetic contributions to cerebrovascular damage in a novel MTHFR^{C677T} mouse model

Authors: *A. M. REAGAN[1], K. E. CHRISTENSEN[3], A. HABER[2], R. ROZEN[3], J. A. MEYER[4], J. PETERS[4], L. L. FIGUEIREDO[4], S. C. PERSOHN[4], A. A. BEDWELL[4], K. ELDRIDGE[4], R. SPEEDY[4], G. W. CARTER[1], M. SASNER[1], P. R. TERRITO[4], G. R. HOWELL[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]The Jackson Lab., Farmington, CT; [3]McGill Univ., Montreal, QC, Canada; [4]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Background: Mechanisms driving cerebrovascular decline during aging and in disease are poorly understood. Methylenetetrahydrofolate reductase (*MTHFR*) is a critical enzyme in the folate/methionine/homocysteine pathway. Variants in *MTHFR*, notably *C677T*, have been associated with AD, vascular dementia, and cardiovascular disorders. Approximately 30% of individuals carry at least one copy of *MTHFR^{C677T}*, causing a 50% decrease in MTHFR enzyme efficiency. Reduced efficiency can lead to high levels of homocysteine in blood, resulting in vascular inflammation and increased risk for cerebrovascular damage. A clinical trial aimed at reducing elevated homocysteine levels using dietary supplements did not slow cognitive decline in AD patients. We hypothesize that brain-specific vascular expression of *MTHFR^{C677T}* in cerebrovasculature drives damaging effects. **Methods**: CRISPR technology was employed to engineer the *Mthfr^{C677T}* allele into C57BL/6J (B6) mice. Vascular health is currently being assessed in 6, 18 and 24 months-old mice using immunofluorescence to examine blood brain barrier integrity in the cerebrovascular unit: endothelium (CD31) smooth muscle (αSMA) pericytes (PDGRFβ) basement membrane (ColIV) and tight junctions (Claudin-5, Occludin, ZO-1) as well as determining the presence of extravascular fibrin. Electron microscopy (EM) is used to examine cross sectional cerebrovascular ultrastructure. *In vivo* PET/CT imaging is utilized to assess blood flow. Bulk RNA sequencing and Reduced Representation Bisulfite Sequencing (RRBS) were performed on half brains to assess differential gene expression and DNA methylation, respectively. **Results**: Our preliminary data show that *Mthfr^{C677T}* mice phenocopy the human condition — mice show a 50% reduction in MTHFR enzyme activity in the liver and elevated levels of plasma homocysteine. Interestingly, young *Mthfr^{C677T}* mice also show a 50% reduction in MTHFR enzyme activity in the brain. PET/CT demonstrates reduced blood perfusion in female mice carrying the variant. In all mice carrying the variant, immunofluorescence shows reduced vascular density in the cortex, and EM reveals endothelial and pericyte apoptosis, reduced luminal size, and increased astrocyte and microglial presence in the microenvironment. **Conclusion**: We have created a novel mouse strain to examine mechanisms by which *MTHFR^{C677T}* could increase risk for vascular dysfunction. This work aims

to identify novel therapeutic approaches that reduce cerebrovascular pathology in AD and other dementias.

Title: Framework and Simulations for Quasi Real-time Access to Artifact-free Muscle Response during Neuromuscular Electrical Stimulation

Authors: *R. PILKAR[1], K. MOMENI[2], M. RAVI[2], E. GARBARINI[2], G. F. FORREST[3]; [1]Ctr. for Mobility and Rehabil. Engin. Res., [2]Reynolds Ctr. for Spinal Stimulation, [3]Kessler Fndn., West Orange, NJ

Abstract: Neuromuscular electrical stimulation (NMES) remains one of the effective rehabilitation modalities for addressing the recovery of neuromuscular function post spinal cord injury (SCI). NMES operates on a basic principle that the application of electrical current to a muscle nerve or muscle belly can elicit action potentials and cause muscle contraction in paralyzed muscles. It has been reported that the NMES interventions that combine volitional efforts are potentially more effective as combining patient's voluntary contractions with electrical stimulation (ES) produces the strongest contraction, targets neuroplasticity, and elicits activation of muscles and multiple modes of afferent stimulation. However, these interventions are limited by the fact that active monitoring of voluntary neuromuscular efforts via electromyography (EMG), particularly at the stimulated muscle, is unattainable due to the presence of stimulation artifact. Although recent developments have produced several software-based approaches for offline processing of EMG data to eliminate ES artifact, currently, no tool exists which will provide real-time access to the neuromuscular responses during NMES. In the current investigation, we evaluate the applicability of a novel, inverse fast Fourier Transform (iFFT)-based method for artifact removal in real-time and compare its performance with our previously published and validated empirical mode decomposition (EMD)-notch filtering method. For our simulations, we utilize pre-recorded EMG data from the rectus femoris (RF)

muscle during NMES (35 Hz, 300 μsec) from five able-bodied (AB) and five individuals with incomplete SCI. To simulate a real-time scenario, samples within the sliding window of N seconds (N = 0.5, 1, 1.5, and 2 seconds) of the raw RF EMG signal are sequentially fed to the iFFT algorithm, and artifact removal operation is performed. The entire raw EMG signal is simultaneously processed using the EMD-notch filtering method. The normalized root-mean-squared-error (nRMSE) between the two outputs are computed. The secondary validation is performed using the cross-correlation of iFFT processed output with the concurrent torque profiles. Based on the nRMSE and cross-correlation coefficients (r) for each window size (N), the window size with the lowest nRMSE and highest r will be used for future experimental validations. This investigation is a significant step towards developing a unique system that will potentially provide real-time access to the inherent neuromuscular responses (intensity of induced contraction, muscle fatigue, motor unit firing rates, etc.) during NMES.

Title: Tolerability and effects of a therapeutic suprathreshold high-frequency rTMS protocol in able-bodied individuals

Authors: *N. BRIHMAT[1], A. HOXHA[2], D. ALLEXANDRE[2], S. H. SALEH[2], J. ZHONG[3], G. H. YUE[4], G. F. FORREST[1];

Abstract: High-frequency repetitive transcranial stimulation (HF-rTMS) is known to induce corticospinal excitability (CSE) increase and to have beneficial effect on motor function in individuals with motor deficits such after Spinal Cord Injury (SCI). A recent animal study has shown the beneficial regenerative and motor effects of a high-intensity, high-frequency rTMS protocol in a mice model of SCI. Here, we examine if a single session of a HF-rTMS protocol, equivalent to the one effective in mice, can be safely administered to able-bodied (AB) individuals. Four right-handed men (30.8 ± 1.9 years old) were included in this pilot study. Using a MagPro X100 device equipped with a figure-of-eight coil, HF-rTMS was delivered over

the left primary motor cortex, in 10 trains of 75 biphasic stimuli at a frequency of 15 Hz at 120% of the resting motor threshold (RMT). TMS safety and side-effects questionnaires were administered at the end of the session. The numeric rating scale (NRS) and Visual Analogue Scale (VAS) were administered to investigate any changes in pain. We assessed CSE with measures of resting (rMEP) and active (aMEP, at 10-25% maximal voluntary contraction) Motor Evoked Potential of the first dorsal interossei (FDI) muscle at 120% motor threshold and motor function using grip strength measures and the Box and Block test (BBT). The session was safely administered and well-tolerated by all the participants without any reported side-effect or pain development. Preliminary results reveals that a single session of HF-rTMS applied at 120% RMT induced an increase of CSE at rest (+24.8 ± 11.7% compared to baseline, d=1.12 using paired t-test) but not during active muscle contraction (-17.9 ± 28.8% compared to baseline, d=0.47). No significant changes were observed for grip strength and BBT measures. The results of this pilot study demonstrate that a single-session of HF-rTMS at 120%RMT can be safely administered to AB individuals without any adverse event. Ten minutes rTMS session induced CSE modulation suggesting that if repeated and combined with motor training could result in motor function improvements. These results should be considered when dealing with clinical population.

Title: Spinal cord transcutaneous stimulation combined with activity-based training can improve sitting balance in people with tetraplegia

Authors: *F. ZHANG, K. MOMENI, M. RAVI, A. BHEEMREDDY, R. PILKAR, G. F. FORREST;
Kessler Fndn., West Orange, NJ

Abstract: Cervical spinal cord injury (SCI) often leads to impairment or loss of motor and/or sensory function in upper limbs, trunk, and lower limbs, resulting in impaired sitting balance. Trunk balance is ranked as the third priority to improving the quality of life of people living with

tetraplegia, even more important than bladder/bowel function and walking. Non-invasive spinal cord transcutaneous stimulation (scTS) is a novel electrical neuro-modulation strategy that has the potential to increase the excitability of these spinal circuits and facilitate functional recovery after SCI. Our preliminary data have shown that low-intensity cervical scTS combined with short-term activity-based training (ABT) can lead to immediate and long-lasting (even further increased at 3 months follow-up) upper extremity (UE) functional recovery in people with complete and incomplete tetraplegia. The goal of this study is to investigate whether the scTS+ABT intervention can also improve sitting balance in individuals with tetraplegia. Three individuals with complete (ASIA Impairment Scale, AIS A) and incomplete tetraplegia (AIS B and D) were trained and tested this study. Each participant received a short-term intervention of scTS combined with ABT for 60 minutes/session and 2-3 sessions/week. Sub-threshold, tonic stimulation (monophasic, 1ms rectangular pulses, 5kHz carrier frequency) was delivered at cervical and thoracic spinal segments over the dorsal skin, when participants received ABT focusing on UE functional tasks. The results showed that scTS combined with ABT led to improved sitting balance in all three participants, even when no specific trunk training was provided. The sitting balance scales in Activity-based Balance Level Evaluation (ABLE) were dramatically increased at post-intervention in two individuals (gains: 6pts and 9pts). In the Modified Functional Reach Test (MRFT), all tested participants demonstrated improved forward reaching distances (increased by 252.78%, 255.56%, and 19.48%, respectively). More importantly, these gains in sitting balance maintained or even further improved during the 1-month follow-up period without receiving any intervention, suggesting the potential for long-term restoration of motor control. The research findings will provide preliminary data for a future large clinical trial to establish clinical efficacy and scientific evidence for understanding the underlying mechanism for functional and neurological recovery.

Title: Improved gait kinematics with spinal cord transcutaneous stimulation during overground walking

Authors: *M. ANJARIA[1], K. MOMENI[1], M. RAVI[1], A. BHEEMREDDY[1], F. ZHANG[1], R. PILKAR[2], G. F. FORREST[1];

[1]Reynold Ctr. for Spinal Stimulation, West Orange, NJ; [2]Ctr. for Mobility and Rehabil. Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: A previous study by our group has shown that spinal cord transcutaneous stimulation (scTS) improves gait kinematics in subjects with complete or incomplete spinal cord injury (SCI) in overground walking using individualized and optimal parameters of scTS such as frequency and amplitude. The goal of this study was to evaluate spatial-temporal parameters and joint kinematics for one participant with an incomplete spinal cord injury during one session of activity-based training with and without stimulation walking overground. Multiple cohorts of scTS was delivered with electrodes on spinal sites between thoracic and sacral spinal sites (cathodes) and bilateral iliac crests (anodes). The stimulation waveform consisted of a monophasic rectangular pulse with 1ms pulse width and 10kHz carrier frequency. Full-body kinematics (*Motion Analysis, Santa Rosa, CA)* were determined while participant walked with and without stimulation. Results show a significant effect of stimulation on intra and inter-limb hip and knee joint kinematics. When overground gait training with stimulation was compared to overground gait training without stimulation: i) the coefficient of variation for left hip and knee joint kinematics during continued stepping decreased by 31% and 35% respectively; ii) the coefficient of variation for right hip and knee joint kinematics during continued stepping decreased by 2.5% and 6.5% respectively and iii) the standard deviation for left and right leg stride length decreased by 81% and 41% respectively. Our preliminary results show that the usage of optimal and individualized scTS parameters during overground gait training can facilitate more consistent gait kinematics in participants with SCI.

Title: Decreased Variability in Gait Kinematics While Walking in Exoskeleton with Spinal Cord Transcutaneous Stimulation

Authors: *A. BHEEMREDDY[1], K. MOMENI[1], M. RAVI[1], M. ANJARIA[1], F. ZHANG[1], R. PILKAR[2], G. F. FORREST[1];

Abstract: The goal of this study was to evaluate the efficacy of non-invasive spinal cord transcutaneous stimulation (scTS) on improvement of exoskeleton gait for motor incomplete spinal cord injury (SCI). ScTS was applied below motor threshold during exoskeleton training. Transcutaneous stimulation (scTS) was delivered on thoracic spinal sites (as cathodes) using individualized parameters of stimulation for an individual with a motor incomplete SCI. A series of temporal and spatial neurophysiological mapping sessions determined the individualized stimulation parameters. During training, a standardized method for the 6-minute walk test (6MWT) was collected weekly with and without stimulation within exoskeleton during over-ground walking sessions. With the 6MWT, additional motion data were collected using inertial measurement unit (IMU) sensors (APDM Opals, USA) placed on the lower limb segments, and trunk (lumbar). Data from IMUs determined bilateral hip, knee and ankle 3-axis joint angles for both stimulation and no-stimulation conditions during exoskeleton gait. For repeated gait cycles, immediate onset of stimulation significantly decreased standard deviation for mean bilateral hip, knee and ankle joint angles. For left hip and bilateral knee the decrease in standard deviation was at least 40%. Longitudinal results show efficacy of training using scTS for one individual with a motor incomplete SCI to facilitate less variable gait profile for people with SCI walking in exoskeleton.

Title: Spinal Cord Transcutaneous Stimulation Elicits Volitional Contraction in an Individual with Motor Complete SCI

Authors: *K. MOMENI[1], M. RAVI[2], A. BHEEMREDDY[2], F. ZHANG[2], R. PILKAR[3], G. F. FORREST[2];
[2]Ctr. for Spinal Stimulation, [3]Ctr. for Mobility and Rehabil. Engin. Res., [1]Kessler Fndn., West Orange, NJ

Abstract: Non-invasive spinal cord transcutaneous stimulation (scTS) is applied to one or multiple spinal segments for neuromodulation, targeting spinal circuity. For individuals with spinal cord injury (SCI), recent studies have shown that spinal sensorimotor networks can be activated when electrical stimulation is delivered to the corresponding spinal segments. Our

preliminary findings have shown that applying scTS with optimized individualized parameters for each individual could target different neural networks after SCI. The goal of this pilot study is to identify the individualized scTS parameters for restoring volitional control during the voluntary initiation and execution of a specific motor task for an individual with a motor-complete SCI. An individual with a motor-complete SCI lesion was recruited to participate in the study. Sub-threshold, tonic scTS was delivered at thoracic and lumbar spinal segments over the dorsal skin, anodes placed on the anterior iliac crests. scTS waveforms were monophasic, rectangular 1ms pulses with a carrier-wave frequency set at 5 kHz. Systematic modulations for stimulation parameters with intensities at subthreshold determined voluntary initiation and extension of left knee in a recumbent, gravity-neutral position. Surface electromyography data were recorded to monitor lower extremity muscle activity. Using several stimulation sites or cohorts (i.e., thoracic and lumbar segments) resulted in initiating and successfully executing targeted motor tasks. These preliminary findings highlight how scTS neuromodulation of the spinal circuitry can restore significant motor function for individuals with motor-complete SCI.

Title: Identifying Optimal Spinal Levels and Spinal Cord Transcutaneous Stimulation Parameters Using EMG Responses after SCI

Authors: *M. RAVI[1], K. MOMENI[1], F. ZHANG[1], A. BHEEMREDDY[1], M. ANJARIA[1], R. PILKAR[2], G. F. FORREST[1];
[1]Reynolds Ctr. for Spinal Stimulation, [2]Ctr. for Mobility and Rehabil. Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: Increasing number of researchers have shown that modulating the circuitry of the spinal cord by using non-invasive Spinal Cord Transcutaneous Stimulation (scTS), usually in combination with activity-based training, can enhance sensorimotor function in lower and upper limbs as well as help with mitigating spasticity for individuals with spinal cord injury (SCI). However, due to the non-invasive nature of scTS, it can be challenging to target specific motor pools for muscles or muscle groups necessary for specific tasks. Multi-site scTS stimulation using specific stimulation parameters (amplitude frequency and waveform mode/phase) and

electromyography (EMG) can determine optimal and individualized spatial and temporal physiological parameters of stimulation. We were able to recruit individuals with SCI (both complete and incomplete) and applied scTS at select spinal levels between cervical and coccyx using anodes placed on the anterior iliac crests bilaterally and EMG was recorded at key lower limb and abdominal muscles. Stimulation waveforms were either monophasic, biphasic or rectified. Carrier-wave frequency was set at 5 kHz for monophasic and biphasic modes of stimulation whereas there was no carrier frequency in the rectified mode. Systematic modulations of amplitude and frequency induced specific EMG responses for different spinal roots. The responses were analyzed by latency - Early Responses (<15ms after stimulation pulse) and Late Responses (>15ms). Results of the analyses, show that the stimulation induced EMG responses can be used to determine the individualized and optimal scTS parameters of subthreshold stimulation to target voluntary control of specific muscles after SCI.

Title: Distinct functional organization of itch-sensing neurons

Authors: *Y. XING, H. R. STEELE, H. HILLEY, T. NIEHOFF, R. NHO, K. LAWSON, L. HAN;
Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA

Abstract: Diverse sensory neurons exhibit distinct neuronal morphologies with varieties of axon terminal arborizations subserving their functions. Due to its clinical significance, the subject of the molecular and cellular mechanisms of itch is undergoing intense study. However, a complete analysis of itch-sensing terminal arborization morphology is missing. Using a novel *MrgprC11*^{CreERT2} transgenic mouse line, we labeled a small subset of itch-sensing neurons that express multiple itch-related molecules including MrgprA3, MrgprC11, histamine receptor H1, IL-31 receptor, 5-HT receptor 1F, natriuretic precursor peptide B, and neuromedin B. By combining sparse genetic labeling and whole-mount PLAP histochemistry, we found that itch-sensing skin arbors exhibit free endings with extensive axonal branching in the superficial

epidermis and large receptive fields. We also found that itch-sensing neurons display distinct morphologies in their central arbors within the dorsal horn of the spinal cord when innervating different body locations. Our optogenetics study also showed that activating the nape of the neck and the hind paw can induce itch behaviors including scratching (nape of the neck) and biting (hind paw). Moreover, the hind paw showed an increased sensitivity to the external light input, suggesting regional differences in itch transmission. These results revealed the unique morphological and functional characteristics of itch-sensing neurons and provide novel insights into the basic mechanisms of itch transmission.

Title: Staphylococcus aureus virulence factors as novel mediators of itch

Authors: *Y. NHO[1], K. LAWSON[1], F. BANOVIC[2], L. HAN[1];
[1]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA; [2]Univ. of Georgia, Athens, GA

Abstract: Atopic dermatitis (AD) is one of the most common, debilitating chronic skin diseases that can often result in lifelong burdens for affected patients, without any available cures. *Staphylococcus aureus* (*S. aureus*) is a major human pathogen that has been found to have a significant presence on the lesional skin of AD patients. While there has been some work to investigate the relationship between *S. aureus* and pain, there has been little research focused on the contributions of the bacteria to itch, a major symptom of AD. Therefore, we examined *S. aureus* virulence factors to investigate cellular and behavioral mechanisms in which the bacteria contributes to AD. Calcium imaging of dorsal root ganglia (DRG) in $Pirt^{GCaMP3/+}$ mice revealed that 10μM of δ-Toxin activated an average of 5.17% of DRG, while 10μM of PSMα2 and PSMα3 activated 30.8% and 23.0%, respectively. These results suggest that *S. aureus* virulence factors can directly activate sensory neurons. To investigate *S. aureus*-mediated activation of specific itch sensing neuron populations, we looked at the overlap in calcium activation by itch-receptor agonists and virulence factors. Results showed overlap in calcium influx between the virulence factors and several itch agonists, including β-alanine, chloroquine, and sphingosine-1-

phosphate. These results indicate, for the first time, potential mechanisms for *S. aureus*-mediated itch through itch-sensing neurons populations including Mas-related g-protein coupled receptor (Mrgpr) D^+, $MrgprA3^+$, and natriuretic peptide B ($NPPB^+$). To examine the behavioral responses induced by individual *S. aureus* virulence factors, we used a cheek injection behavior test in C57BL/6, which effectively differentiates between itch and pain behavior through scratching and wiping, respectively. We found that δ-Toxin, PSMα2, and PSMα3 all induced significant scratching and wiping of the cheek. These results suggest that *S. aureus* virulence factors can mediate itch and pain behavior. In summary, our findings indicate new directions for future studies understanding the contributions of *S. aureus* in itch and AD, as well as the development of therapies against the bacteria in skin disease.

Title: Cerebellin family members are differentially expressed across sensory modalities

Authors: *C. HANSON, K. LAWSON, L. HAN;
Georgia Inst. of Technol., Atlanta, GA

Abstract: The cerebellins (Cbln) family is a group of secretagogues and trans-synaptic enhancers. These hexameric proteins form synapse spanning scaffolds with a pre-synaptic neurexin and post-synaptic delta ionotropic glutamate receptor (GRID). Although their role in synaptic organization has been probed throughout the brain, examination of cerebellins in the periphery and spinal cord has been sparse. We used RNAScope in situ hybridization to provide novel evidence of differential expression of cerebellin family members in distinct groups of dorsal root ganglia (DRG) neurons. Cbln1 is preferentially expressed by non-peptidergic C-fibers that co-express Mas-related G-protein coupled receptor A3 (MrgprA3); these neurons constitute a unique population specifically linked to itch. Cbln2 is expressed by two separate groups of A-fibers that both express mechanosensitive ion channel Piezo2. Two-thirds of Cbln2 neurons are medium sized and marked by Tropomyosin receptor kinase B (TrkB); this group likely represents Aδ low threshold mechanoreceptors (LTMRs). One-third of Cbln2 neurons are marked by parvalbumin (PV) and Tropomyosin receptor kinase C (TrkC) expression, suggesting

this group constitutes proprioceptive neurons. We additionally demonstrate that Cbln+ DRG neurons express an isoform of binding partner neurexin. Within the dorsal horn, Cbln1 expression is concentrated in lamina II, where resident interneurons receive nociceptive afferents. Cbln2 is expressed more ventrally, in regions that receive tactile input from LTMRs. These results support our hypothesis that Cbln family members are differentially expressed across sensory modalities, in both the central and peripheral nervous system.

Title: Mrgprc11+ drg sensory neurons mediate glabrous skin itch

Authors: *H. STEELE[1], Y. XING[2], Y. ZHU[1], H. HILLEY[1], K. LAWSON[1], Y. NHO[1], T. NIEHOFF[1], L. HAN[3];
[2]Biol. Sci., [3]Sch. of Biol. Sci., [1]Georgia Inst. of Technol., Atlanta, GA

Abstract: Although chronic itch is the most common reason for visiting the dermatologist, there remain few effective treatments. Additionally, glabrous skin (palms and soles) itch, has attracted little attention within the field due to a lack of methodology. This is despite glabrous skin itch, which arises from a variety of medical conditions such as plantar and palmar psoriasis, dyshidrosis, and cholestasis, being extremely debilitating. To identify the neuronal populations mediating glabrous skin itch we examined the central peripheral innervation pattern of three previously identified itch-sensing neurons (MrgprA3+, MrgprD+, and MrgprC11+). We found that both MrgprD+ and MrgprC11+ sensory neurons densely innervate glabrous skin, while MrgprA3+ sensory neurons do so only very sparsely. These results indicate, for the first time, the potential mechanistic differences that exist between hairy and glabrous skin itch. As MrgprC11+ neurons are previously uncharacterized, we used immunostaining and RNAscope in situ hybridization to determine that MrgprC11 is expressed in a subset of small-diameter peptidergic neurons that constitute ~18% of DRG sensory neurons, including the majority of both MrgprA3+ and NPPB+ itch-sensing neurons. To investigate and the mechanisms of glabrous skin itch, we developed novel acute and chronic mouse behavioral assays to examine itch sensation arising from the glabrous skin of the plantar hindpaw. We found that mice exhibit specific biting

behavior in response to pruritogens and licking in response to algogens. To confirm this specificity, we also used morphine as an analgesic. We found that although morphine significantly attenuated capsaicin-induced licking behavior, it had no effect on Bam8-22-induced biting behavior. Using this assay, we then demonstrated that chemogenetic activation of MrgprA3+ and MrgprD+ nerves in the glabrous skin do not induce biting behavior, suggesting that they do not mediate glabrous skin itch. In contrast, we found that activation of MrgprC11+ neurons using both chemogenetic activation and the MrgprC11 agonist Bam8-22 induced significant dose-dependent biting behaviors in glabrous skin. Finally, we found that ablation of MrgprC11+ neurons almost completely abolishes both acute (Bam8-22) and chronic glabrous skin itch. These results suggest that MrgprC11+ neurons are a major mediator of glabrous skin itch. In summary, our findings reveal new avenues for future glabrous skin itch study and the development of glabrous-skin specific anti-itch therapies.

Title: The posterior insula contributes to both affective and sensory processing of pain and itch

Authors: *F. KADAKIA, S. DAVIDSON;
Univ. of Cincinnati Neurosci. Grad. Program, Cincinnati, OH

Abstract: Pain and itch are distinct percepts but both are complex emotional, motivational, and cognitive somatosensory experiences that require supraspinal processing. The insular cortex is thought to be involved in encoding the affective and sensory components of nociceptive stimuli. However, it is unknown how the insula controls behavioral responses to nociceptive and pruriceptive stimuli. We hypothesized that the insula regulates the valence of somatosensory information and modulates sensory and affective pain and itch behavior. We conducted anatomical, physiological, and behavioral experiments to characterize the involvement of the insula in pain and itch processing. Anterograde and retrograde tracer experiments revealed that the posterior insula (PIC), not anterior, receives projections from the thalamic posterior triangular nucleus (PoT), a target for ascending somatosensory input. We then tested neural responses in the PIC to complete Freund's adjuvant (CFA)-induced inflammatory pain in the hindpaw which resulted in an increase in cFos-positive cells compared to naive, suggesting that the PIC processes nociception. Next we tested whether chemogenetic activation of excitatory neurons in the PIC altered aversion and somatosensory behavior. Virus expressing hM3D(Gq)

excitatory DREADDs was injected bilaterally into the PIC of naive mice. Activation of the PIC with DREADD agonist compound 21 produced a place aversion. Chemogenetic activation of the PIC also produced an increase in scratching in response to cheek injection of the pruritogen chloroquine. Finally, to determine how the PoT to PIC pathway influences nociceptive processing, we selectively activated the PoT to PIC projection with retro-cre/DIO DREADDs. This resulted in an increase in thermal threshold in naive mice. Together these results suggest the PIC activation promotes aversion or escape behavior to somatosensory stimuli while simultaneously raising thermal sensory threshold. We hypothesize that activation of a negative-emotional valance system in the PIC leads to descending inhibition of noxious somatosensation.

Title: Sustained anti-pruritic effect in mice with TP-2021, a kappa opioid agonist peptide, delivered by subdermal ProNeura Implants

Authors: B. B. LAND[1], S. SREEDHARAN[2], R. PATEL[2], T. BECK[3], K. DEVARNEY[2], M. RUBIN[2], *C. CHAVKIN[1];
[1]Pharmacol., Univ. of Washington, Seattle, WA; [2]Titan Pharmaceuticals, South San Francisco, CA; [3]Med. Univ. of South Carolina, Charleston, SC

Abstract: Chronic pruritus (itch) is associated with a number of serious medical disorders and results in severe, often debilitating itching without relief from conventional topical or systemic agents. Kappa opioid receptor (KOR) agonists have recently demonstrated their clinical potential for the treatment of moderate-to-severe chronic pruritus; however, activation of KOR in the CNS results in dysphoria and psychosis. TP-2021 (formerly called JT-09) is a D-amino acid tetrapeptide designed to relieve pruritus through peripheral KOR agonism therefore potentially mitigating these serious central adverse effects. TP-2021 has demonstrated high potency (EC_{50} = 52 pM) and selectivity for KORs with little to no affinity for mu or delta opioid receptors in the cAMP Hunter™ (Eurofins) assay with cloned human receptors. Pretreatment with TP-2021 or with difelikefalin, (Korsuva™ by Cara Therapeutics, Inc.), was observed to be equally potent in reducing scratching and grooming bouts when injected subcutaneously (0.3 mg/kg in saline) in a 5'-guanidinonaltrindole (5'-GNTI) itch-induced mouse model. Korsuva is under FDA review as a thrice-weekly IV injection in dialysis patients with chronic pruritus. Titan's clinically proven ProNeura® implantable technology is designed to treat chronic medical conditions, where maintaining consistent, around-the-clock blood levels of small molecule medications could

significantly improve patient outcomes. The first ProNeura-based product is a six-month buprenorphine implant, with marketing approvals in the US, Canada and Europe. First, TP-2021 ProNeura prototype implants were formulated and evaluated for release pharmacokinetics in mice compared to TP-2021 subcutaneous injections. Results indicate that a single implant provided sustained plasma concentrations of TP-2021 comparable with the levels observed after acute administration of TP-2021. Next, TP-2021 prototype implants were tested in the 5'-GNTI itch-induced mouse model. Following subdermal placement of one or two implants, the treated and untreated or placebo-implant treated mice were repeatedly challenged bi-weekly with 5'-GNTI. TP-2021 implants produced sustained, statistically significant itch suppression, compared to control implants, for two weeks before reverting to non-treated levels at four weeks. Further refinement of the ProNeura implant formulation is ongoing with the aim of developing a product that could potentially sustain therapeutic anti-pruritic levels of TP-2021 over several months. Title: The irritant receptor TRPA1 mediates the mosquito repellent effect of catnip

Authors: *M. CAPEK[1], N. MELO[2], O. M. ARENAS[1], A. AFIFY[3], A. YILMAZ[2], C. J. POTTER[3], P. J. LAMINETTE[1], A. PARA[1], M. GALLIO[1], M. C. STENSMYR[2]; [1]Dept. of Neurobio., Northwestern Univ., Evanston, IL; [2]Dept. of Biol., Lund Univ., Lund, Sweden; [3]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Catnip (*Nepeta cataria*) is a common garden herb well known for its euphoric and hallucinogenic effects on domestic cats, for its medicinal properties, as well as for its powerful repellent action on insects. Catnip extracts have been proposed as a natural alternative to synthetic insect repellents, such as N,N-diethyl-3-methylbenzamide (DEET), but how catnip triggers aversion in insects is not known. Here, we show that, both in *Drosophila melanogaster* flies and *Aedes aegypti* mosquitoes, the major mediator of catnip repellency is the widely conserved chemical irritant receptor TRPA1. *In vitro*, both catnip extract and its active ingredient nepetalactone can directly activate fly and mosquito TRPA1. *In vivo*, *D. melanogaster* and *Ae. aegypti* TRPA1 mutants are no longer repelled by catnip and nepetalactone. Interestingly, our data show that some, but not all, fly and mosquito TRPA1 variants are catnip targets. Moreover, unlike the broad TRPA1 agonist allyl isothiocyanate (AITC) (an active ingredient of tear gas and wasabi), catnip does not activate human TRPA1. Our results support the use of catnip and nepetalactone as insect-selective irritants and suggest that, despite TRPA1's broad conservation, insect TRPA1 can be targeted for the development of safe repellents.

Title: Optimization of the HiBit peptide to understand the GPR160 and CARTp binding mechanism

Authors: *L. SARVA[1], Y. KYRIUKHA[2], D. SALVEMINI[3], J. CHRIVIA[4], S. KOROLEV[2]; [2]Biochem. and Mol. Biol., [3]Pharmacol. and Physiological Sci., [1]St. Louis Univ., St. Louis, MO; [4]Pharmacol. and Physiological Sci., St. Louis Univ. Sch. of Med., St. Louis, MO

Abstract: Opioids have long been used to treat neuropathic and chronic pain; however, their addictive nature has resulted in extreme misuse. The ongoing opioid crisis and the hesitation to treat with these drugs have deemed it necessary to find alternative treatment options. G protein-coupled receptors are promising areas to explore. Specifically, GPR160, a newly de-orphaned receptor protein has been shown to directly relate to the inhibition of pain perception and metabolic activity when it is bound to its ligand CARTp. GPR160 has not been isolated yet,

therefore studying its interaction is incredibly difficult. To study the CARTp interaction with GPR160 we employed a nano luciferase-based complementation bioluminescence assay. CARTp is fused to a HiBit peptide and GPR160 is tagged with an LgBit luciferase. When the HiBit peptide activates LgBit, it triggers a secondary interaction between the activated LgBit and the substrate. This produces luminescence indicating that HiBit has bound to LgBit. In order to use this as a readout between CARTp and GPR160, the affinity of the HiBit peptide to LgBit must be optimized. Thus, the CARTp peptide is expressed in E. coli and purified using affinity chromatography steps. GPR160 is expressed in THP-1 cells. We introduced various mutations of HiBit to develop variant suitable for this purpose. The implications of this confirmatory project extend to understanding the breadth of the CARTp and GPR160 interaction and its function. It also extends to increased understandings of membrane protein purification and their correlation to pain.

Title: Sting-mediated type-I interferon signaling suppresses osteoclastogenesis and bone fracture pain

Authors: *M. LEE, K. WANG, A. MCGINNNIS, R.-R. JI, C. R. DONNELLY;
Pain Res. Division, Anesthesiol., Duke Univ. Med. Ctr., Durham, NC

Abstract: STING, or stimulator of interferon genes, is an intracellular DNA sensor that serves a crucial role in innate immunity by promoting immune cell-mediated elimination of pathogens and damaged host cells via the induction of type-I interferons (IFN-I) and other cytokines. In addition to its critical functions in immunity and host defense, we recently demonstrated that the STING/IFN-I signaling axis is a potent regulator of pain (nociception). Interestingly, we found

that autocrine or paracrine activation of STING in sensory neurons leads to the production and release of IFN-I, which directly suppresses the excitability of nociceptors. Interestingly, IFN-I signaling has previously been shown to inhibit osteoclastogenesis in naïve mice, and mice deficient for IFN-β or the IFN-I receptor component Ifnar1 exhibit reduced bone density. Bone fracture is not only remarkably painful, but also leads to an extended period in which fracture healing is impaired by inflammation-induced osteoclast overactivation. Thus, in this study we sought to determine the effects of STING agonists on pain, locomotor function, and osteoclastogenesis using a murine model of bone fracture. Notably, we found that acute treatment with the STING agonists DMXAA and ADU-S100 could transiently attenuate behavioral signatures of fracture-induced bone pain. In contrast, repeated administration of STING agonists following bone fracture led to prolonged pain control and improved locomotor recovery. Based on these data, we hypothesized that STING agonists may exert their effects via direct actions on sensory neurons and via direct actions on osteoclasts. In support of this hypothesis, we found that STING agonists dose-dependently inhibited osteoclastogenesis *in vitro*, as measured by differentiation of bone marrow-derived macrophages (BMDMs) or RAW264.7 cells to osteoclasts. Importantly, these effects were dependent on IFN-I signaling, as STING failed to suppress osteoclastogenesis in BMDMs from *Ifnar1*$^{-/-}$ mice and in RAW264.7 cells in the presence of anti-IFN-I antibodies. Based on these data, we conclude that activation of the STING pathway may be of therapeutic utility in fracture-induced bone pain.

Title: Expression of PD-1 in T cells in the peripheral nervous system after neuropathy and its possible role in neuropathic pain

Authors: *A. MCGINNIS[1], R.-R. JI[3], Z. WANG[1], J. ZHAO[4], O. CHEN[2];
[2]Cell Biol., [1]Duke Univ., Durham, NC; [3]Pain Res. Division, Anesthesiol., [4]Duke Univ. Med. Ctr., Durham, NC

Abstract: It is well appreciated that T cell populations affect neuropathic pain pathogenesis, but the molecular underpinnings of their effects are poorly understood compared to other immune cell types. Programmed cell death ligand-1 (PD-L1) is best know to be expressed by cancer cells and to suppress T cell-mediated immunity through activation of its receptor, PD-1, which is abundantly expressed by T cells. We recently demonstrated that PD-1 is also expressed by primary sensory neurons and inhibits synaptic transmission, pain, and opioid analgesia (Chen et al., 2017; Wang et al., 2020). We aim to utilize PD-1's inhibitory effect on T cells to selectively study the contribution of T cell subtypes to pain. In our initial experiments, we sought to: 1) examine PD-1 expression in T cells in the peripheral nervous system (PNS) after nerve injury; 2) characterize T cells infiltrating the PNS after injury (3) determine whether altered PD-1 signaling in T cells contributes to neuropathic pain after nerve injury. To this end, we generated PD-1 reporter mice and examined PD-1 expression in the sciatic nerve and dorsal root ganglion (DRG) of naïve mice and mice with partial sciatic nerve injury (PSNL, 1 week). Both tissues saw notably increased PD-1 levels after PSNL. Double staining with Iba1 showed most but not all PD-1 positive cells to be macrophages, with remaining 1ba1- cells bearing morphological features of T cells. Present studies are underway to characterize these PD-1+ cells using immunohistochemical and flow cytometry assays. We are also generating conditional knockout (cKO) mice by crossing *Pdcd1*$^{fl/fl}$ mice with *Foxp3*-cre mice to investigate the role of PD-1 in regulatory T cells.

Title: Differential Effects of Two Ocular Surface Injury Models on Function and Structure of Regenerating Corneal Cold Sensitive Nerves

Authors: *E. IVAKHNITSKAIA[1], T. NGUYEN[1], V. H. GUAIQUIL[1], Q. ZHOU[1], J. SARKAR[1], H. HIRATA[1], K.-Y. TSENG[2], M. I. ROSENBLATT[1];
[1]Ophthalmology and Visual Sci., Univ. of Illinois - Chicago, Chicago, IL; [2]Anat. and Cell Biol. / Neurosci., Univ. of Illinois At Chicago - Col. of Med., Chicago, IL

Abstract: Corneal nerve dysfunction can manifest as variable sensory disturbances from the ocular surface, spanning from the complete absence of sensation to chronic dysesthesia or pain. Corneal cold sensitive nerves (CSN) are a major functional subtype of corneal innervation and can be subdivided further into two subclasses. Low-Threshold (LT)-CSN regulate basal tearing and blinking, while High Threshold (HT)-CSN are likely responsible for the sensation of pain as well as reflex tearing and blinking responses. The impact of different forms of ocular surface injury on corneal sensation is incompletely understood. This study tested the hypothesis that different corneal nerve injury models lead to discrete alterations in the activity profiles of corneal CSN. We used in vivo extracellular electrophysiological recordings from the trigeminal ganglion and corneal wholemount immunostaining for TUJ1 to compare the functional and structural consequences of CSN regeneration from two clinically relevant models of injury. The first model, Corneal Epithelial Debridement (CED), is a mechanical injury that removes the dense nerve endings that innervate the cornea and was induced using a rotary burr tool. The second model, use of Benzalkonium Chloride (BAK), is a chemical injury that consists of a prolonged (30min+) ocular instillation with 0.01% BAK, a common preservative found in eye drops that can damage corneal epithelium and nerves. Sprague Dawley rats of both sexes were evaluated at 2 and 4 weeks post injury. We found that compared to uninjured corneas (n=14), nerve density is significantly reduced 2 weeks after nerve injury with either CED (n=7) or BAK (n=9) and is restored at 4 weeks post injury in the CED (n=8) but not the BAK injured group (n=7). Since the functional profiles of CSN at 2 vs 4 weeks post either CED or BAK injury did not differ, results from the two time points were combined for further functional analysis and compared to uninjured controls (n=24 LT-CSN, n=11 HT-CSN). We found that following regrowth from CED injury HT-CSN are less sensitive to ocular dryness and hyperosmolar stress (n=12). Unlike the CED group, HT-CSN regenerating from BAK injury (n=8) displayed significantly increased responsiveness to heating of the ocular surface and acute temperature drops. In contrast, the functional profiles of Low Threshold (LT)-CSN did not appear to be altered after either injury (n=5 for CED, n=9 for BAK). Overall, these results suggest that different injury models have

distinct impacts on the properties of corneal nerves regenerating from damage and that the pain-evoking HT-CSN subtype may be preferentially altered during regeneration from injury.

Title: Skin reinnervation by collateral sprouting after peripheral nerve injury

Authors: *S.-M. JEON[1], A. PRADEEP[1], L. MCDONOUGH[1], A. LATREMOLIERE[1], L. K. CRAWFORD[2], M. J. CATERINA[1];
[1]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Univ. of Wisconsin - Madison, Madison, WI

Abstract: Peripheral nerve injury can result in loss of cutaneous sensory function, with associated defects in protective reflexes and tactile function, as well as neuropathic pain. While regeneration from the injured nerve is the best-studied mechanism of reinnervation following injury, it is inherently slow even with surgical augmentation. Collateral sprouting from neighboring uninjured neurons represents an additional mechanism for recovery. In this study, we aim to define the subtype specificity of sprouting mediated skin reinnervation after peripheral nerve injury and then correlate this anatomical recovery with sensory function. We have performed whole-mount immunofluorescence staining of hind paw skin in the mouse spared nerve injury (SNI) model, in which the tibial and peroneal branches of the sciatic nerves are ligated and transected, leaving the sural nerve intact. 7 days after SNI, we observed a large reduction in immunoreactivity (IR) for peptidergic (CGRP) and myelinated (NF-H) nerve fibers in the middle of the ipsilateral hind paw skin. However, progressive reinnervation by CGRP and NF-H nerve fibers from medial and lateral territories into denervated skin was observed at 28 and 56 days after injury. To ask whether low threshold mechanoreceptor (LTMR) subtypes participate in collateral sprouting after nerve injury, we have performed SNI surgery on transgenic mice selectively labeling the LTMR subtypes. An obvious injury-induced reduction in nerve terminal structures was observed for Aβ RA-LTMRs, Aδ RA-LTMRs, Aβ SAI-LTMRs, Aβ Field-LTMRs, and C-LTMRs in the ipsilateral hind paw. Even 56 days after SNI, collateral sprouting of most LTMR fibers into the denervated region was not evident. However, interestingly C-LTMR fibers sprouted new collaterals into denervated skin by 56 days. To define

the functional recovery of collateral sprouts in denervated skin after nerve injury, we carried out optogenetic experiments in $Pirt^{Cre}$; $Rosa26^{LSL\text{-}ChR2\text{-}EYFP}$ mice. Light-induced paw withdrawal frequency on the ipsilateral hind paw of $Pirt^{Cre}$; $Rosa26^{LSL\text{-}ChR2\text{-}EYFP}$ mice dropped dramatically by 3 days after SNI, but returned gradually to basal level over 56 days. We also quantified mechanical sensitivity, utilizing calibrated von Frey monofilaments and an Austerlitz pin applied to the midline of the hind paw. The response frequency to both stimuli decreased markedly 3 days after SNI, but returned gradually to basal level by 28 days. Our findings provide a rationale for targeting specific sensory neuron populations as a therapeutic strategy to promote the progression of sensory recovery and limit unwanted events such as chronic pain after peripheral nerve injury.

Title: Dorsal root ganglionic field stimulation takes analgesic effects by activating Ca^{2+}/calmodulin-dependent protein kinase II

Authors: *H. TRAN[1], D. CHAO[2], Q. H. HOGAN[1], C. M. MECCA[3], B. PAN[2]; [2]Anesthesiol., [1]Med. Col. of Wisconsin, Milwaukee, WI; [3]Anesthesiol., Med. Col. of Wisconsin, Wauwatosa, WI

Abstract: Dorsal root ganglion (DRG) field stimulation (GFS) is effective in relieving clinical pain associated with nerve injury and neuropathic pain in animal models. Its molecular mechanism of analgesic effects has not been determined. Examining molecular mechanism of analgesic effects of GFS will provide us an opportunity to find the key molecule in the development of neuropathic pain. In our previous report, we found that there is reduced Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) activity after painful nerve injury and reduced CaMKII activity plays an important role in hypersensitivity to touch. We hypothesize that GFS might take analgesic effects by activating CaMKII activity. Intra-DRG injection of CaMKII activity inhibitors, KN-93 and autocamtide-2-related inhibitory peptide (AIP), blocked analgesic effects of GFS in rats with tibial nerve injury (TNI). With western blot and immunohistochemistry, we found that GFS reversed reduced protein level of phosphorylated CaMKII (pCaMKII) in DRG neurons from rats with TNI. With teased dorsal root single unit

electrophysiological recordings, we found that intra-DRG injection of AIP blocked effects of GFS on action potential propagation from peripheral sites. Taken together, CaMKII activity controls the analgesic effects of GFS and CaMKII might be one of the key molecules in the development of neuropathic pain.

Title: Action potential firing increases NKCC1 activity to stabilise axonal excitability during ongoing firing in mouse C-fibres

Authors: *R. CARR[1], K. SOHNS[1], V. BONALUME[3], A. KOSTENKO[1], R. RUKWIED[1], V. MAGNAGHI[3], M. SCHMELZ[2];
[1]Exptl. Pain Res., [2]Heidelberg Univ., Mannheim, Germany; [3]Pharmacol. and Biomolecular Sci., Univ. of Milan, Milan, Italy

Abstract: Somatosensory neurons resident in dorsal root and trigeminal ganglia maintain elevated intracellular chloride levels whereby activation of $GABA_AR$ leads to depolarisation and pre-synaptic inhibition in afferent nerve terminals within the spinal dorsal horn. We report here that the peripheral axons of DRG neurons are also depolarised by GABA and that GABA increased axonal electrical excitability. Increases in axonal excitability were predicated on NKCC1 activity and were larger during higher rates of action potential firing. To avoid the confounding effect of ongoing electrical stimulation used to determine axonal excitability, calcium responses to GABA were monitored in DRG neurons using the intensity based indicator Fluo8. DRG neuronal calcium responses to GABA were mediated by $GABA_AR$ and responses diminished in amplitude with successive GABA applications. This reduction in GABA response upon repeat application was exacerbated by NKCC1 blockade but prevented if, in the intervening period, either potassium (45mM) or electrical stimulation (30s @ 20Hz) was applied. This further implicated elevated action potential activity in the loading of DRG neurons with chloride via NKCC1. The physiological implication of activity-dependent chloride regulation in C-fibre axons was explored using activity-dependent conduction velocity slowing (ADS) to quantify excitability loss during 2.5 Hz challenge. ADS was reduced by $GABA_AR$ agonists and

exacerbated by either $GABA_AR$ antagonists or NKCC1 blockade. This illustrates that activation of $GABA_AR$ stabilised C-fibre excitability during sustained firing. We posit that NKCC1 activity increases in proportion to action potential firing rate. This allows axons to maintain their elevated intra-axonal chloride concentration. The resulting chloride gradient can be utilised by $GABA_AR$ to stabilise axonal excitability during ongoing firing. The data imply that therapeutic strategies targeting axonal chloride regulation at peripheral loci of pain and itch may curtail aberrant firing in C-fibres.

Title: Endometriosis (ENDO) induced vaginal hyperalgesia in the rat: establishing the relationship between endocannabinoids (eCBs) and related lipids during development.

Authors: E. ARTHURS[1], A. VARNADOE[2], L. LANG[1], M. VASU[3], ***S. MCALLISTER**[1]; [1]Emory Univ. Sch. of Med., Atlanta, GA; [2]Cornell Univ. Col. of Vet. Med., Ithaca, NY; [3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Endometriosis is a painful disorder defined by the growth of endometrial tissue outside the uterus (cysts). How the cysts contribute to painful symptoms such as dyspareunia (vaginal hyperalgesia) is poorly understood. A rat model of endometriosis (ENDO) is created by autotransplanting pieces of uterus onto abdominal arteries (Vernon & Wilson, 85). These cysts are associated with painful symptoms including vaginal hyperalgesia similar to women with endometriosis. In both rats and women, the cysts recruit their own sensory and sympathetic nerve supply (Berkley et al., 04; 05). Previous studies suggest that the cyst sensory and sympathetic innervation contribute to the development and maintenance of endometriosis-associated vaginal hyperalgesia (McAllister et al, 09; 12; Zhang et al., 08). Further, the cyst sensory and sympathetic innervation express cannabinoid receptors (CB1) and CB1 receptor agonists decrease, whereas CB1 receptor antagonist increase, endometriosis-associated hyperalgesia (Dmitrieva et al, 10; McAllister & Sinharoy, 18). These findings, with the knowledge that the endocannabinoid system (ECS) is involved in uterine function and dysfunction and that exogenous cannabinoids have been used for centuries to alleviate dysmenorrhea, suggest that the

ECS is involved in both endometriosis and its associated pain (Dmitrieva & Berkley, 02; Bradshaw & Walker, 04; Russo, 02). To test this hypothesis further, we analyzed endogenous cannabinoid levels during the time period when cyst innervation and vaginal hyperalgesia are known to develop in the rat model of endometriosis (McAllister et al., 2012). Lipid extraction and tandem mass spectrometry were used to assess levels of eCBs (AEA, 2-AG, NAGly) and related lipids (PEA, OEA, DHEA, SEA) in the ectopic uterus (cysts) of ENDO rats and the eutopic uterus of ENDO rats and controls. All samples were analyzed in estrous stage of proestrus. Overall, results demonstrate that lipid levels are significantly lower in ENDO rats compared to controls. These data suggest that altered eCB biosynthesis and/or metabolism in endometriosis may influence endometriosis-induced vaginal hyperalgesia, perhaps by reduced cannabinoid receptor activation on cyst innervation. These findings provide further support for the involvement of the ECS in mechanisms underlying endometriosis and its associated pain, thereby providing a novel approach for the development of badly-needed new treatments.

Title: Use visceral motor responses to colorectal distension to assess invasive neuromodulatory protocols for managing visceral pain

Authors: *S. ZHANG, L. CHEN, B. FENG;
Biomed. Engin., Univ. of Connecticut, Storrs, CT

Abstract: Managing visceral pain remains an unmet clinical need and conventional pharmacological treatments often lead to severe side effects that outweigh the therapeutical benefits. Neuromodulation has emerged as a non-drug alternative with growing clinical success in relieving chronic pain in joints, muscles, and nerves. Small-scaled clinical studies have indicated neuromodulation as a promising means to treat visceral pain. New neuromodulatory protocols need to be developed and validated in animal models to allow a mechanistic understanding of the pain-relieving effect by neuromodulation. Visceral motor reflex (VMR) to graded colorectal distension (CRD: 15, 30, 45 and 60 mmHg pressure steps) has been extensively implemented to assess the level of visceral pain in awake rodents, which unavoidably

produce movement artifacts to confound the VMR recordings. A single urethane injection preserves the spino-bulbo-spinal reflex to allow the recording of VMR to CRD in anesthetized rats, but it appears to provide unreliable level of anesthesia in mice. Here, we report an optimized protocol with prolonged urethane infusion that allows robust and repeatable recordings of VMR to CRD in mice under deep anesthesia, providing a 3-hour window to assess invasive neuromodulatory protocols. C57BL/6 mice of both sexes (8-16 weeks, 25-40 g) were anesthetized by 2% isoflurane inhalation during all surgical procedures. A dose of 0.4g/kg urethane was administered intraperitoneally before surgery. Two pairs of teflon-coated stainless steel wire electrodes were sutured to the oblique abdominal musculature immediately above the inguinal ligament (both sides). A flexible plastic-film balloon (Φ8 mm x 15 mm) was inserted intra-anally to maintain the 5 mm distance between the end of the balloon and the anus by taping the connected inflating catheter to the tail. 30 minutes after the electrode placement and balloon insertion, another catheter was placed intraperitoneally beneath transversus abdominis musculature and urethane was administered continuously at 0.05~0.1 µg per kg per hour (µg/kg·h) via a syringe pump. This protocol allows mice under deep anesthesia without spontaneous or volitional movement for at least 3h in all 8 mice tested. VMR to CRD was reliability recorded from 8 mice for at least 3h. We applied this *in vivo* behavioral model to assess the effect of L6 DRG stimulation in suppressing visceral pain from distal colon and rectum. Stimulation of 50 and 100 Hz at L6 DRG reversibly blocked the VMR to CRD. This validated *in vivo* mouse model of prolonged urethane anesthesia will allow objective assessment of various invasive neuromodulatory strategies that alleviated visceral pain.

Title: The pathway of cMyc-EZH2-SIRT3 plays an important role in HIV-related neuropathic pain model

Authors: X. ZHU[1,2], H. YI[1], J. GU[1], K. HAYASHI[1], K. TAKAHASHI[1], Y. KASHIWAGI[1], S. LIU[1], H. LI[2], ***S. HAO**[1];

Abstract: Chronic opioid application enhances HIV entry into immune cells. Emerging clinical data demonstrate that repeated use of opioid pain killers increases neuropathic pain in people living with HIV. Therefore, it is important to elucidate the molecular mechanisms of HIV-related chronic pain. HIV-1 envelope protein gp120 increases the expression of transcription factor c-Myc in cell proliferation. Morphine increases c-Myc expression. Epigenetic writer, EZH2 is a histone methyl transferase subunit of a polycomb repressor complex. EZH2 silences gene expression by generating a methylated epigenetic mark at H3K27me3. Sirtuins 3 (Sirt3) deacetylates MnSOD and thereby activates it for scavenging mitochondrial superoxide. In the present study, we investigated the pathway of cMyc, EZH2, and Sirt3 in gp120 with morphine (gp120/M)-induced neuropathic pain state using epigenetic approach. HIV-related neuropathic pain was induced by repeated administration of intrathecal recombinant gp120 with morphine. Protein expression of spinal cMyc, EZH2, and SIRT3 was examined using Western blots. Intrathecal antisense oligonucleotides against cMyc, GSK126 (EZH2 inhibitor) or recombinant Sirt3 (rSirt3) was given intrathecally. HIV-gp120/M upregulated the expression of cMyc and EZH2, and down-regulated Sirt3 in the spinal dorsal horn. Intrathecal administration of antisense oligonucleotides against cMyc, GSK126 (EZH2 inhibitor), or recombinant rSirt3 reduced mechanical allodynia and thermal hyperalgesia in the gp120/M pain model. Knockdown of cMyc reduced spinal EZH2 expression in gp120/M rats. Chromatin immunoprecipitation (ChIP) assay showed that **the enrichment of** cMyc binding to *ezh2* gene promoter region was increased in gp120/M treated rats compared to that in control group. Spinal GSK126 reversed the lowered Sirt3 expression in gp120/M rats. ChIP assay showed that **the enrichment of H3K27me3** binding to *sirt3* gene promoter region was increased in gp120/M treated rats compared to that in control group. These results demonstrated that spinal cMyc-EZH2-H3K27me3-Sirt3 pathway played an important role in the HIV gp120-related neuropathic pain state, and provided a new insight into novel therapy for HIV/opioid-related neuropathic pain.

Title: Alterations in peripheral and central nociceptive signaling circuits during HIV/SIV infection contribute to the development of HIV-associated chronic pain

Authors: *R. WARFIELD, J. ROBINSON, M. SMITH, T. BURDO;
Dept. of Microbiology, Immunol. and Inflammation, Temple Univ., Philadelphia, PA

Abstract: With the development of combined anti-retroviral therapy (ART), human immunodeficiency virus (HIV)-associated comorbidities, including development of chronic pain related to HIV-associated distal sensory polyneuropathy (HIV-DSP), has remained prevalent. Using a simian immunodeficiency virus (SIV)-infected rhesus macaque model (N=18) we examined potential mechanisms of peripheral and central sensitization in SIV/HIV-associated chronic pain. Elevated macrophage (CD68+) and T cell (CD3+) numbers were seen in the lumbar spinal cord of SIV-infected (SIV+) macaques (N=6) compared to uninfected animals (N=6) and did not fully return to uninfected levels in the SIV+/ART treated animals (N=6). Thus, these data indicate spinal neuroinflammation occurs in SIV and persists with ART. Similarly, in regard to the dorsal root ganglia (DRG), we have previously shown atrophy in nociceptive neurons is associated with increased inflammatory monocyte traffic to the DRG during SIV infection where neuroinflammation remains despite ART. Here, we demonstrate a significant increase ($P \leq 0.01$) in expression of nociceptive ion channels; transient receptor potential vanilloid (TRPV) and anykrin (TRPA) in the DRGs of SIV+/ART treated rhesus macaques compared to SIV+/ART-naïve group. Nociceptor sensitization in the DRG and central nervous system inflammation can contribute to the development of chronic neuropathy through the release brain derived neurotrophic factor (BDNF) into the dorsal horn. Our data identifies a significant upregulation of the precursor form of BDNF, proBDNF, ($P \leq 0.01$) and not the mature, mBDNF, within the DRGs of SIV+/ART treated macaques. These data indicate a shift in the overall processing or release of BDNF from the primary afferents in the DRGs of SIV+/ART treated animals. To study the mechanism by which alterations in nociceptive ion channels and the pro-/mBDNF ratio within the DRG may affect peripheral sensitization, we have established and characterized a human induced pluripotent stem cell (hPSC)-derived peripheral sensory neuron (PSN) model. We found that sensory neurons derived from both male and female hIPSCs expressed pan neuronal marker, beta 3 tubulin, and peripheral neuron marker, peripherin. The hIPSC PSN expressed both, TRPV and TRPA, and neurotrophin, BDNF, confirmed by both immunocytochemistry and RT-qPCR. In conclusion, we identified neuroinflammation in the spinal cord as a potential mechanism for central sensitization in SIV. Additionally, alterations in nociceptive ion channels and the pro-/mBDNF ratio within the DRG may contribute to peripheral sensitization in HIV-associated chronic pain.

Title: Sigma 1 antagonist haloperidol reduces tolerance induced by morphine in rats with neuropathic pain

Authors: *L. C. MENA-VALDÉS, Y. BLANCO-HERNÁNDEZ, F. J. LOPEZ-MUÑOZ; Cinvestav-Unidad Coapa, Ciudad de Mexico, Mexico

Abstract: Haloperidol (Hal) is a butyrophenone prototype widely used as an antipsychotic agent. Recently, some authors have described the anti-nociceptive effects of Hal mediated by sigma-1 receptor (S1R) antagonism. Morphine (Mor) is currently used in neuropathic pain (NP) therapy; however, there is increasing evidence that opioid therapy might be associated not only with the development of tolerance, but also with increased pain sensitivity. This work evaluated the interaction between haloperidol and morphine on tolerance induced by morphine in rats with neuropathic pain. Methods: Male Wistar rats (220-250 g) from Cinvestav-Coapa bioterim were used for experiments. The chronic constriction injury (CCI) model was developed to induce NP. The effect of Hal as an S1R antagonist on Mor-induced tolerance was evaluated in experiments conducted at 7, 10 or 14 days. The anti-allodynic effects of repeated administrations (twice/day) of Hal (0.01778 mg/kg), Mor (0.0316 mg/kg) and their combination were evaluated by the cold allodynia test. The effects of sigma-1 antagonist BD-1063, the sigma-1 agonist PRE-084, and the opioid agonist naloxone were used in the tolerance protocols developed. Results: Animals administered in repeated doses of Mor 0.0316 mg/kg presented tolerance to opioids after 5 days of treatment in the 3 protocols evaluated, at 7,10 and 14 days. Although in the animals that received the combination, tolerance was delayed until day 8. PRE-084 and naloxone administered on day 5 in animals treated with the combination resulted in a blockade of its anti-allodynic effects. Conclusions: The interaction between sigma-1 receptor and the opioid system opens a window in neuropathic pain treatment. This study showed that haloperidol potentiates the antinociceptive effects of morphine and, in addition, modulates the tolerance induced by the opioid.

Title: Sex-dependent modulation of nociceptive behavior through the inhibition of fatty acid amide hydrolase and monoacylglycerol lipase in rats following peripheral neuropathy

Authors: *L. BOULLON[1,2,3,4], S. LEAHY[1], C. CALITZ[1], D. FINN[1,2,3,4], A. LLORENTE-BERZAL[1,2,3,4];

Abstract: Several reports have demonstrated involvement of the endocannabinoid system (ECS) in the regulation of nociceptive processing. In particular, pharmacological modulation of the ECS in the periaqueductal grey (PAG) induces antinociceptive effects though the inhibition of neurotransmission. In this study, we investigated the effects of systemic inhibition of the anandamide-catabolizing enzyme fatty acid amide hydrolase (FAAH) and the 2-arachidonylglycerol (2-AG)-catabolizing enzyme monoacylglycerol lipase (MGL) in male and female rats following peripheral nerve injury. Administration of the FAAH and MGL inhibitors, URB597 (0.3mg/kg; i.p.) and MJN110 (1mg/kg; i.p.) respectively, commenced 7 days post-surgery (Sham/Spared Nerve Injury (SNI)) with rats receiving one injection/day for 15 days. Von Frey and acetone drop tests evaluated the effect of vehicle/URB597/MJN110 treatment on SNI-induced mechanical and cold hypersensitivity. *Post-mortem* analysis of the PAG investigated endocannabinoid (AEA, 2-AG) and related *N*-acylethanolamine (PEA, OEA) levels using liquid chromatography tandem to mass spectrometry. Furthermore, FAAH, MGL, CB_1-, and CB_2-receptor mRNA levels were measured using RT-qPCR. Nerve injury induced mechanical and cold hypersensitivity in male and female animals, but to a significantly greater extent in in females as previously described (Boullon et al., 2021). Chronic administration of URB597 increased mechanical paw withdrawal threshold (i.e. reduced mechanical hypersensitivity) of female-SNI but not male-SNI rats. Similarly, reduction of acetone-induced nociceptive responses was only observed in URB597 treated female-SNI animals. MJN110 had no significant effect on SNI-induced mechanical or cold hypersensitivity; however, it did reduce paw withdrawal threshold in male-Sham rats. MJN110-treated animals had higher levels of 2-AG in the PAG, compared with vehicle-treated controls. URB597 administration had no effect on AEA levels in the PAG, however it did significantly increase PEA and OEA levels in both sexes. No differences were observed in CB_1, CB_2, FAAH or MGL mRNA levels in the PAG between the groups. These data provide evidence for sexual dimorphism in the antinociceptive effects of FAAH inhibition, which were evident in female rats but not male rats following SNI. The sex-dependent effects of FAAH inhibition on nociceptive were not associated with sex-dependent alterations in components of the endocannabinoid system in the PAG.

Title: Dopaminergic modulation in auditory decision-making.

Authors: *A. P. F. CHEN[1,2], J. MALGADY[1], L. CHEN[1], K. SHI[1], A. ZETO[1], E. CHENG[1], J. L. PLOTKIN[1], S. GE[1], Q. XIONG[1];

Abstract: The basal ganglia are implicated in perceptual decision-making, incorporating sensory stimuli and action-outcome encoding. The auditory striatum, a sensory portion of the basal ganglia, is critical for transforming auditory stimuli into ongoing actions. We investigated how dopamine (DA) regulates auditory striatal activity in a frequency discrimination task. Viral retrograde mapping demonstrates that the lateral portion of the substantia nigra (SN) is the primary DA input to the auditory striatum. Cue-locked optogenetic inhibition of this population impaired auditory choice performance on a trial-by-trial basis. Given this impairment, we next investigated how SN activity regulates auditory choice and whether it is important for auditory striatal neuron task engagement. Using ex vivo physiology, optogenetic, and chemogenetic methods, we show that SN activity is critical for regulating auditory striatal DA levels, striatal activity, and auditory task performance. Our study uncovers a phasic mechanism of how the nigrostriatal system regulates auditory decisions, by stably modulating ongoing perceptual performance.

Title: Role of the cholinergic system in early sensorimotor acquisition

Authors: *S. E. ELNOZAHY[1], J. LAWLOR[1], F. ZHU[1], T. RAAM[1], A. WANG[1], K. KUCHIBHOTLA[2];
[2]Psychological and Brain Sciences, Neurosci., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Acquisition of sensorimotor learning in a go/no-go task is much faster and more stereotyped than previously considered (Kuchibhotla et al., 2019). We trained mice to respond to one tone for a water reward (S+) and withhold from responding to another (S-). We interleaved reinforced trials with those where reinforcement was absent ("probe"). Early in learning, animals discriminated between S+ and S- in probe but not reinforced trials. This unmasked a rapid acquisition phase of learning followed by a slower phase for reinforcement, termed 'expression'. What role does neuromodulation play in task acquisition? Prior work has pointed to cholinergic projections from the basal forebrain as a mediator of auditory cortex plasticity. Here, we test the hypothesis that phasic, cholinergic neuromodulation provides a 'teaching signal' that drives primary auditory cortex (A1), and links stimuli with reinforcement. We exploit our behavioral approach and combine this with two-photon imaging of cholinergic activity in A1 during discrimination learning. We report robust stimulus-evoked cholinergic activity to both S+ and S- throughout learning. While this activity mildly habituates in a passive control, in behaving animals the S+ and S- stimulus-evoked activity is enhanced (S+: duration, S-: amplitude and duration) during early learning, on a timescale matching acquisition of the task. Additionally, we test the hypothesis that phasic, cholinergic neuromodulation impacts the rate of task acquisition. We bilaterally express ChR2 in cholinergic neurons within the basal forebrain of ChAT-cre mice and activate these neurons on both S+ and S- trials throughout learning. Probe trials, lacking optogenetic activation, serve as a readout for task acquisition rates. By phasically stimulating cholinergic neurons in the reinforced context, animals acquired the task faster than control groups. This improvement in acquisition rates early in learning is driven largely by a reduction in false alarm rate during probe trials, indicating that phasic activation of the basal forebrain accelerates response inhibition. These results suggest that phasic bursts of acetylcholine, projecting widely to cortical regions, directly impact the rate of discrimination learning.

Title: Optogenetics manipulation of GABAergic neurons in the posterior Nucleus Basalis of Meynert modulates auditory information perception.

Authors: *K. THOMAS, H. AZIMI, M. SANDERS, M. HARVEY, G. RAINER;
Univ. de Fribourg, Fribourg, Switzerland

Abstract: The posterior Nucleus Basalis of Meynert (pNB) cholinergic projections to the auditory thalamus and cortex have been extensively documented. However, pNB also contains a population of GABAergic projection neurons, which have been much less studied. Here, we investigate how optogenetic up- und downregulation of GABAergic pNB neurons impacts performance of an auditory detection task using PV-Arch, PV-Chr2 and mDlx-Chr2 constructs. We adapted an auditory detection paradigm, such that freely moving rats were trained to hold down a lever and release it upon the presentation of a narrow bandpass-filtered auditory target stimulus presented with variable amplitudes in the presence of a broad bandpass-filtered masking noise. Spiking activity in auditory primary cortex (A1) and Medial Geniculate Nucleus (MGN) to the target was positively correlated with target amplitude, and significantly attenuated in the presence of the masking noise. Rats acquired the task in about 4 weeks, as we verified using the distribution of lever-holding duration during each session. Behavioral detection performance was closely related to target amplitude, consistent with neural recording data. For functional validation, we demonstrated pulse entrained spiking activity in pNB in response to 40Hz light pulses using blue 473µm light, as well as suppression of pNB spiking during continuous yellow 593µm light in animals transfected with PV Cre-locked AAV5-Chr2 or AAV5-Arch3 constructs respectively. We found specific inhibition of PV GABAergic neurons impaired task performance and increased reaction times for low amplitude targets. Specific activation of pNB PV cells, produced weak effects that were limited to a slight decrease in performance for high amplitude targets. Non subtype-specific activation of the GABAergic population, using a mDlx-Chr2 viral construct, produced general faster reaction times, as well as frequency-specific improvement in detection task performance for low amplitude targets correlated with task engagement. Our findings suggest that under- as well as overactivation of pNB PV neurons is detrimental for detecting an auditory target in the presence of noise. While pNB PV under-activation impairs attentional filtering for low amplitude targets, overactivation reduces performance for high amplitude targets consistent with a more general withdrawal of task resources. Behavioral changes observed following activation of the non-specific pNB GABAergic population points towards an involvement of non-PV inhibitory circuits, i.e. the somatostatin population, in modulating attention in the auditory pathway.

Title: Basal forebrain cholinergic neuronal activity across attentional and arousal states during auditory go/no-go behavior

Authors: E. HANSON[1,3], J. W. DE GEE[2,3], M. THOMPSON[2,3], **K. JASPE**[2,3], B. R. ARENKIEL[1,2,3], M. J. MCGINLEY[2,3,4];

Abstract: Behavioral state characteristics like attention and arousal potently impact numerous cognitive functions, including sensory perception and decision making. Effects of attention and arousal in sensory and decision circuits are mediated, in part, by cholinergic neuromodulation originating in the basal forebrain. However, the precise computational roles of basal forebrain cholinergic signaling in mediating effects of arousal and attention remain open questions. Here we describe an approach that combines a novel auditory go/no-go discrimination task, which requires different degrees of attentional effort, with fiber photometry and pupillometry to investigate the role of basal forebrain cholinergic signaling in attention and arousal-linked modulation of decision-making. In this task, reward size is varied in blocks, allowing us to control the utility of attention and thus manipulate the degree of expended attentional effort. We assay arousal using pupil diameter, and attentional effort via reward block and associated computational measures of behavioral performance changes. This approach allows us to dissociate the effects of arousal and attentional effort on behavior and elucidate the neural underpinnings. To determine the role of basal forebrain cholinergic signaling in task performance across attention and arousal states in the attentional effort task, we use fiber photometry to record from basal forebrain cholinergic neurons in the horizontal limb of the diagonal band of Broca during the task performance. We then correlate basal forebrain cholinergic neuronal activity with pupil diameter, task parameters (reward size and trial timing) and behavior (licking, reward consumption, and running) by applying signal detection theory, drift diffusion modeling, and regression approaches. Ultimately, this approach will allow us to examine precisely when and to what extent basal forebrain cholinergic neurons respond to task-evoked changes in attention, arousal, and reward expectation, and how they influence sensory discrimination and decision-making processes.

Abstract: Research into conscious perception has revealed that a rapid (within one second), stereotyped pattern of neuronal activity changes in both cortical and subcortical areas of the brain occurs following presentation of perceived stimuli but not following identical unperceived stimuli. These and almost all studies conducted on conscious perception have been performed in humans, where methods for establishing causal relationships between neuronal activity and behavior are limited. Mice exhibit many of the same behaviors evocative of conscious perception in humans including selective attention and decision making informed by external stimuli, but as a model have access to robust methods for recording and manipulating neuronal activity. To establish a model for studying conscious perception in mice, we have developed a paradigm for training mice to self-report perception or non-perception of an auditory stimulus within a lick-left/lick-right auditory discrimination task. Adult c57bl6 mice were surgically implanted with a steel headplate and water restricted following recovery. The mice were head-fixed above a running wheel flanked by speakers and presented with two water spouts. Mice were initially trained to lick one spout in response to a primary auditory stimulus, and the other in response to a secondary stimulus following presentation of a light. The spout associated with each sound was randomized for each mouse. The secondary stimulus was then titrated in volume to associate the absence of a stimulus following the light with the secondary stimulus' spout. Mice exhibited lick responses discriminating the presence and absence of an auditory stimulus with an average accuracy of 71% across all sessions. The mice achieved an accuracy significantly greater than chance within 37 sessions or 46 days. These results suggest mice can be trained to provide a behavioral response that distinguishes their perception or non-perception of a stimulus. Using this behavioral task, future electrophysiological or photometric assays may provide insight into mouse brain activity during conscious perception, and optogenetic manipulations may allow causal relationships between neuronal responses and conscious perception to be established.

Title: Adaptive increases in attentional effort manifest as suppressed exploratory behavior and reduced physiological arousal

Authors: *J. DE GEE[1], Z. H. MRIDHA[1], M. HUDSON[1], Y. SHI[1], H. RAMSAYWAK[1], S. SMITH[1], N. KAREDIYA[1], M. THOMPSON[1], K. JASPE[1], W. ZHANG[1], M. J. MCGINLEY[2]; [2]Neurosci., [1]Baylor Col. of Med., Houston, TX

Abstract: Depending on the current estimate of a task's utility, one's goal might be to harvest as much reward as possible (exploitation) or disengage from the task to seek alternatives (exploration). One prominent theory argues that increased neuromodulation promotes a shift from exploitation to exploration (Aston-Jones & Cohen, Annu. Rev. Neurosci, 2005). Another prominent theory argues that increased neuromodulation mediates attention (Hasselmo & McGaughy, Progress in Brain Research, 2004). Experimental data constraining and arbitrating between such theories is limited, due to the difficulty to assay and manipulate neuromodulatory systems in behaving animals.

To study the physiological signals that implement attention allocation and adjustments of the exploration-exploration trade-off, we developed an "attentional effort task" for head-fixed mice. In the task, mice lick for sugar-water reward upon detection of temporally unpredictable coherence in a sustained tone-cloud. We manipulate task utility by changing the reward size in blocks of trials. Thus, mice should expend more attentional effort (exploit more) in high reward blocks and disengage more in low reward blocks. We simultaneously recorded pupil size, walking speed, and two-photon images in auditory cortex. We imaged either acetylcholine via $GRAB_{ACh}$ (GPCR-based sensor), cholinergic axons, or projection-specific local neuronal population activity.

Here, we report behavioral and physiological signatures of adaptive shifts in behavior in >75 mice. First, mice better detected the weak sensory signal in the high vs low reward context, indicating that increased task-utility caused an increase in the efficacy of exploitation. Second, in both the high and low reward context, pre-trial baseline pupil size and walking speed were negatively correlated with perceptual sensitivity, and bias had an inverted-U dependence on pupil size, indicating that a low to moderate arousal state is optimal for the task. Pre-trial baseline pupil size and walking speed were higher in the low reward blocks, particularly after

false alarms, indicating that mice are overly aroused and engage in exploratory behaviors when task utility is low. Finally, acetylcholine concentration phasically increased after correct and incorrect licks, in a reward-context dependent manner.
In sum, we find that (pupil-linked) arousal and cholinergic signaling underlie adjustments of the exploration-exploration trade-off in mice. In ongoing work, we are determining the roles of frontal-sensory interactions and other neuromodulatory systems in mediating these adaptive shifts in attentional state.

Title: Rapid and adaptive shifts in mouse decision-making to changes in task utility

Authors: J. DE GEE[1,2], ***Z. MRIDHA**[1,2], M. HUDSON[1,2], Y. SHI[1,2], H. RAMSAYWAK[1,2], S. SMITH[1,2], N. KAREDIYA[1,2], M. THOMPSON[1,2], K. JASPE[1,2], A. BANTA[1,2,3], W. ZHANG[1,2], M. J. MCGINLEY[1,2,3];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Duncan Neurolog. Res. Inst., Texas Children's Hosp., Houston, TX; [3]Electrical and Computer Engin., Rice Univ., Houston, TX

Abstract: The brain has a remarkable capacity to adaptively shift processing to support a diverse array of behavioral goals, contextual demands, and environmental changes. In sensory domains, the brain can enhance the processing of difficult-to-perceive stimuli when they are important (Kahneman, 1973; Miller and Cohen, 2001) such as when correct discrimination leads to a large reward. Matching effort to potential gains is a key feature of adaptive behavior and must be re-continuously calibrated. To study if and how mice adapt processing to momentary environmental conditions, we have developed an “attentional effort task” for head-fixed mice.
In the attentional effort task, mice learn to lick for sugar-water reward to report detection of the unpredictable emergence of temporal coherence in an ongoing tone-cloud. This acoustic signal is analogous to coherent motion in common visual tasks. To detect all weak-coherence signals, mice would need to sustain an infeasibly high level of attentional effort across the 90-minute sessions. Thus to probe adaptive effort allocation, we switched the sugar-water reward size

(droplet volume) between high and low values in blocks of 60 trials. Thus, mice should expend more attentional effort in high reward blocks.
Here, we report behavioral and algorithmic signatures of rapid and adaptive shifts in attentional effort allocation in >75 mice. First, mice exhibited at least five attentional effort shifts within a single session, which were tightly time-locked to the switches in reward context. Second, increased attentional effort in high reward blocks manifested as improved detection of the weak signals (higher d'). Third, this effect was strongest for signals that occurred relatively late in the trial, indicating that attentional effort in the high vs low reward context was not only higher but also more sustained. Fourth, fitting reaction time data with an accumulation-to-bound model of decision-making revealed that in high reward blocks mice integrated the weak sensory evidence more efficiently within trials (higher drift rate) and more reliably across trials (lower lapse rate / lower drift rate variability).
In sum, we find that mice adapt their allocation of cognitive resources to changes in task utility. In ongoing 2-photon imaging work, we are determining the roles of frontal-sensory interactions and neuromodulatory signals in mediating these shifts in overt behavior.

Abstract: Motion is a critical aspect of vision. We studied the representation of motion in mouse retinal bipolar cells and found, surprisingly, that some bipolar cells possess motion-sensing capabilities that rely on their center-surround receptive fields. Using a glutamate sensor, we directly observed motion-sensitive bipolar cell synaptic output, which was strongest for local motion and dependent on the motion's origin. We characterized bipolar cell receptive fields and found that there are motion and non-motion sensitive bipolar cell clusters, with the majority of clusters being motion sensitive. This motion sensitivity allows bipolar cells to respond in a selective manner to looming motion and directional motion. Motion sensitive bipolar cell clusters were aligned with anatomical bipolar cell types, and were found throughout the sublayers of the inner plexiform layer. Next, we used these bipolar cell receptive fields along with connectomics to design biophysical models of downstream cells in the direction selective circuit. The models demonstrated that bipolar cells pass motion-sensitive excitation to starburst amacrine cells through direction-specific signals mediated by bipolar cells' center-surround receptive field structure. We confirmed some of these model predictions experimentally using 2-photon imaging of calcium sensors expressed in populations of starburst amacrine cells. As bipolar cells provide excitation to most amacrine and ganglion cells, their motion sensitivity may contribute to motion processing throughout the visual system.

Title: Visual circuits underlying threat anticipation

Authors: *M. L. ARANDA, E. MIN, L. LIU, T. M. SCHMIDT;
Northwestern Univ., Evanston, IL

Abstract: There is a clear evolutionary survival advantage in detecting the presence of threats in an animal's environment. The visual system is one of the primary senses used by mammals to respond to and detect changes in the environment. Moreover, it is crucial that animals are able to anticipate potential dangers in their environment. However, whether and how the visual system may influence these pathways is not fully understood. In this work, we tested the hypothesis that the melanopsin-expressing, intrinsically photosensitive retinal ganglion cells (ipRGCs) are critical for the ability to anticipate the future appearance of a previously experienced threat. To do this, we developed a novel Visual Threat Anticipation paradigm in which we exposed control and melanopsin knock-out (MKO) mice to a threatening, "looming" stimulus. After two days, we measured the degree to which mice anticipate the appearance of that same threatening, looming stimulus in the identical context. Control mice readily learned to anticipate the appearance of this threatening stimulus. Surprisingly, we found that male, but not female, MKO animals lacked threat anticipation, indicating that ipRGCs are required for this behavior. Behavioral measures of vision and anxiety indicated that these deficits were not the result of altered general anxiety or visual deficits. In order to describe this novel circuit, we analyzed c-Fos expression in our Visual Threat Anticipation paradigm, and identified the Perihabenular Region (PHb) and the Nucleus Accumbens (NAcc) as potential candidate brain regions for driving visual threat anticipation. Using choleric toxin β-subunit tracer and Cre-dependent viruses, we observed that ipRGCs project to the PHb, which in turn sends axons to the NAcc. In order to test the functional sufficiency of ipRGC-PHb circuit in visual threat anticipation, we chemogenetically excited PHb-projecting ipRGCs in MKO mice. We found that excitation of PHb-projecting ipRGCs rescued the deficits we observed in threat anticipation. We next tested whether GABAergic neurons in the PHb are necessary for visual threat anticipation by chemogenetically silencing this population. For that we injected Cre-dependent Gi-DREADDs in PHb from $Gad2^{Cre/+}$ and we found that male mice showed reduced visual threat anticipation. Overall, our results suggest that an ipRGC-PHb-NAcc circuit drives visual threat anticipation.

Title: Identification and testing of candidate molecular factors that mediate asymmetric inhibitory connectivity in the direction-selective retinal circuit

Authors: *J. TWORIG[1], A. TIRIAC[1], K. BISTRONG[2], R. MORRIE[1], M. FELLER[1];
[1]Mol. and Cell Biol., [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Direction-selectivity in the retina is mediated by asymmetric inhibitory connections between starburst amacrine cells (SACs) and direction-selective ganglion cells (DSGCs). This wiring occurs in a DSGC subtype-specific manner, such that individual SAC dendrites preferentially synapse onto DSGCs that are tuned to stimuli moving antiparallel to the SAC dendrites[1]. Thus, any given DSGC subtype receives input from SAC dendrites that are oriented in that DSGC's null direction. The molecular basis of subtype-specific SAC-DSGC wiring is unknown, but it is likely that DSGCs tuned to motion in different axes express distinct markers that permit synaptogenesis with SAC dendrites oriented in a certain direction. To test this, we have performed RNA sequencing on isolated ON-OFF DSGC populations tuned for either nasal or ventral motion. Differential expression analysis revealed a variety of candidate genes with known functions in cell adhesion or synaptogenesis. We validated expression of several candidates using fluorescent in situ hybridization and immunohistochemistry. We will report progress on testing the role of one candidate, the inhibitory synaptic organizer cerebellin-4 (Cbln4), in the development of direction-selective tuning.

Title: Novel object detection and multiplexed motion representation in retinal bipolar cells

Authors: J. A. GAYNES, S. A. BUDOFF, M. J. GRYBKO, J. B. HUNT, *A. POLEG-POLSKY;
Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Antagonistic interactions between the center and surround receptive field (RF) components lie at the heart of the computations performed in the visual system. Center-surround

RFs are thought to enhance responses to spatial contrasts (i.e., edges), but how they contribute to motion processing is unknown. Here, we addressed this question in retinal bipolar cells, the first visual neuron with classic center-surround interactions. We found that bipolar glutamate release emphasizes objects that emerge in the RF; their responses to continuous motion are smaller, slower, and cannot be predicted by signals elicited by stationary stimuli. The alteration in signal dynamics induced by novel objects dwarfs the enhancement of spatial edges and can be explained by priming of RF surround during continuous motion. These findings echo the salience of human visual perception and demonstrate an unappreciated capacity of the center-surround architecture to facilitate novel object detection and multiplexed encoding of distinct visual data streams.

Title: A role for retinal waves in the development of retinal direction selectivity

Authors: *K. BISTRONG, A. TIRIAC, J. TWORIG, M. B. FELLER;
Univ. of California Berkeley, Berkeley, CA

Abstract: In the developing visual system, neurons in the retina form precise connections to accurately represent features of the visual scene and transduce them into physiologically-relevant outputs. For some features, like direction selectivity, these connections are already established before the onset of vision. The factors that set up these connections during this developmental period remain unknown. During development, the retina exhibits spontaneous waves of neural activity that sweep across its surface. We tested the influence of these retinal waves on the development of the direction selective circuit by characterizing direction selective responses in a mouse model (β2-nAChR-KO) that exhibits perturbed retinal waves. These mice present a severe deficit in direction selective responses to motion along the horizontal axis. This is reminiscent of a recent study where genetic deletion in mice of a gene linked to a human disease model for nystagmus, FRMD7, leads to a severe reduction in horizontal direction selectivity in the mouse

retina. We therefore tested whether FRMD7 expression is influenced by cholinergic retinal waves during development. Using fluorescent in situ hybridization and immunohistochemistry, we find that starburst amacrine cells have normal levels of FRMD7 expression in β2-nAChR-KO mice. This work establishes a role for retinal waves in the development of horizontal direction selectivity.

Title: Systematic reduction of the dimensionality of natural scenes allows accurate predictions of retinal ganglion cell spike outputs.

Authors: *J. FREEDLAND, F. M. RIEKE;
Univ. of Washington, Seattle, WA

Abstract: Natural visual scenes contain complex spatial features that are reliably encoded by the mammalian visual system. During early-stage encoding, the retina captures structure in natural scenes through linear and nonlinear spatial integration. Although some of the individual retinal mechanisms that control spatial integration are well-understood, spike predictions to natural scenes remain elusive. This is likely because natural scenes engage multiple circuit mechanisms that interact in poorly understood ways. Here, we identify spatial integration mechanisms relevant for natural scene encoding and use computational modeling to predict spike outputs in primate On- and Off-parasol RGCs. Our approach was to empirically determine how the structure of naturalistic stimuli can be simplified without eliciting major changes to the spike response of parasol RGCs. We were then able to leverage the statistical simplicity of the resulting scenes to investigate spatial mechanisms and predict encoded spike responses.
The simplification of natural stimuli consists of dividing individual frames of natural movies into discrete spatial regions and replacing the spatial structure in each region with a uniform luminance. This luminance value is equal to the linearly-integrated pixel value within each region of the original movie. We find that reducing natural movies to 16-linearly integrated regions is sufficient to describe 80-90% of the structure in the spiking responses of On- and Off-parasol RGCs. We test simplified stimuli by replacing each reduced region with an entirely different image that contains the same integrated luminance. Responses to these spatial metamers are very similar to those to the original natural movie. Finally, we computationally investigate

this 16-dimensional space and observe the underlying center-surround and rectification mechanisms that convert luminance into the cell's 1-dimensional spike output.

Title: Metabotropic glutamate receptor 8 creates an unconventional receptive field in a novel interneuron in the mouse retina

Authors: *A. JO[1], S. DENIZ[1], J. XU[2], S. H. DEVRIES[1], Y. ZHU[1];
[1]Ophthalmology, [2]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: In the retina, with the exception of mGluR6, the roles of group-III mGluRs in visual processing remain unclear. Here we used Cre/tTA intersectional mouse genetics to identify a novel amacrine cell type, named Scg2-AC2. Scg2-AC2 is a narrow-field amacrine cell broadly stratified in the ON layer of the inner plexiform layer . However, contradictory to the ON-layer stratification, Scg2-AC2 is activated in the dark but inhibited by the light, as revealed with GCaMP imaging. Furthermore, it exhibits high contrast sensitivity, and shows an unconventional "surround excitation, central inhibition" receptive field. iGluSnFr imaging showed Scg2-AC2 received direct glutamatergic input from ON-bipolar cells in the light. To our surprise, pharmacology experiments revealed that L-AP4 and mGluR8-specific agonist (S) 3,4 DCPG effectively abolished both the dark activation and light inactivation in Scg2-AC2. These results suggest that mGluR8 is expressed in the Scg2-AC2 circuit and mediates the inhibition in light and in response to L-AP4 application. We are currently assessing Single cell RNA-seq and In Situ Hybridization of Scg2-AC2. Our results suggest that its unconventional receptive field, along with its high contrast sensitivity, allow Scg2-AC2 to exert a strong but well-controlled inhibition on the "ON' and/or "ON-OFF" RGCs to enhance visual sensitivity in the dark.

Title: Toward a comprehensive account of orientation selectivity in the retina

Authors: *M. L. ZIPPERER[1], B. G. BORGHUIS[2];
[1]Univ. of Louisville Anatom. Sci. & Neurobio., Louisville, KY; [2]Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Retinal Ganglion Cells (RGCs)form functionally distinct ‘channels’that selectively encode features ofthe visual input including direction of motion, contrast, size, and color. A highly conserved visual channelamongst vertebrates conveys orientation selectivity, i.e., the selective firing of neuronal cells in responseto elongated stimuli along a preferred orientation. Orientation selectivity is a critical computation andseveral studies have reported aspects of it, including apparent cell type identity in anatomicalreconstructions, and functional characterization of at least two different identified RGC types. But howcell types in the different studies relate is not well resolved, and the mechanisms that generate theorientation selective responses in mice remain incompletely understood.The goal of this study was to comprehensively characterize Orientation Selective (OS)RGC typesin the mouse retina and to elucidate the mechanisms that contribute to their tuning properties. We usedpopulation calcium imaging and clustering algorithms to identify orientation selective RCGs in retinalexplants. We then targeted these cells for detailed morphological, molecular marker, andelectrophysiological study. Comparison with published data enabled cross-linking morphological,molecular, and functionally defined types of previous studies.Our survey of RGC populations in the Thy1-GcaMP6f mouse line revealed multiple cell typesselective for both horizontal and vertical orientations. Based on data from calcium imaging andelectrophysiological whole-cell recording, the horizontal-tuned cluster appears to comprise at least 3distinct types. Analysis of light-evoked synaptic currents shows one cell with fast transient inhibition andanother with slow tonic inhibition. A third type was distinguished by tuned excitation and inhibition inresponse to a drifting grating stimulus. Sulforhodamine and neurobiotin tracing revealed gap junctioncoupling in select OS cells, which raises the possibility that electrical synapses contribute to their tuning.Based on our morphological data we conclude that one type is the Tbr1-S2 cell described in Liu et al.,(2018)and that this is the same cell type as the 4on type in the eyewire museum classification(www.eyewire.com).This study has identified multiple OSGC types in mouse and provides insight into some of thecircuit-level tuning mechanisms of these cells. We have begun to resolve correspondences betweenreported OS RGCs and incompletely categorized cell types

from previous studies, contributing to a morecomplete understanding of RGC types and their functional role in the mouse retina.

Title: Endogenous opioid signaling in the retina modulates sleep/wake behavior

Authors: *C.-T. BEREZIN[1], N. BERGUM[2], K. A. LUCHINI[2], J. VIGH[2];
[1]Cell and Mol. Biol., [2]Biomed. Sci., Colorado State Univ., Fort Collins, CO

Abstract: Light is perhaps the most important environmental factor influencing sleep/wake behavior. In mammals, sleep/wake cycles are set to light/dark cycles in the environment (i.e. photoentrainment) by intrinsically photosensitive retinal ganglion cells (ipRGCs); ipRGCs fire action potentials in response to light which, in nocturnal mice, promotes sleep. Importantly, ipRGC firing is inhibited by μ-opioid receptor (MOR) activation. MOR-selective neuromodulators that alter the activity of ipRGCs can presumably influence light-driven behaviors mediated by ipRGCs. Thus, we hypothesize that the endogenous opioid peptide β-endorphin modulates sleep/wake cycles via MORs on ipRGCs. Our immunohistochemical experiments reveal that there is a statistically significant increase in β-endorphin expression in the retina in nighttime versus daytime, as well as in dark versus light conditions. In addition, telemetric recordings of sleep-wake behavior in transgenic mice which lack functional MORs on ipRGCs show reduced wakefulness during the subjective night compared to wild-type mice. Therefore, we conclude that β-endorphin expression in the retina depends on both circadian timing and light exposure, which is consistent with previous studies showing circadian regulation of β-endorphin expression in the brain. In addition, our data support the hypothesis that endogenous opioid signaling in the retina contributes to healthy sleep-wake cycles. Furthermore, these results suggest that aberrant MOR signaling in ipRGCs might contribute to the sleep disturbances associated with chronic opioid use.

Title: Classification of retinal ganglion cells using electrophysiology and functional imaging

Authors: *Z. F. JESSEN, G. W. SCHWARTZ;
Ophthalmology, Northwestern Univ., Chicago, IL

Abstract: Typology of retinal neurons is critical to our understanding of retinal circuitry, yet our knowledge of retinal cell types is incomplete, and typing is used inconsistently across the literature. Typology of retinal ganglion cells (RGCs) has historically relied on functional, transcriptomic, or morphologic approaches, each of which capture a limited amount of inter-type variability relevant to classification. We recently reported a large-scale, intersectional classification of RGCs in which we found that electrophysiological responses to a simple light stimulus were sufficient to separate RGC types with surprising accuracy. Here we present the results of our early attempts to align electrophysiology- and functional imaging- based classifications using a similar approach. Using this alignment we aim to describe how hyperacuity may arise at the level of locally-complete populations of individual RGC types.

Title: Developmental dysfunction of parvalbumin expressing inhibitory neurons

Authors: *C. WARD, E. SABRI, R. BATISTA-BRITO;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Central to understanding the role of inhibitory neurons in cortical network function, is understanding their contributions through a neurodevelopmental lens. To address this, we disrupted the expression of a critical regulator of neuronal maturation in interneuron precursors. Myocyte enhancer factor-2C (Mef2c) is a transcription factor linked to neurodevelopmental disorders that regulates the expression of genes involved in the differentiation, migration, survival, and synaptic function of excitatory neurons, yet its role in the function of inhibitory neurons is unknown. Among the three major subtypes of cortical inhibitory interneurons, neurons expressing the calcium-binding protein Parvalbumin are highly enriched for Mef2c expression. Parvalbumin-Expressing Inhibitory Interneurons (PV-INs) sample input from large populations of pyramidal cells and synapse onto the soma and axon initial segment, allowing them powerfully to regulate excitatory activity within the cortex. Embryonic removal of Mef2c in PV-IN precursors leads to both signatures of impaired maturation in PV-INs throughout the cortex and a reduction in PV expression within cortical layer IV, the target of sensory inputs from the thalamus. To understand how PV-IN maturation & integration into cortical circuits is affected by loss of Mef2c, we performed awake extracellular electrophysiology recordings within the primary visual cortex across behavioral states. We observed that mutant mice showed altered temporal patterns of network activity, particularly during periods of quiescence, or in the absence of movement. Mutant mice had increased synchronous activity and display hyper-synchronous events. Mutants also showed altered visual responses, including increased noise correlations. Together, our data show that early removal of Mef2c leads to abnormal circuit function. These studies serve as a foundation for examining the contribution of PV-INs toward signatures of altered state-dependent network activity and sensory processing.

Abstract: Mammalian neocortex contains a stunning diversity of inhibitory interneurons, each with distinct morphological, functional, and transcriptomic features. While much progress has been made in studying the connectivity of interneurons at the level of broad molecular sub-classes such as PV, SST, and VIP, each class is known to contain multiple types. It remains difficult to relate these more specific neuronal subtypes to their connectivity. Here, we address this problem using a millimeter-scale electron microscopy volume of mouse visual cortex, with cells and synapses segmented using state-of-the-art machine learning and a highly scalable proofreading framework. To obtain an unbiased population of cortical cells, we generated a columnar "core sample" containing all cells whose nuclei were located within a 100 µm x 100 µm x 700 µm region, spanning from mid-layer 1 to the start of white matter. We found 1343 neurons, 1182 excitatory and 161 inhibitory based on morphological features. In order to understand the distribution of synaptic input in the column, we proofread the dendritic arbors of all columnar neurons and identified dendritic compartments for excitatory cells. Neurons were cell-typed by laminar position, connectivity, and morphological features. The result is a complete input budget based on 4 million synapses across the column, with each categorized by location, postsynaptic cell type, and postsynaptic compartment. In order to measure the morphology and synaptic targeting rules for inhibitory neurons in their local columnar environment, we further extensively proofread the axonal arbors of all inhibitory neurons. Importantly, the size of the volume was such that most proofread arbors were fully contained within the dataset. By comparing the cell-specific patterns of output with the synaptic budget, we not only characterized the outgoing connectivity of each interneuron but also significant deviations from target-specific synapse abundances in the column. In addition to a precise description of the synaptic output of individual cells, our data reveal novel principles of cell-type specific connectivity in cortex.

Abstract: Neuronal cell types can be defined by multiple cellular properties, including morphology, transcriptomic profile, and electrophysiology; however, these modalities may not always agree. Adding synaptic connectivity data can further define a cell type and provide greater insight into that cell's role within the circuit. Martinotti cells (MCs), a class of inhibitory interneurons in the mammalian cortex, have been characterized by the expression of somatostatin (Sst) and axon that elaborates in Layer 1 (L1). The term "Martinotti" likely encompasses multiple cell types as MCs have diverse morphologies, including "T-shape" and "fanning". Furthermore, recent work in the mouse primary visual cortex (VISp) shows several cell types from the Sst subclass with congruent morphology, transcriptomics, and physiology, with distinct axonal arborizations, including L1 innervation (Gouwens & Sorensen et al., 2020). We hypothesize that Martinotti cells with distinct morphologies will also have distinct postsynaptic target distribution patterns.
To test this hypothesis, we completed reconstructions of 11 L4-5 Martinotti (at least 3 cells per distinct morphology) in mouse VISp from a millimeter-scale serial-section electron microscopy (EM) dataset. We proofread both axon and dendrite to remove any erroneous processes and extend processes to a natural end or as far as the data allowed. Skeletons were then extracted from these complete reconstructions and morphological features were calculated from the skeletons. These morphological features were compared with those from VISp Sst+ cells reconstructed from biocytin fills from slice (Gouwens & Sorensen et al., 2020). Additionally, the output synapses from these complete reconstructions were identified by machine-learning (Turner et al., 2020), and a subset were manually confirmed. We identified the postsynaptic cell type and structure (spine vs shaft) for 5% of the output synapses (~70-700 synapses/cell) to determine the postsynaptic target distribution pattern for each cell. From this fraction of synapses, we observe different targeting patterns for these morphologically-distinct sets of neurons.

Title: Vip-expressing interneurons in the mouse primary visual cortex control how the arousal state is reflected in the neuronal activity

Authors: *E. SABRI, R. BATISTA-BRITO;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The mouse primary visual cortex (V1) is the first area where visual information arrives in the neocortex. The cortical circuitry that underlies the sensory processing in V1 is fairly well described in terms of different populations of excitatory and inhibitory neurons residing across the layers of the cortex. Based on our current understanding, inputs from the thalamus mostly target layers 4 and 6 of the sensory cortices, after which information is distributed to the more superficial layers, then is carried to the neurons in layer 5, which in turn send this processed sensory information to other regions. Recent findings have shown that the arousal state of the animal influences the processing of sensory information in cortical sensory areas. However, we don't have a clear picture of the circuitry behind the modulation of sensory information with arousal. Vasoactive Intestinal Polypeptide (VIP)-expressing interneurons reside mainly in superficial layers and receive neuromodulatory and corticocortical connections. These anatomical characteristics put VIP interneurons in a unique position to mediate the effect of arousal on visual information processing. To assess this hypothesis, we silenced the activity of VIP neurons of V1 by using optogenetics in transgenic mice that express inhibitory opsin ArchT exclusively in VIP cells (VIP-cre+/-; Ai40+/−, n=6). During the opto-inhibition of VIP neurons, we recorded the extracellular activity of V1 neurons using a 64-channel linear probe that covers all layers. We used the pupil diameter and the facial movement of the animals to measure the arousal level. We observed that the inhibition of VIP cells slightly decreased the activity across the population both during the low-arousal and high-arousal states ($p=0.037$ and $p=0.005$ respectively) as expected since it is known that VIP cells disinhibit the pyramidal cells. However, the inhibition of VIPs strengthened the level of modulation by arousal. We observed that: 1) 11% of neurons (15/131) showed an enhanced activity during high arousal, and silencing

of VIPs intensified this enhancement (p=0.041). 2) 10% of neurons (14/131) showed a suppressed activity during high arousal, and silencing of VIPs intensified this suppression (p=0.021). Taken together, this data suggests that VIP interneurons are part of the circuitry that controls the transfer of the information about the arousal state to V1. Furthermore, the inactivity of VIPs opens the gate for the influence of arousal state on neuronal activity in V1.

Title: Visual perception depends on the spatial footprint of cortical inhibitory neuron activity

Authors: *J. DEL ROSARIO[1,2], S. COLETTA[1], K. PEELMAN[2,1], B. WILLIAMS[1], A. OTSUKI[1], A. DEL CASTILLO VALERIO[1], K. WORDEN[1], L. T. BLANPAIN[2,1], L. LOVELL[1], B. HAIDER[1,2];

Abstract: The role of cortical inhibitory neurons during visual perception remains debated. Parvalbumin-expressing (PV) and somatostatin expressing (SST) inhibitory neurons show different spatial preferences for visual stimuli (Adesnik et al., 2012), and provide different spatial spread of inhibition (Kato et al., 2017). It is unknown how the spatial footprint of PV or SST mediated inhibition modulates visual perception. We explored this question by pairing spatiotemporally precise optogenetic activation of PV or SST neurons with simultaneous neural recordings in mice performing a visual contrast detection task.
We trained mice to detect visual stimuli by licking for water (9 mice, 105 sessions). Visual stimuli appeared in blocks of trials across different contrasts in two separate positions: one in central visual space, the other 70° away in peripheral visual space (Speed et al., 2019). Perceptual performance was quantified using signal detection theory. During trials of stimulus detection in the central visual field, PV or SST inhibitory neurons were activated in the part of V1 representing peripheral visual space (~0.8 mm away from V1 site representing central visual space; laser ~0.3 mm full-width half max profile). This allowed us to probe how the spatial spread of inhibition in cortical space affected perception of distant stimulus-evoked activity. PV or SST stimulation exerted unique effects on perceptual performance. SST stimulation largely impaired low contrast stimulus detection but spared high contrast detection, changing the slope

of the psychometric contrast sensitivity curve (~70% decrease in slope; 10% increase in lapse rate). PV stimulation however decreased performance at all contrasts with a smaller change in slope (~35% decrease in slope; ~10% increase in lapse rate).
We next investigated V1 activity during these perceptual changes by performing multisite extracellular recordings during distant optogenetic stimulation in awake mice (n = 6 mice; 28 recordings). During detection of stimuli in the central visual field, distant PV stimulation decreased both excitatory neuron and PV neuron activity in the region of V1 corresponding to the central visual field. At these same sites, distant SST stimulation instead increased SST activity, and also simultaneously decreased PV and excitatory neuron activity. The inhibitory effects of distal SST stimulation on excitatory neurons were twice as large as effects from PV stimulation. These results suggest that cortical inhibitory neuron subtypes drive unique spatial profiles of inhibition that distinctly shape the sensitivity of visual perception.

Title: Chemogenetic suppression of VIP interneurons disrupts top-down alpha-band synchrony during visual oddball paradigm

Authors: *G. S. BASTOS[1,2], J. T. HOLMES[1], A. M. RADER[1,2], J. P. HAMM[1,2];
[1]Georgia State Univ., Atlanta, GA; [2]Ctr. for Neuroinflam. and Cardiometabolic Dis., Atlanta, GA

Abstract: Temporal synchronization among distributed regions and cell types in the cortex tends to oscillatory in nature. Given the diverse intrinsic properties of individual neurons and synapses, distinct neuro-oscillatory frequency bands may serve to selectively route information processing in cortical networks. Feedback inputs from higher level brain regions are known to modulate sensory processing in lower sensory regions in accord with context and behavioral goals. The interplay between long range connectivity and frequency specific modulation of local cell populations could be a way to encode context and modulate stimulus specific responses in sensory cortex, aligning the status of microcircuits towards a behavioral goal. Interneuron population are specially qualified to be the mediators of long range information processing due

to their inhibitory nature that defines the timing and flow of activity in local circuits.In here, we recorded local field potentials (LFP) from the anterior cingulate cortex (ACa, analog to pre frontal cortex in humans) and primary visual cortex (V1) of male and female mice to explore the oscillatory synchrony between regions during a visual oddball paradigm. The visual oddball paradigm probes the ability of the mice to discriminate between a repetitive stimulus (redundant, shown 87.5% of the time) over stimuli that deviates from it (deviant, shown 12.5% of the time). We found that during the task, ACa and V1 are phase-locked at theta to alpha frequency (6-10hz), showing a high value of oscillatory coherence between both regions. In addition, using optogenetics to rhythmically activate ACa axons in V1, results show an increased activation of VIP interneurons and pyramidal cells and decreased activation of somatostatin (SST) interneurons, specifically when the input was driven at theta to alpha band (6-10hz), but not other frequencies (e.g. delta, beta, or gamma). This suggests that top-down inputs to V1 engage a canonical VIP to SST inhibitory motif in V1 previously reported in the literature.To further test the role of VIP interneurons on the frontal-sensory circuit, we recorded LFP signals from both ACa and V1 while de-activating of VIP cells using chemogenetics during the oddball paradigm (with hm4D(i), n=6 mice) and CNO-only controls (n=7 mice). We found that theta-alpha specific oscillatory coherence significantly decreased after VIP suppression. Further, deviant-stimulus evoked responses in the LFP were also attenuated, suggesting that this manipulation disrupted context processing. The results point to a role of VIP interneurons in mediating theta-alpha synchrony in ACa-V1 circuits during the visual processing of context.

Fast synaptic GABAergic inhibition shapes both spontaneous and sensory-evoked cortical activity. Cortical inhibitory GABAergic neurons are highly heterogeneous, and this rich diversity of cell types is responsible for specific connectivity patterns with excitatory principal neurons (PNs). The result is an efficient control of cortical activity via a highly specialized division of labor of different interneuron types. In particular, perisomatic inhibition from parvalbumin (PV)-expressing basket cells (BCs) onto PNs orchestrates and sets the dynamic range of cortical networks. Cannabinoid receptor type 1 (CB1)-expressing interneurons also target the perisomatic region of PNs and are known to express several forms of cortical plasticity. However, the connectivity and function of these elusive - yet prominent - neocortical GABAergic cells is unknown. In order to identify the circuit properties of CB1 interneurons, we combined mouse genetics, *in vitro* whole-cell patch clamp recordings and *in vivo* two-photon calcium imaging in awake head-fixed mice. We found that the connectivity pattern of CB1 BCs strongly differs between primary and high-order cortical visual areas. Tonic CB1 signaling constitutively suppresses GABA release from CB1 BCs in the medial secondary visual cortex (V2M), but not primary (V1) visual area. This area-specific connectivity and endocannabinoid-dependent modulation of GABA release from CB1 BCs is responsible for a much higher spontaneous activity of PNs in V2M, as compared to V1 in vivo. In addition,
visual area-specific tonic CB1 signaling modulates PN coordinated activity in V2M but not in V1. Thus, CB1 BCs operate a visual area-dependent dynamic inhibitory control of PNs that will likely play a major role in visual perception.

Title: Investigating the role of GABA-mediated visual intracortical inhibition in aging with transcranial magnetic stimulation

Authors: *D. KHAMMASH[1], K. J. MICHON[1], M. SIMMONITE[1], M. VESIA[2], S. F. TAYLOR[3], T. A. POLK[1];
[1]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michigan, Sch. of Kinesiology, Ann Arbor, MI; [3]Psychiatry, Univ. of Michigan Dept. of Psychiatry, Ann Arbor, MI

Abstract: Deficits in the inhibitory neurotransmitter γ-aminobutyric acid (GABA) are associated with a number of motor and psychiatric disorders and may also play a role in age-related cognitive decline. However, there are limited ways of probing GABA and inhibitory function in vivo in humans. While Magnetic Resonance Spectroscopy (MRS) can assess the concentration of GABA, this measure may not be indicative of local inhibitory activity. Instead, paired-pulse transcranial magnetic stimulation (ppTMS) allows investigation of inhibitory networks mediated through the GABA-A receptor at the level of interneurons within the primary motor cortex. However, the association between GABAergic inhibition and aging in the visual domain is poorly understood. We recently demonstrated the feasibility, reliability, and optimal stimulation parameters of a ppTMS measure of inhibition by means of short-interval intracortical inhibition of the primary visual cortex (V1). While TMS of the motor cortex elicits measurable muscle-twitches, stimulation of V1 elicits short-lived visual percepts called phosphenes, which can be objectively measured using a tracing paradigm. In the present study, we utilize this new method to investigate visual intracortical inhibition in aging. Younger (18 to 29 years) and older (65+ years) adult participants completed both an MRS session to assess left primary visual GABA concentration and a ppTMS session to assess intracortical inhibition in left V1. Preliminary data in 11 older and 16 younger adults indicate a strong positive relationship between spectroscopy measures of GABA and the ppTMS measure of functional inhibition in V1 ($r = .66$, $p < .001$). We also observed a trend of reduced visual intracortical inhibition with age ($p = .09$). The results demonstrate the possibility of assessing GABAergic function in cortical areas outside of the motor cortex, critical for characterizing the role it plays in both disease and healthy aging.

Title: Exploring the role of interneurons on cortical ensembles

Authors: *S. PONTES QUERO[1], R. YUSTE[2];
[1]Neurotechnology Center, Dept. of Biol. Sci., Columbia Univ., New york, NY;
[2]Neurotechnology Center, Dept. of Biol. Sci., Columbia Univ., New York, NY

Abstract: Coordinated neuronal activity is increasingly being considered key for cortical information encoding and processing, as individual neuronal activity seems to be too variable to precisely represent sensory stimuli. Recent work is showing that it is possible to represent sensory information with lower dimensional activity spaces defined by groups of neurons with coordinated activity, called ensembles, extracted from the highly variable and multidimensional excitatory cortical activity. However, the cortex also contains inhibitory interneurons that, although fewer in number, are also essential for normal information processing. The study of interneurons in the cortex has been mostly focused on their effects on the activity of individual excitatory cells but their own coordinated activity and its influence on excitatory ensemble dynamics is still poorly characterized. This is partially due to the greater diversity of interneuronal cell types with different electrophysiological properties, which, with current genetic targeting and identification methods, either decreases the amount of analyzed cells (hampering population analyses) or introduces additional response variability. In our work we set out to explore this by using genetic targeting of interneuron and two photon calcium imaging and holographic optogenetics in mouse primary visual cortex *in vivo* during the presentation of a diverse set of visual stimuli in two ways. First, by recording inhibitory activity in the full interneuronal cortical population, irrespectively or their electrophysiological diversity, we analyze their global activity and extract their population dynamics in combination with excitatory cells. Second, using a recently developed transgenic line to specifically target chandelier cells, a very distinctive and specific interneuronal subtype, we examine and probe their precise role in modulating excitatory cortical activity. Our data shows that a considerable number of interneurons, including chandelier cells, are highly correlated with locomotion and pupil diameter (as a proxy for arousal state). However, we also observed additional structuring of their population dynamics in relation to visual stimulation, with particularly strong correlation between chandelier cells. Additional analysis of the network properties of these populations,

their response to visual stimuli and optogenetic perturbations during perceptual habituation would further reveal the effects of inhibition in the dynamical cortical activity.

Dept. of Psychology, Stanford, CA

Abstract: Cortical activity is highly dependent on behavioral state of an animal with different states, such as sleep and wake, having profound impact on cognition and cortical processing. The circuitry responsible for sensing behavioral state and modifying cortical activity to generate cortical states remains unknown. Here, we propose that long-range cortical inhibitory neurons in the cortex play a crucial role in the generation of low frequency activity, a hallmark of multiple cortical states. Using an array of complementary techniques, we have begun to characterize this unique cell type. We examine the input and outputs of these long-range inhibitory neurons in mouse primary visual cortex using whole mount light sheet microscopy and monosynaptic rabies tracing. These data show inputs almost exclusively from local cortical neurons and the lateral geniculate nucleus unique from other inhibitory neurons which have connections from many cortical and subcortical structures. While the input is mostly local, outputs span across cortical and subcortical regions. To compliment this, we combine multiple in vivo recording modalities. First, using 2 photon calcium imaging, we show that these cells are active during periods of low arousal states with increased low frequency activity and suppressed by movement. Using electrophysiology and optogenetics, we show that activation of long-range inhibitory neurons leads to increased low-frequency activity. Taken together, these data suggest long-range inhibitory neurons broadly sense local network activity, relaying it to long range targets to temporally synchronize activity during periods of low arousal and increased low frequency activity.

Title: Long term effects of sexual behavior on brain activity in female rats evaluated by manganese-enhanced magnetic resonance imaging (MEMRI)

Authors: *J. AGUILAR MORENO[1], J. ORTÍZ[1], S. ALCAUTER[1], R. G. PAREDES[2];
[1]Inst. de Neurobiología, Querétaro, Mexico; [2]Escuela Nacional de Estudios Superiores Juriquilla, Querétaro, QRO, Mexico

Abstract: We used manganese-enhanced magnetic resonance imaging (MEMRI) to evaluate the activation of different brain regions in females that did not and that paced the sexual interaction. Female rats were divided in four groups: 1) control, 2) exposed to a male without mating, and two groups that mated 3) with the male or 4) the female controlling the sexual interaction. The tests were done once a week, for 1 h, for 10 weeks. In session 1, 5 and 10, all females were administrated with 16 mg/kg of manganese chloride ($MnCl_2$) 24 h before testing. Immediately after the tests, subjects were scanned for MEMRI evaluating the olfactory bulb (OB), bed nucleus of the stria terminalis (BNST), amygdala (AMG), the medial preoptic area (MPOA), the ventromedial hypothalamus (VMH), nucleus accumbens (NAcc), the striatum (STR), the hippocampus (Hipp) and the ventral tegmental area (VTA). Consistent with our previous observations we found an increase in signal intensity in most areas evaluated in session 5 in comparison to session 1 in both groups that mated. No differences were observed between females that did not pace the sexual interaction and those that did. When we compared the socio-sexual circuit between the groups we found a significant increase of signal intensity in session 5 in the non-paced mating group against the control group. On the reward circuit, the no paced and paced mating groups had a higher signal intensity compared to the group exposed to the male. Differences across time were found in both circuits in all groups, except for the control. Sessions 5 and 10 had an increased signal intensity compared to their respective session 1. Our results give new insights of how brain activation can be modified across time depending on the duration, quantity and quality of the stimulation that a female receive from a stimulus male.

Title: Female dorsal raphe serotonin responses to sexual stimuli

Authors: *E. L. TROCONIS, C. SEO, A. GURU, M. R. WARDEN;
Cornell Univ., Ithaca, NY

Abstract: Serotonin—a widely-projecting neuromodulatory system—has been implicated in a variety of emotional brain states and behaviors, including mating. Previous work in both humans and animal models has shown that pharmacological compounds that interact with the serotonin system can modulate female sexual behavior. However, whether female serotonin neurons normally respond to sexual stimuli during mating is unknown. Here, we used fiber photometry to record population calcium activity of dorsal raphe serotonin neurons in the female brain during mating. We found that this population becomes active in the female at the time of ejaculation (GCaMP6, n=14; GFP, n=3; $p<0.001$). To understand which stimuli during ejaculation trigger this neuronal activity in the female, we developed surgical techniques that perturb various aspects of ejaculatory physiology in males with intact mating behavior. First, we tested the role of ejaculatory fluid release into the vaginal canal by redirecting the male urethra to a stoma in the abdominal wall. Then, we tested the role of penis erectile function by partially transecting a pair of muscles that control penis behavior. We found that the female elevated serotonin neuronal activity at ejaculation disappeared only when her mating partner had undergone both modifications in combination (surgery, n=7; control, n=7; $p<0.01$). Moreover, artificial mechanical vaginal stimulation was sufficient to trigger serotonin neuronal activity in the female (GCaMP6, n=6; GFP, n=3; $p<0.05$). Together, these results suggest that both penis behavior and release of ejaculatory fluid inside the vaginal canal are important mechanical stimuli to which female dorsal raphe serotonin neurons respond during ejaculation. Sensing ejaculation may be crucial for regulating various aspects of female sexual behavior and physiology, such as receptivity in subsequent mating encounters and fertility. Overall, our work sheds light on a novel vagina-brain axis that likely plays a critical role in female reproduction.

Title: Oxytocin and testosterone shape viewing preference for perinea over faces in potential sexual partners

Authors: Y. JIANG, M. L. PLATT;
Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: As primates, faces as well as perinea of potential sexual partners naturally demand our attention. Many primates also visually check conspecifics of the same sex for information regarding their dominance and reproductive status. Different hormones may bias our visual attention to different types of displays. Using a free viewing task in which images of monkey faces and perinea were simultaneously displayed, we found that male rhesus macaques showed a significant and consistent preference for perinea over faces, regardless of the sex of the depicted monkey. Male rhesus also universally preferred unobstructed frontal views of faces and perinea of both sexes, possibly due to the richness of visual information presented. In addition, they preferred direct gaze in female faces and open mouths in male faces, suggesting a trade-off between mating interests and monitoring the dominance status of others. Administering both oxytocin and testosterone in male monkeys amplified their innate preference for female but not male perinea, specifically by further dampening attraction to less-preferred faces and increasing attention to more-preferred perinea. Together these results strongly endorse a pre-existing bias in primates to attend to perinea rather than faces, and implicate both oxytocin and testosterone in the process of mate evaluation through visual orienting.

Title: Water is necessary for photoperiodic testicular recrudescence in zebra finches but not vocal state change

Authors: *J. SANTOLLO, S. M. FERGUSON, C. E. HARPOLE, B. T. BOWLING, N. R. SOMMERS, C. M. CASSONE;
Univ. of Kentucky, Lexington, KY

Abstract: Zebra finches are considered opportunistic breeders as early reports attributed gonadal recrudescence and the induction of mating behavior to water availability. More recent studies, however, demonstrated a role for photoperiod in regulating zebra finch reproductive behavior. It is not known, however, whether photoperiod and water availability interact to control reproductive function. We, therefore, tested the hypothesis that both long photoperiods and water access are necessary for gonadal recrudescence and vocalizations in male zebra finches. Thirty-nine male zebra finches were divided into two groups that received either *ad libitum* access to water or 0.5 ml of water/ twice per week, while being maintained on a short day (SD) light cycle (06:18 L:D). After four weeks of SD housing, half of the subjects in each fluid access condition were switched to a long day (LD) light cycle (14:10 L:D) for an additional six weeks. Blood samples were taken biweekly, and daily vocalizations and activity were monitored throughout the duration of the study. At the end of the study birds were euthanized, and testes and brains were collected. Analysis of testes weight demonstrated that birds housed under LD with *ad libitum* water access had significantly larger testes compared to all other groups ($p < 0.05$). Locomotor activity and vocalization, however, were greater in LD housed birds but were not influenced by water access ($p < 0.05$). Ongoing studies are examining aromatase and vasotocin expression, as well as morphometric analyses of song nuclei and hypothalamic structures in the brain using cytochrome oxidase histochemistry. These findings are novel in two ways by demonstrating that hydration status gates the ability of photoperiod to induce reproductive capacity and disassociating gonadal function from song vocalizations, an important aspect of songbird mating behavior.

Title: Hypothalamic circuit mechanism for temporal control of female sexual behavior

Authors: *S. INOUE[1], R. YANG[1], A. TANTRY[1], C.-H. DAVIS[1], T. YANG[1], J. R. KNOEDLER[1], Y. WEI[1], E. L. ADAMS[1], S. THOMBARE[1], S. R. GOLF[1], R. L. NEVE[2], M. TESSIER-LAVIGNE[1], J. B. DING[1], N. M. SHAH[1];
[1]Stanford Univ., Stanford, CA; [2]Massachusetts Gen. Hosp., Cambridge, MA

Abstract: Behaviors are associated with relevant internal physiological states. In many species, including mice, females dramatically change their sexual behaviors to match their ovulatory status. Females of many species are sexually receptive exclusively during the estrus, ovulatory phase of the estrous cycle, while they are not receptive, and in fact actively rejecting, during other phases. Sex hormones such as estrogen and progesterone are required for both ovulation and female sexual behavior. Although central and peripheral mechanisms of ovulation are well characterized, neural circuit mechanisms underlying the estrus-associated change of the behavior are poorly understood. We have previously shown that progesterone receptor (PR) expressing neurons in the ventromedial hypothalamus (VMH) are essential for female sexual behavior. Targeted ablation of PR+ VMH neurons abolished female sexual behavior while leaving the estrous cycle intact. However, whether PR+ VMH neurons play a role in the estrus-associated change of female sexual behavior or control the behavior independent of estrus is unclear. We examined whether PR+ VMH neurons play a role in the estrus-associated change of female sexual behavior. We find that PR+ VMH neurons significantly strengthen their functional and anatomical connections during estrus with the anteroventral periventricular nucleus. This cyclic increase in connectivity depends on estrogen signaling in PR+ VMH neurons. We further find that these projections are essential for female sexual receptivity during estrus because optogenetic inhibition of these connections abolishes this behavior. These findings demonstrate that periodic remodeling in this behaviorally salient neural pathway plays a critical role in coordinating female sexual behavior with an internal physiological state that coincides with the window of fertility. We will present these and more recent findings to discuss hypothalamic circuit mechanisms that control the timing of female sexual behavior.

Title: Evaluation of the olfactory sexual incentive in high- and low-yawning female rats

Authors: *A. MORA-BOLAÑOS[1], C. CORTES[1], J. EGUIBAR[2];
[1]Inst. of Physiol., [2]Res. Office, Vice-rectory of Res. and Postgraduate Studies, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: Sexual attraction in rodents depends on different stimuli such as: smell, audition, and vision, which then activate attention, approach, and finally mating. We selectively bred two sublines from Sprague-Dawley rats that differ in their spontaneous yawning behavior. High-yawning (HY) male rats had a mean of 20 yawns/h and the low-yawning (LY) with just 2 yawns/h. Previously we demonstrated that LY males preferred to mate with HY and SD female rats.The aim of the present study was to evaluate odor discrimination using different bedding soiled from SD, HY and LY sexually experienced male rats. We used an open field arena (OFA) to evaluate odor preference. The bedding material from SD, LY or HY males were randomly assigned to each corner of OFA, and the remaining corner had the same amount of clean wood-shavings. An ovariectomized female rat from each group of rats with an estrous induced by 17-β estradiol followed 44 h later of progesterone was putt gently in the central square of OFA. We measured the bouts and duration of sniffing on each corner, the latency for the first sniffing bout and the return interval to each corner.Our results showed that HY female rats prefer the odors from SD and HY male rats with respect to LY ($P < 0.05$) and they also had the lowest return interval. In conclusion, male pheromones produce a "chemical sexual adornment" that give information at a distance capable of attracting females, and consequently can increase the potential for reproductive success.

Title: Impact of a ketogenic diet on sexual behavior in male Sprague-Dawley rats

Authors: C. TZIANABOS, ***L. MARTINEZ**;
Trinity Col., Hartford, CT

Abstract: Ketogenic diets (KDs) are high fat, low carbohydrate, and adequate protein formulations that have shown therapeutic potential for a range of neuropsychiatric disorders, including drug addiction. Previous studies have found that rats administered a KD exhibit reduced cocaine-induced locomotor activity, as well as reduced cocaine- and alcohol-seeking

behaviors. The extent to which KDs impact the expression of behaviors associated with natural rewards such as sex, however, remains to be determined. Given that the limited available evidence from studies utilizing human research participants on KDs has not identified any consistent alterations in sexual function by these diets, we predicted that sexual behavior would remain largely unchanged in male Sprague-Dawley rats administered a KD. To determine if this was indeed the case, sexually-naïve males were assigned to either a KD or a standard chow diet (SD), and then were paired with ovariectomized, hormone-primed females for a series of sexual behavior tests. We found that rats administered a KD exhibited more mounts (across all tests), more intromissions (third and fourth tests) and were less likely to ejaculate (second test) compared to SD males. These data indicate that administration of a KD does impact sexual behavior in male rats, although the high levels of mounts and intromissions seen in these males suggests that motivation to engage in sex remains intact. Future work will determine the extent to which sexual behavior in females may be impacted by KDs.

Title: A skin-to-brain circuit for pleasurable touch and sexual receptivity

Authors: *L. J. MIDDLETON[1], M. D. SCHAFFLER[1], I. K. SUCCI[2], W. FOSTER[2], L. EJOH[1], I. ABDUS-SABOOR[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Columbia Univ., New York, NY

Abstract: Affiliative social touch not only provides pleasurable hedonic value to relationships but is critical for mental and physical well-being as a means of social buffering. Yet, we lack an understanding of the mechanisms by which we perceive the rewarding valence of social touch, especially how and which peripheral neurons communicate to reward centers in the brain. While C-tactile afferents are thought to convey the affective component of social touch in humans, analogous populations of dorsal root ganglion (DRG) neurons in mice have yet to be implicated

in social behaviors, limiting the power of our experimental models. Here we demonstrate that a small population of mouse DRG neurons marked by developmental expression of Mrgprb4 are both necessary and sufficient for touch-dependent social behaviors and for engaging neural circuits of social reward in the brain. Transdermal optogenetic activation of Mrgprb4-lineage neurons (B4 neurons) in the back skin produces a conditioned place preference, suggesting their focal activation is reinforcing, and thus pleasant. The same focal optogenetic stimulus to the back induces a striking dorsiflexion posture, reminiscent of the lordosis sexual receptivity posture, or dipping their back to crawl underneath cagemates. This posture represents the first acute behavioral response to the optogenetic activation of social touch neurons, positioning social touch in the ranks with itch and pain for yielding a stereotyped, quantifiable motor output upon selective activation. To determine whether B4 neurons are required in natural touch-dependent social postures, we genetically ablated the neurons and examined social behaviors. First, we assessed lordosis. While females without B4 neurons had normal lordotic receptivity on the first pairing with a male, their receptivity fell on subsequent pairings, while controls increased in receptivity. This diminution in receptivity suggests that the B4 neurons are encoding a sensation that positively reinforces female sexual receptivity. To assess whether B4 neurons directly signal to reward centers, we used fiber photometry with the $GRAB_{DA}$ dopamine sensor to measure dopamine release in nucleus accumbens during optogenetic activation of B4 neurons. Further, we measure dopamine release during mating in both intact and B4 neuron-ablated females to see whether B4 neurons are required for reward during sexual encounters. We conclude that B4 neurons are required to mediate touch-dependent social postures, sufficient to replicate them in socially isolated mice, and therefore represent the first neurons of a potential skin-to-brain circuit for social postures and sexual receptivity.

Title: Gut Barrier Dysfunction, Type 2 Immunity, and Compulsive Behavior: A Narrative Review of the Literature

Authors: *C. FIELDS;
Yale Univ., New Haven, CT

Abstract: To date, much of the focus of gut-brain axis research has been on gut microbiota regulation of anxiety and stress-related behaviors. Much less attention has been directed to potential connections between gut microbiota and compulsive behavior. The focus of this poster is to review literature suggesting a link between gut barrier dysfunction and compulsive behavior that is mediated through "type 2" rather than "type 1" inflammation. This poster explores connections between compulsive behavior and type 2 inflammation in Tourette syndrome, obsessive-compulsive disorder, autism, addiction, and post-traumatic stress disorder. Potential connections between gut barrier dysfunction, type 2 inflammation, and compulsive behavior are also discussed. I posit a mechanism whereby gut barrier dysfunction-associated type 2 inflammation may drive compulsive behavior through histamine regulation of dopamine neurotransmission. In sum, understanding how gut microbiota affect systemic allergic immune mediators that affect compulsive behavior circuits yields the gut as a readily accessible target for the treatment of compulsive behavior disorders.

Title: Alterations in Murine B Lymphocyte Subsets In Response to Stress

Authors: *E. ENGLER-CHIURAZZI, G. TALKINGTON, W. CHASTAIN, C. CASTILLO, B. SWEETEN, B. WHITE, D. CORBIN, J. SIMPKINS, G. BIX, J. TASKER;
Tulane Univ., New Orleans, LA

Abstract: The immune system has emerged as a key regulator of mood, providing novel opportunities for the treatment of debilitating stress disorders such as major depressive disorder (MDD). Several emerging findings highlight key roles for B lymphocytes in modulating the response to stress. For instance, B cell subtype-specific changes were noted in circulation of MDD patients such that while levels of total B lymphocytes were not significantly altered, there were reduced levels of immune-regulating B cells. B lymphocytes have the cellular machinery needed to respond to stress signals and alterations of B lymphocyte numbers in peripheral immune cell compartments have been reported in response to exposure to a number of stress paradigms preclinically. As well, recent evidence of a brain-spleen communication pathway along with our discovery of an age-dependent maladaptive response to the acute swim stress in B lymphocyte deficient mice and our ability to partially ameliorate this phenotype by replacing B cells, further supports this notion. B lymphocytes have been shown to traffic to brain parenchyma in times of neurological challenge (such as stroke). Whether psychosocial stress represents a sufficient neurological challenge to warrant B lymphocyte recruitment to brain is not yet clear. Here we evaluated changes in numbers of splenic and brain B lymphocyte subtypes (total, naïve, antibody-secreting, memory, and regulatory) in response to various acute, chronic and traumatic stress paradigms in young adult C57BL/6 mice. Further, we evaluated age-related changes in splenic B lymphocyte subsets in unstressed mice. We noted stressor-, age-, tissue-, and subtype-specific changes in B lymphocyte numbers. These data contribute support for a growing appreciation for a role for B lymphocytes in modulating the response to stress. Future work will evaluate behavioral and neurobiological responses to stress when B cell numbers are methodically manipulated in vivo.

Title: Role of Drosophila Stat92E signaling in alcohol addiction-like behavior.

Authors: E. PERIANDRI, ***E. PETRUCCELLI**;
Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Alcohol use disorder (AUD) is a worldwide health burden; yet our understanding of how repeated alcohol exposure impacts neuromolecular signaling to reinforce maladaptive behaviors like addiction remains incomplete. Similar to human AUD and rodent models, recent transcriptomic analyses in *Drosophila* have demonstrated that memory-associated neurons show changes in the expression of *signal transducer and activator of transcription* (*STAT*), a well-studied innate immune signaling transcription factor, following repeated alcohol exposure. More specifically, flies that make odor cue-associated memories of intoxication, switch from expressing the *Stat92E^{-RI}* isoform, a negative regulator of the JAK/STAT pathway, to *Stat92E^{-RH}* in mushroom body neurons (MB), suggesting that repeated alcohol exposure activates STAT signaling (Petruccelli et al, 2020). Here we explore the necessity of STAT signaling in behavioral sensitization, an enhanced locomotor response to alcohol following pre-exposure. We also examine STAT reporter activity in adult brains and develop a light cue-based associative paradigm in which to further test neuromolecular signaling across addiction-like assays. Ubiquitous *Stat92E* knockdown had a minimal effect on naïve alcohol-induced locomotion, but significantly increased behavioral sensitization in flies previously exposed to alcohol. STAT reporter activity was not altered upon alcohol pre-exposure, but showed restrictive expression to the α/β MB lobes upon pan-neuronal overexpression of constitutive active STAT. Lastly, we provide preliminary evidence that blue light can be used as an associative cue for intoxication experience, which will aid in further evaluating the role of STAT signaling in conditioned preference behavior. Together this work begins to resolve the complex spatiotemporal neuroimmune signals underlying addiction-associated behaviors.

Sch. of Univ. of São Paulo, São Paulo, Brazil; [9]The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: More than 30% of patients infected by SARS-CoV-2 (COVID-19) experience long-lasting neurological symptoms (e.g., headache, dizziness, mental status changes), which could have long term consequences. However, the evaluation of COVID-19-related neurological deficits is often subjective and underlying neural substrates are not understood. Eye movements have been traditionally used as a non-invasive readout of many brain dysfunctions, and thus deficiencies in oculomotor behavior can provide insights into the neural substrates impacted by COVID-19 infection. We used a highly sensitive and precise video-based eye-tracking technology to evaluate OVRT-C deficits in patients who recovered from acute COVID-19 infection. Adult men and women were recruited at the Allegheny General Hospital (N=13) and University of São Paulo School of Medicine, Brazil (N=13), under approved IRB protocols. Subjects (N=26) were tested at various times following recovery with a battery of OVRT-C tests delivered by a portable videonystagmograph (Dx100, Neurolign Technology, Inc.), and reported neurological symptoms using the Neurobehavioral Symptom Inventory (NSI). Patients' OVRT-C metrics were compared with FDA-cleared normative data of 466 males and females 18-45 years old. Various OVRT-C deficits were present in a percentage of patients. These included deficits in: a) oculomotor tests such as saccade (30% and 33% of patients for horizontal and vertical, respectively) and vergence (33%); b) vestibular tests such as optokinetic nystagmus (OKN, 27.3%); c) reaction time tests (15% and 12% for visual and auditory, respectively); and d) cognitive tests such as antisaccade (36%) and predictive saccade (27.3%). Preliminary evaluation of the relationship between NSI data and OVRT-C deficits showed that dizziness and balance symptoms were strongly correlated with gaze tests ($p=0.03$), fatigue with antisaccade errors ($p=0.04$), and irritability with gain in OKN tests ($p<0.05$). Logistic regression univariate model identified OVRT-C metrics that discriminated between controls and patients. These included gain in the OKN test (60 deg/s; AUC 0.86), percentage of predicted saccades (AUC 0.82), and percentage of prosaccade errors in the antisaccade test (AUC 0.79). These preliminary results suggest that videonystagmography can successfully identify OVRT-C deficits. Early identification of neural deficits caused by COVID-19 may help to better understand the neural substrates impacted by COVID-19 infection, aid in its management, and ideally prevent its long term consequences.

Title: Exploring the effects of adolescent amphetamine sensitization and trait anxiety on NF-kB and TNF-a protein expression in a male Long-Evans rat model

Authors: *C. CALHOUN[1], S. ROY[1], J. SEVERINO-PEREZ[1], V. LEWIS[1], B. PLOTKIN[1], T. DONALDSON[2];
[1]Univ. of Massachusetts, Boston, MA; [2]Univ. of Massachusetts Boston, Boston, MA

Abstract: Mammalian adolescence is a developmental period that confers increases in impulsive and reward-seeking behavior paralleled by heightened sensitivity to affect and stress. Both human and rodent literature highlight the dynamic remodeling of the mesocorticolimbic pathway in this behavioral shift and in the vulnerability to drug abuse. Advances in addiction neuroscience center the toll-like receptor 4 (TLR4) system within substance abuse paradigms and emphasize the role of downstream transcription factors and cytokines in the neuroplasticity associated with progressive stages of drug addiction. The present study aims to explore the expression of TLR4-downstream substrates, Nuclear Factor kappa-light-chain-enhancer of activated B cells (NF-kB) and Tumor Necrosis Factor alpha (TNF-α) protein expression, after exposure to an AMPH sensitization protocol. Thirty adolescent male Long-Evans rats were phenotyped on the elevated-plus maze (EPM) for extreme high (HAn) and low (LAn) anxiety-like behavior. Following EPM screening, animals went through a 4-day repeated AMPH protocol, where animals were injected with AMPH (4.0 mg/kg IP) or vehicle (0.9% NaCl) and tested in the open field chamber for locomotor activity. HAn adolescents exhibited the most hyperactivity to the acute AMPH injection across Days 2-4 and HAn animals displayed the greatest locomotor response to a low challenge dose of AMPH (1.0 mg/kg IP) after a 7-day

withdrawal period. Histological analyses indicated differential expression of TLR4 protein in the basolateral amygdala, with higher expression in HAn rats. These results suggests that extreme trait anxiety-like phenotypes can differentiate responses to repeated AMPH exposure and map onto differential proinflammatory responses in an adolescent rat model.

Title: Developmental role of mast cells in adult mouse emotional behaviors and neuroinflammatory responses.

Authors: *N. DUQUE-WILCKENS[1], A. ROBISON[2], A. J. MOESER[1];
[2]Neurosci., [1]Michigan State Univ., East Lansing, MI

Abstract: Mast cells (MCs) are bone marrow derived innate immune cells distributed throughout nearly all tissues, including the brain. MCs can store and release a wide spectrum of preformed and newly synthesized biologically active mediators, including neurotransmitters, affecting the function of multiple systems. Most of the knowledge about MC function *in vivo* has been derived from studies on constitutive, KIT-dependent MC deficiency models, which do not allow for the differentiation developmental vs. acute effects. Here we crossed the Mcpt5-Cre mouse line with the Cre-dependent B6-iDTR (Jax®) mice to render MCs susceptible to ablation following diphtheria toxin (DTX) administration with the objective of determining the developmental role of MCs in adult behavior and brain neuroinflammatory responses. We injected the F1 litters with 30ng/g of DTX every 7 days starting at different developmental stages until adulthood (8 weeks old). Adult animals were tested in the elevated plus maze and sucrose preference tests to assess behavior, and then injected intraperitoneally with 1mg/kg of lipopolysaccharide (LPS) to measure acute thermoregulatory and inflammatory responses to an immune challenge. Compared to MCPT5-Cre-;iDTR (controls), MCPT5-Cre+;iDTR (ablated), show increased time spent in the open vs. closed arms in the elevated plus maze when DTX injections start between PN1 and PN28, but not when MCs were ablated in adulthood, suggesting an organizational role of MCs during adolescence on neural circuits modulating anxiety. Ongoing measures include quantification of circulating cytokines and neuroinflammatory responses to LPS. The results of

these studies will provide new knowledge about the critical periods in which MCs exert developmental effects on neuroimmune systems regulating anxiety behavior.

Title: Localized infusion of C20 ceramide triggers reversible short-term behavioral changes in female and male rats

Authors: *L. SAMBOLIN-ESCOBALES[1], A. FELICIANO-QUIÑONES[2], C. SUAREZ-GOMEZ[2], L. TIRADO-CASTRO[2], W. FONSECA-FERRER[3], K. SANTOS-AVILES[2], M. COLON-ROMERO[2], A. HERNANDEZ-LOPEZ[2], J. PORTER[2];
[1]Basic Sci., [2]Ponce Hlth. Sci. Univ., Ponce, PR; [3]Univ. of Puerto Rico, Ponce, PR

Abstract: Previous data showed that rats with depressive-like behavior showed increased concentration of C20 ceramides in serum. Moreover, depressive-like behavior has been associated with increased microglia and the production of inflammatory mediators. However, it is unclear whether increasing C20 ceramides in the brain is sufficient to induce depressive-like behaviors and activate microglia and astrocytes which could induce localized production of inflammatory mediators. We hypothesized that infusion of C20 ceramides into the ventral hippocampus (VH) of rats would activate microglia and astrocytes to induce depressive-like symptoms. To test this hypothesis, adult male and female rats received 7 single infusions of C20 ceramides or vehicle into the VH every 48 hours to assess short-term behavioral changes. Twenty-four hours after each C20 ceramide infusion, a sucrose preference test (SPT) was used to determine changes in anhedonia-like behavior. Animals injected with C20 ceramides showed less preference for sucrose suggesting increased anhedonia-like behavior. Five days after the last infusion of C20, a sucrose grooming test (SGT) and forced swim test (FST) were performed to examine long-term changes in anhedonia and depressive-like behaviors. All groups showed similar behavior in the SGT and the FST, suggesting that behavioral changes induced by the C20 ceramide infusions was reversible. Animals were sacrificed after the final FST, and immunofluorescence staining was performed to determine the expression of Iba-1 and GFAP to

assess microglia and astrocyte activation. The infusion of C20 ceramides increased the number of microglial cells in the VH, but no changes were noted in the expression of astrocytes. In conclusion, our data suggest that the localized presence of C20 ceramides in the VH of rats is sufficient to cause short-term reversible behavioral changes and activate microglia.

Title: Repeated allergen exposure triggers behavioral and neuroinflammatory changes in a mouse model of asymptomatic cow's milk allergy

Authors: *D. GERMUNDSON[1], A. BRISHTI[2], N. A. SMITH[3], K. NAGAMOTO-COMBS[2]; [1]Pathology, [2]Biomed. Sci., Univ. of North Dakota SMHS, Grand Forks, ND; [3]Pathology, Univ. of North Dakota Sch. of Med. and Hlth. Sci., Grand Forks, ND

Abstract: Growing evidence suggests that neuropsychiatric disorders are often associated with food allergies in both children and adults. Using a mouse model of non-anaphylactic cow's milk allergy, we previously demonstrated that allergic sensitization of male C57BL/6J mice produced aberrant behaviors and brain pathology without inducing severe reactions upon allergen challenge. While these results suggested the causal role of food allergy in behavioral changes after acute allergen exposure, the effects of prolonged allergen exposure on the brain are unknown. Since allergic individuals with mild symptoms can consume offending foods without life-threatening consequences, they may be subjected to repeated allergen challenges. We hypothesized that repeated allergen consumption by mildly allergic individuals could promote neuroinflammation and behavioral changes via chronic systemic inflammation. To test our hypothesis, we orally sensitized 4-week-old male C57BL/6J mice to a bovine whey allergen, β-lactoglobulin (BLG), and placed them on a diet containing 0.3% whey proteins for 2 weeks to simulate repeated allergen exposure. The tail suspension test showed increased depression-like behavior in BLG-sensitized mice on the whey diet compared to sham mice. Despite the absence of obvious allergic symptoms in the BLG-sensitized mice, serum histamine and allergen-specific

IgE were elevated. Plasma levels of IL-6, IL-17, and IFNγ were also elevated in BLG-sensitized mice, indicating that peripheral inflammation was maintained by continued allergen consumption. In the brain, we observed increased IgG immunoreactivity in the parenchyma and GFAP-immunoreactive hypertrophic astrocytes in perivascular regions, suggestive of immunoglobulin extravasation from 'leaky' blood-brain barrier (BBB) and neuroinflammation, respectively. Greater numbers of mast cells and elevated histamine levels were also found in the brains of BLG-sensitized mice, likely contributing to the observed changes in BBB permeability. Importantly, we found a decrease in the density of myelination in the motor and somatosensory cortices in BLG-sensitized mouse brains. Our findings indicate that repeated allergen exposure significantly altered behavior of BLG-sensitized mice, likely through neuroinflammation and demyelination. In certain individuals, neuropsychiatric symptoms may be triggered or exacerbated by subclinical immune responses that ultimately affect brain function when prolonged. Thus, food allergy testing and allergen avoidance may prove useful as strategies for treating and preventing neuroinflammatory and neuropsychiatric disorders.

Title: Mast cell-serotonin interactions as a potential mechanism underlying anti-anxiety effects of mast cells

Authors: *R. TEIS[1], N. MARADIAGA[2], A. J. MOESER[2], A. ROBISON[3], N. DUQUE-WILCKENS[4];
[1]Michigan State Univ. Neurosci. Program, East Lansing, MI; [2]Large Animal Clin. Sci., [3]Neurosci., [4]Physiol., Michigan State Univ., East Lansing, MI

Abstract: Mast cells (MCs) are known for their involvement in peripheral diseases such as allergy, but they are also present in the brain where they can modulate behavior. MC deficient (Wsh/Wsh) mice show a phenotype consistent with anxiety/anhedonia: compared to wild type mice, Wsh/Wsh spend less time in the open vs. closed arms of the elevated plus maze test as well as reduced sucrose preference. We show that these phenotypes can be normalized by central reconstitution of Wsh/Wsh mice with wild type bone marrow derived mast cells (BMMC),

suggesting that brain MCs exert mood-stabilizing effects. MCs could reduce anxiety by modulating the brain's serotonergic neural network, as MCs can synthesize, store, and quickly release a variety of molecules that directly affect neuronal activity, including histamine, cytokines like IL-6, and serotonin itself. Indeed, both pharmacological activation and conditional knock-out of MCs affect serotonin content in various brain nuclei, although it is not clear whether this contribution is a direct result of MC serotonin release or MC modulation of neural serotonergic circuits. Here we used immunohistochemical quantitation of serotonin and c-Fos to characterize the number, distribution, and activation levels of dorsal raphe serotonin neurons in wild type, Wsh/Wsh, and Wsh/Wsh mice with central or peripheral BMMC reconstitution after acute exposure to mild stress. Preliminary data demonstrate that, compared to wild type, Wsh/Wsh mice show less serotonin+ cells in anterior dorsal raphe and that this is partially reversed by both peripheral and central reconstitution with BMMCs, suggesting that circulating MC products could modulate central serotonin expression. Ongoing studies are assessing dorsal raphe expression of mRNA encoding for serotonin transporter as well as tryptophan hydroxylase 1 and 2 in Wsh/Wsh and wild type mice. Our findings indicate the MCs within and outside the brain can regulate serotonergic neurons, a potential mechanism by which these innate immune cells may affect mood and anxiety.

Title: Neuronal activation induced by social communication in syrian hamsters

Authors: *J. W. VANDER VELDEN, N. POURSHIRAVI, B. W. HORNE, J. H. TAYLOR, K. L. HUHMAN, H. E. ALBERS;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Social communication plays a critical role in nearly all social interactions. Many mammalian species communicate with chemosensation, and for solitary species chemosensation can be critical for social interactions. Chemosensation also allows some species to communicate indirectly because chemical signals such as odor marks can be used to mark territory and to indicate reproductive or social status. Syrian hamsters engage in a scent marking behavior called flank marking during social interactions and in response to the odors of other hamsters. In the

present study, we investigated whether odor-induced flank marking results in the activation of neurons in hypothalamic regions, such as the anterior hypothalamus (AH), paraventricular nucleus (PVN), and supraoptic nucleus (SON), that are important for social behavior in hamsters. Male and female hamsters (n=8 each) were exposed to either a clean cage (control) or a cage that was previously marked by a conspecific. The number of flank marks observed in hamsters exposed to conspecific odors (26.27±3.35; Mean±SEM) was significantly greater than in controls (13.31±3.35) (p=0.01). Ninety minutes after behavioral testing, brains were taken and processed for immunohistochemical localization of cFos. In hamsters exposed to conspecific odors, expression of cFos in the AH (p=0.044) and the PVN (p=0.036) was significantly greater than in controls. We also observed a trend in the SON (p=0.073) for less neuronal activation in odor-exposed hamsters compared to controls. These data support the hypothesis that activation of neuronal activity in the AH and PVN along with inhibition of neuronal activity in the SON may contribute to the regulation of odor-stimulated flank marking. Title: Melanotan II increases oxytocin-dependent neuronal activity in social brain areas

Authors: *C. L. FORD, IV[1], A. A. MCDONOUGH[1], L. J. YOUNG[2];
[2]Ctr. for Translational Social Neurosci., [1]Emory Univ., Atlanta, GA

Abstract: Autism spectrum disorders (ASD) are characterized by deficits in social cognition, yet there are no pharmaceuticals approved to treat these deficits and the efficacy of behavioral therapies are limited by the social nature of communication with a therapist. The neuropeptide oxytocin increases the salience of social stimuli and induces pro-social behavioral effects in animals and humans. Activation of the oxytocin system is therefore a potential therapeutic target for ASD. However, most studies testing intranasal administration of oxytocin have yielded small effect sizes due to limited brain penetration and short half-life in peripheral circulation. Moreover, no studies have attempted to enhance behavioral therapy with oxytocin. We propose that pharmacologically activating the endogenous oxytocin system immediately prior to

behavioral therapy may offer therapeutic benefits. Melanotan II (MTII), a melanocortin receptor agonist, induces the release of endogenous oxytocin in the hypothalamus. Our previous studies in socially monogamous prairie voles demonstrated that 10 mg/kg MTII injected IP accelerates pair bond formation in an oxytocin-dependent manner and potentiates the release of oxytocin in the nucleus accumbens. Here, we investigate the neural effects of centrally administered MTII. First, we injected MTII ICV at different doses (0, 0.001, 0.01, 0.1, 1.0 nmol) and assessed behavioral stereotypies in a dose-response curve. Results indicated 0.1 nmol was the optimal dose for future studies. We next infused 0.1 nmol MTII, 0.1 nmol MTII combined with an oxytocin antagonist, or aCSF ICV and exposed voles to either a novel object or a social experience with a novel conspecific. To assess the neuronal activity induced by MTII, we quantified expression of the immediate early gene protein c-Fos as a proxy for neuronal activity in brain regions involved in social cognition. We found MTII increased c-Fos expression in the prelimbic cortex ($p<.05$) in both social and nonsocial contexts. This effect in the social context was blocked by coadministration of an oxytocin antagonist. Additional brain regions are being analyzed, but preliminary data suggest MTII may evoke the release of endogenous oxytocin and thereby activate brain networks involved in social cognition. Therefore, administering MTII immediately prior to behavioral therapy may increase social information processing by evoking endogenous oxytocin release and thus has potential to increase the efficacy of therapy in treating the social deficits of ASD.

Title: Mood sensitivity to sex hormone flux predicts oscillatory correlates of fronto-limbic affective processing

Authors: *E. ANDERSEN, K. BARESICH, S. GIRDLER;
Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Background: The pubertal transition (PT, peripuberty) is characterized by pronounced sex hormone fluctuation, dramatic neuromaturation and marks a divergence between the sexes in

risk of depression in girls. A heterogeneous pattern of fronto-limbic neural development, with more rapid growth of limbic affective regions overshadowing a delayed maturation of frontal networks critical for top-down emotion regulation, predisposes adolescents to dysfunctional emotional reactivity. The functional coupling of distributed frontal and limbic neural networks relies on synchronous neural oscillations in theta (4-8 Hz) and beta (12-30 Hz) frequencies, which can be directly measured using EEG. Sex hormones, including testosterone (T) and estrone (E1), exert significant modulatory effects on frontal and limbic affective systems and have been associated with depression symptoms; however, the neurophysiological mechanisms linking sex hormones with affective state change in the PT have yet to be defined. The objective of the present study was to determine whether mood sensitivity to weekly changes in T and E1 differentially impacted frontal theta and parietal beta in response to emotional stimuli, indexing dysregulated fronto-limbic affective processing.
Method: 44 peripubertal females (ages 11-14, within 1 year of menarche) provided 8-weekly salivary hormone (T, E1) samples (pg/mL) and mood assessments, and completed an emotional go-no/go task during EEG recording. Event-related theta (4-8 Hz) and beta (12-30 Hz) power was extracted from frontal (Fz) and parietal (Pz) midline electrodes, respectively, in response to emotional facial stimuli. Within-person correlations between weekly change in hormone (T, E1) and corresponding mood ratings were performed to determine individual differences in mood sensitivity to hormone flux.
Results: Peripubertal females who were mood-sensitive to T exhibited enhanced frontal theta oscillatory activity ($F(1,42=11.06$, $p=.002$, $\eta_p^2=0.21$), whereas, participants mood sensitive to E1 demonstrated increased parietal beta activity in response to negative emotional stimuli ($F(1,42=6.51$, $p=.014$, $\eta_p^2=0.13$), reflecting exaggerated attention and emotional reactivity.
Conclusion: For the first time, results suggest that susceptibility to T and E1 fluctuations and affective state change may rely on unique neurophysiological mechanisms, with E1 targeting beta-dependent localized limbic networks, and T implicated in frontal regulation of behavior and emotion. Thus, aberrant frontal theta and parietal beta activity may link sensitivity to hormone change and mood symptoms during this pivotal developmental window.

Title: Impact of estrous cycle on reward-based probabilistic behavior in female rats

Authors: A. TEJADA, J. BEZENAH, B. VAZQUEZ, D. GARCIA, M. ESPINOSA, ***L. R. AMODEO**;
Psychology, CSU San Bernardino, San Bernardino, CA

Abstract: Emerging evidence has shown that sex differences are present in probabilistic decision-making when using a rat version of the Iowa gambling task or a delay discounting task. While much of the research investigating probabilistic decision-making, or risk-taking behavior, has been conducted in male subjects, the evidence that exists regarding an influence of estrous cycle in decision making is mixed. Changes in estrus cycle can be associated with behavioral alterations, particularly approach, anxiety and cognitive behaviors. Thus, we propose to investigate whether probabilistic choice behavior shifts depending on stage of estrous cycle. Parous and nulliparous female Long-Evans rats were tested for risk-preference using a 2-choice probabilistic gambling paradigm. For this task, rats were given an option between a 'large-risky' choice (3 sugar pellets delivered on a probabilistic VR schedule) and 'small-certain' choice (1 sugar pellet delivered on a FR1 schedule). Once rats learned to discriminate reward magnitudes, one level of risk (16%, 33%, 67%) was randomly assigned to the 'large-risky' choice. Each rat was randomly presented with the probabilities twice for a total of 6 sessions. Phases of estrous cycle (diestrus, proestrus, or estrus) were determined cytologically through vaginal lavage taken 30 minutes after completing each behavioral session. Our preliminary findings indicate that female rats discriminate between varying probabilistic schedules with estrous cycle not impacting overall risk-preference.

Title: Estrogen regulates voluntary running behavior

Authors: *V. MATHIS, L. J. POINTS, B. POPE, L. WINTER, S. CLAYTON, L.-L. YUAN;
Des Moines Univ., Des Moines, IA

Abstract: Despite the myriad social and health benefits of exercise, humans display heterogeneous levels of participation. Significant progress has been made in identifying molecular events, systems, and mechanisms that support exercise's beneficial effects, but it is not

clear yet what regulates exercise behavior itself or serves to maintain prolonged chronic exercise behavior. The human heterogeneity in voluntary exercise can be recapitulated in a rodent model of wheel running, a behavior with high rewarding properties. While rats given continuous access to running wheels all began with low running activity, a 3-week training program dramatically increased running activity and revealed a wide range of individual differences. In addition, we have also identified intriguing sex differences. Compared to age-matched males, female rats exhibited significantly higher levels of average daily running; individual females also exhibited a repetitive peak-valley pattern of running activity, with peaks coinciding with the proestrus stage (highest estrogen level) in the rat estrous cycle. Ovariectomy (OVX) not only drastically lowered their running activity, but also completely eliminated the running peaks. Furthermore, baseline estrogen replacement via osmotic mini-pumps in an OVX background restored running activity to pre-OVX levels, and acute estradiol injections were able to mimic running peaks. Collectively, our results suggest estrogen regulates running activity which offers a unique opportunity to examine the mechanisms responsible for driving exercise behaviors. Further studies identifying molecular mechanisms that mediate estrogen's effects are currently underway.

Title: Brain derived neurotrophic factor changes in response to different sucrose binge drinking concentrations in adolescent male rats

Authors: *Z. SIMSEK[1], A. TORRES[1], J. SANTOS[3], C. TYLER[2], O. DARBANDI[2], K. HOANG[4], K. S. CURTIS[5], D. B. VAZQUEZ SANROMAN[1];
[1]Anat. and Cell Biol., Oklahoma State Univ., Tulsa, OK; [2]Oklahoma State Univ., Stillwater, OK; [3]Oklahoma State Unievrsity Osteo. med. Sch., Tulsa, OK; [4]Univ. of Tulsa, Tulsa, OK; [5]Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

Abstract: Binge-like consumption of sucrose causes an escalation in intake over time similar to self-administration of drugs of abuse, suggesting that sugar binge drinking (SBD) may lead to a sensitization of the reward system. High levels of sugar intake trigger release of brain-derived neurotrophic factor (BDNF) in the brain. Nevertheless, it is not clear how SBD translates into changes in BDNF levels in brain reward areas. Therefore, the specific aim of this study was to determine the effect of SBD on proBDNF and MatureBDNF (mBDNF) in the adolescent PFC and Nacc. **Methods**: Male rats [Postnatal day (PND) 26] were randomly assigned to the SBD

group (5% or 15%) or the control group, water and chaw were available ad libitum. SBD sessions consisted of intermittent access to either 5% or 15% sucrose concentrations (120 minutes/day for five consecutive days), with having water always available. After the last SBD session, rats were sacrificed, and brains were extracted and prepared for immunoassay analysis (ELISA) for identifying pro- and mBDNF levels. **Results:** adolescent rats showed a 10-fold increase in proBDNF levels compared to adults. Also, juvenile rats displayed more pronounce SBD behavior at 5% compared to 15 % sucrose concentration. Furthermore, SBD at 5% but not at 15% increased proBDNF level in the Nacc. Surprisingly, SBD at both 5 and 15% concentration increased levels of proBDNF in the PFC. Thus, adolescent binge sucrose drinking may sensitize the reward system by selective alterations in BDNF levels.

Title: The reciprocal relationship between estrogen and binge alcohol drinking

Authors: *L. J. ZALLAR, J. K. RIVERA, K. E. PLEIL;
Pharmacol., Cornell University: Weill Cornell Med. Col., New York, NY

Abstract: Pathological alcohol use is a widespread public health concern that incurs significant societal and personal costs. Estrogen (17β-estradiol; E2) is a sex steroid hormone synthesized in the brain and periphery through the process of aromatization, in which the rate-limiting enzyme aromatase converts the steroid hormone testosterone to E2. In females, E2 produced in the ovaries fluctuates across the estrous/menstrual cycle to promote pro-survival and reproductive behaviors including reward/aversion sensitivity and learning, and anxiolysis. As such, E2 may promote early alcohol drinking behavior in females via modulation of reward and stress-sensitive neural circuits, as well as behavioral and pharmacological interactions with alcohol. Our preliminary data show that female mice with high ovarian E2 status binge drink more and display decreased anxiety compared to when they are in a low E2 state. Further, direct E2 administration to the BNST recapitulates these behavioral effects and increases glutamate release onto $BNST^{CRF}$ neurons, which we have previously shown drive drinking behavior, suggesting that $BNST^{CRF}$ neurons may be a target for E2's behavioral effects on binge drinking. E2 has been

shown to act as a neurotransmitter in the brain, including in the BNST, allowing it to rapidly regulate many behaviors via binding to E2 receptors. In addition, chronic alcohol exposure may be able to promote aromatization through a currently unknown mechanism. We have found that binge alcohol consumption is sensitive to pharmacological aromatase inhibition following 3 weeks of exposure in males and 10 weeks in females. Thus, there may be a feedforward relationship between E2 and alcohol consumption in both sexes, such that alcohol exposure recruits aromatase leading to increased synthesis of E2, which in turn signals in the BNST to drive further alcohol consumption. Ongoing experiments are utilizing slice electrophysiology, western blot, and other converging techniques to characterize the sources and mechanisms by which alcohol and E2 interact.

Abstract: Single-minded homolog 1 (Sim1) is a transcription factor that is essential for development of the paraventricular nucleus (PVN) of the hypothalamus. Global haploinsufficiency of Sim1 in both humans and mice is associated with hyperphagic obesity. Conditional knock-out of estrogen receptor beta (ERB) in Sim1 ($Sim1^{Cre}$/ $ERB^{fl/fl}$) containing neurons in mouse PVN produced increases in body mass in both males and females on a regular chow diet. The precise subpopulation of Sim1 neurons which produces these body mass changes is presently unknown, but Sim1 neurons in the PVN overlap with oxytocin, corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP)-containing neurons. In the present study, $ERB^{fl/fl}$ mice were cross-bred to CRH^{Cre} mice to produce a novel transgenic mouse with ERB knocked out of CRH neurons (CRH^{Cre}/ $ERB^{fl/fl}$). Changes in both feeding behavior and anxiety-like behavioral assays were observed in a sex-specific manner. Female CRH^{Cre}/ $ERB^{fl/fl}$ mice exhibited an increase in food intake over time compared to CRH^{Cre} and $ERB^{fl/fl}$ female controls ($p<0.05$). Male CRH^{Cre}/ $ERB^{fl/fl}$ mice exhibited increases in both total time spent

moving and total distance traveled in the elevated plus maze assay compared to CRH^{Cre} and $ERB^{fl/fl}$ male controls ($p<0.05$). These findings suggest a potential role for neurons containing both ERB and CRH in mediating anxiety-like behavior in males and feeding behavior in females.

Abstract:
Background: The aim of the current study is to prospectively characterize neuroendocrine reactivity among adolescent AN patients and correlate them with long term prognostic outcomes.**Methods:** AN patients referred to the ambulatory clinic, day care facility and in patient unit of the Herman Dana Child Psychiatry Center were assessed using a structured clinical interview with repeated psychological and physical assessments. Hormonal assays were sampled at baseline and following treatment, correlated with treatment response measures, and compared with healthy age matched adolescents. **Results:** AN patients demonstrate a significant prospective increase in BMI compared with baseline, and improvement in pathological eating attitudes at follow up. Findings replicate previously described hypercortisolism, partly adaptive

to chronic malnourishment and that be informative regarding long term weight restoration. Additional hormonal reactivity including DHEA-S, and testosterone has been similarly analyzed and will be described. **Significance:** Reprograming of neuroendocrine function may be in part be adaptive and may be informative regarding long term weight restoration.

Title: Antagonism of dopamine DR2 receptors by sulpiride does not alter the metabolic profile of female and male mice

Authors: *D. VÁZQUEZ CARRILLO[1], A. OCAMPO-RUIZ[2], A. BÁEZ-MEZA[2], G. RAMÍREZ-HERNÁNDEZ[2], E. ADÁN-CASTRO[2], J. F. GARCÍA-RODRIGO[2], M. G. ORTIZ-ARBALLO[2], G. MARTÍNEZ DE LA ESCALERA[2], C. CLAPP[2], Y. MACOTELA[2];

Abstract: Sulpiride is a second-generation antipsychotic that acts as a selective antagonist of the dopamine D2 receptor and it is commonly used in the treatment of schizophrenia, depression, and gastroparesis. In several studies, second generation antipsychotics have been linked to detrimental effects on metabolism, resulting in increased body weight and hyperglycemia in humans. It is unclear whether those deleterious effects are derived from hyperprolactinemia. In rats, there is a sex dependent effect of sulpiride on metabolic parameters. Treatment with sulpiride in female rats result in body weight gain but no alterations in glucose and insulin levels, whereas male rats do not show increased body weight but develop hyperglycemia and hyperinsulinemia. A recent study in male rats has proven that long term administration of sulpiride induces fatty liver and insulin resistance. Since there are no studies on the effects of sulpiride on the metabolic profile of mice, our aim was to evaluate the effects of sulpiride on basic metabolic parameters in both female and male mice. We used 8 weeks-old C57BL/6 mice, and treated them with sulpiride (30 mg/kg/day) during 30 days. Our results showed that sulpiride increased PRL levels to 69.8 ± 10.1 ng/mL, while in vehicle treated animals PRL levels were 9.2

± 1.2 ng/mL. Sulpiride did not increase body weight neither in females nor males. Also, fasting serum glucose, insulin and triglyceride (TG) levels were not altered in any sex. Regarding white adipose tissue, sulpiride didn't change the tissue weight, or the size and number of adipocyte cells. Taken together our results show that at this dose, regardless of sex, chronic treatment with sulpiride does not alter the metabolic profile of mice even when there is a marked hyperprolactinemic effect. A dose of 30 mg/kg/day for 30 days in male and female mice is a good model to study the effects of chronic sulpiride and hyperprolactinemia in neuroendocrine and behavioral parameters without confounding effects on metabolism.

Title: Characterisation of behavioural, safety and pharmacokinetics (PK) properties of psilocybin and psilocin in rodents

Authors: *G. A. HIGGINS[1], N. CARROLL[1], M. BROWN[1], C. MACMILLAN[1], A. TOSCAN[1], J. A. ARAUJO[1,2], M. SLASSI[2], R. RAMAROHETRA[3], C. CASSIDY[3], C. TAYLOR[3], L. MAGOMEDOVA[1], I. A. M. DE LANNOY[1];
[1]InterVivo Solutions Inc, Fergus, ON, Canada; [2]MindSet Pharma Inc, Toronto, ON, Canada; [3]Transpharmation Ltd, London, United Kingdom

Abstract: Psychedelic drugs, e.g. psilocybin (PSY) are becoming widely recognized for their therapeutic potential to treat psychiatric conditions including depression and addictive disorders. PSY is rapidly metabolised to psilocin (PSI) which underlies its primary pharmacological properties. Despite PSY being evaluated in Phase 2/3 clinical trials, relatively little preclinical data for PSY exists to address issues such as PK/PD relationship between behaviours associated with CNS 5-HT_{2A}R engagement, e.g head twitch (HT; mouse) and wet dog shakes/back muscle contractions (WDS/BMC; rat). Also, the relationship between target engagement and clinically relevant plasma exposure is still poorly understood. In male C57BL/6 mice, PSY induced a dose related incidence of HT with an ED_{50} of 0.45 mg/kg SC. The incidence of HT was relatively low vs. reference 5-HT_{2A}R agonists, and confined to 10-15 min post dose. Following 1 mg/kg SC, PSY was rapidly converted to PSI, with a plasma C_{max} for PSI of 67$\pm$20 ng/ml attained at 15 min (T_{max}) and a half-life of 2.8$\pm$0.8 h; thus the duration of HT was not strictly related to drug exposure. At higher PSY doses (1-10 mg/kg SC), hypolocomotion and hypothermia emerged

(e.g. 10 mg/kg vs. vehicle: -5.6±0.5°C core body temperature; -78±3% distance travelled; both P<0.01). These effects likely impacted the expression of HT. In male Sprague-Dawley rats, PSY-induced (0.1-3 mg/kg SC) WDS/BMC were relatively mild in magnitude and not closely coupled to plasma or CSF levels of PSI. For example, following 1 mg/kg SC PSY, PSI C_{max} was 83±13 ng/ml (plasma), 35±11 ng/ml (CSF), and half-life 1.2±0.2 h (plasma), 2.5±0.8 h (CSF), yet WDS were essentially restricted to 5-20 min post treatment. The present studies suggest that while the plasma levels of PSI at ED_{50} for induction of HT (mouse) and WDS (rat) show equivalence to clinical exposures associated with psychedelic effect (~20 ng/ml; e.g. Madsen et al (2019) Neuropsychopharmacol. 44: 1328-1334), the incidence of these signs are relatively brief and not reflective of a longer half-life of PSI. Signs reflective of adverse tolerability and safety (hypolocomotion, hypothermia) emerge at higher doses and limit HT/WDS expression. These data begin to define the PD/PK relationship and safety margins for PSY in rodents and are important for benchmarking newer psychedelic drugs.

Title: Zelquistinel (GATE-251) is an orally bioavailable novel NMDA receptor modulator that exhibits rapid and sustained antidepressant-like effects

Authors: J. S. BURGDORF[1], X.-L. ZHANG[2], P. K. STANTON[2], J. R. MOSKAL[3], J. E. DONELLO[1];
[1]Gate Neurosciences Inc., Evanston, IL; [2]Cell Biol. & Anat., New York Med. Col., Valhalla, NY; [3]Falk Ctr. for Mol. Therapeut., Northwestern Univ., Evanston, IL

Abstract: Nearly half of all patients with major depressive disorder (MDD) have inadequate response to antidepressants, which often take weeks to reach full effect and are associated with adverse events that can lead to discontinuation of treatment. New therapies with novel mechanisms of action and rapid onset of action would be advantageous to patients with MDD. Modulation of N-methyl-D-aspartate receptors (NMDARs) can produce rapid and sustained clinically relevant antidepression effects. Recent studies suggest that both negative and positive modulation of N-methyl-D-aspartate receptors (NMDARs) can produce rapid antidepressant effects. Here we report that zelquistinel (AGN-241751), a novel, positive NMDAR modulator,

exhibits high oral bioavailability and dose-proportional exposures in plasma and the central nervous system and produces sustained antidepressant-like effects in rodents by improving synaptic plasticity. NMDAR-mediated functional activity was measured in cultured rat brain cortical neurons (calcium imaging), hNR2A or B subtype-expressing HEK cells, and rat hippocampal and medial prefrontal cortex slices (plasticity assays). Pharmacokinetics were evaluated in rats following oral administration. Antidepressant-like effects were assessed in the rat forced swim test and the chronic social deficit mouse model. Safety/tolerability profile was assessed using PCP-induced hyperlocomotion and rotarod rodent models. Following a single oral dose, zelquistinel (0.1-100 µg/kg) produced rapid and sustained antidepressant-like effects in the rodent depression models. Antidepressant-like doses of zelquistinel also increased NMDAR function and rapidly and persistently enhanced activity-dependent synaptic plasticity (long-term potentiation), indicating zelquistinel may produce antidepressant-like effects by enhancing NMDAR function and synaptic plasticity. Positive modulation of NMDARs by zelquistinel was further exhibited in a PCP (an NMDAR antagonist)-induced hyperlocomotion assay where antidepressant-like doses of inhibited PCP-induced hyperlocomotion. Zelquistinel produces rapid and sustained anti-depressant effects by positively modulating the NMDAR and improving synaptic plasticity. Zelquistinel is currently in phase 2 development as a treatment for MDD.

Title: Rapid acting antidepressants in motivation: the effect of psychedelic drugs in the rat progressive ratio task

Authors: *F. DUNPHY-DOHERTY[1], D. KOZAREVA[1], J. R. KELLY[2], J. PRENDERVILLE[1,3];
[1]Transpharmation Ireland Ltd, Dublin, Ireland; [2]Trinity Ctr. for Hlth. Sci. and Tallaght Hosp., Dublin, Ireland; [3]Discipline of Physiology, Sch. of Medicine, Trinity Col., Dublin, Ireland

Abstract: Psychedelic compounds acting through the serotonin 5-hydroxytriptamine 2A (5-HT2A) receptor, have demonstrated clinical efficacy in major depressive disorder (MDD). Dysregulated motivation and reward processing have been linked to putative endophenotypes in several neuropsychiatric conditions and represent a potential transdiagnostic treatment target. Low doses of ketamine and microdoses of psilocybin have been shown to increase motivation in the rat progressive ratio task. Here, we investigated the long-term effects of ketamine and the

psychedelic 2,5-Dimethoxy-4-iodoamphetamine (DOI) on motivation.Male Sprague-Dawley rats (n=25) were trained in an operant progressive ratio task designed to measure effort-based motivation. Rats were treated with DOI (1mg/kg) and tested daily for 5 days. In a separate group of rats (n=9-10 per group), the effect of ketamine (0.1 and 0.5mg/kg) and DOI (0.2 and 1mg/kg) was investigated. Drugs were administered by subcutaneous injection. All results were compared to baseline and statistical analyses were one or two-way repeated measures ANOVAs with Fisher's LSD post-hoc.In the initial study the (1mg/kg) dose of DOI significantly decreased the number of presses ($P<0.0001$) and the breakpoint ($P<0.0001$) 30 mins after administration but showed significant increases at days 3($P<0.01$) and 5($P<0.01$) for both lever pressing and breakpoint.In the follow up study, 1mg/kg dose of DOI significantly decreased the number of presses ($P<0.0001$) and the breakpoint ($P<0.0001$) 30 mins after administration but showed significant increases at days 4($P<0.05$), 5($P<0.01$) and 6 ($P<0.05$) for lever pressing and days 5 ($P<0.01$) and 6 $P<0.05$) for breakpoint. The 0.1mg/kg dose of ketamine significantly increased the number of lever presses ($P<0.05$) and the breakpoint ($P<0.05$) 30 mins and 48 hours after administration.These data suggest biphasic temporal effects of psychedelic drugs on motivation, which may have implications for the treatment of neuropsychiatric disorders presenting with anhedonia, including MDD, or motivational dysregulation, manifesting as addiction or impulsivity. The long-lasting effects of psychedelic drugs described here, shows similarities to clinical findings demonstrating long-lasting antidepressant effects following a single dose.

Title: The aperiodic exponent: a non-invasive measure for detecting depression treatment response from resting-state EEG

Authors: *S. SMITH[1], D. PRINTZ[2,3], B. VOYTEK[5,6,1,7], M. SOLTANI[3,4];
[1]Neurosciences Grad. Program, Univ. Of California San Diego, La Jolla, CA; [2]Psychiatry, VA San Diego Hlth. Syst., San Diego, CA; [3]Dept. of Psychiatry, [4]Dept. of Psychiatry and Family Med., Univ. of California Hlth. Syst., San Diego, CA; [5]Cognitive Sci., Univ. of California San

Diego, La Jolla, CA; [6]Halıcıoğlu Data Sci. Inst., La Jolla, CA; [7]Kavli Inst. for Brain and Mind, La Jolla, CA

Abstract: Treatments for Major Depressive Disorder (MDD) include medication, therapy, and stimulation procedures like electroconvulsive therapy (ECT). These interventions target a variety of neurophysiological processes including neurotransmitter imbalances or pathological electrophysiological activity. Ultimately, these therapies aim to restore physiological activity and ameliorate depressive symptoms. However, research investigating the precise mechanisms behind these treatments remains inconclusive, often due to the lack of reliable clinical indicators. For instance, frontal alpha asymmetry, the most common electrophysiological indicator of depressive disorders in clinical contexts, has been repeatedly demonstrated to be invalid (van der Vinne et al, 2017; Kolodzeij et al, 2021).

Here, we evaluated electrophysiological signatures of the effects of ECT on neural activity in a unique dataset of 10 clinical MDD patients receiving ECT treatment. In this study, resting-state EEG data and clinical symptom ratings (QIDS) were collected from MDD patients over a 12-session ECT treatment. Data were collected before and after the first, fourth, eighth, and twelfth ECT session to permit analysis of short term effects within a single session, and long-term effects over the course of treatment. We characterize these data in the frequency domain using spectral parameterization, a cutting-edge tool with the capacity to measure features of both periodic and aperiodic neural activity (Donoghue et al, 2020).

Our results reveal that aperiodic activity significantly changes with ECT treatment. Specifically, the aperiodic exponent increases in frontal electrodes acutely following an ECT session ($p < 0.00001$). Importantly, this change in the aperiodic component of the power spectrum results in an apparent reduction in canonical alpha (8-13 Hz) band power. However, alpha oscillatory power above the aperiodic component does not significantly change ($p = 0.694$), indicating no change in genuine oscillatory activity. Additionally, on a longer timescale, the aperiodic exponent also increases (becomes less flat) progressively over the course of treatment ($p = 0.031$). We further generalize these findings by comparing aperiodic activity changes in a broader MDD population undergoing a sertraline treatment by leveraging the EMBARC dataset. These results identify aperiodic activity as a potential clinical indicator for depression treatment and suggest that the insufficiency of indicators like frontal alpha asymmetry is potentially a result of the reliance on traditional methods of spectral analysis.

Title: A Family of Genetically Encoded Biosensors for Rapidly Acting Antidepressants (RAADs) inside Neurons

Authors: K. BERA[1], E. LIN[1], E. J. FINE[1], Z. BLUMENFELD[1], A. V. SHIVANGE[1], B. N. COHEN[1], J. S. MARVIN[2], C. H. KIM[1], J. H. WANG[1], P. DESHPANDE[1], L. L. LOOGER[2], H. A. LESTER[1];
[1]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Rapidly acting antidepressants (RAADs) partially relieve depression in < 1 day and have sustained antidepressant effects for several days. This onset is 10- to 100-fold faster than selective serotonin and norepinephrine reuptake inhibitors (SSRIs and SNRIs). RAADs have various structures. Some RAADs are ketamine enantiomers (R-Ket/S-Ket), metabolites [(2R, 6R)-HNK/ (2S, 6S)-HNK], or analogs such as methoxetamine (MXE), and radafaxine (Rad). Other RAADS such as scopolamine (Scop), are best known as muscarinic antagonists and are structurally unrelated to ketamine. The mechanism(s) of RAAD action are largely unknown at levels ranging from their molecular target, their signaling pathway, the cell types they affect, and other circuits they may influence. Thus, it is important to visualize and quantify RAADs inside subcellular regions of neurons.
Therefore, we developed the "intensity-based RAAD-Sensing Fluorescent Reporter" [iRAADSnFR] genetically encoded biosensor family for RAADs. This biosensor family structurally resembles a previously published nicotine biosensor: a fusion between a mutated bacterial periplasmic binding protein OpuBC, interdomain linkers, and circularly permuted green fluorescent protein (GFP). Biosensor mutations are created by site-saturated mutagenesis and are tested with, high-throughput fluorescence screens, and fluorescence measurements with their purified protein form, and computational docking models. We have mutated residues at the binding site to produce selectivity and pharmacologically relevant sensitivity to various RAADs.
iRAADSnFR - EC_{50} - $\Delta F_{max}/F_0$: iS-KetSnFR - 164 nM - 3.2; iS-HNKSnFR - 110 nM - 3.6; iR-KetSnFR - 130 nM - 4.0; iR-HNKSnFR - 1.1 µM - 3.3; iMXESnFR - 47 nM - 8.6; iRadSnFR - 1.6 µM - 6.3; iScopSnFR - 510 nM - 2.8.
We incorporate additional sequences to the iRAADSnFR constructs to target the sensors to the plasma membrane (PM), cytoplasm, peroxisome, mitochondria, endoplasmic reticulum (ER), nucleus, Golgi, lysosome, and synaptic vesicles. Fluorescence dose-response experiments to test the efficacy of various iRAADSnFRs in live mammalian cells have progressed. Fluorescence microscopy shows that, at the nM concentrations relevant to the antidepressant action, RAADs enter and leave the various organelles within a few seconds, attaining extracellular levels. We also recently utilized adeno-associated virus (AAV) capsids to facilitate efficient and noninvasive iRAADSnFR gene transfer to the central and peripheral nervous systems which may help us unravel RAADs' mechanism of action in zebrafish and mice.

Title: Immune Phenotypes of Oligodendroglial-Lineage Cells in MDD and in Response to Microglial-Derived Inflammation

Authors: *M. M. MADEIRA, A. G. KOKKOSIS, S. H. KLEIN, Z. M. HAGE, S. E. TSIRKA; Pharmacol. Sci., State Univ. of New York, Stony Brook, Stony Brook, NY

Abstract: Background Major Depressive Disorder (MDD) is a complex psychiatric disorder affecting more than 300 million people worldwide. Though the mechanisms underlying MDD are not fully understood, a subset of depressive patients can manifest chronic neuroinflammatory responses. Brain-imaging studies in MDD patients have provided evidence of white matter reductions and such changes are hypothesized to lead to disruption of Oligodendroglial-Lineage cells (OLN) homeostatic mechanisms, resulting in destabilization of emotional/cognitive circuitry. The present goal of the study is to investigate whether these histopathological alterations are linked with chronic inflammation through single-nucleus transcriptomics of MDD patients and using *in vitro* techniques.**Methods** *Bioinformatics:* Raw counts were downloaded from GEO (GSE144136), and expression objects created using Seurat. OLN were subsetted, clustered (using UMAP), and annotated based on their expression of OLN markers. Pseudotime trajectory analysis was conducted using Moncle3. *In vitro:* OPCs and Microglia werederived from Neonatal (P1-P3) mice. To induce an M1-like polarization in Microglia, the cells were treated with LPS. Conditioned Media was then collected and used to treat OPCs at multiple time points and concentrations. To assess dysfunction in proliferation and the adoption of immune phenotypes, immunofluorescent studies were conducted. **Results** Separate clustering of MDD and Control samples yielded four similar clusters labeled based on their geneexpression as: OPCs, Committed OPCs, Immature Oligodendrocytes (OLs), and Mature OLs. One MDD-specific cluster was also obtained and labeled as Immune OLs (ImOL), given its expression of immune genes, such as: *CD74*, and *P2RY12*. Further analysis of the ImOL cluster revealed expressionof markers associated with later phases of OLN progeny. Finally, a predictive model of pseudotime trajectoryrevealed alterations in the progression of OLN progeny in MDD

samples. We then sought to identify ImOL in culture. MHCII and P2RY12 were examined in conjunction with OLN markers (PDGFRα and MBP). To assess whether cytokines derived from activated microglia affected the proliferation of OPCs, Ki67 was used. Interestingly, the presence of inflammatory cytokines from microglia caused significant changes in the OPCs, rendering the ImOL as potential contributors to pathophysiology.**Conclusions** Together, our computational and *in vitro* work shows that OLN can swiftly respond to inflammatory processes arising from innate immune cells, and adopt an immune-like phenotype, potentially contributing to the white matter disturbances observed in MDD.

Title: Dietary aryl hydrocarbon receptor ligands as potential antidepressants

Authors: *C. MADISON[1], G. ALBRECHT[1], J. KUEMPEL[1], L. HILLBRICK[1], S. SAFE[2], A. JAYARAMAN[1], R. CHAPKIN[3], S. EITAN[4];
[1]Texas A&M Univ., College Station, TX; [2]Vet. Physiol. and Pharmacol., [3]Col. of Agr. and Life Sci., Texas A&M Univ., TX, TX; [4]Dept of Psychology, Behavioral & Cell. Neurosci Program, Texas A&M Univ., College Station, TX

Abstract: Depression is a major public health issue that has significantly worsened since the beginning of the COVID-19 pandemic. Current pharmaceutical treatments for depression, such as selective serotonin reuptake inhibitors (SSRIs), are sometimes ineffective and may have unwanted side effects that interfere with patient compliance. Tryptophan (Trp) is an amino acid precursor for serotonin, and altered Trp metabolism is believed to contribute to the psychopathology of depression. Decreased Trp levels have been found in patients who have depression and those who have died by suicide. Gut microbiota play a role in Trp metabolism, and gut flora composition has been linked to depressive disorders in humans and depressive-like behavior in rodents. The Aryl-hydrocarbon receptor (AhR) is an intracellular transcription factor present in various somatic and immune cells, and it is known to be activated by certain Trp metabolites. It has been hypothesized that AhR may play a role in the gut-brain-immune axis in multiple disease states including neurological disorders. Anhedonia is a hallmark sign of Major Depressive Disorder (MDD) and is one of the two criteria necessary for diagnosis under the Diagnostic and Statistical Manual of Mental Disorders (5th ed; DSM-5). The current study induced an anhedonia-like state in female C57BL/6 mice using unpredictable chronic mild stress

(UCMS). Diindolylmethane (DIM) and 1,4-dihydroxy-2-naphthoic acid (DHNA) are plant- and microbe-derived AhR ligands, respectively. For three weeks prior to UCMS mice were fed one of two ligands for the AhR, DIM or DHNA; a second group was subjected to two weeks UCMS before ligand administration began. Both compound successfully prevented and reversed anhedonia-like behavior as measured by the sucrose preference test (SPT). Furthermore, an isomer of DHNA which is inactive with respect to AhR, did not prevent the UCMS-induced anhedonia-like behavior. Additionally, both DIM and DHNA did not significantly alter anxiety levels and did not cause spatial learning deficits. The results suggest dietary AhR ligands as potential antidepressants. Future studies are necessary to elucidate the role of AhR in depression-like states and the underlying mechanisms.

Title: Defining Neural Signatures of Auditory Information Processing in Youth with Obsessive Compulsive Disorder

Authors: *D. CASS[1], J. MEYER[2], M. KOROSTENSKAJA[3], E. HARRIS[4], I. BASU[1]; [1]Neurosurg., [2]Col. of Med., Univ. of Cincinnati, Cincinnati, OH; [3]Univ. of North Florida, Jacksonville, FL; [4]Psychiatry, Cincinnati Children's Hosp., Cincinnati, OH

Abstract: Obsessive compulsive disorder (OCD) is one of the most common psychiatric disorders and involves obsessive thoughts or compulsive behaviors which may be related to abnormalities in information processing involving an impaired inhibitory process. While the average age of onset is in late adolescence, OCD is also commonly diagnosed in children. Resting state gamma activity abnormalities have been observed in adults with OCD as well as other psychiatric disorders. Reduced local circuit inhibition leading to inability to synchronize neural responses to sensory input is hypothesized to lead to increased non-specific gamma activity. Further characterization of pediatric pathophysiology is necessary to understand patterns of disease progression and allow for development of neurophysiological markers that can assist in diagnosis.
Magnetoencephalography (MEG) is suitable for examining high frequency, low amplitude

activity such as gamma band oscillations. First, we examined whole brain resting state gamma activity in 10 OCD and 10 healthy youth who ranged in age from 11-17. We hypothesized based on the adult literature that absolute gamma power would be elevated in pediatric subjects with OCD compared to healthy controls. While we found no differences in mean and absolute gamma power, minimum absolute gamma power was significantly higher in OCD compared to healthy subjects.
As described above, symptoms of OCD can be related to abnormalities in sensory processing. Our previous auditory evokes response study demonstrated a delayed latency of auditory evoked responses in pediatric subjects with OCD. Given that gamma is the primary working frequency of the auditory system, it is possible to drive the sensory cortex with stimuli oscillating at gamma frequencies and examine its ability to synchronize cortical activity. A subset of the 5 healthy subjects and 5 with OCD in whom resting state activity was examined were exposed to an auditory chirp stimulus generated using a 1000Hz tone that was amplitude modulated by a sinusoid linearly increasing in frequency from 0-100Hz over 2 seconds. This stimulus has been used to demonstrate a reduced ability of subjects with other developmental disorders (Fragile X Syndrome and Autism Spectrum Disorder) to synchronize neural activity at higher frequencies in the gamma range. We hypothesize that there may be a common developmental phenotype amongst these disorders and that subjects with OCD will exhibit similar deficits in neural synchronization in the gamma frequency range when exposed to the auditory chirp stimulus. Characterizing this response could lead to development of a diagnostic tool for early detection of OCD.

Title: The selective GPR139 agonist TAK-041 reverses anhedonia and social interaction deficits in rodent models related to negative symptoms in Schizophrenia

Authors: *H. SCHIFFER, J. ATIENZA, H. REICHARD, V. MULLIGAN, J. CILIA, H. MONENSCHEIN, D. COLLIA, W. J. RAY, G. KILPATRICK, N. BRICE, M. CARLTON, S. HITCHCOCK, G. CORBETT, R. HODGSON;
Takeda Develop. Ctr. Americas, Inc., San Diego, CA

Abstract: Negative symptoms in schizophrenia (SCZ) are poorly treated and interfere with the function of patients. Studies focusing on structural and functional imaging and non-invasive

electrophysiology implicate perturbations of the frontocortico-temporal circuits and disruption of cortico-striatal loops to negative symptoms in SCZ. GPR139 is an orphan GPCR that is specifically expressed in the CNS and enriched in the habenula, a brain structure involved in reward and motivation. Structural and functional alterations of the habenula have been found in SCZ patients, who show deficits in feedback processing and lack habenula activation in response to negative outcomes. Rodent experiments demonstrate the involvement of direct projection from the cortex to the habenula controlling social behavior. Alterations in habenula activity have been correlated with depression, and normalization of aberrant habenula activity has been proposed as therapeutic strategy to reverse anhedonia. Building on data previously reported, we further explored modulation of GPR139 receptors and habenula circuitry *in vivo* as a novel mechanism to treat negative symptoms in SCZ. The selective GPR139 agonist, TAK-041, increased cFOS expression in the habenula in wild type mice, but not in GPR139 knock out mice. No desensitization of cFOS in the habenula was observed after chronic dosing of TAK-041. TAK-041 reduced amphetamine- and nicotine-induced dopamine release in the NAc in rats. In the rat unpredictable chronic mild stress (uCMS) model, acute and chronic treatment with TAK-041 reversed the anhedonic and anxiolytic effects, as measured by the forced swim test and the novelty-suppressed feeding test, respectively. Additionally, uCMS-exposed rats developed a disrupted circadian regulation of corticosterone secretion, which was also normalized by TAK-041 treatment. Furthermore, TAK-041 reversed the uCMS-induced atrophy in the basal dendrites of pyramidal neurons in the hippocampus and the uCMS-induced hypertrophy of medium-spiny neurons in the NAc. These results suggest a potential benefit of TAK-041 in the treatment of anhedonia and possibly depression. TAK-041 also reversed social interaction (SI) deficits in the maternal immune activation poly-I:C model of SCZ, the subchronic PCP-SI model and in Balb/C and BTBR mice. The GPR139 agonist TAK-041 is proposed as a modulator of habenula circuitry to treat negative symptoms in SCZ based on efficacy in reversing anhedonia and social interaction deficits in multiple rodent models related to negative symptoms in SCZ.

Title: Tianeptine, but not fluoxetine, decreases avoidant behavior in a mouse model of early developmental fluoxetine exposure

Authors: *E. A. PEKARSKAYA[1], E. S. HOLT[2], J. A. GINGRICH[1,3], M. S. ANSORGE[3,4], J. A. JAVITCH[2,4,5], S. E. CANETTA[2,3];
[1]Neurobio. and Behavior, [2]Mol. Therapeut., [3]Developmental Neurosci., [4]Psychiatry, [5]Pharmacol., Columbia Univ., New York, NY

Abstract: Depression and anxiety are two of the most common mental health disorders, often co-occurring and with overlapping symptoms and treatments. Unfortunately, roughly half of patients do not respond to frontline selective serotonin reuptake inhibitors (SSRIs), or other monoamine targeting treatments. Currently, finding the most effective treatment for an individual is a process of trial and error. To better understand how disease etiology may predict treatment response, we studied mice exposed developmentally to the SSRI fluoxetine (FLX). Human epidemiological data indicates that patients with developmental exposure to FLX have a higher risk of both adult affective disorders and treatment resistance to SSRIs. Similarly, developmentally exposed mice show the murine equivalent of anxiety- and depression-like symptoms in adulthood and are resistant to subsequent FLX treatment. Therefore, we investigated whether tianeptine (TIA), an atypical antidepressant which exerts its therapeutic effects through the mu-opioid receptor instead of directly targeting monoaminergic systems, would be more effective in this model.C57BL/6J (C57) male and female pups were injected with either FLX (10 mg/kg, i.p) (n = 39, 18m, 21f) or vehicle (n = 31, 14m, 17f) from postnatal (PN) day 2 to 11, a period in which mouse brain development parallels that of the third trimester of a human pregnancy. Prior work established that adult 129SvEv (129) mice exposed to FLX in this time period showed increased avoidant behaviors, which are common in mouse models of anxiety and depression. We performed baseline testing in adulthood and confirmed that C57 PN-FLX animals share a similar avoidant phenotype to that reported in 129 PN-FLX mice. As sex did not significantly impact the variables measured, we report the data from the sexes combined. Animals were then pseudorandomly assigned into adult administration groups, and received either FLX (18 mg/kg) (PN-FLX = 20, PN-VEH = 16) or vehicle (PN-FLX = 19, PN-VEH = 15) in their drinking water for 3 weeks. We evaluated the effect of adult FLX treatment on two tasks that measure avoidant behavior - the open field and novelty suppressed feeding (NSF) tasks. This treatment failed to improve, and even exacerbated, avoidance in PN-FLX mice. By contrast, when the same animals later underwent chronic treatment with TIA (30 mg/kg, 2x/day, i.p.), avoidance behavior decreased in both the open field and NSF tasks. Overall, this demonstrates that TIA may be a promising alternative treatment to typical antidepressants, especially in patients whose serotonergic system has been altered by in utero exposure to SSRIs.

Title: Individual differences in plasticity evoked by ketamine in a mouse-model of Anorexia Nervosa: Analysis of drebrin, an F-actin binding protein in postsynaptic spines of the medial prefrontal cortex

Authors: *R. TEMIZER[1], C. J. AOKI[2], Y.-W. CHEN[3];
[1]New York Univ. Ctr. For Neural Sci., New York, NY; [2]Ctr. Neural Sci., [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Anorexia Nervosa (AN) is a mental illness with highest rates of mortality and relapse, and no approved pharmacological treatment. Chen, Aoki et al. (2018) used the Activity-Based Anorexia (ABA) mouse model of AN to examine the ameliorative role of ketamine (KET) for AN, as KET is used to treat anxiety and depression, both of which are comorbidities of AN. It was shown that 30 mg of KET is effective in enhancing food consumption and reducing the maladaptive behavior of excessive running, when administered during mid-adolescence (P42) with noticeable individual differences in the drug's efficacy. Like its action as an antidepressant, KET's ameliorative effect upon ABA was long-lasting (>2 weeks), potentially protecting against relapse and possibly promoting structural plasticity, such as spinogenesis and synaptogenesis. We hypothesized that KET's ameliorative effects upon ABA involves altered expression of drebrin, an F-actin-binding protein that up-regulates in expression during developmental phases of robust spinogenesis, such as mid-adolescence. Moreover, since drebrin was shown previously to mediate the activity-dependent trafficking of NMDARs into and out of dendritic spines and correlate with ABA vulnerability through enhanced anchoring of NMDARs post-synaptically, we surmised that KET could contribute to ABA resilience through reduced localization of drebrin within postsynaptic spines. To test this hypothesis, we conducted electron microscopic immunocytochemistry (EM-ICC) to quantify drebrin immunoreactivity (ir) within postsynaptic spines of mice that underwent two cycles of ABA induction and received 30 mg (efficacious) versus 3 mg (non-efficacious) of KET during the first ABA induction in mid-adolescence. The Prefrontal Cortex (PFC) is the most important brain region for decision-making and layer 1 of PFC has been implicated as a site of action of KET. We therefore focused our analysis upon this brain region.EM-ICC revealed that the level of drebrin at plasma membrane correlated negatively with the percent of body weight restored of mice 6 days after the end of the food

restricted (FR) period (equal to 8 days after having received 30 mg of KET during FR) (r=-0.9, p=0.078, N=4). This suggests that those animals with the highest levels of plasma-membranous drebrin were the individuals least able to restore their body weights (least resilient). In contrast, synapse density did not correlate with the extent of body weight restoration (r=-.07, p=0.9, N=4), indicating no detectable effect of KET on spinogenesis. We will continue with these analyses by increasing sample size, and comparing to drebrin-ir of animals that received 3 mg of KET.

Title: Effects of whole blueberry supplementation on symptoms of depression and anxiety in a rural Louisiana population: behavioral outcomes and inflammatory cytokines from a double-blind, placebo-controlled, crossover study

Authors: *K. VENABLE[1], D. KELLEY[1], H. J. CRULL[1], P. EBENEZER[1], S. O'BRYAN[1], A. JEANSONNE[2,3], C. C. LEE[1], S. JONES[4], V. VATSAVAYI[5], J. FRANCIS[6];

Abstract: Blueberries are densely nutritional with high antioxidant capacity and anti-inflammatory properties demonstrating beneficial effects on health and multiple disease states in numerous preclinical and clinical studies. Depression and anxiety are prevalent and costly disorders, with increased incidence observed during the pandemic. Emerging evidence supports a relationship between depression and the immune system, with chronic, low-grade, systemic inflammation observed in a subset of individuals diagnosed with depression; connections between anxiety and the immune system are less clear at this time. To understand how blueberries might support physiological health and emotional wellbeing of individuals diagnosed with depression or anxiety, we collaborated with a Louisiana rural health clinic system, Louisiana Health Care Practitioners (LHCP), and designed and implemented a randomized, placebo-controlled, crossover study at 2 LHCP sites. This study consisted of two 12-week arms with baseline, mid, and post treatment assessments in each arm and a 4 week washout period between; in arm 1, participants were randomly assigned to either whole, freeze-dried blueberry

powder or a matched placebo control powder which they suspended in water and ingested (24 g) each day (for 12 weeks). At crossover, those who were assigned to blueberry in arm 1 switched to placebo in arm 2 and vice versa. At all time points we collected blood samples and MDI and GAD7, self-report measures of depression and anxiety symptoms, respectively. At baseline and post assessments, we also administered the SIGH-D, a verbal interview utilizing the Ham-D scale and the IDSC. To investigate cytokine expression in participant plasma samples, we used Luminex multiplex assays targeting IL-1β, TNF-α, Il-6, IL-10, IFNγ, and CRP. We confirmed no measured behavioral correlation to CRP, but found a weak correlation to IL-1β; certain individuals' depressive and anxious symptoms were more tightly correlated inflammatory cytokines. Some individuals' depression symptoms were ameliorated in the blueberry condition ("responders"), relative to placebo, whereas others showed no response. Blueberry treatment attenuated anxiety symptoms compared to placebo, but this effect was only observed in the first arm. We plan to use mixed effects modeling to analyze the relationship between blueberry treatment, inflammatory cytokine expression, and behavioral outcomes. This pilot study appears to support the growing momentum toward more personalized forms of nutrition and medicine; this need is especially prominent in psychiatric realms and for disorders as complex as depression and anxiety.

Title: Dorsal medial prefrontal cortex neural firing correlates of compulsive drinking in alcohol preferring P rats

Authors: N. M. TIMME[1], B. MA[1], D. LINSENBARDT[2], E. CORNWELL[1], T. GALBARI[1], C. LAPISH[1];

[1]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Drinking alcohol despite negative consequences (so called "compulsive drinking") is a hallmark of an advanced alcohol use disorder (AUD). At this stage, treatments tend to be less effective, so understanding the cause of this behavior is critical to identify more effective treatment approaches. To better understand this phenomenon, we recorded neural activity in dorsal medial prefrontal cortex (dmPFC, a brain region known to be involved in decision-making) during challenged drinking in adult male Wistar rats (control) and P rats (bred to prefer alcohol, model for genetic risk for excessive drinking). These animals were acclimated to alcohol in home cage and then trained to consume alcohol in a 2-way cued access protocol (2CAP). Behavioral and neural firing data were gathered during the 2CAP task in maintenance and quinine adulterated alcohol (0.1 g/L, challenged drinking test) sessions. P rats continued to consume quinine adulterated alcohol (compulsive drinking) while Wistar rats showed a dramatic decrease in consumption (non-compulsive drinking). Analysis of neural firing in P rats demonstrated that dmPFC representations of seeking were strengthened, while representations of behavioral control variables (e.g., approaching the sipper and drinking) were weakened. Conversely, Wistars showed a strengthening of behavioral control variables during challenged drinking. Furthermore, this Wistar neural response appeared to be driven by increased neural excitation. Therefore, we increased excitation in dmPFC in P rats using a chemogenetic technique, which resulted in a suppression of the progression of compulsive drinking. These studies further elucidate dmPFC's role in compulsive drinking.

Title: Neural correlates of transdiagnostic psychiatric symptom factors in Veterans with alcohol use disorder

Authors: *L.-T. TENEKEDJIEVA[1], A. N. GOLDSTEIN-PIEKARSKI[1,3], K. H. MACNIVEN[2], M. MADORE[1,3], M. KAUR[1], L. WILLIAMS[1,3], C. PADULA[1,3];
[1]Dept. of Psychiatry and Behavioral Sci., [2]Dept. of Psychology, Stanford Univ., Stanford, CA; [3]Veterans Affairs Palo Alto Hlth. Care Syst., Palo Alto, CA

Abstract: Over the past decades, researchers have made great strides in delineating the neurobiological correlates underlying alcohol use disorder (AUD). However, individuals with AUD have high rates of psychiatric comorbidities, which are critical to consider to fully understand the heterogeneity of AUD. The specific symptoms underlying depression, anxiety, and PTSD overlap across diagnoses, highlighting the need to obtain a transdiagnostic understanding. Thus, the current study aims to identify psychiatric symptom factors across diagnostic categories using a data-driven approach and to determine how they relate to the neural circuitry of addiction. A total of 80 Veterans with AUD (22W) completed a psychodiagnostic interview, self-report questionnaires and a 2-hour MRI session. The MRI session included functional MRI scans while participants completed four tasks: emotion processing of faces, monetary incentive delay, alcohol cue reactivity, and a go-no go task. To understand transdiagnostic symptom compositions, we performed factor analysis on self-reported symptoms measured by the Depression, Anxiety and Stress Scale (DASS) and the PTSD Checklist scale (PCL-5). Symptom component scores were calculated based on the factor solution and neural correlates with a-priori defined regions of interest in the four tasks were assessed. Factor analysis revealed four symptom components corresponding to trauma distress, negative emotionality, somatic anxiety and hyper-arousal. Significant associations were revealed between trauma distress score and reduced reward regions activity (L. postInsula) and increased cognitive control activity (dACC). Negative emotionality was related to lower activation in reward regions (R. putamen, L. postInsula and R. dlPFC) and alcohol cue reactivity regions (R. dlPFC, L. mOFC), but higher activation in cognitive control (R. dlPFC) and threat regions (antInsula). Somatic anxiety was associated with decreased activation in reward (R. putamen, R. antInsula) and cue reactivity (R. dlPFC) and increased activation in threat networks (R. antInsula). Higher hyper-arousal scores related to lower activation in reward regions (R. putamen, R. antInsula, L. postInsula, R. antIPL) and increased activation in threat networks (R. antInsula). These findings offer transdiagnostic symptom factors that are differentially associated with neural function and guide us towards a brain-based classification of psychiatric dysfunction in AUD. Future studies will assess the relationship between symptom factors and relapse rates, with the goal of understanding the interplay of relapse risk and mood and trauma symptoms.

Title: Inhibiting beta-noradrenergic receptors suppresses compulsion-like alcohol drinking more effectively than alcohol-only intake, and not through the Anterior Insula

Authors: T. DE OLIVEIRA SERGIO, S. WEAN, S. KATNER, ***F. HOPF**;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Compulsion-like alcohol drinking (CLAD), where consumption continues despite negative consequences, is a major obstacle to treating alcohol use disorder. Norepinephrine receptor (NER) signaling in forebrain cortical regions have been implicated in adaptive responding under stress, which is conceptually similar to compulsion-like responding (adaptive responding despite the presence of stress or conflict). We have previously shown that anterior insula (aINS)-to-brainstem connections inhibited CLAD but not alcohol-only drinking (AOD), while alpha-1 NERs (inhibited systemically or within aINS with prazosin) regulate compulsion-like intake and AOD (de Oliveira Sergio et al., 2021 *Neuropsychopharm*). Here, we examine the importance of beta NERs for CLAD and AOD. While alpha1-NER inhibition suppresses CLAD and AOD equivalently at effective doses of prazosin, the beta-NER blocker propranolol shows a different plan, where a middle dose (5 mg/kg) inhibits CLAD but not AOD, while a higher dose (10 mg/kg) inhibits both CLAD and AOD and a lower dose (2.5 mg/kg) has no effects. In addition, combining a subthreshold, ineffective dose of propranolol (2.5 mg/kg) with a subthreshold, ineffective dose of prazosin (0.25 mg/kg) significantly reduces both CLAD and AOD, supporting the use of a combination therapy in human problem alcohol drinkers to decrease alcohol drinking while reducing other side effects. To investigate brain regions where propranolol acts to suppress alcohol drinking, we first examined propranolol effects in the aINS. Surprisingly, and unlike alpha1-NERs, inhibiting beta-NERs in the aINS over a broad dose range (1-10 ug/side) had no effect on CLAD or AOD. We are presently testing propranolol in the mPFC, since some evidence (Funk and Stewart, 1996) suggests that some autonomic functions may be regulated by beta-NERS in mPFC more than aINS. We are also examining inhibitors specific to particular beta-NERs. Together, our findings suggest (1) that different aspects of the noradrenergic system can differentially regulate compulsion-like vs alcohol-only drinking, with beta-NERs perhaps more selective for CLAD than alpha1-NERs, (2) that CLAD is likely regulated by different receptors across different regions of the salience network, and (3) that alpha1-NERs, beta-NERs, and a combination therapy using subthreshold doses, all may have clinical utility in treating problem alcohol drinking in humans. Supported by AA024109 (FWH).

Title: To fight or not to fight: activation of neural circuits in VTA-mPFC for aggressive motivation and decision making after ethanol consumption in a novel murine model

Authors: *K. MICZEK[1], N. AKDILEK[1], M. LEONARD[1], V. M. M. FERREIRA[2], H. COVINGTON, III[1];
[1]Tufts Univ., Medford, MA; [2]Univ. de Brasilea, Brasilea, Brazil

Abstract: Assessing the neural mechanisms for the motivation to fight remains a challenge for preclinical models, particularly with inbred strains of mice. The effects of alcohol on the decision to engage in aggressive behavior in preference over sociosexual contact is hypothesized to be based on medial Prefrontal Cortex-Ventral Tegmental Area (PFC-VTA) connections that differ from those necessary for the actual execution of these pro- and anti-social behaviors. In a newly developed procedure we studied social choice in male C57BL/6J mice based on preferentially seeking access to sociosexual interactions with a female partner vs. attacking an intruder male. While deciding to engage in aggressive vs. sociosexual behavior, neural activation was studied with c-fos immunohistochemistry in cortical, amygdaloid and tegmental regions of interest. Adult male B6 mice demonstrated sexual competence by siring offspring. During repeated confrontations with an intruder male in their home cage they exhibited pursuit, threat and attack behavior within less than 5 min. The mice were then conditioned to respond at an illuminated operandum in an experimental chamber attached to their home cage; completion of 10 responses (Fixed Ratio 10; FR10) was reinforced by access to either a female or a male intruder which were presented in the resident's home cage. Brains were harvested at the moment of choice between the concurrently available aggressive and sociosexual options. Immuno-stained c-fos in 10 brain regions of interest was analyzed by fluorescence microscopy. The effects of ethanol self-administration were examined on choice for aggressive behavior and on c-fos expression in the mPFC-VTA pathway. Six out of 50 mice chose to complete consistently the FR 10 response option that was reinforced by aggressive behavior toward a male intruder, while not responding on the concurrently available option that was reinforced by sociosexual contact with a female. Self-administered alcohol (1-1.5 g/kg) increased responding for the aggressive option in most mice. When choosing the aggressive, but not the sociosexual option, the prelimbic area of the PFC revealed more c-fos activity prompting more detailed inquiry.

Abstract: Alcohol is one of the most widely used drugs in the United States with approximately 85% of adults reporting drinking in their lifetime. Although there are many reasons people drink, one strong motivating factor is anxiety. Indeed, alcohol use disorder and mood disorders, like generalized anxiety disorder, are highly comorbid. The intimate relationship between alcohol and anxiety is partly controlled by the basolateral amygdala (BLA), which plays a role in expressing anxiety-like behaviors, as well as mediating the negative aspects of alcohol withdrawal. However, it is unclear how alcohol changes activity in the BLA to influence anxiety-like behavior. We hypothesized that alcohol could influence network oscillations in the BLA which in turn influences behavior. Network oscillations, created by rhythmic and synchronous neuronal activity, can exist at different oscillatory frequencies that are associated with different behavioral states, like fear and anxiety. Therefore, we characterized the effects of alcohol on network oscillations by recording local field potentials (LFPs) in male and female C57BL/6J mice after acute and repeated exposure to alcohol (1 g/Kg I.P.). We demonstrate that alcohol is capable of altering BLA network states in a sex dependent manner. Further, we have shown that GABAergic parvalbumin (PV) interneurons in the BLA are critical for generating these oscillations and can shift between specific frequencies to influence freezing behavior in mice. Our lab has shown that δ-subunit containing $GABA_A$ receptors are specifically expressed on PV interneurons in the BLA and others have demonstrated that these receptors are uniquely sensitive to low levels of alcohol. Therefore, we hypothesized that alcohol may modulate BLA oscillations via δ-$GABA_A$ receptors on PV interneurons. To test this hypothesis, we repeated the experiment cited above in male and female global delta knockout (KO) mice. We found subtle differences in the effects of alcohol in the KO mice, suggesting delta is not solely responsible for alcohol's effects on BLA oscillations.

Title: Kappa-opioid receptor function in the nucleus accumbens shell differentially affects ethanol drinking depending on history of intake and sex

Authors: *B. PIRINO[1], B. A. CARPENTER[1], G. R. CURTIS[1], A. T. GARGUILO[1], A. N. KARKHANIS[2], J. R. BARSON[1];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Binghamton University- SUNY, Binghamton, NY

Abstract: The kappa-opioid receptor (KOR) has been investigated as a potential therapeutic target for alcohol use disorder, but the role of the KOR in the nucleus accumbens (NAc) shell, a major reward region, remains unclear. We have previously shown that activation of the KOR in the rostral NAc shell suppresses dopamine release, with no differences detected in males compared to females. Here, we sought to elucidate the effect of KORs in the rostral NAc shell on ethanol drinking, and determine if these effects varied by sex. First, we trained adult male and female Long-Evans rats to drink 20% v/v ethanol under the intermittent access two-bottle-choice paradigm. We then bilaterally microinjected them, prior to daily ethanol access, in the rostral NAc shell with the selective KOR agonist U-50,488H (0.8 or 8.0 nmol) or saline vehicle (0.3 µl), using a within-subject Latin-square design. In male rats, stimulation in the rostral shell significantly decreased ethanol drinking ($p < 0.05$), with effects evident during the first half-hour of daily access, when intake typically is highest. In female rats, however, while KOR activation tended to suppress ethanol drinking in those with a history of lower-level 24-hour intake, it instead significantly enhanced drinking in those with a history of higher-level intake ($p < 0.05$). Conversely, when we injected the long-acting KOR antagonist nor-binaltorphimine (18 mmol) into the rostral NAc shell of ethanol-drinking female rats, we found, 24 hours later, that those with lower-level drinking now showed significantly enhanced ethanol intake, confirming that these effects were physiologically relevant. When we trained a separate group of adult male Long-Evans rats to drink 2.5% w/v sucrose under the same intermittent access paradigm and then microinjected them in the rostral NAc shell with U-50,488H (0.8 or 8.0 nmol) or saline vehicle (0.3 µl), we found no change in sucrose drinking, suggesting that the effects of KOR stimulation on ethanol drinking are substance-specific. These results demonstrate that KOR function in the rostral shell can affect ethanol, but not sucrose, drinking, and that this effect is dependent on sex and history of ethanol intake. Thus, while the KOR represents a promising target for pharmacotherapy to treat alcohol use disorder, such an approach may be more appropriate for specific populations and under specific conditions.

Title: High and Low Alcohol Consuming Rodent Genotypes Exhibit Divergent Responses to 10mM Alcohol on Cerebellar Processing, Cerebellar Output to VTA, and Cerebellar Dependent Behavior

Authors: *D. J. ROSSI[1], C. M. ERIKSON[1], K. T. DOUGLAS[1], T. O. THUET[1], N. A. MCLEAN[1], B. D. RICHARDSON[2];
[1]Integrative Physiol. & Neurosci., Washington State Univ., Pullman, WA; [2]Pharmacol. & Neurosci., Southern Illinois Univ., Springfield, IL

Abstract: Identifying neural processing targets of low concentrations of alcohol ([EtOH]; 10mM, the blood concentration achieved by an adult human consuming two standard units) is critical for understanding initial psychological reactions to recreational EtOH consumption, for which individual variation influences risk for developing an alcohol use disorder. Emerging evidence has revealed that the cerebellum, traditionally associated solely with motor coordination, is centrally involved in a variety of cognitive processes and maladies including EtOH abuse. We used *ex vivo* patch-clamp and *in vivo* single unit recording, viral tract-tracing, and behavioral assays in high and low EtOH consuming rodent genotypes to determine how 1) molecular/cellular actions of 10mM EtOH vary across rodents with divergent EtOH consumption genotypes, and 2) how such differential actions affect cerebellar neural processing and associated behavioral responses to EtOH. In low EtOH consuming rodent genotypes (DBA/2 mice [D2], C57BL/6N mice [B6N], and Sprague Dawley rats [SDRs]), 10mM EtOH significantly enhances GABAergic inhibition of cerebellar granule cells (GCs), but suppresses such inhibition in high EtOH consuming C57BL/6J (B6J) mice and prairie voles (PVs). To determine how such differences in EtOH's action on GCs affects signal processing through the cerebellar cortex, we recorded action potential output from cerebellar Purkinje cells (PCs; sole output of cerebellar cortex) in slices of cerebellum from 3 genotypes, and *in vivo* in awake B6J mice. In slice experiments, 10mM EtOH did not affect basal PC firing in any genotype, but it selectively increased afferent-evoked PC action potential output in B6J mice. Similarly, with *in vivo* recordings, 10mM EtOH increased sensory/motor-evoked PC output without affecting basal firing rate in B6J mice. To determine how such enhanced afferent-evoked transmission through the cerebellar cortex in B6J mice might interact with more traditional reward circuitry, we injected virally driven channel rhodopsin into the cerebellar dentate nucleus, and found functional direct excitatory (glutamatergic) synaptic connections to neurons within the VTA. In

behavioral studies of EtOH-induced motor impairment, IP injections of EtOH that led to BECs of ~10mM disrupted performance on the rotorod in SD rats, but had no impact in B6J or D2 mice. Moreover, differences in EtOH consumption between genetically similar B6J and B6N mice were not due to differences in taste perception, suggesting a post consumptive, neurological underpinning. Our data identify genotype selective actions of 10mM EtOH in the cerebellum that may influence EtOH consumption.

Title: Adolescent binge drinking alters a key peptidergic population in the cortex

Authors: *A. SICHER, W. STARNES, N. CROWLEY;
Penn State Univ. Neurosci. Program, University Park, PA

Abstract: Somatostatin (SST) is a neuropeptide expressed throughout the brain, and is known for its role in multiple psychiatric disorders, but its role in alcohol use disorder has been under-investigated. Ongoing work from our lab has shown key alterations in prelimbic (PL) cortical SST neurons following adulthood exposure to multiple models of alcohol, but little research exists probing SST peptide signaling and neurons during adolescent binge drinking. Multiple lines of evidence point to alcohol-induced alterations of GABAergic and glutamatergic neurons within the cortex following adolescent models of exposure. Here, we use a combination of behavioral, electrophysiological, and optogenetic techniques to elucidate how adolescent binge drinking in the drinking-in-the-dark (DID) paradigm alters SST neuronal properties in the PL cortex. Male and female SST-IRES-Cre x Ai9 mice underwent a modified adolescent version of the DID paradigm of voluntary binge ethanol consumption. Mice were provided access to alcohol throughout the adolescent period (post-natal day 28-60). During this adolescent exposure, mice were provided 20% ethanol weekly for 3 x 2 hr exposures and 1 x 4 hr exposure, 3 hr into the dark cycle. 24 hr after the final ethanol exposure, mice were sacrificed for

electrophysiology, optogenetic manipulations, and other experiments. SST neurons were patched using membrane characteristics and the presence of fluorescence, while pyramidal neurons were identified based on gross morphology and membrane characteristics (cell capacitance and membrane resistance). PL cortical SST neurons in both male and female mice displayed altered intrinsic excitability following alcohol - modifications that were opposite of those seen with adulthood DID exposure. We also demonstrate complementary changes in pyramidal neurons in the same mice. Further experiments demonstrated the time course of adolescent-DID modifications to PL SST neurons (I.e., in acute withdrawal and later in adulthood). Ongoing work will explore the role of SST peptide transmission in this adolescent DID-induced modification of PL SST intrinsic excitability.

Title: Deficits in GABA(A) signaling following withdrawal from chronic ethanol exposure in VTA GABA neurons

Authors: *E. H. MITTEN[1], E. MARRON[2], B. HAIDER[3], K. D. WICKMAN[2];
[1]Grad. Program of Neurosci., [2]Pharmacol., [3]Grad. Program of Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Chronic ethanol exposure has been shown to produce a variety of molecular adaptations within the ventral tegmental area (VTA), with investigations largely focusing on VTA dopamine (DA) neurons. VTA gamma-aminobutyric acid (GABA) neurons are the second largest neuron population (~35%) of the VTA. VTA GABA neurons regulate the excitability of VTA DA neurons as well as other neuronal populations through local and long range projections, respectively. Baseline firing rates of VTA GABA neurons are higher in acute withdrawal following chronic ethanol exposure in vivo. While this has been shown to be due in part to increased glutamate neurotransmission, adaptations to inhibitory signaling contributing to this effect have yet to be fully elucidated. To investigate possible deficits in inhibitory control of VTA GABA neurons, male and female GAD67-eGFP mice were subjected to 3-4 weeks of chronic intermittent ethanol vapor exposure, with subsequent slice electrophysiological

experiments targeting VTA GABA (GFP-positive) neurons performed 1-7 days following the final day of exposure. Animals exposed to air were used as controls. All data were separated by sex and analyzed by two-way ANOVA to assess for sex differences. If no sex differences were detected, data was pooled and analyzed using a Kolmogorov-Smirnov test or Welch's t-test, as appropriate. We found that chronic ethanol exposure suppressed the frequency ($p = < 0.0001$) and amplitude ($p = 0.0375$) of spontaneous GABA(A) receptor-dependent inhibitory postsynaptic currents (sIPSCs) in VTA GABA neurons ($n = 13\text{-}14$). To determine whether these ethanol-induced adaptations reflected postsynaptic GABA(A) receptor density or efficacy, we next measured somatodendritic currents induced by rapid application of the GABA(A) receptor agonist muscimol. Preliminary data show that muscimol-induced currents are significantly reduced in VTA GABA neurons, suggesting that GABA(A) receptor signaling in VTA GABA neurons is significantly reduced following repeated ethanol exposure. Ongoing investigations are directed at identifying relevant GABA(A) receptor subtypes in VTA GABA neurons impacted by repeated ethanol exposure, presynaptic contributions that would produce a reduction in sIPSC frequency, and the behavioral relevance of this form of ethanol-induced neuroplasticity.

Title: A novel assessment of rule-learning in mice using operant touch screen boxes

Authors: *R. CHASSE[1,2], P. A. PERRINO[3], R. H. FITCH[1,2];
[1]Psychological Sci., Univ. of Connecticut, Storrs, CT; [2]Inst. of Brain and Behavioral Sci., Murine Behavioral Neurogenetics Facility, Storrs, CT; [3]Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Historically, the development of valid and reliable methods for assessing higher order cognitive ability (e.g., rule learning and transfer) has been tricky in rodent models. One barrier is verifying that subjects are actually using cognitive processes assumed by investigators, versus unexpected approaches to solve the task. To date, limited evidence supports the existence of higher cognitive abilities such as rule generation and complex decision making in mice, rats, and rabbits. Although rats have shown marginal evidence of being able to learn and transfer information from one set to another (e.g., attentional set shifting), mice have shown limited

abilities in this domain. Yet the exploding use of engineered mouse models to study genetic disorders characterized by cognitive disruption would benefit tremendously from the inclusion of such a task in mouse phenotyping batteries. For the current experiment, we sought to develop a task that would require mice to learn a visual discrimination task of increasing complexity, following fixed parameters or "rules." Mice would then be asked to apply the remembered rules to a novel (new) image set. Twenty-eight (28) wild-type male c57 mice performed the initial visual discrimination, which was conducted in Bussey-Saksida touchscreen operant boxes. We used 2 different image sets, counterbalanced for the image set each group received first. Results showed that mice were able to quickly learn the first image set, and could learn the "rule" based on performance curves that were significantly better than initial learning when image sets became more complex. They could also remember this information many weeks later. However, the mice appeared unable to transfer the rule to a *new* set of stimuli. Specifically, they showed visual discrimination curves for the new image set that was no better than the first (naïve) round of learning. We continue to revise this task to optimize stimulus parameters and maximize task sensitivity, hoping to better tap these important cognitive measures in mice.

Title: Menstrual Cycle Influences on the Intrinsic Network Structure of the Brain

Authors: A. GIANCOLA[1], N. MCLACHLAN[1], B. C. DICKERSON[2], L. F. BARRETT[3], E. K. TOWLSON[4], *J. ANDREANO[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Dept Neurol, Massachusetts Gen. Hosp. Dept. of Neurol., Charlestown, MA; [3]Dept. of Psychology, Northeastern Univ., Boston, MA; [4]Computer Sci., Univ. of Calgary, Calgary, AB, Canada

Abstract: Growing research indicates that changes in ovarian hormone levels over the menstrual cycle and the lifespan can have significant influences on brain function. Prior studies have indicated ovarian effects on connectivity, particularly between nodes of the default mode network (DMN) and salience network (SN), two intrinsic networks known to play an important role in learning, memory, and affect, leading us to hypothesize that cyclic changes in connectivity may lead to ‘windows of vulnerability’ to affective disorder (1). No study to date, however, has examined the possibility that the organization of resting networks themselves may

change in response to ovarian signals. Here we present data from 100 resting-state fMRI scans in 22 women taken at three hormonally distinct phases of their menstrual cycle: (i) early follicular (EF), when ovarian hormone levels are low; (ii) late follicular (LF), when estrogen levels reach their peak; and (iii) mid-luteal (ML), when both estrogen and progesterone are elevated. We constructed whole-brain functional connectomes for each participant at each of the three menstrual phases by calculating the Pearson's correlation coefficient between regional fMRI timeseries. We then identified 6 communities, or subnetworks, within the brain via the Louvain algorithm (2) applied to averaged connectomes for EF, LF, and ML groups. The resulting community structure of the brain was then compared between menstrual phases. Specifically, we investigated the changing assignment of nodes to subnetworks, and the connectivity distributions within and between the subnetworks. Differences were quantified using the Mann-Whitney Test.The results indicated significant changes in intrinsic network structure between phases. Notably, our findings indicate a stronger functional fractionation of the midline and temporal components of DMN during the LF phase. Additionally, the mid-cingulate cortex, a network hub engaged by difficult tasks, shifted its connections from the DMN and SN in EF and ML to the dorsal attention network in the LF phase. These changes in network organization accompanied phase-related differences in cognition and affect that were similarly centered on the LF phase. Potential links between connectivity changes and sex/phase differences in affective disorder, as well as their implications for women's health, will be considered. 1. Andreano, JM. et al. Title: Cortical Amygdala Nuclei Involvement in Olfactory Fear Memory Processing

Authors: *C. DE SOLIS, A. ASOK, J. LOPEZ-ROJAS, P. CHEN, E. R. KANDEL; Columbia Univ., New York, NY

Abstract: The memories of our lives, good and bad, are constructed from our senses. In the past decades, we have learned a great deal about the fascinating neurobiological mechanisms that enable sensory information to be woven into a memory. In addition to visual, gustatory, tactile, and auditory information, our representation of the world and how we behave in it is heavily influenced by our ability to detect odors. For example, the smell of burning rubber, blood and gasoline can serve as potent retrieval cues, particularly among individuals suffering from fear- and anxiety-related psychiatric disorders. Yet, our knowledge of how learned olfactory information is encoded and updated is relatively incomplete, especially regarding aversive memories. Here, we examine the involvement of amygdala cortical nuclei in the formation of olfactory fear memories. We find that a subdivision of these nuclei show increased activation in response to olfactory fear conditioning, as detected by levels of intracellular calcium and immediate early gene expression. We then silenced this region during classical fear conditioning to an olfactory, auditory or visual conditioned stimulus, however, while deficits in long-term olfactory memory retrieval were apparent, visual and auditory retrieval was left intact. We then performed neuronal tracing experiments to identify the cortical nucleus projections to the medial prefrontal cortex (mPFC). Using a dual-viral approach to deliver chemogenetic and optogenetic tools to this discrete circuit, we determined that amygdala cortical nuclei neurons projecting to the mPFC play a role in the acquisition of odor fear memories.

Title: Repeated & predictable information dominates the neural representation of complex events

Authors: *P. RAYKOV[1], K. BROMIS[2], L. WICKENS[2], W. ROSEBOOM[2], C. M. BIRD[3]; [1]Sussex Univ., Brighton, United Kingdom; [2]Univ. of Sussex, Brighton, United Kingdom; [3]Sch. of Psychology, Univ. of Sussex, Falmer, Brighton, United Kingdom

Abstract: An episodic memory is specific to an event that occurred at a particular time and place. However, the elements that comprise the event – the location, the people present, their

actions and goals – might be shared with numerous other similar events. Does the brain preferentially represent certain elements of a remembered event? If so, does it prioritise the familiar and predictable elements that are shared across similar events, or the novel elements that define a specific event? We addressed this question by using a novel experimental paradigm combined with fMRI. Multiple events were created involving conversations between two individuals, using the format of a television chat show. Chat show "hosts" occurred predictably in multiple events, whereas the "guests" were unique to only one event. Before learning the conversations, participants were scanned while viewing images or names of the (famous) individuals to-be-used in the study, in order to obtain person-specific activity patterns. After learning all the conversations over a week, participants were scanned for a second time while they recalled each event multiple times. We found that during recall, person-specific activity patterns within the posterior midline (PM) network were reinstated for the hosts of the shows but not the guests, and that reinstatement of the hosts was significantly stronger than reinstatement of the guests. These findings demonstrate that the familiar and predictable elements of an event are represented in the brain more robustly than the novel, yet event-defining, elements.

Title: High channel-count neural recordings in monkeys reveal the diverse underpinnings of novelty detection across brain circuits

Authors: *K. ZHANG[1], E. S. BROMBERG-MARTIN[5], F. SOGUKPINAR[2], K. KOCHER[5], I. E. MONOSOV[5,1,2,3,4];
[1]Dept. of Biomed. Engin., [2]Dept. of Electrical Engin., [3]Dept. of Neurosurg. Sch. of Med., [4]Pain Ctr., Washington Univ. in St. Louis, St. Louis, MO; [5]Dept. of Neurosci., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Humans and other primates learn by exploring novel objects, but the neuronal mechanisms of novelty detection are unclear. It is well known that neurons in many brain areas respond differently to novel versus familiar objects (Ranganath et al., 2003). Several classes of theories propose that these novelty responses are derived from computations of sensory surprise

(Kumaran, 2007) or recency (Vogels, 2015). However, these mechanisms could be interdependent. Novelty responses may arise from computations of both sensory surprise and recency, or neither. Also, novel objects mediate behavior on different timescales, flexibly depending on context. But whether novelty-sensitive neurons display heterogenous timescales of novelty-to-familiarity learning to support such behavioral flexibility remains unclear. To study these issues, we recorded thousands of neurons across temporal cortex, amygdala, hippocampus, basal ganglia, and the prefrontal cortices while two monkeys participated in a behavioral procedure that tested the relationship of novelty, sensory surprise, and recency. During neural recording, monkeys viewed sequences of visual fractal objects. These fractals could be novel or familiar, more or less recent, and more or less surprising. Across many brain areas, we found that neurons selectively responding to novel objects also tended to respond to sensory-surprising objects and non-recent objects in the same direction. Among novelty-excited neurons, there were significant positive correlations between neurons' novelty sensitivity and their sensory surprise and recency sensitivities. Moreover, novelty neurons also showed spatial clustering, with particular enrichment in the anterior ventral medial temporal regions. In general, brain areas with a higher percentage of novelty responsive neurons tended to have higher percentages of sensory surprise responsive and recency responsive neurons. Control experiments indicated that these response patterns were not simply due to other aspects of the behavioral procedure such as general arousal or reward. Finally, we studied neuronal novelty-to-familiarity transformations during learning across many days from repeated exposure to novel fractals. We found a wide spectrum of timescales in neurons' learning rates and forgetting rates across multiple days that is well suited to support flexible adaptive behavior to novel objects. Our findings show that novelty detection arises on multiple timescales due to diverse but related computations of sensory surprise and recency, and shed light on the logic and computational underpinnings of novelty detection in the primate brain.

Title: Are intrinsic timescales innate or emergent? Intrinsic timescales by brain region in human neonates and adults.

Authors: A. TRUZZI[1], *R. CUSACK[2];
[1]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland; [2]Trinity College, Dublin, Ireland, Dublin, Ireland

Abstract: In adults, each brain region has a characteristic intrinsic timescale over which it integrates information. Electrophysiology in macaques and EEG/MRI in humans have shown that these timescales follow a gradient from shorter in primary sensory regions to longer in higher-order regions. Disruption to intrinsic timescales has been associated with cognitive impairments and can predict the severity of symptoms in Autism Spectrum Disorders. It has not been established how timescales develop in infancy. The characteristic timescales of brain regions might be an innate property that guides subsequent learning. Or, the timescales might emerge in the course of learning, with more persistent representations emerging as the statistics of the environment are learned. Here, we characterised the timescales using resting-state fMRI in low-movement neonates (FD < 0.25mm) from the developing human connectome project (dHCP, N_infant = 267) and low-movement adults from the CamCAN project (N_adult = 252). Timescales were calculated for 400 regions-of-interest (ROIs) using an autoregressive model. The order of the model was selected on a subset of the dHCP data and cross-validated on an independent subset. Timescales across ROIs in the two independent dHCP groups were strongly correlated (Spearman's $r = 0.77$). In some brain systems, the timescales in a neonate's brain follow a similar gradient to the one found in adults, from shorter in primary sensory regions to longer in higher-order regions. However, unimodal and transmodal regions showed different patterns in infants and adults (Kruskal-Wallis $H = 395.5$, $p < 0.001$). No significant difference was found between unimodal and transmodal networks in infants, whereas a significant difference between the two types of networks was found in adults (Mann-Whitney $U = 14797$, $p < 0.05$, $d = 0.36$). Moreover, infants showed overall longer timescales compared to adults, both in unimodal (dHCP Group1: Mann-Whitney $U = 227$, $p < 0.001$, $d = 3.18$; dHCP Group2: Mann-Whitney $U = 238$, $p < 0.001$, $d = 3.18$) and transmodal regions (dHCP Group 1: Mann-Whitney $U = 10462$, $p < 0.001$, $d = 0.58$; dHCP Group2: Mann-Whitney $U = 10605$, $p < 0.001$, $d = 0.53$). Differences in the timescales between brain regions are therefore present already at birth and are likely to shape learning. However, infants' primary sensory and motor regions show a slower intrinsic timescale at birth compared to adults. Since slower neural processes allow the integration of incoming information across longer timescales it might help the human infants to "take it slow" and to create more regularised, and holistic representations of the input which, in turn, could improve later memory and decision making.

Title: Disrupting GABAergic transmission impairs category recognition on a mouse object category recognition task

Authors: *H. A. COLLETT[1], S. D. CREIGHTON[3], J. L. FOURNIER[2], R. A. PANDIT[2], K. H. JARDINE[1], B. D. WINTERS[1];
[1]Psychology, [2]Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada; [3]Psychology, Univ. of Toronto, Mississauga, ON, Canada

Abstract: Recognizing visually distinct objects as belonging to the same category - and distinguishing between different categories - is necessary for producing object-appropriate behavioural responses. Objects from a familiar category may be recognized with the use of generalized category representations which may be refined through exposure to various category exemplars. Presumably, to refine category representations, extraneous object features must be inhibited, to allow distinction between category representations and to enable recognition of a novel object from a familiar category. Parvalbumin-containing GABAergic interneurons (PVINs) has been implicated in visual stimulus learning, including the enhancement and inhibition of relevant and irrelevant stimuli, respectively. Furthermore, PVINs has been identified as providing feedforward inhibitory control in the perirhinal cortex (PRh), an area which is necessary for object recognition and object feature-binding. To determine the role of GABAergic transmission in the refinement of object category representations, male C57/BL6 mice were administered a $GABA_A$ receptor antagonist (bicuculline; 0.5mg/kg, i.p.) prior to exposure to various category exemplars and were subsequently tested on a mouse object category recognition (OCR) task. Mice require previous exposure to category exemplars to perform the OCR task with long retention delays, such as 1-h. Mice administered bicuculine prior to exposure to these exemplars were not able to discriminate between a novel and familiar category object after a 1-h delay on the OCR task. Next, to specifically examine the role of GABAergic PVINs in the PRh in the formation of generalized category representations, we infused male PV^{cre} mice intracranially with adeno-associated virus containing inhibitory designer receptors exclusively activated by designer drugs (DREADDs) to control the activity of PVINs in the PRh. The DREADD agonist 21 (11-(1-piperazinyl)-5H-dibenzo[b,e][1,4]diazepine; C21) was administered systemically (i.p., 1mg/kg) prior to exposure to object category exemplars. Mice administered C21 prior to pre-exposure sessions also failed to discriminate between a novel and familiar category object when tested subsequently on the OCR task with a retention delay of 1-h. These findings suggest that GABAergic transmission, and specifically PVIN activity in the PRh, may play an essential role in the refinement of object category representations, and further our understanding of the processes that facilitate category learning and recognition.

Title: Revealing hidden sensorimotor memories in mice with AD-relevant pathology

Authors: S. MOORE[1], A. WANG[1], J. LAWLOR[1], K. FOGELSON[1,2], ***A. SANTI**[1], K. KUCHIBHOTLA[1,3];
[1]Dept. of Psychological and Brain Sciences, Krieger Sch. of Arts and Sci., Johns Hopkins Univ., Baltimore, MD; [2]Biomed. Sci. PhD Program, University of California San Diego, La Jolla, CA; [3]Dept. of Neurosci. Sch. of Med., The Solomon H. Snyder, Johns Hopkins University, MD

Abstract: Memories must be accessible for them to be useful. Alzheimer's disease (AD) is a progressive form of dementia in which cognitive capacities slowly deteriorate due to underlying neurodegeneration. Interestingly, anecdotal observations have demonstrated that Alzheimer's patients can exhibit cognitive fluctuations during all stages of the disease. In particular, it is thought that contextual factors are critical for unlocking these hidden memories. To date, however, exploration of the neural basis of cognitive fluctuations has been hampered due to the lack of a behavioral approach in mouse models to dissociate memories from contextual performance. Our previous work demonstrated that interleaving 'reinforced' trials with trials without reinforcement ('probe' trials) in an auditory go/no-go discrimination task, allows us to distinguish between acquired sensorimotor memories and their contextual expression. Here, we used this approach, together with two-photon calcium imaging on behaving AD-relevant mice (APP/PS1+), to determine whether amyloid accumulation impacts underlying sensorimotor memories (measured using 'probe' trials) and/or contextual-performance (measured using 'reinforced' trials) in an age dependent manner. Importantly, peripheral auditory function, measured using the threshold for detecting an auditory brainstem response, was similar between WT and APP/PS1+ mice. We found that while contextual-performance is significantly impaired in young adult APP/PS1+ mice compared to age-matched controls, these animals show only minor impairments in the underlying sensorimotor memories. However, middle aged APP/PS1+ mice show deficits in both domains. The impairment found in the young adults was accompanied by a reduction in stimulus selectivity in the auditory cortex of APP/PS1+ mice that was particularly apparent in reinforced trials. Ongoing analyses aim to identify whether this impairment is cortex-wide or is concentrated near Aβ plaques. Finally, these effects were recapitulated by using a reinforcement learning model that accounts for changes in contextual signals. The main network model parameters affected between the control and the APP/PS1+ mice were those governing contextual scaling and behavioral inhibition. These results suggest

that Aβ deposition impacts circuits involved in contextual computations before those involved in acquiring knowledge.

Title: Model connectivity: a new approach to functional connectivity that leverages the power of voxelwise encoding models to eliminate confounding noise and increase interpretability

Authors: *E. X. MESCHKE[1], M. VISCONTI DI OLEGGIO CASTELLO[2], J. L. GALLANT[3]; [1]Univ. Of California, Berkeley Neurosci. Grad. Program, Berkeley, CA; [2]Univ. Of California, Berkeley, Berkeley, CA; [3]Univ. of California Berkeley, Berkeley, CA

Abstract: Complex cognitive functions are subserved by anatomically coupled networks of brain areas. The most common method for identifying these networks in the human brain is to use neuroimaging data to estimate functional connectivity (FC). FC is defined as the correlation of BOLD signals over time between spatially distinct brain areas. Although FC studies are popular, they suffer from two fundamental flaws. First, because FC correlates BOLD signals directly, true signal correlations that reflect underlying anatomical connectivity cannot be separated from noise correlations that contaminate all functional MRI studies. This makes it difficult to use FC to draw valid conclusions about the coupling of brain areas. Second, it is difficult to determine what information is represented in networks identified with FC without additional experiments.
To overcome both flaws, we developed model connectivity (MC). MC builds on the voxelwise encoding model (VM) framework. In VM, the activity in each voxel is modeled in terms of stimulus- or task-related features. Regularized regression is used to predict brain activity from those features, and model prediction accuracy is estimated on a separate test dataset. This produces model weights that quantify how voxels represent stimulus-related features. Using separate data sets to fit models and to evaluate performance ensures that model weights are based on predictable signals, not noise. MC uses the correlations between model weights to recover functional networks that are not contaminated by noise and which have a clear functional

assignment.
To compare MC to FC, we applied both methods to an fMRI dataset in which participants listened to narrative stories (Huth et al., 2016). For MC, we used VM to predict brain activity from the semantic content of the stories, and we used hierarchical clustering to identify networks based on model weights. For FC, we applied hierarchical clustering to the pre-processed BOLD activity. We make three observations about the networks produced by these two methods. First, we find that MC excludes noisy voxels that constitute a large part of networks recovered by FC. Furthermore, networks recovered by MC are more spatially specific than those recovered by FC. Finally, because the MC networks are based on voxelwise encoding model weights, they are more interpretable than the FC networks.
We conclude that MC is a powerful new method for identifying functional networks in the human brain. This approach does not suffer from noise confounds that contaminate conventional FC studies and produces networks with clear functional assignments.

Title: Basal forebrain cholinergic circuit orchestrates adult hippocampal neurogenic niche to regulate neural stem cells

Authors: *L. J. QUINTANILLA[1,2], J. M. SIMON[3,4,5], Y. SU[6], Y. LUO[2], B. ARISCAN[2], D. TART[2], Y. LI[2], J. SONG[2,3];

Abstract: The adult mammalian hippocampus contains endogenous neural stem cells (NSCs) that provide a self-renewable source for continuous replenishment of new neurons throughout life. The NSCs reside in a specialized niche within the dentate gyrus (DG) that comprises diverse populations of niche cells. Our recent studies demonstrate that these local niche cells can regulate the activation/quiescent state of NSCs and subsequent production of newborn progeny. Whether there is a master regulator that can orchestrate the actions of these local niche cells to

regulate NSCs remains unknown. Here we identified a basal forebrain cholinergic circuit projected from Diagonal Band of Broca (DB) to the DG, which exerts broad actions on multiple types of local niche cells. Functionally, activation of the DB-DG cholinergic circuit increased proliferation of NSCs and production of newborn progeny. Interestingly, the dominant signaling onto NSCs is glutamatergic upon stimulation of the DB-DG circuit, suggesting that cholinergic signaling acts upon intermediary niche cells capable of releasing glutamate to regulate NSCs. To further address cholinergic circuit induced effects in a cell-type specific manner, we performed single nuclei RNA-Seq of the DG upon stimulation of the DB-DG cholinergic circuit. Notably, we identified broad distribution of differentially expressed genes (DEGs) across multiple types of niche cells, including various types of interneurons, mossy cells (MCs), granule cells (GCs), and astrocytes. The common DEGs associated with these cell clusters were involved in trans-synaptic signaling, membrane ion transport, and synapse formation, suggesting DB cholinergic activation of these cell clusters. Importantly, these niche cell types, upon activation, are capable regulating NSCs directly or indirectly through glutamatergic signaling. Consistent with cholinergic activity dependent regulation of NSCs through glutamatergic signaling, we identified the DEGs in NSCs involved in NMDA glutamate receptor activity, voltage gated ion channels, and calcium ion transmembrane activity. Together, our results support that the basal forebrain cholinergic circuit acts as a master regulator to orchestrate neurogenic niche and regulate NSCs.

Title: Cellular mechanisms of context dependent feature selectivity in hippocampal CA3: inputs and plasticity

Authors: *Y. LI;
Howard Hughes Med. Inst., Houston, TX

Abstract: Hippocampal place cells are believed to encode “where” in spatial navigation and episodic memory. Place cells are not passively driven by the specific content features, but fire in a context dependent manner. That is, the same feature in completely different environments will produce disparate place cells firing, or trigger distinct memory traces. However, how environmental context determines the place field and drives place field remapping is still an open

question. Here I am trying to uncover the source of context dependent remapping that is the strongest in hippocampal CA3. I trained head-fixed mice running on a linear treadmill with different feature cues. The corresponding subthreshold membrane potentials and action potentials have been recorded and measured through whole-cell intracellular voltage recordings. I firstly examined the BTSP (behavioral time scale plasticity) in CA3, and found that the dendritic calcium plateau potentials, rather than spike trains, could produce a large potentiation in CA3 as in CA1, but with a completely different plasticity kernel. The kernel in CA3 is symmetric compared to the asymmetric one in CA1, which endue CA3 to produce a current map relative to the predictive map in CA1. These two maps together could provide the current and future information to downstream. Meanwhile, I found that CA3 cells activity could be separated into 5 categories during the task, which may contribute to build an attractor network within CA3 to generate a sequence covering the entire "space" of the task. And the mismatch of sequence and spatial cue can well explain different remapping behavior of CA3 place cells after shifting the reward location. Thus, we think the role of CA3 attractor network is to generate a specific sequence/trajectory for different contexts. Next, I am trying to optogenetically manipulate CA3 and its upstream activity, to examine their role in building the CA3 attractor network.

Title: Structural plasticity of apical dendritic spines in hippocampal CA1 is modulated by sex-specific steroid hormones

Authors: *N. WOLCOTT[1], W. REDMAN[2], K. SIT[3], M. GOARD[4];
[1]Molecular, Cellular, and Developmental Biol., Univ. of California Santa Barbara Neurosci., Santa Barbara, CA; [2]Dynamical Neurosci., Univ. of California Santa Barbara, Goleta, CA; [3]Psychology and Brain Sci., Univ. of California: Santa Barbara, Goleta, CA; [4]Molecular, Cell. and Developmental Biol. / Psychological & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Dendritic spines are highly dynamic and motile structures that serve as the postsynaptic sites of excitatory synapses in the hippocampus. Previous *in vitro* studies suggest that the structural and functional plasticity of dendritic spines may be tied to sex-specific steroid

hormones such as estradiol and progesterone, the concentrations of which fluctuate over the course of the 4-5 day murine estrous cycle. However, the *in vivo* turnover dynamics of apical dendritic spines in hippocampal pyramidal cells remain unknown. Estrous-dependent fluctuations in dendritic spine density were consistently observed over consecutive cycles using our recently developed chronically implanted hippocampal microperiscope in awake mice. When identifying estrous stage, human error was greatly reduced by implementing EstrousNet, a novel unsupervised machine learning approach that provides unbiased stage classification. Using these novel techniques, we found that apical dendritic spines in female hippocampal CA1 experience a 15.3% increase in density in late proestrous, followed by a 20.6% decrease in spine density in early estrous. In both sexes across 10 days we found only a 23.5% net loss in original spines, indicating that majority of spine turnover takes place within an isolated population of transient spines. Taken together, these findings inform our understanding of structural and functional plasticity in hippocampal pyramidal cells as they relate to sex-specific steroid hormones.

Title: Long-term transverse imaging of the hippocampus with glass microperiscopes

Authors: *W. REDMAN[1], N. WOLCOTT[2], L. MONTELISCIANI[7], G. LUNA[3], T. MARKS[3], K. SIT[4], C.-H. YU[5], S. L. SMITH[5], M. GOARD[6];

Group, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The transverse axis of the hippocampus consists of a stereotyped neuronal circuit repeated along the septal-temporal extent of the structure. This circuit contains distinct subfields with well-described connectivity that supports crucial cognitive processes, such as episodic and spatial memory. While extensive research has provided insight into hippocampal function,

existing physiological approaches do not allow for comprehensive measurement of the transverse hippocampal circuit *in vivo*. To address this, we developed an approach for two-photon imaging of the transverse hippocampal plane in awake, behaving mice via chronically implanted glass microperiscopes. This microperiscope allows optical access to all major hippocampal subfields (i.e. CA1-3, and dentate gyrus) in the same animal, as well as to the apical and basal dendrites of the pyramidal neurons. Using this approach, we chronically imaged spines on apical CA1 dendrites and characterized spine turnover across days, finding both transient and stable populations. We then used calcium imaging to quantify the prevalence of place and speed cells across subregions, finding a non-uniform distribution of spatial selectivity along the DG-to-CA1 axis. In particular, we found that cells in dorsal CA3/CA2 had the lowest spatial information, and that cells in proximal CA3 had values that were most similar to DG cells. This approach will extend the existing toolbox for structural and functional measurements of the hippocampal circuitry supporting memory formation.

Title: Novel experience enhances flexible learning by resetting hippocampal-prefrontal circuitry

Authors: *A. PARK[1], A. HARRIS[1], K. MARTYNIUK[1], C.-Y. CHANG[1], A. I. ABBAS[3], D. C. LOWES[2], C. KELLENDONK[4], J. GOGOS[1], J. A. GORDON[5];
[2]Pharmacol., [1]Columbia Univ., New York, NY; [3]Columbia University/NYS Psychiatric Inst., New York, NY; [4]Columbia Univ. Press, New York, NY; [5]Office of the Director, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Adapting to novel situations is essential for everyday life, and this flexibility is often impaired in psychiatric disorders. Thus, understanding whether and how novelty prepares, or primes, the brain to promote cognitive flexibility has important translational relevance. Here, we show that novel experience, either spatial or social, primes the brain by resetting the ventral hippocampus (vHPC)-medial prefrontal cortex (mPFC) circuit in a dopamine D1-receptor (D1R)-dependent mechanism. This reset boosts adaptation to new rules. Data analyses were blind to the groups of a total of 132 mice (both gender). We trained mice to freely choose either arm of a T-maze for rewards (‘free choice’). Over three days, mice developed a strategy to

simply choose one particular arm (arm bias). Then, in the same maze, the mice underwent 'flexible choice' training, which required them to overcome their arm bias and flexibly choose a goal under new rules (delayed-non-match-to-sample). Mice exposed to a novel arena or a novel mouse 1-hour before training overcame their arm bias more rapidly than mice exposed to familiar conditions. We also performed electrophysiological recordings in the HPC and mPFC as they govern spatial learning. Novelty persistently amplified vHPC theta (4-12 Hz) oscillations at least for 1-hour until the onset of flexible choice task and entrained vHPC neurons to the trough of theta oscillations. Moreover, three independent measures (vHPC activity-triggered mPFC neuronal spiking, the phase-locking of mPFC neurons to vHPC theta oscillations, and optogenetically evoked vHPC-to-mPFC synaptic transmission) indicated that novelty weakened existing vHPC-mPFC connectivity. This weakened connectivity re-strengthened as novelty-exposed mice adapted to the flexible choice task. Machine learning and information theory analyses revealed that novelty reduced adherence to arm bias by vHPC theta entrainment and vHPC-mPFC connectivity weakening. Also, task-specific strategy updating occurred as the weakened connectivity re-strengthened. Conversely, in familiar conditions, vHPC-mPFC connectivity remained stable, and mice adhered to their arm bias. Finally, this effect of novelty was mimicked by the D1R agonist dihydrexidine treatment, while blocked by infusing the D1R antagonist SCH23390 into the vHPC or optogenetic inhibition of novelty-tagged vHPC neurons expressing D1Rs. Hence, novel experience primes the brain by D1R-mediated resetting of vHPC-mPFC circuitry, facilitating new learning. As pathologic vHPC-mPFC connectivity is prominent in many psychiatric disorders, our work provides new mechanistic insight for therapeutic interventions.

Title: Determining the true magnitude of recognition impairments following neurotoxic lesions of the hippocampus in nonhuman primates: A meta-analysis

Authors: *S. J. WATERS[1,2], B. M. BASILE[3], E. A. MURRAY[2];
[1]Interdisciplinary Program In Neurosci. (IPN), Georgetown Univ., Washington, DC; [2]Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD; [3]Psychological Sci. Dept., Vassar Col., Bethesda, NY

Abstract: Studies of localized brain damage provide powerful evidence for the causal link between neural structure and cognitive function. Despite decades of research on memory function following experimentally induced lesions of medial temporal lobe structures, the role of the hippocampus in recognition memory remains disputed, particularly with nonhuman primate subjects. We aim to resolve this dispute by analyzing both individual and aggregate data collected from 14 publications that assess visual item recognition in nonhuman primates with and without selective neurotoxic lesions of the hippocampus. Subgroup and cumulative meta-analyses indicated the overall distributions of recognition performance scores for subjects with and without hippocampal lesions overlap by approximately 74 percent (Hedges' g = -0.66). Paradoxically, a meta-regression that investigated the relation between lesion extent and effect size indicated that more damage to the hippocampus significantly predicted better memory on visual item recognition tasks. Additionally, the impact of methodological differences on effect-size estimates is assessed. We conclude that hippocampal integrity, alone, is not necessary for visual item recognition in nonhuman primates.

Title: Defective memory engram allocation in Down syndrome

Authors: Á. FERNÁNDEZ-BLANCO[1], A. ZAMORA-MORATALLA[1], C. GONZÁLEZ-ARIAS[2], G. PEREA[2], M. DIERSSEN[1];
[1]Systems Biol., Ctr. for Genomic Regulation, Barcelona, Spain; [2]Functional and Systems Neurobio., Inst. Cajal, Madrid, Spain

Abstract: Cognitive dysfunction in Down syndrome (DS) has an extremely heterogeneous and complex pathophysiology, not yet understood. Technological and conceptual breakthroughs in neuroscience have made possible to visualize and manipulate the neural correlates of memory, leading to the concept of memory engrams. Neuronal and synaptic signaling alterations in DS mouse models, suggest DS as a model of inherently defective engrams. We have investigated engram-specific alterations using engram tagging techniques and chemogenetic intervention in Ts65Dn, a validated DS mouse model. Using immunostaining and recombinant AVV-TRE-tight-

hM3Dq-mCherry, we detected sparser neuronal activation in Ts65Dn 3 month old male mice both after learning and after recall, as shown by the reduced number of cells expressing *c-Fos* and *Arc* immediate early genes in the dentate gyrus. Engram reactivation using chemogenetic intervention with clozapine N-oxide (CNO) did not recover Ts65Dn memory deficits. This would indicate that the trisomic engram is not properly formed, thus preventing the memory to be completely recalled in the future. We conclude that neuronal allocation to an engram is a possible mechanism of engram pathology in DS that would underlie memory deficits.

Title: Environmental enrichment improves memory and synaptic plasticity in cognitively impaired animals due to chronic exposure to a high-fructose and high-fat diet.

Authors: *E. GUTIERREZ-LOPEZ[1], F. BERMUDEZ-RATTONI[1], K. GUZMAN-RAMOS[2]; [1]Dept. de Neurociencias, Inst. De Fisiologia Celular, UNAM, Mexico City, Mexico; [2]Dept. de Ciencias de la Salud, UAM Lerma, Lerma de Villada, Mexico

Abstract: Metabolic deregulations like the excessive accumulation of body fat, hyperglycemia, and overweight are considered risk factors for the development of cognitive and neuronal plasticity impairments. The mechanisms underlying these declines are unknown. However, several studies indicate that chronic exposure to high-calorie diets affects neuronal plasticity and reduces the catecholaminergic levels in hippocampus, these neurotransmitters act as neuromodulators for the formation of declarative memory and plastic changes that underly memory trace formation and maintenance. Increasing catecholaminergic levels with an intra-hippocampal microinjection of nomifensine in rats that were chronically exposed to high-calorie diets recovers memory and synaptic plasticity, showing that the restoration of dopaminergic activity reverse the deterioration of recognition memory and long-term plasticity. However, it is not known whether implementing a non-pharmacological treatment that increases the amount of catecholamines in hippocampus, such as environmental enrichment, could reverse the negative effects of chronic consumption of these diets on synaptic plasticity and memory. To test this hypothesis, a group of male mice were exposed to a high-fructose and high-fat diet for 6 months

and compared to control group of male mice exposed to standard diet during the same period. Behavior was evaluated by object location memory task and neuronal plasticity was evaluated by long-term potentiation in the perforant pathway to dentate gyrus synapsed. The high-fructose and high-fat diet caused an increase in adiposity and glucose intolerance, constituting a model of metabolic deregulation. The behavioral results indicate an impairment of the spatial memory and long-term potentiation shows a deficiency in the synaptic strength in mice with the aforementioned diet. In addition, concomitant 6-month enrichment environment consisting of frequent replacement of a variety of toys in of different sizes, colors, shapes and textures within the home-cage of mice with high-fructose and high-fat diet produced an increase in synaptic strength similar to controls. Likewise, mice with metabolic deregulations exposed to environmental enrichment behaved similarly to controls in spatial recognition memory tests. These results show that the enriched environment can prevent the deterioration of recognition memory and long-term plasticity. These results will help to lay the foundations for the understanding of protective factors and treatment approaches for the deterioration of memory associated with chronic consumption of hypercaloric diets.

Title: Physiological and optogenetic assessment of the role of engram ensembles in spatial working memory in mouse dentate gyrus

Authors: *L. K. WILMERDING[1], I. KONDRATYEV[2], S. RAMIREZ[2], M. E. HASSELMO[3]; [1]Boston Univ. Grad. Program For Neurosci., Boston, MA; [3]Psychological and Brain Sci., [2]Boston Univ., Boston, MA

Abstract: The hippocampus has been studied extensively for its role in navigation and episodic memory. To analyze the nature of specific episodic experiences and their role in memory-guided navigation behavior, we examined ensembles of co-active cells, 'engrams', in mouse Dentate Gyrus (DG). The DG has been shown to encode engrams of emotionally valenced experiences and is necessary for spatial working memory tasks such as the Delayed-Non-Match-to-Place (DNMP) task. Male and female wild type mice were trained to perform the DNMP task on a T-maze for water reward. Using the fos tet-tag activity-dependent labeling system, DG engram ensembles were tagged with eGFP as mice explored a novel T-maze context. In one experiment, animals were re-exposed the following day to the same maze context, a subsection of that maze, or a novel open field context. Immunohistochemical staining for the colocalization of eGFP and c-Fos revealed the degree of overlap between the initial DG spatial engram and the ensemble representation during subsequent exposure to the different maze contexts. In a second experiment, DG granule cells active on a single route of the T-maze were tagged with the excitatory opsin and fluorescent label, ChR2-eGFP. Over 5 days of re-exposure to the full DNMP T-maze context, 20Hz pulsatile optogenetic stimulation was delivered bilaterally to DG during different sample phases of the task. Within-subjects analysis of trial accuracy, speed, and choice point occupancy were used to assess the behavioral outcomes of artificial spatial engram reactivation during ongoing navigation. These results extend previous findings on the role of the DG in spatial working memory tasks and the nature of episodic spatial experience used in subsequent neural representations and memory-guided decision making for navigation.

Title: Decoding the neuronal basis of paired-associate learning strategies in mice

Authors: *Z. HAQQEE[1], E. WILSON[2], S. WILLIAMS[3], M. P. BRANDON[3];
[1]Integrated Program in Neurosci., [3]Psychiatry, [2]McGill Univ., Montreal, QC, Canada

Abstract: Standardized behavioural tests offer a means to reliably translate experiments across laboratories, animal models, and even to clinical human populations. Touchscreen operant conditioning chambers are specifically designed with these advantages in mind. One behavioural test designed to isolate spatial memory processes uses an object location memory task in a touchscreen-automated operant conditioning chamber. This object-location paired-associate learning (PAL) task tests location-dependent associative memory performance in mice using touchscreen-automated operant conditioning chambers. The task is sensitive to hippocampal manipulations, with post-, but not pre-acquisition lesions to the hippocampus causing significant impairment in subsequent performance in mice. Here, we explore behavioural and neurophysiological changes as mice learn and perform the PAL task using miniaturized microscopes and one-photon calcium imaging of the hippocampus. We observe that mice developed increasingly stereotyped trajectories to solve the PAL task across time, which coincided with increasingly robust task-dependent calcium activity and spatial tuning in the hippocampus. In well trained mice, spatial tuning was conjunctive for trial-type-specific behavioral performance. Interestingly, task-tuned neural activity became more predictive of behaviour over multiple timescales, both within a recording session and across days. These data suggest that the hippocampus forms a gradual representation of object-location associations that reflect a stereotyped learning strategy.

Title: Population dynamics of spatial reorientation in the thalamic head direction system

Authors: *Z. AJABI[1], A. T. KEINATH[1], X. WEI[3], M. P. BRANDON[2];
[2]Psychiatry, [1]McGill Univ., Montreal, QC, Canada; [3]Univ. of Texas at Austin, Austin, TX

Abstract: The mammalian head direction (HD) system is commonly referred to as a neural compass. However, contrary to a mechanical compass, the HD system does not have a universal across-environment reference frame. Instead, the internal HD representation is anchored to local environmental cues such that a rotation of these cues causes a similar rotation of the whole

network. Here, we study the population dynamics that underlie how the head direction system is anchored to visual sensory information. We recorded up to 239 HD neurons, simultaneously, using a head-mounted miniaturized microscope, in unrestrained mice. We designed experiments that alternated between light and dark conditions, while a single visual cue was shifted from one location to another. These experiments caused rapid rotations of the HD network (resets) in order to realign with the changing direction of the cue. We defined a 'network gain' that reflected the neural population activity and found that modulation of this quantity was highly correlated with reset behavior (i.e. speed and range). On the other hand, darkness periods were associated with slower, yet, predictable drifts of the internal HD representation which seemed to revert to its baseline configuration, even after cue manipulation. This phenomenon was accompanied by a remarkable change in the network gain landscape, showing peaks of activity at the internal location not only of the immediately preceding cue but also those further in the past. These patterns highly depended on the duration of cue exposure and so, may indicate the involvement of synaptic plasticity in maintaining neural traces of salient environmental cues. This internal alternation between the visual reference frame, in light conditions, and baseline reference frame, during darkness, was also confirmed with a continuously rotating visual cue. Notably, this manipulation caused persistent drift biases, in darkness, matching the direction and speed of cue rotation, which shows the important role of the optic flow in calibrating the integration of vestibular information in the head direction system.

Title: Neural correlates of environmental alterations in retrosplenial cortex and high-resolution infrared tracking of behavior

Authors: *L. C. CARSTENSEN[1], A. S. ALEXANDER[1], G. W. CHAPMAN, IV[2], A. J. LEE[1], M. PATEL[1], Y. GU[1], M. JALAL[1], M. BETKE[1], M. E. HASSELMO[2];

Abstract: Flexible and efficient spatial navigation through the external world and the ability to adapt to changing environments is important for many complex behaviors. The retrosplenial cortex (RSC) is an association area that is interconnected with numerous regions of the brain important for spatial memory and navigation, including the hippocampal formation (HPC), rhinal cortices, and anterior thalamic nuclei. Neurons in these regions are known to display diverse spatial correlates, such as encoding the past or present location of objects, proximity to objects or boundaries, and position in the observable environment. Additionally, studies in both rodents and humans have shown that RSC is important for spatial memory, such as tracking distance from a location or landmark, contextual information about a known environment, orientation within an environment, and knowledge of distances between objects. These reasons and the connectivity of RSC show the importance of determining precisely how RSC neurons represent available cues such as objects or boundaries and their relationships within the local environment. In the current work, we performed in vivo electrophysiological recordings in RSC while rats free foraged in arenas that could contain an object or in which the local environment was altered. Building upon previous work, we report that RSC neurons display systematic changes in mean firing rate responding to alterations of the environment. These alterations include the boundaries of the arena rotating, changing size or shape, or an object being introduced into the arena. These results distinguish RSC as a region important in orientation and mapping features of spatial environments. Separate from our neural recordings in RSC, we analyzed high-resolution infrared behavioral tracking data of head and body orientation and position to better understand the relationship between elements of behavioral pose including head direction, body direction, movement direction and speed of the animal. This will allow for more in-depth analyses of the neural correlates of behavioral pose, movement, and directional relationships in future studies of animal behavior.

Title: Laminar and projection-specific calcium imaging of spatial memory related retrosplenial cortex dynamics in freely moving rats

Authors: *A. S. ALEXANDER, B. B. SCOTT, M. E. HASSELMO;
Ctr. for Systems Neuroscience; Dept. of Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Retrosplenial cortex (RSC) neurons encode a variety of spatial variables in allocentric, route-centric, and egocentric coordinate systems (Alexander et al., 2015; 2017; 2020). Lesions or inactivation of the area indicate that it is important for navigation and mnemonic processing. RSC activation supporting these processes in freely moving rats has primarily been characterized using in vivo electrophysiology. One-photon calcium imaging in behaving animals allows observation of larger populations of simultaneously recorded neurons. In retrosplenial cortex, imaging large populations affords an examination of interactions amongst neurons with activity anchored in distinct spatial coordinate systems which could reveal critical processing modes for the construction and use of internal maps for navigation and memory. In the current work, we utilized in vivo one-photon calcium imaging in Thy1-GCaMP6f transgenic rats to characterize population dynamics of hundreds of retrosplenial cortex neurons while animals learned and performed multiple tasks requiring spatial memory. We gained optical access to RSC ensembles by using microprism lenses which enabled a comparison of activation between deep and superficial layers of the region during behavior. Finally, retrograde-mediated transduction of GCaMP7 was used to investigate differences and similarities in task-related calcium signals between RSC neurons that project to the anterior thalamic nuclei or the extended hippocampal formation.

Title: Dissociating object versus spatial pattern separation: frombehavior to neuronal activation

Authors: *M. OULÉ[1,2], C. P. KRAMAR[1,2], A. T. KEINATH[1,2], L. M. SAKSIDA[3], T. J. BUSSEY[3], M. P. BRANDON[1,2];

Abstract: The large number of mature granule cells and the presence of neurogenesis in the dentate gyrus (DG) have led to the hypothesis that this region is especially sensitive to small changes in input, making it particularly important when encoding highly similar stimuli, a processed named 'pattern separation'. The entorhinal cortex (EC) is the main source of cortical inputs to the DG: while its medial segment (MEC) preferentially forwards spatial information, its lateral part (LEC) rather sends object-related information. The contribution of mature and immature granule cells to spatial versus object pattern separation remains less clear. While recent work has made important progress to understand the network-level computation that underlies spatial pattern separation in the DG, very little is known about the physiology and contribution of each type of granule cell to support object pattern separation. To address this question, we established a new task that specifically assesses object pattern separation and evaluate the role of immature granule cells in this task. Using c-fos immunofluorescence labeling of activated neurons, we studied the activation of different brain regions in the object pattern separation compared to well-established spatial pattern separation tasks. We further seek to use the UCLA miniscope to study – before and after ablation of immature granule cells – how the DG differentially processes object versus spatial pattern separation.

Title: The Hippocampal Representation of Space is Modulated by the Availability of Visual Information

Authors: *D. J. SHEEHAN[1], B. A. FORDYCE[2], A. S. ALEXANDER[3], M. E. HASSELMO[4]; [1]Boston Univ. CILSE, Boston, MA; [2]MGH, Boston, MA; [4]Psychological and Brain Sci., [3]Boston Univ., Boston, MA

Abstract: Abstract: In mammalian species the hippocampus and associated regions have been demonstrated to be critical and necessary for many forms of complex navigation, especially memory guided wayfinding. Hippocampal place cells are believed to be a component of the neural substrate onto which ongoing active experience can be mapped. While many path-integration based theories of navigation focus on the internalized drive in creation of place fields, manipulations regarding the external state of the environment have often resulted in alterations of place cell coding. Further, spatially receptive fields have been shown to be sensitive to various reference frames, which can be externally or internally anchored. In this study here we employ a linear track task with tetrode recording of the spiking activity of principal cells of the dorsal CA1 region of the rat hippocampus. Recordings were performed during outward and inward runs in epochs with or without visual information being present. We show here that the hippocampus is sensitive to environmental lighting manipulations that do not signal a change in task structure or behavioral demands, indicating that hippocampal representations of space are modulated by availability of visual stimuli and optic flow.

Title: Examining the role of medial septal cell types in entorhinal grid cell generation

Authors: *J. C. ROBINSON[1], M. P. BRANDON[2], M. E. HASSELMO[1]; [1]Psychological and Brain Sci., Boston Univ., Boston, MA; [2]Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: The medial entorhinal cortex (MEC) is a cortical region critical for spatial navigation and memory processing. The MEC contains several cell types which together represent different spatial aspects of the current environment; these neurons include 1) grid cells which fire at distinct locations that form a repeating hexagonal pattern, 2) boundary vector cells which fire when close to the boundaries of the spatial field, and 3) head direction cells which fire in relation to the animal's head orientation. Input from the medial septum (MS) is essential for MEC function. Inactivation of the entire MS results in the complete abolition of grid cell spatial firing. The MS is made up of three distinct populations: cholinergic, GABAergic and glutamatergic neurons. Here we have evaluated the role of MS GABAergic and glutamatergic neurons in grid cell generation. We have specifically targeted either GABAergic or glutamatergic neurons in the MS using optogenetic activation of Archaerhodopsin to selectively silence each cell type while recording grid cells in the MEC. For both groups, an optic fiber was placed above the MS for light delivery, and a four-tetrode microdrive was implanted into the MEC for grid cell recordings. Our results show that silencing septal glutamatergic neurons did not affect MEC theta power nor frequency; however, silencing of this population resulted in a distortion and an overall broadening of individual grid fields. Next, we found that optogenetic silencing of septal GABAergic neurons resulted in up to a 60% reduction in MEC theta power. We used two stimulation protocols: 30 second inactivation followed by a 30 second recovery period as well as a 30 second inactivation period followed by a 60 second recovery period. Grid cell spatial firing was disrupted during both the 30 second laser on and 30 second laser off period. However, with a longer recovery period between inactivations (60 seconds), grid cell spatial firing was mostly maintained with only subtle spatial distortions to the grid pattern. Preliminary results suggest that the extent of the distortion to the grid cells may be related to degree of spatial periodicity during baseline recordings. Cells with a higher gridness score may be more resilient to septal GABAergic inactivation. These results reveal an important role of MS GABAergic neurons in grid cell spatial firing, while MS glutamatergic neurons appear to play a more subtle role in modulating the grid cell spatial pattern.

Title: The long-term dynamics of the CA1 spatial code preserve the relative structure of contextual representation

Authors: *A. T. KEINATH, C.-A. MOSSER, M. P. BRANDON;
McGill Univ., Verdun, QC, Canada

Abstract: The hippocampal formation is thought to mediate episodic memory through the instantiation and reinstatement of context-specific cognitive maps. However, recent longitudinal experiments have challenged this view. These studies find that the majority of hippocampal cells change their tuning properties over a timescale of days even in the same environment, yielding maps of the same context that are as different across time as maps of different context when assessed by various population-level measures. Despite these population-level dynamics, a minority of cells can maintain their tuning properties across a months-long timescale, at least under some circumstances. Often referred to as *drift*, these dynamics raise a variety of questions about the representational capacity and content of the hippocampal code. One critical question is whether and how these dynamics impact the contextual code. On one hand, such dynamics might lead to a reorganization of the contextual representation, whereby the representation of each context drifts independently of other contextual representations. On the other hand, if drift is coordinated across contexts then such dynamics might instead preserve the relative structure of contextual representation, allowing consistent readout of contextual information across long timescales. To adjudicate between these possibilities, we imaged large CA1 populations over more than a month of daily experience as freely behaving mice explored six differently-shaped environments in an extended geometric morph paradigm. This paradigm elicited partially-correlated population-level maps, allowing us to characterize the evolution of the relative representational structure over long timescales. We found that individual cells represent context to varying degrees through heterogenous but stereotyped changes to their spatial tuning properties, leading to an attractor-like population response which develops over the course of extended experience. Characterizing the full representational structure revealed that long-timescale changes in population activity occurred orthogonally to the representation of context in network space. Thus, despite continued representational changes over the course of the experiment, the relative representational structure of context was preserved, allowing for consistent readout of contextual information across weeks. Together, these results demonstrate that long-timescale changes to the CA1 spatial code preserve the relative structure of contextual representation, a result which holds multiple fundamental theoretical implications.

Title: Spatial coding of topologically deformed environments in CA1 across protracted experience

Authors: *J. Q. LEE[1], A. T. KEINATH[1], E. CIANFARANO[2], M. P. BRANDON[2];
[2]Psychiatry, [1]McGill Univ., Montreal, QC, Canada

Abstract: Recent modelling and empirical studies present multiple alternative views on the spatial encoding of environments in the hippocampus. While classic models on hippocampal mapping suggest a euclidean spatial metric determines place cell firing, others suggest a non-euclidean embedding, or that the hippocampus encodes predictive topological relationships. Adjudicating between these models requires a rich dataset capable of quantitatively assessing the unique and often nuanced predictions distinguishing each model. To this end, we performed a series of systematic topological deformations of a familiar space over a month-long period in freely-behaving animals while recording large neuronal populations in mouse CA1 with miniscope calcium imaging. Next, we leverage these data to quantitatively assess euclidean, non-euclidean, and predictive models of hippocampal mapping via representational similarity analysis (RSA) - an approach that allows for systematic characterization and comparison of data and models alike. Our results characterize the hippocampal representation of environmental connectivity with a new level of precision, and will serve as a benchmark by which to judge existing and future models of hippocampal mapping.

Title: Hippocampal neurons encode behavioral space

Authors: *M. YAGHOUBI[1,2], C. MOSSER[2], A. NIETO[2], T. GISIGER[2], E. WILSON[2], S. WILLIAMS[2], M. P. BRANDON[2];
[1]Integrated Program in Neurosci. (IPN), McGill Univ., Montreal, QC, Canada; [2]Dept. of Psychiatry, McGill University, Douglas Hosp. Res. Ctr., Montreal, QC, Canada

Abstract: The cognitive map theory of hippocampal function has largely focused on mapping the allocentric spatial dimensions of the external world [1]. More recent evidence points to a broader role of the hippocampus in forming maps for other non-spatial aspects of the environment [2,3]. Beyond encoding allocentric space or external salient features, we ask if the hippocampus encodes an animal's behavioral repertoire after they become an expert in solving a difficult-to-learn delayed non-match to location task. We specifically explore whether the hippocampus preferentially encodes behavioral sequences used to solve the task (behavioral space) over allocentric space. We recorded the activity of up to one thousand individual hippocampal neurons as well-trained mice perform the Trial-Unique Nonmatch to Location (TUNL) touchscreen task [4]. Here, a white square is presented in one of five positions on the touchscreen. A nose poke to this square makes it disappear and starts a delay period (increasing from 2 to 8s as the mice learn the task). Following the delay, two white squares are displayed, and the mouse must choose the nonmatching square to receive reward located on the back wall of the touchscreen chamber. In contrast to prior work that describes behavior with a few variables such as position, reaction time, etc, here we develop and apply a deep-learning-based approach that clusters and quantifies the transition statistics between sequences of egocentric body movements. This pipeline is subtle enough to reveal individual differences between mice. CA1 neurons were spatial tuned yet, our analysis show that egocentric behavioral information is strongly encoded and is better correlated with task performance than allocentric spatial information. Decoding analysis revealed that behavioral choices can be predicted from either neuronal activity or behavior many seconds before decisions are executed. While egocentric behavioral sequences could predict future choice, decoding of future choice from neural activity outperformed behavioral decoding during the sample, delay, and choice phases of the TUNL task, providing evidence for a prospective neural memory trace that is independent of mouse behavior. Together, our results suggest that, in well-trained animals, the hippocampus encodes behavioral space more reliably than allocentric space, which may function to support memory-guided behavior to solve the TUNL task. Title: Investigating emergent hippocampal dynamics through standardized high-throughput behavior and neuronal imaging using the McGill-Mouse-Miniscope platform

Authors: *C.-A. MOSSER, M. YAGHOUBI, A. NIETO-POSADAS, Z. HAQQEE, T. GISIGER, E. WILSON, S. WILLIAMS, M. P. BRANDON;
Psychiatry, McGill University, Douglas Hosp. Res. Ctr., Montréal, QC, Canada

Abstract: Recent technical advances enable the recording of large neuronal populations during behavior resulting in increasingly complex datasets. Despite bold and important open-science and data-sharing policies, these datasets across laboratories tend to apply unique data acquisition methods, behavior, and file structures. Discrepancies between protocols present key challenges including the comparison of results between brain regions, laboratories, and species. We have established the McGill-Mouse-Miniscope platform (M3, www.m3platform.org) to combine miniscope calcium imaging with standardized touchscreen-based behavioral testing. Our mission is to curate an open-source and standardized framework for acquiring, analyzing, and accessing high-quality data of the neuronal dynamics that underly behavior and cognition throughout the brain in mice, and in a near future marmosets. Each experiment provides up to 1000 simultaneously recorded neurons from a single brain region over the course of ~3 months as animals initially learn and master the task. We have collected several datasets to highlight the feasibility of this approach, including hippocampal CA1 and CA3 recordings during the delayed trial-unique nonmatching-to-location (TUNL) task. In this task, a white square is presented in one of five positions on the touchscreen. A nose poke to this square starts a delay period. Following this delay, two white squares are displayed, and the mouse must choose the nonmatching square to receive reward. As expected, CA1 and CA3 neurons are spatially modulated, however, they are also sensitive to other behavioral and task-related features. We found that 1) ~10% of neurons participate in sequences tiling the delay period, 2) delay sequences are unique to the sample square location, 3) the fidelity of sequence predict performance, and 4) delay sequence cells were reliably activated during reward. We are now examining how this structure emerges in CA1 and CA3 regions during the initial learning of this task, and how network activity restructures when memory load is changed. These data will help to shed light on how large populations of hippocampal neurons encode a complex memory task, and will allow for comparison across laboratories, mouse models, and species.

Title: Optogenetic inactivation of septal GABAergic neurons causes remapping in time cells with no deficits in behavior.

Authors: *H. YONG[1], H. CHANG[3], M. P. BRANDON[2];
[1]Integrated Program in Neurosci., McGill Univ., Verdun, QC, Canada; [2]Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Neurons in the hippocampus are sequentially activated during the delay period of a delayed spatial alternation task. This sequential readout is dependent on an intact medial septum and is hypothesized to require theta oscillations and to support behavioral performance. However, these conclusions are based on work that used a long-acting GABA receptor agonist to inhibit the activity of all medial septum neurons for the entire testing session, raising the possibilities that 1) septal contributions other than theta generation may support delay encoding, and 2) that memory deficits could be the result of septal inactivation outside of the delay period. To confront these possibilities, we applied an optogenetic strategy to selectively silence the theta-generating GABAergic population in the medial septum (MS) specifically during the delay period as mice performed the delayed spatial alternation task. Mice were trained to run on a treadmill for 10 seconds between each alternation lap on the T-maze. Septal GABAergic neurons were pseudo-randomly inhibited in 50% of the trials, for the entire 10 second duration of the delay period. We show that inhibition of these neurons significantly reduced the amplitude of hippocampal theta oscillation (mean theta reduction: 60%), and induced remapping in many of hippocampal neurons that encoded the delay period. Moreover, the decoding accuracy for trial identity significantly decreased with the inactivation. Thus, we observed a new delay sequence only on trials when the septal GABAergic input to the hippocampus was suppressed. These phenomena were not observed in laser-on GFP-only expressing control experiments. This result suggests the possibility that region CA1 of the hippocampus receives competing delay sequences from CA3 and the medial entorhinal cortex (MEC), both of which are known to contain delay

cells. We suggest the possibility that MS inactivation disrupts the MEC delay sequence (similar to the effect of MS inactivation on MEC grid cells), which then gives the CA3 input more influence over CA1 sequences. To our surprise, remapping of the delay sequence had no impact on behavioral performance on the T-maze delayed alternation task. Inhibition of MS GABAergic neurons outside of the delay period did not induce memory deficits either. This suggest several possibilities including 1) the identity of the sequence is not critical for performance, and/or 2) choice information is still preserved in the remapped sequence. We are exploring these possibilities.

Title: Three activity states of hippocampal principal neurons: the silent, primed and engaged

Authors: *X. CHEN, Y. ZHOU;
Univ. of New Hampshire, Durham, NH

Abstract: Memory-eligible neurons (or primed neurons) are a subset of sparsely distributed neurons in memory-related regions that can sustain long-term synaptic modifications to hold memories. Memory-eligible neurons “activation” during memory acquisition and “re-activation” during memory retrieval are widely thought to mediate memory formation and retrieval, respectively. Hence, memory-eligible neurons, like neurons mediating innate physiological function, are widely perceived to have two activity states: the silent and active. Here we show that hippocampal principal neurons exhibit at least three distinct activity states during trace fear conditioning. They are termed the silent, primed, and engaged states, as distinguished by their basal activity levels, activity plasticity, calcium entry, burst synchronization, and importantly, memory-engaging status. During the period when a small portion of primed neurons fulfill learning and mnemonic duties by transitioning back and forth between the primed and engaged states, most hippocampal CA1 principal neurons have very weak activity and stay in the silent state. Memory-eligible neurons in the primed state are sensitized with high excitability and exhibit irregular activity prior to training, in which they are primed to modify activity pattern

(and likely synaptic efficacy). Memory-eligible neurons in the engaged state are synergistically committed to encoding memory information and display burst synchronization and robust calcium entry. We have developed a computational method based on *in vivo* calcium imaging data in freely behaving mice to numerically define primed neurons. In the healthy brain, memory-eligible neurons can readily transition from the primed to the engaged state, and vice versa. Nevertheless, the transition kinetics between the silent and the primed states are much slower, likely because the primed-silent hierarchy among hippocampal neurons is well-maintained within a certain period. We propose that hippocampal memories are formed, not simply due to memory-eligible neurons "activation" directly from the silent state, rather because primed neurons with random dynamics are induced to form burst synchronization. That is a transition process from the primed to engaged state. Likewise, hippocampal memories are retrieved, not because of memory-eligible neurons "re-activation" from the silent state, rather because the same subset of primed neurons successfully transitions to the engaged state.

Title: Investigation of the effect of age and remapping status on the number of cell assemblies in hippocampus CA1 pyramidal cells

Authors: S. Y. CAMPBELL[1], J. ESEONU[1], K. ALI[1,2], L. A. SCHIMANSKI[3], C. A. BARNES[4,5], S. L. COWEN[6,4], *M. TATSUNO[1];

Abstract: Normally aged rats express a reduced capacity to consolidate and recall episodic memories. Furthermore, hippocampal place fields in aged rats can undergo "spontaneous remapping," a phenomenon in which spatial representations reconfigure when animals are re-

exposed to a familiar environment. The neuronal mechanisms underlying age-associated deficits in memory consolidation and increased spontaneous remapping are not well understood. Cell assemblies, defined as anatomically and/or functionally connected groups of neurons that exhibit a temporal pattern of activity, are thought to represent mental and perceptual entities. We therefore hypothesize that age-associated memory decline and spontaneous remapping in aged rats are related to a reduction in the number of cell assemblies. We tested the hypothesis on single-unit recordings that were acquired from CA1 pyramidal cells in five young and six old rats while they learned a place-dependent eyeblink conditioning task (Schimanski et al., 2013). The number of cell assemblies was estimated by a recently proposed method (Russo and Durstewitz, 2017), which allows systematic detection of cell assemblies across a range of temporal bin sizes (3 ms to 100 ms). A preliminary analysis indicated that there may be more cell assemblies in young versus old rats and in non-remapping versus remapping rats; however, these results were obtained without separating behavior epochs from sleep epochs and remain to be validated. It also appeared that cell assemblies were most abundant during the first few days of eyeblink conditioning training, suggesting that we may find an effect of learning on the number of identified assemblies.

Title: A test of the hypothesis that factors acting to protect synapse function are at the core of the biological basis of cognitive reserve

Authors: *D. T. GRAY[1], L. DO[2], S. O. KHATTAB[1], I. SINAKEVITCH[1], T. P. TROUARD[2], C. A. BARNES[1,3];

[1]Evelyn F. McKnight Brain Inst., [2]Biomed. Engin., [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: One hallmark of normative brain aging is the vast heterogeneity in whether older people succumb to or are able to resist age-associated cognitive decline. Such variability among people may arise in part as a result of some brain property that enables neuronal networks to maintain cognitive performance in the face of accumulated insults that could compromise brain function. This is known as cognitive reserve. For a brain property to be considered cognitive reserve, it must moderate the relationship between brain functions that change with advanced age and cognition. We assess the degree to which synapse health minimizes the cognitive burden of age-associated structural changes in grey and white matter utilizing legacy brain tissue from a large experiment designed to study the molecular mechanisms of cognitive aptitude in male F344 rats across the lifespan, including young (6-8 mo), middle-aged (15-17 mo), and old (23-25 mo) rats. All rats underwent a series of structural and diffusion-weighted MRI scans. Rats were categorized as average-, low-, or high-performing for their age group through a large battery of cognitive assessments of both medial temporal lobe and frontal cortical brain function. Histological hippocampal sections were prepared and labelled to identify two distinct proteins critical for synapse function: immediate-early gene neuronal pentraxin 2 (NPTX2) and markers for a specialized extracellular matrix structure called perineuronal nets (PNNs). In the MRI data we have uncovered several brain measures that change with advanced age but are not associated with the cognitive status of the rats: diffusion weighted MR analysis of fractional anisotropy, apparent diffusion coefficient, axial diffusivity, and radial diffusivity as scalar parameters. Whole brain and white-matter masked estimates of all these scalar parameters were different in the aged rats compared to the middle-aged and young rats, yet none showed an association with the cognitive status of rats within an age group. We present the results of a multiple regression model designed to assess the degree to which the expression of markers of synapse function moderates the relationship between these structural brain measures in the MRI and cognition. If synapse health is central to cognitive reserve, the expression of proteins associated with synapse function will be highest in the high cognitive functioning rats in all 3 age groups. This may indicate that synapse integrity at all points of the lifespan helps define the trajectory that an individual's cognitive function will take as age-associated changes in brain structure and function begin to accumulate.

Title: Aged rats display more accurate allothetic cue-based goal navigation in response to sudden changes in environmental cues

Authors: *A. W. LESTER[1], G. A. JORDAN[1], Z. P. PHILPOT[1], C. A. BARNES[1,2];
[1]Evelyn F. McKnight Brain Inst., [2]Departments of Psychology, Neurology, and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: As with older adults, aged rats show pronounced impairments on a number of different spatial navigation tasks as well as a bias toward relying on self-motion (i.e., idiothetic) over environmental (i.e., allothetic) cue-based navigation strategies (Lester et al., 2017). The Instantaneous Cue Rotation (ICR) task used here requires animals to navigate to a reward location that is always aligned to the projected visual cues in the environment (Lester et al., 2018). By instantaneously rotating the cues we are able to put allothetic and idiothetic feedback in direct and immediate conflict and characterize how quickly and accurately young and aged animals utilize environmental cues to navigate to a new rotated goal location. Behavioral data from 10 young and 10 aged rats suggest that both old and young rats were able to utilize allothetic cues to navigate to a cue aligned goal, even when cues were suddenly rotated during ongoing behavior. Results from the young rat cohort indicated that, while the behavior of these animals was reliably influenced by allothetic cue rotation, they also showed a tendency to overshoot the goal, even during baseline trials (i.e., before cues were rotated). Additionally, following cue rotation, young rats tended to slightly under-rotate relative to the cues. That is, when cues were rotated backward or forward, young rats tended to stop at a position that was just past or ahead, respectively, of where they tended to stop prior to the cues being rotated. The behavior of the aged rats, in contrast, was more accurate on average and showed more complete control by the cues. Comparisons of the velocity profiles during periods surrounding cue rotation from the two age groups indicate that aged rats tended to show a greater decrease in running speed immediately following cue rotation and that the degree to which animals from either age cohort decelerated following cue rotation was predictive of their subsequent goal navigation accuracy. Taken together, these findings suggest that aged rats may actually demonstrate more accurate allothetic cue-based goal navigation, possibly because they are more attentive to changes in the environmental cues.

Title: Aged rats exhibit a reduced hippocampal gamma frequency response to changes in running speed, altered spatial information in place fields, and increased spike-field coherence

Authors: *L. M. CROWN[1], D. T. GRAY[1], L. A. SCHIMANSKI[4,1], C. A. BARNES[1,2], S. L. COWEN[3,1];
[1]Evelyn F. McKnight Brain Inst., [2]Departments of Psychology, Neurology, and Neurosci., [3]Dept. of Psychology, Univ. of Arizona, Tucson, AZ; [4]Psychology, Capilano Univ., North Vancouver, BC, Canada

Abstract: Hippocampal gamma (30-120 Hz) and theta (5-10 Hz) oscillations are associated with mnemonic and navigational processes. An important property of these oscillations is that they adapt to changes in an animal's behavioral state to optimize the processing of spatial information. For example, it has been shown that gamma and theta frequencies increase with increasing running speed. Whether the dynamic scaling of gamma frequencies with behavior is altered with age has not yet been investigated. In this study, we examined local-field and place cell activity in the hippocampus CA1 region of five old and six young rats as they performed a spatial eye-blink conditioning task across 31 days. We found that while mean gamma frequency was not different between age groups, the slope of the increase in gamma frequency with increasing running speed was shallower in old rats. By contrast, theta frequencies scaled with running speed similarly in young and aged rats, although overall theta was shifted to lower frequencies in aged rats. We also found that place cells in aged animals have reduced spatial information content per field accompanied by reduced within-field, but not out-of-field, firing rates. Controlling for reduced firing rates, we found that spatial information per spike was significantly greater in older rats. Finally, we observed that spike phase-locking to gamma, but not theta, was greater in older animals. Together, these results highlight the importance of accounting for locomotor activity and oscillatory dynamics when analyzing electrophysiological data as well as indicate a dissociable impact of age on theta- and gamma-generating mechanisms. Changes in the responsiveness of gamma and theta oscillations to locomotor activity could contribute to altered navigational performance in older individuals.

Title: Progesterone-induced reductions of age-related deficits in cognition and long-term potentiation in C57BL/6 male mice.

Authors: *S. BANERJEE[1], K. JENROW[1], J. ROSSIGNOL[2], R. BOSE[1,3], G. L. DUNBAR[1,4]; [1]Psychology, Neurosci. Program, Field Neurosciences Inst. Lab. for Restorative Neurol., [2]Neurosci. Program, Col. of Medicine, FNI Lab. for Restorative Neurol., Central Michigan Univ., Mount Pleasant, MI; [3]Neurosci., Karolinska Inst., Stockholm, Sweden; [4]Field Neurosciences Inst., Ascension St. Mary's Hosp., Saginaw, MI

Abstract: Progesterone functions as both a sex hormone and a neurosteroid, with proven neuroprotective effects in both male and female animals. Because serum progesterone levels decline with age in human males, we hypothesized that the exogenous administration of progesterone would reduce age-related deficits in cognition in male mice. To test this, we used groups of young (4-month-old) and aged (24-26-month-old) male C57BL/6 mice. Daily subcutaneous injections of progesterone (5 mg/kg) or equivalent volumes (200µl) of vehicle (30% 2-hydroxy beta-cyclodextrine) were administered to mice for 21 consecutive days. Cognitive functioning was assessed using a water-T-maze reversal task during the entire 21-day treatment period. Briefly, mice had to locate a hidden platform in one of two arms of the T-maze, in which the location was switched once the mouse achieved an 80% success rate in a single day. At the end of the 21-day treatment period, long-term potentiation (LTP) was assayed *in vivo* in the dentate gyrus (DG) following theta-burst stimulation of the medial perforant path. After completing the LTP assay, mice were euthanized to collect and measure serum progesterone levels and LTP-induced immediate early gene (IEG) expression in the ipsilateral and contralateral hemispheres. Results revealed that aged, vehicle-treated mice attained fewer reversals and required more days to complete each reversal than young vehicle-treated mice. LTP was also impaired in these aged mice. Progesterone improved the performance of aged mice, resulting in an increase in number of reversals attained and requiring fewer days to complete each reversal. LTP was also improved and was closer to that observed in young vehicle-treated mice. No significant changes were observed in young mice receiving progesterone treatments. Measures of serum progesterone levels and IEG expressions are ongoing and are hypothesized to correlate with the behavioral and LTP data. Our findings suggest that progesterone may be a potential therapy for age-related cognitive deficits.

Title: Global and regional and diffusion-weighted MRI analysis of rodent brains as a function of age and cognition

Authors: *L. DO[1], M. ZEMPARE[2], A. S. BERNSTEIN[1], P. K. BHARADWAJ[3], N. J. CAREY[2], C. NGUYEN[2], G. E. ALEXANDER[3,2], C. A. BARNES[2,4], T. P. TROUARD[1,2]; [1]Biomed. Engin., [2]Evelyn F. McKnight Brain Inst., [3]Dept. of Psychology, [4]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Translational studies of rodent brains have been and will continue to be crucial to characterizing the aging human brain. Magnetic Resonance Imaging (MRI) can quantitatively measure anatomy, connectivity and microstructure in both human and rodent brains and serves an important role in comparative studies of humans and rodents. Diffusion-weighted MRI (DMRI), in particular, is an established tool for the examination of white matter microstructure and connectivity and has been used to understand the effects of age and brain pathology. In the current work, adult male F344 rats were studied at three different ages: young (6mo), middle-aged (15mo) and aged (23mo). Cognitive performance of each rat was measured using a battery of behavioral tasks over the course of six weeks, including the Morris watermaze to test spatial and working memory, and the spontaneous object recognition task and a spatial location novelty and temporal ordering task. The spatial watermaze was used to categorize each animal as high, average or low cognition for its age group. DMRI of each rat was carried out at 7T and scalar metrics, including fractional anisotropy (FA), apparent diffusion coefficient (ADC), radial diffusivity (RD), and axial diffusivity (AD), were calculated. Additionally, fiber density and cross section was calculated using constrained spherical deconvolution and fixel-based analysis. ANOVA test of global DTI measures revealed a significant effect of age-group with follow-up pairwise comparisons revealing a small but significant decrease in FA, ADC, RD and AD between young and aged and middle-aged and aged, but no significant difference between young and middle-aged animals. There was no significant difference in global FA, ADC, RD and AD between any cognitive groups. Regional and voxel-based analysis is currently being carried out

and will characterize age-related changes in important learning centers of the brain and their relationship to cognitive performance.

Title: Higher microglia densities are associated with reduced perineuronal net accumulation around parvalbumin-expressing neurons in the retrosplenial cortex of memory-impaired aged macaques

Authors: *S. KHATTAB[1], D. T. GRAY[1], K. E. MCDERMOTT[1], I. SINAKEVITCH[1], R. SCHWYHART[1], W. HARTIG[3], C. A. BARNES[1,2];
[1]Evelyn F. McKnight Brain Inst., [2]Departments of Psychology, Neurology, and Neurosci., Univ. of Arizona, Tucson, AZ; [3]Univ. Leipzig, PFI, Leipzig, Germany

Abstract: Altered synaptic plasticity is thought to play a central role in age-associated cognitive decline. Microglia have been shown to regulate synaptic plasticity through a number of mechanisms including remodeling and engulfment of extracellular matrix (ECM) structures (Crapser et al., 2019; Nguyen et al., 2020). With advanced age microglia show a number of phenotypic changes suggesting that they become more active compared to microglia in younger animals (Conde & Streit, 2006; Spittau, 2017). One such change is an increase in density indicating a greater proliferation. Perineuronal nets (PNNs) are specialized ECM structures that preferentially surround parvalbumin (PV) neurons, which are thought to regulate aspects of synaptic plasticity (Sorg et al., 2016). In rodents, there is limited evidence that fewer neurons are associated with PNN structures in aged animals compared to young. We sought to investigate whether 1) similar reductions occur in the brains of aged primates, and 2) whether changes in PNNs accumulation are associated with an animal's cognitive abilities. Our goals were to further understand the contributions of PNNs and microglia densities to age-associated cognitive decline and determine whether there is a relationship between microglia densities and PNN accumulation in older brains. To these ends, we used fluorescence labeling and unbiased quantification of the

PNN markers Wisteria floribunda agglutinin (WFA) and Aggrecan (ACAN), as well as the microglial marker IBA1 on the brains from a colony of 30 rhesus macaque monkeys ranging in age from 7 to 32 years (human equivalent ~21 - 96 years). All monkeys underwent tests of spatial short-term memory, object recognition memory, and object discrimination, which allowed analyses of relationships between the density of PNNs, microglia expression and cognition. Aged animals had a lower proportion of PV cells associated with WFA+ and ACAN+ PNNs in the retrosplenial cortex (RSC) than did younger animals, although total WFA and ACAN accumulation was not different. This decrease was also correlated with impaired performance specifically on object-based memory tasks but not on spatial memory tasks. Microglia densities were higher in aged animals and were associated with poorer performance on the object-based memory tasks. Importantly, a negative relationship emerged between microglia density and the proportion of PV-containing cells associated with ACAN. These results suggest that enhanced microglial activity with age may contribute to an age-associated degradation in ECM structures that has a circuit-specific impact on cognition in aged monkeys, likely through a destabilization of synapses.

Title: Locus coeruleus neuronal, glial, and vascular populations remain stable with age in cognitively impaired rhesus macaques

Authors: *K. MCDERMOTT[1], I. SINAKEVITCH[1], D. T. GRAY[1], S. O. KHATTAB[1], W. P. PYON[4], W. I. SCHNAPP[2], C. A. BARNES[1,3];

Abstract: The Locus Coeruleus (LC) is a brainstem nucleus best known for being the primary central nervous system site of noradrenaline production and is involved in the modulation and optimization of numerous behaviors in mammals. The LC is a molecularly and anatomically

heterogeneous region that is densely innervated by blood vessels and glial cells. The LC appears to be especially vulnerable to age-related neurodegeneration and is one of the first regions to show evidence of pathological changes associated with Alzheimer's disease (Mather & Harley, 2016). It is unclear, however, whether neurodegeneration of the LC is specific to neurodegenerative diseases such as Alzheimer's, or if LC neuron loss is part of the normal aging process. Our research utilizes 30 μm coronal brainstem sections from a colony of 30 cognitively assessed rhesus macaques ranging in age from 7 to 32 years (human equivalent ~21 - 96 years). All monkeys underwent tests of spatial short-term memory (delayed response), object recognition memory (delayed nonmatching-to-sample), and object discrimination. We used immunofluorescence techniques to identify neuronal nuclei (NeuN), catecholaminergic neurons (TH), vasculature (STL), and astrocytes (GFAP). The entirety of the locus coeruleus region for each immunolabeled section was imaged bilaterally at 40X on a high-resolution confocal microscope to obtain 3-dimensional volumes of the entire rostrocaudal extent of the LC. Neuron, glial cell, and vascular densities were determined using unbiased stereological techniques. These data were then assessed with respect to the age and cognitive status of the monkeys. Preliminary results from partial LC populations from 30 animals indicate that overall TH+ density and total neuron density remain stable in the older monkeys compared to the adults. Furthermore, vascular and GFAP staining density were not different between the adult and aged animals. These data appear to indicate that cell loss, changes in vascular innervation, and increases in astrocyte reactivity do not occur in the LC region of aged macaques, and lend support to the hypothesis that LC degradation is a distinguishing trait between normative and pathological brain aging.

Title: Age-related compartment-specific volume reductions in macaque locus coeruleus: a combined MRI, Nissl and Immunofluorescence study

Authors: *I. SINAKEVITCH[1], K. E. MCDERMOTT[1], S. O. KHATTAB[1], G. A. JORDAN[1], D. T. GRAY[1], C. A. BARNES[1,2];
[1]Evelyn F. McKnight Brain Inst., [2]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: The Locus Coeruleus (LC) is a brainstem nucleus with the largest group of noradrenaline-producing neurons in the brain. Dysregulation of LC systems contributes to cognitive dysfunction in both healthy aged brains and brains that succumb to Alzheimer's disease. Notably, the LC is heterogeneous along both the rostral-caudal and dorsal-ventral axes with respect to neuron morphology, projection targets, and vulnerability to the impacts of normative brain aging and neurodegenerative disease. In particular, the rostral LC projects to cortical and hippocampal brain regions critical to cognition. In this study, we describe in detail the standardized 3D anatomy of the LC nucleus using Nissl stains, TH-immunoreactivity, and MRI data. To this end, 30 μm coronal brainstem sections were examined along the rostral-caudal axis of the LC from a colony of 30 cognitively assessed rhesus macaques ranging in age from 7 to 32 years (human equivalent ~21 - 96 years). Prior to perfusion, these animals underwent structural MRI scans. AMIRA software was employed to reconstruct the LC from the TH-immunofluorescence and Nissl stains and aligned with MRI data that was collected prior to the histological procedures. After careful analyses of the high-resolution images collected from Nissl-stained serial sections and sections immunoassayed with anti-TH antibodies, we identified three distinct subnuclei in the macaque LC: a medial nucleus that is confined to the central gray area, a lateral nucleus that lays outside of the gray area laterally and abuts the mesencephalic tract (me5), and a central region within the LC medial nucleus that is characterized by densely packed TH-expressing neuronal somas. The volumes of these three LC compartments were delineated using TH+ cell bodies and large cell bodies in Nissl stains that are characteristic of this nucleus. Preliminary data from 23 animals indicate that the macaque LC extends approximately 2000 μm along the rostro-caudal axis. We observed a core LC nucleus with high TH+ cell densities that became more scattered in more rostral brain sections. Overall volumes that comprised both lateral and medial LC nucleus varied between 1.5 and 3 mm^3. Older monkeys tended to have smaller LC medial nucleus volumes than younger individuals. For the lateral nucleus, there were no differences in volume. This analysis pipeline will allow specific sites along the rostral-caudal axis of the LC to be identified for further neuronal analyses aimed at understanding the mechanisms responsible for LC vulnerability and its impacts on cognition in normative aging and disease. Furthermore, our data indicate that aging impacts distinct compartments of the LC uniquely.

Title: MRI micro- and macro-structural biomarkers linked to nonpathological brain aging in macaques

Authors: *L. DIECKHAUS[1], ***L. DIECKHAUS**[2], K. E. MCDERMOTT[1], A. MURLIKRISHNAN[3], E. M. FOIRYOLO[3], D. T. GRAY[1], E. B. HUTCHINSON[4], C. A. BARNES[1,5];
[1]Evelyn F. McKnight Brain Inst., [3]KEYS Res. Internship, BIO5 Inst., [4]Biomed. Engin., [5]Departments of Psychology, Neurol. and Neurosci., [2]Univ. of Arizona, Tucson, AZ

Abstract: Imaging biomarkers that can distinguish normal aging processes from age-related pathology such as Alzheimer's Disease (AD) may improve clinical diagnosis and advanced microstructural MRI may provide novel markers. Because nonhuman primates provide an excellent model for studying non-pathological, or normative brain aging - i.e., they do not spontaneously develop AD - we performed high resolution *ex vivo* imaging on the perfused whole brains of 12 behaviorally characterized female bonnet macaques ranging from 10 to 25 years old (30 to 75 human equivalent years). Three different micro-structural MRI metrics were examined: fractional anisotropy (FA) from diffusion tensor imaging (DTI), myelin water fraction (MWF) from multi-echo T2 and bound pool fraction (BPF) from selective inversion recovery magnetization transfer MRI. Targeted assessment of metric values in the hippocampus and in white matter was performed by manual region of interest (ROI) analysis. Processing for DTI using the TORTOISE software package and for MWF and BPF using the REMMI MATLAB toolbox was executed on the University of Arizona's high-performance computing (HPC) clusters using MATLAB, Python, and bash scripts. High-resolution maps were calculated for each brain and manual ROI segmentation masks for the hippocampus and white matter were created manually using ITKsnap and FA, MWF and BPF metric values were extracted for these regions. Correspondence between these metrics as well as alterations associated with advanced age in the absence of overt pathology were assessed by Pearson's correlation. ROI analysis of the whole hippocampus and white matter did not reveal any statistically significant correlation with age from any of the MRI map metrics collected. A significant positive correlation (R= 0.688, p= 0.013) was observed between MWF and BPF for the hippocampus, but low correlation was observed between FA and MWF (R= 0.07, p= 0.82) and FA and BPF (R= 0.29, p= 0.36). For white matter, a significant positive correlation was observed between FA and MWF (R=0.72, p= 0.008) but low correlation was observed between FA and BPF (R= -0.14, p= 0.66) and MWF and BPF (R= 0.094, p= 0.77). This observation indicates that both MWF and BPF mapping provide information on white matter condition that is distinct from that provided by more traditional FA measures. Together, these data lay the foundation for a rigorous imaging pipeline that will provide novel foundational observations regarding multiple radiological changes that occur in nonpathological brain aging.

Title: Connectomes of organelles in developing and adult mouse brains

Authors: *S. TURBIARZ[1], G. WILDENBERG[2], H. LI[3], N. B. KASTHURI[3], A. MASELLI[1]; [1]Chicago State Univ., Chicago, IL; [2]Univ. of Chicago/Argonne Natl. Lab., Chicago, IL; [3]Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Understanding the development of organelles is important. Large volume electron microscopy (LVEM) is an excellent technique that helps to examine the development of organelles because most membranes and structures are labeled with ocimum. In LVEM data sets of adult mouse brains we observe mitochondria and the nuclear pore clusters on the nuclear membrane in close proximity to one another. The nuclear envelope plays a significant role in protecting the genetic code, as well as enabling transport of the mRNA into the cytoplasm through the nuclear pores. It has been established that the in- and outward flow of mRNA occurs through the nuclear pores, however little is known about the inward transport of the energy molecules that fuel many processes. To examine the spatial relationship between the nuclear pores and the mitochondria we annotated two LVEM data sets - one from an adult mouse and one from a P14 mouse using VAST Lite software to outline these structures. The mitochondria were found and annotated using 3D Unet parallelized on Argonne supercomputers. Approximately 1000 serial sections were annotated altogether for comparison purposes. Lastly, the distance between randomly selected nuclear pore clusters and mitochondria will be calculated using an algorithmic formula in Matlab. In comparison with the scientific data on the proximity of mitochondria to the nuclear pores and our observational data, we hypothesize that the distance is strongly related to the cluster formation of the pores in the membrane. We conclude that LVEM has excellent potential to answer whether distance plays a role in the formation of the nuclear pore clusters.

Title: Off-the-shelf Achromatic Objective Design for use with GRIN Lens

Authors: *M. D. YOUNG[1], E. A. GIBSON[3], D. RESTREPO[2];
[1]Bioengineering, [2]Cell & Dev. Biology, Neurosci. Program, Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [3]Bioengineering, Univ. of Colorado Denver, Aurora, CO

Abstract: Gradient refractive index (GRIN) lenses have found a ubiquitous use in the field of neuroscience. GRIN lenses allow optical imaging of deeper brain regions with minimal tissue damage by achieving high numerical apertures with small diameter rod lens designs (Jung & Schnitzer, 2003).
GRIN rod lenses are typically monochromatic and are susceptible to chromatic aberration and are thus more suitable for monochromatic or near-monochromatic applications such as linear fluorescence microscopy. While there are commercially available GRIN rod lenses that accomplish the achromatic correction by using a doublet refractive lens joined to a GRIN rod lens, these lenses are prohibitively expensive. In addition, GRIN lenses are implanted in an animal and it is difficult to remove and clean for continuous use.
Here, we present an objective lens that uses commercial-off-the-shelf (COTS) lenses. This objective lens is designed in conjunction with a commercially available, inexpensive GRIN singlet lens and is adjusted to compensate for the chromatic aberration of the combined image system. Achromatic performance is evaluated at two wavelengths and secondary spectrum is not optimized. Design embodiments are presented for combinations of linear (1P) and multiphoton (2P) sources, e.g., 920 nm and 488 nm. This allows imaging at 1P and 2P wavelengths without adjustment of the image plane. The collection efficiency of epifluorescent light evaluated using nonsequential ray tracing (Beaurepaire & Mertz, 2002) (Zinter & Levene, 2011) (Oheim, Beaurepaire, Chaigneau, Mertz, & Charpak, 2001).
The design is compared against the monochromatic and polychromatic performance of the GRIN lens without an objective lens and with an objective lens from Thorlabs (TL10X-2P). A bill of materials for the lens components is provided.
In addition, we consider how field correction may be added in the future to improve irradiance across the field of view.

Title: Minian an open-source miniscope analysis pipeline

Authors: *Z. DONG[1], W. MAU[1], Y. FENG[1], Z. T. PENNINGTON[1], L. CHEN[1], Y. ZAKI[1], K. RAJAN[1], T. SHUMAN[1], D. AHARONI[2], D. CAI[1];

Abstract: Miniature microscopes have gained considerable traction for *in vivo* calcium imaging in freely behaving animals. However, extracting calcium signals from raw videos is a computationally complex problem and remains a bottleneck for many researchers utilizing single-photon *in vivo* calcium imaging. Despite the existence of many powerful analysis packages designed to detect and extract calcium dynamics, most have either key parameters that are hard-coded or insufficient step-by-step guidance and validations to help the users choose the best parameters. This makes it difficult to know whether the output is reliable and meets the assumptions necessary for proper analysis. Moreover, large memory demand is often a constraint for setting up these pipelines since it limits the choice of hardware to specialized computers. Given these difficulties, there is a need for a low memory demand, user-friendly tool offering interactive visualizations of how altering parameters at each step of the analysis affects data output. Our open-source analysis pipeline, Minian (Miniscope Analysis), facilitates the transparency and accessibility of single-photon calcium imaging analysis, permitting users with little computational experience to extract the location of cells and their corresponding calcium

traces and deconvolved neural activities. Minian contains interactive visualization tools for every step of the analysis, as well as detailed documentation and tips on parameter exploration. Furthermore, Minian has relatively small memory demands and can be run on a laptop, making it available to labs that do not have access to specialized computational hardware. Minian has been validated to reliably and robustly extract calcium events across different brain regions and from different cell types. In practice, Minian provides an open-source calcium imaging analysis pipeline with user-friendly interactive visualizations to explore parameters and validate results.

Title: ezTrack: an open-source video analysis pipeline for the investigation of animal behavior

Authors: *A. R. LABANCA, T. R. FRANCISCO, S. I. LAMSIFER, K. S. DIEGO, O. LIOBIMOVA, Z. T. PENNINGTON, D. J. CAI;

Abstract: Tracking animal behavior by video is one of the most common tasks in neuroscience. Although commercial software exists for executing this task, they often present enormous costs to the researcher and can entail purchasing expensive hardware that lacks adaptability. In addition to this, tracking animal behavior often requires extensive experience working with code, making it challenging for those without a programming background. To address these issues, we created and validated ezTrack: an open-source, user-friendly pipeline that makes tracking small animal behavior easy for those with and without programming experience. ezTrack's two modules, the Location Tracking Module and Freeze Analysis Module, can be used for the positional analysis of an individual animal, amenable to a wide range of behavioral tasks, and to

analyze defensive freezing behavior respectively. For both modules, a range of interactive plots and visualizations are available to confirm that chosen parameters produce the anticipated results. Moreover, batch processing tools for rapid analysis of multiple videos are provided and frame-by-frame output makes alignment with biological recording data simple. We now present step-by-step instructions for the use of ezTrack, as well as various tips to make using the software as easy and efficient as possible. Additionally, we present updates made to ezTrack since its original publication, including a mechanism for defining regions of an arena to be excluded from analysis, a wire removal algorithm, and a downsampling feature.

Abstract: Deep-brain stimulation (DBS) can provide substantial clinical motor benefit to patients with Essential Tremor (ET), when implanted in the ventro-intermediate nucleus of the thalamus (VIM) [1]. Knowing the extent of DBS cortical effects on functional connectivity (FC) are essential for enhancing future DBS implantations, stimulation delivery, and optimization procedures. However, the cortical impacts of DBS and its potential side-effects are difficult to study using conventional neuroimaging tools such as Positron Emission Tomography (PET) due

to radiation exposure and limited temporal resolution, and functional Magnetic Resonance Imaging (fMRI) due to safety concerns from contraindications. To address these limitations, we used a previously validated High Density Diffuse Optical Tomography (HD-DOT) system with 96 sources and 92 detectors [2] to understand the neural mechanisms underlying the cortical effects of VIM DBS in ET patients. Ten ET patients (2f; ages 53-70) and 11 age-matched controls (8f; ages 52-71) were scanned using this HD-DOT device during resting state, auditory, and visual tasks. The control group underwent an fMRI scan with the same protocol. We demonstrated the feasibility and sensitivity of HD-DOT in imaging controls and ET patients with VIM DBS ON and OFF using an established data analysis pipeline [3]. Task activations and resting state networks in ET patients anatomically co-aligned with the data collected from the controls. These preliminary results validate the feasibility and resolution of HD-DOT in accurately mapping task responses and FC within the ET population (Figures 1 and 2). In the future, we aim to evaluate network connectivity differences between ET and control cohorts and between on/off conditions. **References:** [1] Gallea C, et al. *Brain,* 2015. Title: An Implantable, Mechanically Flexible Neural Interface for All-Optical Fluorescence Imaging and Optogenetic Stimulation

Authors: *E. H. POLLMANN, H. YIN, K. L. SHEPARD;
Columbia Univ., New York, NY

Abstract: Understanding the human brain is one of the greatest scientific challenges. Despite many advancements in brain-computer interfaces (BCI) during the last few decades, there is still little understanding of neuron-level connectivity in brain computations and information processing. Recently, optical techniques have gained popularity over electrophysiological techniques because of the ability to record in-vivo (using genetically encoded calcium indicators) and stimulate (using optogenetic indicators) neural activity at the single cell-level with action-potential sensitivity. However, state-of-the-art fluorescence microscopes are expensive, bulky, and stationary and do not allow for free-behaving animal studies. In the current state-of-the-art, a variety of head-mounted miniature microscopes have been demonstrated; however, the bulky lenses preclude full implantation. High selectivity for optoelectronic stimulation available through the use of, for example, spatial light modulators with free-space optics is also largely unavailable in this form factor. We have been exploring fully implantable optoelectronics devices, imagers, and light-emitting diodes, by exploiting advances in complementary metal-oxide-semiconductor (CMOS) microelectronics and heterogeneous package integration. Here, we show one such form factor, a ~150-μm-thick, mechanical flexible form-factor that can conform to the surface of the brain. The device consists of an array of 160×160 time-gated monolithic single-photon avalanche photodiodes (SPAD) detectors low-light-intensity imaging and dual color (blue and green) flip-chip bonded micro-LEDs (μLED) as light sources both for optogenetic stimulation and fluorescence excitation. For fluorescence imaging, we co-optimized a hybrid absorption/interference filter, which is deposited and packaged directly on the surface of the imager, along with the μLED arrays to reject the 470-nm blue excitation light in favor of 520-nm green emission with an optical density (OD) exceeding six. Furthermore, we leverage computational imaging techniques used to obtain large field-of-view (FoV), high-resolution images without the use of focusing lenses. The CMOS chip is die-thinned to approximately ~7.5μm to be mechanically flexible, and the chip is packaged on a flexible printed circuit board. This fully implantable camera displaces an implant volume of less than $10mm^3$ while implementing all the components of fluorescence-based neural interface device.

Abstract: In recent years, miniaturized fluorescence microscopes (miniscopes) have taken a central role in behavioral neuroscience due to their reduced size and weight. When used in conjunction with genetically encoded calcium indicators (GECIs) these head-mounted lightweight imaging devices have enabled researchers to study the dynamics of neural populations with single cell resolution in freely behaving animals. The goal of the open-source UCLA Miniscope Project is to advance the field of neural imaging in freely behaving animals through continued open-source development and dissemination of new tools and techniques. Here we present the current state of the UCLA Miniscope Project, covering a comprehensive set of open-source devices and data acquisition (DAQ) hardware/software under development and recently released. This work is aimed at democratizing access to transformative tools while also advancing, integrating, and streamlining neuro-behavioral research. These devices include our newest generation of epifluorescence Miniscopes capable of electronic focusing, cranial window imaging, and single cell resolution across greater than a 1mm diameter field-of-view (FOV). Building off this new generation of Miniscopes, we also have developed dual channel systems for sequential imaging or imaging plus optogenetics, electrophysiology integrated Miniscopes, and wire-free Miniscopes. In addition, we have developed a large FOV Miniscope for rats and larger animals capable of single cell resolution imaging at video frame rates across a 3.2mm x 2.5mm FOV. In order to streamline the integration of neural and behavioral data, we have developed a new open-source behavioral camera, MiniCAM, with a 5MP image sensor, interchangeable lenses, and a nIR LED illumination ring. All devices share common modular open-source DAQ hardware and software. The software handles the connection, control, visualization, streaming, and data logging of many devices simultaneously. It includes a real-time dF/F display, GPU accelerated data visualizations, and built-in pose estimation using

embedded Python and Deeplabcut-Live. Open-source UCLA Miniscope devices have been adopted into hundreds of labs across over 18 countries and have laid the foundation for novel modifications and advancements by many other groups. Through open-source development and engagement with the scientific community we hope to continue addressing economic and technical hurdles and broaden access to these technologies.

Title: Imaging genetically encoded neurotransmitter sensors using head-mountable miniscopes

Authors: K. ZITELLI[1], J. ZAPATA[1], D. HOUTTEMAN[2], P. BONNAVION[2], A. DE KERCHOVE D'EXAERDE[2], *A. STAMATAKIS[1];
[1]Inscopix, Palo Alto, CA; [2]Univ. Libre de Bruxelles, Brussels, Belgium

Abstract: Genetically encoded dynamic fluorescent sensors, such as calcium and voltage sensors, are powerful tools for monitoring neural activity. Recently developed neurotransmitter sensors represent a promising addition to this family of sensors. To date, genetically encoded neurotransmitter sensors have been imaged primarily in vivo with fiber photometry, which lacks spatial resolution. In vivo 2-photon microscopy offers high spatial resolution, but requires head fixation, limiting the free behavior of the test subject. Miniscopes such as the nVista^{TM} system have been used to image genetically encoded sensors such as GCaMP, allowing for free behavior while monitoring neural activity with high spatial resolution. Here, we demonstrate the feasibility of imaging genetically encoded neurotransmitter sensors during free behavior using Inscopix miniscopes. Mice were injected with the GPCR-activation-based dopamine sensor $GRAB_{DA}$ in the dorsal striatum or nucleus accumbens (NAc, Shell), and with the opsin ChrimsonR in the substantia nigra or ventral tegmental area (VTA), respectively. Using the optogenetically-enabled miniscope nVokeTM system, $GRAB_{DA}$ activity was monitored as mice explored an open field. Dopamine release was elicited from nigral or dopaminergic VTA fibers via stimulation of ChrimsonR, mediating a significant increase in $GRAB_{DA}$ signal in both the dorsal striatum and NAc. In another experiment, amphetamine (4 mg/kg) administered to mice led to a marked increase in $GRAB_{DA}$ signal in both brain areas. These findings demonstrate that miniscopes are an excellent tool for imaging genetically encoded neurotransmitter sensors, and pave the way forward for taking full advantage of such imaging platforms, including leveraging

the multiple channels and spatial resolution of the nVueTM system to simultaneously image cellular-resolution GCaMP activity alongside red neurotransmitter sensors.

Title: Highly stable head-holders for experiments in head-fixed animals

Authors: J. FODOR[1], J.-F. LEGER[2], ***L. BOURDIEU**[3], C. VENTALON[2];
[1]Ymetry, Bagnolet, France; [2]CNRS - Ecole Normale Superieure, PSL, Paris, France; [3]École Normale Supérieure, Paris, France

Abstract: The past fifteen years have been marked by spectacular progresses in the field of integrative neurophysiology, underlid by technical innovations enabling the study of neuronal processes in behaving animals. In particular, recordings in head-fixed animals (mice, rats or ferrets) have provided original information that have revolutionized our understanding of the cellular and network mechanisms underlying sensory processing, motor planning, memory and learning and higher order cognitive processes. To perform such experiments, the animal needs to carry a miniaturized head holder that allows easy fixation of its head to the recording apparatus. These holders should be light enough to be carried easily by the animals in their cage. They should provide optimal stability with sufficient access to the region of interest. They should be compatible with providing unrestricted sensory inputs (e.g. visual or tactile inputs) to the animal. For chronic recordings they should allow recording with a high positional repeatability. They should also provide the possibility to integrate multiple measurement systems on the same animal as for example 2-photon microscopy for optical recording and/or perturbation of neuronal activity using optogenetic tools, optical fibers for photometry or photoactivation / inhibition,

electrophysiological systems (EEG, EMG, LFP or unit activity), drug delivery or electrical micro-stimulation systems. Current commercially-available solutions only satisfy a set of well-defined and standard experimental situations. They are mainly limited to large and flat head plates that can strongly hindered sensory inputs and do not integrate additional measurements. Using 3D-printing in titanium, we have developed innovative custom head-holders based on an original design that minimizes weight and perturbations to the animal behavior and maximizes mechanical stability and experimental repeatability. They benefit from the use of Titanium and of a 3D design that provide uniquely both rigidity and lightness at low cost. Several different prototypes have already been designed, produced and used. Thanks to their design methods, novel head-holders can be adapted to different animal models, brain areas and to integrate multiple measurement / perturbation systems.

Abstract: The Human Neocortical Neurosolver software (HNN, https://hnn.brown.edu) is a neural modeling software developed to understand and interpret the cellular and circuit neural underpinnings of human magneto-/electro-encephalography (M/EEG) signals. The foundation of HNN is a biophysically-detailed neocortical model along with workflows to interact with this

model through layer-specific synaptic activation patterns to simulate the most commonly measured M/EEG signals including event related potentials (ERPs) and low-frequency brain rhythms. HNN-core (https://jonescompneurolab.github.io/hnn-core) is a new lightweight library that provides a Pythonic interface to the HNN functionality for simulating macroscale human M/EEG signals. HNN-core is designed to simulate primary electrical current dipole time courses and compare directly against source-localized MEG and EEG data in physical units (Ampere-meters). HNN-core is distributed with examples for simulating brain rhythms following the workflows in the HNN tutorials: https://HNN.brown.edu/tutorials.
The goal of HNN-core is complementary to HNN. Its object-oriented design allows the computational neuroscience community to understand and contribute to the development and use of the HNN software suite, following best practices in open-source software. The Python Application Programming Interface (API) allows easy batch processing and integration with other Python based packages, such as MNE-Python. Furthermore, the HNN-core API is designed to promote a community-driven software development effort. The package is unit tested with 90% code coverage and new changes are checked using continuous integration tests to avoid regression bugs. The codebase adheres to modern Python style conventions and is extensively documented using function docstrings. The first version of HNN-core is available to install on PyPi. Here, we will provide examples of using HNN-core, including new features such as the ability to insert recording electrodes in the extracellular medium to measure Local Field Potentials (LFPs), functions to modify local network connectivity, and template network models to reproduce published results. We are currently working on optimization of model parameters to match source-localized data and a lightweight GUI interface to HNN-core using IPywidgets, designed to mimic the functionality in the current HNN GUI. Future work will focus on incorporation of layer-resolved LFP and current source density plots, parameter sensitivity analysis and uncertainty estimation of learned parameters, and interoperability with existing tools such as Netpyne, NeuroML and LFPy.

Title: Laminar specificity of the auditory awareness negativity under multitone masking: a biophysical modeling study

Authors: C. FERNANDEZ PUJOL, E. G. BLUNDON, *A. R. DYKSTRA;
Univ. of Miami, Coral Gables, FL

Abstract: Electroencephalography (EEG) and magnetoencephalography (MEG) are excellent mediums for capturing human neural activity on a millisecond time scale, yet little is known about their underlying laminar and biophysical basis. Here, we used a reduced but realistic cortical circuit model - Human Neocortical Neurosolver (HNN) - to shed light on the laminar specificity of brain responses associated with auditory conscious perception under multitone masking. HNN provides a canonical model of a neocortical column circuit, including both excitatory pyramidal and inhibitory basket neurons in layers II/III and layer V. We found that the difference in event-related responses between perceived and unperceived target tones could be accounted for by additional input to supragranular layers arriving from either the non-lemniscal thalamus or cortico-cortical feedback connections. Layer-specific spiking activity of the circuit revealed that the additional negative-going peak that was present for detected but not undetected target tones was accompanied by increased firing of layer-V pyramidal neurons. These results are consistent with current cellular models of conscious processing and help bridge the gap between the macro and micro levels of analysis of perception-related brain activity.

Title: Neocortical microcircuit changes underlying neocortical plasticity: a computational study

Authors: *M. Z. KHALIL[1], P. SKOSNIK[2], M. A. SHERIF[3];
[1]Psychiatry and Behavioral Hlth., Pennsylvania State Univ., Hershey, PA; [2]Psychiatry, Yale Univ. / VA Connecticut Healthcare Syst., New Haven, CT; [3]Psychiatry, Brown university / Carney Inst. of Brain Sci. / Lifespan Physician Group, Providence, RI

Abstract: Neocortical plasticity plays an essential role in multiple psychiatric disorders, including major depressive disorder (MDD), PTSD, and schizophrenia. Long-term potentiation (LTP) is the hallmark of cortical synaptic plasticity in animal models, mediated by the insertion of AMPA receptors (AMPARs) into postsynaptic membranes following tetanic stimulation.

Assessing neocortical plasticity directly in humans has been possible using an EEG-LTP task [1,2,3,4,5]. In the task, sensory event-related potentials (ERPs) are recorded before and after tetanic stimulation in the auditory or visual modalities. The LTP marker in the task is an increase in the absolute amplitude of the N100 ERP component following the tetanic stimulation. Understanding the microcircuit changes underlying the LTP marker in humans will allow us to infer neocortical microcircuit abnormalities in patients suffering from brain disorders affecting plasticity. To examine if the increase in N100 amplitude could be reproduced by increasing AMPA receptors density in the postsynaptic terminals in neocortical columns, we used the Human Neocortical Neurosolver (HNN), a validated neocortical microcircuit model for the EEG/MEG dipole [6,7]. HNN consists of 100 multicompartmental layer 2/3 and 100 layer 5 pyramidal neurons, implemented using the simulation platform NEURON, with fast-spiking interneurons in both layers. HNN simulates the ERP waveform using thalamocortical and cortico-cortical inputs to the model. We ran simulations to examine increasing the AMPAR density on the distal apical dendrites of layers 2/3 and layer 5 pyramidal neurons and on the interneurons in layer 2/3. Doubling the AMPAR density at these locations did not change N100 amplitude. So we ran another set of simulations to examine if augmenting AMPARs on postsynaptic terminals sharing a common input source, as reflected by input synchronization in the cortico-cortical inputs, would replicate the LTP marker. Interestingly, synchronizing the input to the target cells increased the absolute N100 amplitude by 30%. Thus, tetanic stimulation in the EEG-LTP task seems to potentiate synapses receiving inputs from a common source. Our results provide specific predictions about the cortico-cortical connectivity in the EEG-LTP task. Combining EEG tasks and modeling hold the potential to infer microcircuit changes in patients struggling with disorders like MDD, where cortical plasticity and dendritic functioning are impaired.

Title: Multi-scale dynamical modeling for spike and LFP activity using a NeuroBondGraph Network

Authors: *Y.-J. CHANG[1], Y.-I. CHEN[1], H.-C. YEH[1], S. R. SANTACRUZ[1,2,3];
[1]Biomed. Engin., [2]Electrical and Computer Engin., [3]Inst. for Neurosci., Univ. of Texas At Austin, Austin, TX

Abstract: The brain exhibits computational structure across a variety of scales: from single neurons (micro-scale) to functional areas (meso-scale) to cortical networks (macro-scale). In neuropsychiatric conditions, pathological activity is typically neural circuit-wide, impacting dynamics at multiple scales, either directly or indirectly. Combining information on changes in brain dynamics at multiple scales can shed new light on the biological cause of neuropsychiatric disorders. As neural dynamics illuminate the causal interactions between neurons or networks, it is necessary to develop a neural dynamics-based framework to assess the brain computations governing cognitive functions. While single-level neural dynamics encode rich information giving rise to behavior, the different levels of brain network can communicate with each other. However, *how* the activity and information at one level interact with other levels is seldom explored. Evidenced by the success of cross-scale modeling between local field potentials (LFP) and signals recorded from screw type electrodes implanted in the skull via the NeuroBondGraph Network (NBGNet) in the previous work, we develop the multi-scale NBGNet to study neural communications between spike and LFP in the brain networks. Neural representation extracted from multi-scale NBGNet can potentially explain the naturalistic behaviors, which will be validated in real-time brain-machine interface experiments. With the incorporation of realistic brain constraints in the multi-scale NBGNet, this neurobiologically realistic framework holds great potentials to improving our understanding of complex brain functions in unprecedented detail.

Title: Simulation based inference in the Human Neocortical Neurosolver neural modeling software uncovers circuit mechanisms of primate motor cortical 15-29 Hz beta activity during motor planning

Authors: *N. TOLLEY[1], P. L. RODRIGUES[2], A. GRAMFORT[2], J. DONOGHUE[1], C. VARGAS-IRWIN[1], S. R. JONES[1];
[1]Brown Univ. Grad. Dept. of Neurosci., Providence, RI; [2]Univ. Paris-Saclay, Inria, CEA, Palaiseau, France

Abstract: Beta frequency (~15-29 Hz) activity in the neocortex has a well documented association with sensorimotor information processing, however, its circuit level generation remains poorly understood. We employed the Human Neocortical Neurosolver (HNN), a framework whose foundation is a cortical column model with cell and circuit level detail designed to connect macroscale signals to meso/microcircuit level phenomena (Neymotin 2020). This model was applied to study the cellular and circuit mechanisms of beta generation using local field potential (LFP) recordings from the non-human primate (NHP) motor cortex.
To characterize beta producing mechanisms, we employed simulation based inference (SBI) in the HNN modeling tool. SBI is a framework that leverages machine learning techniques and neural density estimators to characterize the relationship between a large space of model parameters and simulation output. In this setting, Bayesian inference can be applied to models with intractable likelihood functions (Gonçalves 2020, Papamakarios 2021).
To predict neural mechanisms underlying beta activity with SBI in HNN, we utilized multi-electrode array neural recordings from NHP's performing an instructed delay reach-to-grasp task. Motor cortical LFP beta activity presented as transient 50 ms events with a stereotyped waveform shape, consistent with prior studies (Sherman 2016; Bonaiuto biorxiv 2021). Further analysis demonstrated a significant decrease in beta event amplitude after behavioral cues, consistent with event related desynchronization.
Our previous modeling studies have suggested that beta events emerge from coincident layer specific excitatory inputs that contact the proximal and distal dendrites of layer 5 cortical pyramidal neurons. These predictions were supported by laminar recordings in mice and NHPs (Sherman 2016), and more recently with high density human magnetoencephalography (Bonaiuto biorxiv 2021). Building from this prior work, we applied SBI in HNN to features of NHP LFP beta events and revealed the novel prediction that the timing between proximal and distal synaptic drives can account for changes in beta event amplitude.
Preliminary analysis of NHP data suggests that beta activity plays a strong modulatory role over spiking activity. Increased beta activity was associated with a reconfiguration of single unit activity into discrete nodes with more stereotyped firing patterns indicative of increased computational similarity (Hynes biorxiv 2019). We are currently working to incorporate these observations into our HNN inference framework to provide functional predictions for beta regulated information processing.

Abstract: Magneto- and electro-encephalography (MEG/EEG) recordings allow scientists, neurologists and psychiatrists to non-invasively record brain activity from human subjects with a relatively fast temporal resolution. These powerful datastreams help uncover human information processing and diagnose neuropathologies, as well responses to therapeutics. However, the neural origins of these macroscale recordings are difficult to interpret, hindering their translational relevance. The Human Neocortical Neurosolver (HNN) neural modeling software tool was created to help researchers and clinicians develop and test hypothesis on the cellular and circuit level origin of M/EEG recordings (Neymotin et al eLife 2020; https://hnn.brown.edu). This project adds a new capability to HNN to simulate laminar local field potential (LFP) and the associated current source density (CSD), which are necessary to validate and inform HNN predictions with laminar recordings from animal models. We describe how the HNN modeling framework can be applied to simulate LFP and CSD by using line source approximations (LSA) and point source approximations (PSA) and new methods being developed to compare simulation results to empirical data from non-human primates (NHP). Our group is developing novel methods to extract features from simulated and experimental data representing canonical patterns of cortical activation in sensory event-related potentials, and to compare results with different temporal and spatial scales across species. Here, we focus on somatosensory evoked responses in humans and NHPs. This critical HNN expansion provides a new way to validate and inform HNN predictions about multi-scale laminar activity in the human neocortex by drawing on data collected from microelectrode recordings in animals.

Title: The impact of light propagation, neural morphology and network effects on the effective spatial resolution of optogenetic stimulation

Authors: *D. BERLING, L. BARONI, J. ANTOLÍK;
Fac. of Mathematics and Physics, Charles Univ., Prague, Czech Republic

Abstract: Enabling neuron-type specific stimulation and a higher biocompatibility than electrode-based approaches, optogenetic stimulation has become a powerful tool for studying the brain with a clinical application in neural prosthetic systems. Major experimental research effort is being invested into high resolution stimulators with focused light profiles [1] and methods to express light-sensitive channels at subcellular precision [2]. However, the combined effect of light propagation in cortical tissue, the distribution of light-sensitive channels across the neuron morphology, and the contribution of network effects onto the effective spatial resolution of the stimulation remains unclear. Recent biophysically accurate single neuron models which simulate the full neuron morphology under optical stimulation [3] and large-scale point-neuron network models with functionally specific cortical circuitry [4] partially address this open issue. However, the contribution of neural morphology in the context of functionally specific recurrent cortical networks remains unexplored, due to the challenge of simulating a large quantity of biophysically accurate single cell models.
Here, we address this open problem through a hybrid approach. Using data from a multi-compartment model of a cat V1 L2/3 pyramidal neuron [adapted from 3] we have trained a deep-neural network (DNN) to rapidly predict the light-induced currents into the soma for various illumination conditions. We then use these DNN-predicted currents as an input into a point-neuron network model of cat V1 to model the network behavior induced by optical stimulation [4].

The resulting simulation framework allows for the testing of different optogenetic transfection strategies, e.g. expression of channels preferentially at the soma or throughout the cell [2], as well as predicting the key characteristics of evoked activity for different specifications of cortical optogenetic stimulation setups.

Abstract: A key feature of human brain organization are long-range connections that mediate the communication across distributed networks in a massively expanded cortex. Here we profiled functional connectivity distance across the cortical mantle and assessed associations to cortical

microcircuity and cognitive taxonomies. We studied two datasets (50 healthy adults from our local acquisitions, 325 unrelated healthy adults from the HCP dataset) who underwent multimodal magnetic resonance imaging (MRI). In those individuals we combined cortex-wide functional MRI connectivity analysis and geodesic distance mapping, to profile a region's embedding within short- versus long-range functional networks. These functional connectivity distance computations were associated with the mapping of microstructural gradients based on quantitative T1 relaxometry in the same individuals, and post-mortem cytoarchitecture derived from BigBrain, as well as gene expression analysis derived from Allen Human Brain Atlas. Moreover, we utilized Neurosynth to decode gradients of functional connectivity distance, to examine associations to cognitive ontologies. Spatial correlation analysis employed non-parametric spin tests, to control for autocorrelations. We observed reproducible topographies of functional connectivity distance in both datasets running from sensory/motor areas with short-range connectivity towards transmodal systems such as the default mode network that are characterized by long-range connectivity. Spatial variations in connectivity distance were correlated with microstructural gradients based on in vivo MRI ($r = 0.75$, $p < 0.001$), as well as post-mortem cytoarchitecture ($r = 0.35$, $p < 0.001$). Similar associations were observed with respect to the principal component of gene co-expression, and gene enrichment indicated layer and cell specific genetic signatures of long-range connectivity. Finally, meta-analytical decoding revealed that higher-order functional terms such as 'social cognition' and 'reward' were associated with longer-range connectivity, while regions with shorter connectivity distance related to sensory/motor functions. Our findings provide novel insights into the correspondence of microstructural, functional, and cognitive hierarchies in the human brain.

Title: Mapping inter-individual functional connectivity variability in TMS targets for major depressive disorder

Authors: *S. HARITA[1,4], D. MOMI[4], F. MAZZA[2,4], J. D. GRIFFITHS[3,4];
[1]Inst. of Med. Sci., [2]Dept. of Physiol., [3]Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [4]Krembil Ctr. for Neuroinformatics, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Background: Transcranial magnetic stimulation (TMS) is an emerging alternative to existing treatments for major depressive disorder (MDD). However, the effects of TMS on brain physiology and therapeutic outcomes are known to be highly variable from subject to subject. Proposed reasons for this variability include individual differences in neurophysiology, in cortical geometry, and in brain connectivity. Standard approaches to TMS target site definition tend to focus on individual brain regions implicated in MDD, such as the dorsolateral prefrontal cortex (dlPFC) and orbitofrontal cortex (OFC). Additionally considering the functional connectivity (FC) of these sites has the potential to improve subject-specificity of TMS targeting and, in turn, improve treatment outcomes. Objective & Hypothesis: We studied the FC of dlPFC and OFC TMS targets, based on induced electrical field (E-field) maps. We hypothesized that individual differences in spontaneous brain FC would contribute more to downstream network engagement than individual differences in cortical geometry (E-field variability). Methods: Tetrahedral head models were generated from T1-weighted MR images for 12 subjects from the Human Connectome Project database, and used to generate individualized E-field maps on the cortical surface for each subject. F3 and Fp1 electrode positions were used to target the left dlPFC and left OFC, respectively. We analyzed inter-subject variability in the shape and location of these TMS target E-field patterns, their FC, and the major functional networks to which they belong. Results: We observed key differences in TMS target FC between the dlPFC and OFC, and how this FC varied across subjects. Three major functional networks were targeted across the dlPFC and OFC: ventral attention, fronto-parietal (FPN) and default-mode (DMN) networks in the dlPFC, and the FPN and DMN in the OFC. Inter-subject variability in cortical geometry and FC was high. Our analyses showed that use of group-average subject E-field and FC allow prediction of which networks are targeted, but fail to accurately quantify the relative loading of TMS targeting on each of the principal networks. Conclusions: Based on our results, the high inter-individual variability in cortical geometry and FC, leading to high variability in distributions of targeted brain networks, may account for the high levels of variability in physiological and therapeutic TMS outcomes. We hope these insights prove useful as part of the broader effort by the psychiatry, neurology, and neuroimaging communities to help improve TMS therapy, through a better understanding of the technology and its neurophysiological effects.

Title: Vitamin D modulates cortical transcriptome and behavioral phenotypes in Mecp2 heterozygous Rett syndrome model mice

Authors: M. C. RIBEIRO, A. SINHA, ***J. L. MACDONALD**;
Dept. of Biology, Program in Neurosci., Syracuse Univ., Syracuse, NY

Abstract: Rett syndrome (RTT) is an X-linked neurodevelopmental disorder caused by mutations in the transcriptional regulator *MECP2* (*Mecp2* in mouse). *Mecp2* loss-of-function leads to the disruption of many cellular pathways, including aberrant activation of the NF-κB pathway. Genetically attenuating the NF-κB pathway in *Mecp2*-null mice ameliorates hallmark phenotypes of RTT, including reduced dendritic complexity, raising the question of whether NF-κB pathway inhibitors could provide a therapeutic avenue for RTT. Vitamin D is a known inhibitor of NF-κB signaling; further, vitamin D deficiency is prevalent in RTT patients and male *Mecp2*-null mice. We previously demonstrated that vitamin D rescues the aberrant NF-κB activity and reduced neurite outgrowth of *Mecp2*-knockdown cortical neurons *in vitro*, and that dietary vitamin D supplementation rescues decreased dendritic complexity and soma size of neocortical projection neurons in both male hemizygous *Mecp2*-null and female heterozygous mice *in vivo*. Here, we have identified over 200 genes whose dysregulated expression in the *Mecp2*+/- cortex is modulated by dietary vitamin D. Genes whose expression is normalized with vitamin D supplementation are involved in dendritic complexity, synapses, and neuronal projections, suggesting that the rescue of their expression could underpin the rescue of neuronal morphology. Further, motor and anxiety-like behavioral phenotypes in *Mecp2*+/- mice correlate with circulating vitamin D levels, and there is a disruption in the homeostasis of the vitamin D synthesis pathway in *Mecp2*+/- mice. Thus, our data indicate that vitamin D modulates RTT pathology and its supplementation could provide a simple and cost-effective partial therapeutic for RTT.

Title: Rapid Phenotypic-based Target Identification, Hit Stratification, and Clinical Translation Using Human iPSC-derived Neurospheroids to Improve Early Identification of Safe and Effective Compounds

Authors: P. NEGRAES, N. SODHI, I. FERNANDES, D. PHAN, ***B. ANSON**, B. VAN HESE, C. TRUJILLO, C. CARROMEU;
Stemonix, Minnesota, MN

Abstract: iPSC-derived neurospheroids offer a promising *in vitro* cellular tool for human-first, early-stage studies to rapidly and accurately screen compound safety and efficacy. Three-dimensional, iPSC-generated models created from clinical populations have been shown to have altered, *in vitro* phenotypes that can be 'rescued' by compounds, followed by target identification and hit stratification from selected reference libraires and combinatorial analytical approaches. Here we generated iPSC-derived neurospheroids from healthy and patient populations, characterized their unique phenotypes, and used them to identify compounds that rescue the disease phenotype without inducing neurotoxicity. Neurospheroids in 384-well plates underwent chronic treatment with a library of 296 well-characterized compounds followed by simultaneous multiplexed functional, structural, and viability evaluation for phenotypic rescue and/or neurotoxicity. Functional assessment employed FLIPR-based readouts of neural activity; over 70 individual endpoints were quantified and used to rank-order rescue while multiplexed, structural, and viability assessments were performed with microscopy-based and ATP-based endpoints to determine potential adverse compound interactions. Example results include 1) compounds that showed toxic responses without any phenotypic rescue; 2) compounds that showed various levels of rescue with evidence of toxicity at higher doses; and 3) 27 compounds that showed good to excellent rescue without any functional, structural, or viability-based toxicity. Compounds eliciting phenotypic recovery spanned several cellular pathways including (but not limited to) the serotonergic, dopaminergic, cholinergic, and GABAergic pathways. Further dissection of cholinergic-based rescue revealed that the primary effect was due to inhibiting the action of acetylcholinesterase. Our results demonstrate a highly specific platform for simultaneously uncovering potential neurotoxicity while identifying the most effective compounds capable of restoring neural function from both healthy and patient-derived material and provide a promising *in vitro* cellular model for early-stage, human-first studies to identify the safest and most effective compounds for pipeline progression and decreased late-stage attrition.

Title: Novel unsupervised machine learning approaches for discovering brain state dynamics in human sleep EEG data

Authors: *C. HUANG[1,2], A. MAHAT[1,2], M. MALETIC-SAVATIC[1,2], A. BUCKLEY[3], M. MCGINLEY[1,2,4];
[1]Baylor Col. of Med., Houston, TX; [2]Jan and Dan Duncan Neurolog. Res. Inst., Houston, TX; [3]Natl. Inst. of Mental Hlth., Bethesda, MD; [4]Rice Univ., Houston, TX

Abstract: Brain activity during sleep is highly dynamic and can be severely altered in patients with neurodevelopmental disorders. Sleep brain state is typically classified using manual polysomnography (PSG) into 5 stages (wake; rapid eye movement, REM; and non-REM 1, 2, 3). This approach presents three major issues: 1) manual PSG is time-consuming and subjective, 2) it has low temporal resolution (typically in 30 seconds segments), and 3) the number and characteristics of sleep stages motivated by normal human sleep might be inappropriate for the abnormal brain states in neurodevelopmental disorders. Here, we use a Hidden Markov Model (HMM) approach to describe brain activity during sleep as rapid (2-sec long) epochs of quasi-stable brain states. We then compare the HMM state dynamics between healthy subjects and Rett syndrome patients and further compare to conventional manual scoring on the same subjects. Five channels (Fp1, F7, C4, O1, T4) electroencephalogram (EEG) was obtained from 22 healthy children and 18 girls with Rett syndrome. Power spectra were filtered to 7 frequency bands: slow delta (0.5-1.5 Hz), fast delta (1.5-4 Hz), slow theta (4-6 Hz), fast theta (6-8 Hz), alpha (8-12 Hz), slow sigma (12~14 Hz), and fast sigma (14~ 16Hz) and used as the model input. A Gaussian HMM was employed to infer a number of discrete states, each of which was modelled as a multivariate normal distribution. Variational Bayes inference was used to estimate the model parameters, including initial states probability, the state statistics, and inter- and intra-state transition probabilities. For the control group, we found that 9 inferred states can well describe the sleep EEG statistics. Some states were highly specific to conventional PSG stages, while others appeared to capture the micro-structure of ambiguous, perhaps transitional stages. The transition matrix captured the trajectories of switching within and between stages, showing prominent transitions from NREM3 to REM. In Rett, the number of inferred states varied between individuals and no states were highly specific to the REM stage, suggesting within and cross-subject REM heterogeneity. Transitions from states highly specific to NREM stages, to states specific to putative wake stages, were frequent compared to controls. A leave-one-out validation procedure showed that the model trained on controls poorly fits Rett data. The proposed HMM framework can help discover short-lived transient brain states, the

heterogeneities in the Rett group, and the difference between the control and Rett during sleep, complementing traditional PSG and providing new windows into brain state pathology in neurodevelopmental disorders.

Title: Towards artificial escape of the CDKL5 gene by in vivo DNA methylation editing

Authors: *J. HALMAI[1], C. GONZALEZ[2], F. BUCHANAN[3], J. L. CARTER[5], J. WALDO[3], D. CAMERON[3], P. DENG[4], K. FINK[6];

Department, Stem Cell Program and Gene Therapy Center, MIND Institute, Inst. for Regen, kdfink@ucdavis.edu, Sacramento, CA

Abstract: A disproportionate amount of genes causative for intellectual disability are located on the X chromosome. There are approximately 140 X-linked intellectual disability (XLID) genes with 27% of genes demonstrating a similar or more severe clinical manifestation in females than males. Few treatment options currently exist for these disorders. In somatic cells of female carriers, one X chromosome randomly becomes epigenetically inactivated. This leaves a druggable, silenced wildtype allele behind, which has the potential to rescue phenotypes when the this gene is reactivated. A significant number of X-linked genes escape from the X chromosome inactivation dosage compensation mechanism in female somatic cells. These escape genes are associated with a distinct epigenetic signature. One epigenetic modification that strongly correlates with escape from XCI that we sought to recapitulate in XLID target genes is reduced DNA methylation in promoter regions. In our previous publication we demonstrated artificial escape by editing DNA methylation on the promoter of *CDKL5*, a gene causative for an infantile epilepsy, from the silenced X-chromosomal allele in human neuronal-like cells. We identify that a fusion of the catalytic domain of TET1 to dCas9 targeted to the*CDKL5* promoter using three guide RNAs causes significant reactivation of the inactive allele in combination with

removal of methyl groups from CpG dinucleotides. Strikingly, we demonstrate that co-expression of TET1 and a VP64 transactivator have a synergistic effect on the reactivation of the inactive allele to levels above 60% when compared to the active allele. We further used a multi-omics assessment to determine potential off-targets on the transcriptome and methylome. We find that synergistic delivery of dCas9 effectors is highly selective for the target site. Our findings further elucidate a causal role for reduced DNA methylation associated with escape from X chromosome inactivation. Delivery of the catalytic domain of TET1 fused to dCas9 via adeno-associated virus (AAV) is restricted due to the limited packaging size of the AAV genome. Here, we use dual AAVs for the delivery of trans-spliced dCas9-intein fusion proteins that are then reconstituted in the mouse brain. Optimization of the dual AAVs enables transcriptional reprogramming and targeted DNA demethylation in a mouse model of *Cdkl5* deficiency and demonstrate therapeutic efficacy of our approach. Understanding and remodeling the epigenetics associated with escape from X chromosome inactivation in human neuronal-like cells and *in vivo* has potential for those suffering from X-linked neurodevelopmental disorders.

Title: The temporoammonic (TA) input to CA1 synapse is hyperexcitable in MeCP2 -/Y mice

Authors: *A. ASGARIHAFSHEJANI, J. PRESSY, M. SERRANILLA, M. WOODIN; Univ. of Toronto, Toronto, ON, Canada

Abstract: Rett syndrome (RTT) is a neurodevelopmental disorder caused by mutations in the X-linked methyl-CpG-binding protein 2 (MeCP2); MeCP2 regulates chromatin organization and global gene transcription. RTT patients demonstrate severe impairments in learning and memory due to alterations in hippocampal network connectivity. In the entorhinal cortex (EC), most neurons in layers II and III have severe synaptic dysfunction. The temporoammonic (TA) pathway provides input directly from layer III of the EC to the distal dendrites of CA1 pyramidal neurons in the stratum lacunosum-moleculare (SLM) of the hippocampus. The TA pathway synapses influence the firing of CA1 pyramidal neurons and modulate the flow of information to the hippocampus. Despite the importance of the TA pathway synaptic input to the CA1 pyramidal neurons for its influence on the firing of CA1 pyramidal neurons, spatial navigation,

learning, and memory, this pathway has not been fully characterized in the context of Rett syndrome. The objective of this study is to electrophysiologically characterize the TA-CA1 and schaffer collateral (SC) -CA1 pathways in a MeCP2-mouse model of RTT to determine the effect of MeCP2 mutations on synaptic and network connectivity. To test this objective, we made whole-cell patch clamp recordings in the hippocampus of Mecp2-/Y mice. The SLM neurons in Mecp2-/Y mice were found to be hyperexcitable showing increased action potential firing rate, with a significantly larger sag potential and post inhibitory rebound potential observed compared to matched wild-types. Additionally, evoked EPSCs of CA1 pyramidal and SLM neurons were significantly larger under TA-CA1 pathway stimulation, with no change in evoked IPSCs compared to wild-types. Moreover, the reversal potential for GABA (EGABA) was measured using a high intracellular chloride concentration (30 mM) and found to be depolarized compared to wild-types controls. Finally, to assess network connectivity we examined hippocampal long-term potentiation induction and paired pulse ratio, which were both found to be unaffected in TA-CA1 and SC-CA1 pathway in the MeCP2-/Y mouse.Taken together, these data demonstrate that CA1 pyramidal neurons have increased intrinsic excitability, revealing a potential mechanism of changes in GABAergic signaling and providing preliminary evidence for a novel mechanism that may contribute to synaptic dysfunction and disease progression.

Title: Potentiation of mGluR(7) rescues neurophysiological features in a mouse model of Rett Syndrome

Authors: H.-W. DONG[1,2], K. WEISS[3], K. BAUGH[1,2], C. M. NISWENDER[3], J. L. NEUL[1,2]; [1]Pediatrics, Neurolog. Div., [2]Vanderbilt Kennedy Ctr., Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Pharmacology, Warren Ctr. for Neurosci. Drug Discovery, Vanderbilt University, Sch. of Med., Nashville, TN

Abstract: Rett syndrome (RTT) is a neurodevelopmental disorder (NDD) primarily caused by mutations in the *Methyl-CpG binding protein 2* (*MECP2*) gene. Currently, there are no well-validated biomarkers in RTT to predict disease prognosis or treatment responses. Previously, we characterized the changes of a variety of neurophysiological features in female R255X *Mecp2* mutation mice and found that specific changes were associated with disease severity, supporting the feasibility of utilizing neurophysiological assessments as non-invasive and translatable biomarkers to predict disease progress and evaluate treatment responses. We have recently found that metabotropic glutamate receptor 7 ($mGlu_7$), a G protein-coupled receptor that regulates presynaptic neurotransmitter release, is reduced in brain tissue from people with RTT and RTT mouse models. Treatment of RTT mice with a compound that acts as a positive allosteric modulator (PAM) of $mGlu_7$ activity (VU0422288) improved phenotypes, suggesting a novel therapeutic approach for RTT. We investigated whether $mGlu_7$ PAM treatment could alter neurophysiological assessments in RTT animals to evaluate their potential of serving as pharmacodynamic or early treatment response biomarkers. Our results showed that acute dosing of VU0422288 (30mg/kg, i.p.) in wildtype female mice did not have any effect on auditory evoked potential (AEP) form or peak amplitudes. However, acute injection of VU0422288, but not vehicle, improved the AEP waveform and increased AEP N1 and P1-N1 peak amplitudes in female $Mecp2^{Null/+}$ mice. Additionally, both auditory evoked power spectrum and inter-trial phase coherence were also improved in RTT animal by VU0422288 administration. These findings suggest that potentiation of $mGlu_7$ functionally improved neural circuit synchrony to auditory stimuli in RTT animals, and that this acute response could represent a pharmacodynamic biomarker useful for dose finding and potentially as an early treatment response biomarker.

Title: Rett Syndrome mice have aberrant astrocyte gene expression and morphological maturation during CNS refinement

Authors: *R. D. HERNANDEZ[1,2], L. M. HOLT[3], N. L. PACHECO[4], M. L. OLSEN[2];
[1]Grad. Program in Translational Biology, Medicine, and Hlth., Virginia Polytechnic Inst. and State Univ., Roanoke, VA; [2]Sch. of Neurosci., Virginia Polytechnic Inst. and State Univ., Blacksburg, VA; [3]Nash Family Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Lab. of Epidemiology and Population Sci. (LEPS), Natl. Inst. on Aging, Baltimore, MD

Abstract: Rett Syndrome (RTT) is an X-linked neurodevelopmental disorder caused by mutations in the MECP2 gene. The MeCP2 protein is a critical transcriptional regulator in the CNS responsible for neurotypical function and maturation. Persons with RTT experience symptom onset after a period of typical development between 6 to 18 months of age, causing regressions in motor abilities, development of breathing abnormalities, and intellectual impairment. $Mecp2^{-/y}$ mouse models similarly recapitulate symptoms and onset, providing a basis for understanding cellular contribution to disease progression. $Mecp2^{-/y}$ mouse studies have specifically demonstrated that astrocytes contribute to RTT pathogenesis, but the exact mechanisms are not well understood. Astrocytes undergo postnatal maturation alongside neurons (~P14 - P30), indicated by changes in cellular function, and development of a complex morphological phenotype. Interestingly, $Mecp2^{-/y}$ mice first display symptom phenotypes during this period of astrocyte refinement. Using cell-specific isolation of cortical astrocytes, we used next-generation RNA-Sequencing to evaluate gene expression in WT and $Mecp2^{-/y}$ male mice from early postnatal development through adulthood (P7, P14, P28, P45, and P60, n = 3-5 per genotype x age). We found the highest number of significant ($p < 0.05$) differentially expressed genes (DEGs) during the period of murine astrocyte morphogenesis (P14 - P28) in WT animals. Comparison of WT vs. $Mecp2^{-/y}$ cortical astrocytes at P14 and P28 time points revealed 33 DEGs and 7,251 significant DEGs between groups, respectively. Gene Ontology pathway analysis was only possible for P28 time points given the low DEGs at P14, where we found that WT astrocytes have pathway enrichment in cellular morphology and maturation, while these pathways are disrupted in $Mecp2^{-/y}$ astrocytes. Evaluating astrocyte morphology using an AAV construct for visualization, we determined that $Mecp2^{-/y}$ animals have deficits in astrocyte morphogenesis at the end of this developmental period at P30, but not prior to it at P14. These results suggest that developmental disruption of astrocyte morphogenesis and gene pathways of maturation in RTT may have functional relevance that further implicate astrocytes as disease contributors.

Title: The neuropeptide Galanin exerts inhibitory effects on cortical spreading depolarization via the Galanin receptor 2

Authors: F. GIMENO-FERRER[1], A. EITNER[2], R. BAUER[3], A. LEHMENKUHLER[4], H.-G. SCHAIBLE[1], ***F. RICHTER**[1];
[1]Inst. of Physiol. I / Neurophysiol., [2]Dept. of Trauma, Hand and Reconstructive Surgery, Exptl., [3]Inst. of Mol. Cell Biology, CMB-Center for Mol. Biomedicine, Univ. Hosp. Jena, Jena, Germany; [4]Pain Inst., Duesseldorf, Germany

Abstract: The neuropeptide Galanin reduces neuronal excitability in rat cerebral cortex, increases the threshold for elicitation and interferes with amplitudes and propagation velocities of cortical spreading depolarization (CSD). Here we tested, whether the Galanin receptor 2 (GalR2) could be the reason for these effects and checked its localization. In spontaneously breathing anesthetized adult rats (sodium thiopentone, 100 mg/kg, i.p.) the electrocorticogram was recorded with arrays of glass microelectrodes in two areas (treated and untreated) that were separated by a wall made from dental acrylic. Recordings were performed in both areas at cortical depths of 400 and 1200 µm. CSD was induced by KCl microinjection. CSD-related direct current (DC) potential shifts, changes in extracellular potassium concentration and in regional cerebral blood flow were continuously monitored. In group 1 we applied the GalR2 antagonist M871 at a concentration of 3 nM for 2 h as pretreatment, followed by 2 h application of Galanin at 0.1 µM. In group 2, the $GABA_A$ receptor antagonist Bicuculline at 1µM was applied for 1 h alone followed by Galanin at 1 µM for 3 h. In group 3, a mixture of both with same concentrations was applied for 3 h. Native rat brain slices were stained for the GalR2 and for parvalbumin interneurons. The GalR2 antagonist alone reduced the CSD amplitudes in treated brain area for 30 to 60 min, and then amplitudes returned to normal. A subsequent application of Galanin did not further influence CSD. The pretreatment with Bicuculline caused some spontaneous CSD starting in the treated area and propagating across the whole cortex. A subsequent application of Galanin did not affect CSD. In animals with coapplication of Bicuculline and Galanin no spontaneous CSD occurred and CSD were not influenced either suggesting that a neuronal network is involved in Galanin functions. The precise localization of GalR2 is under investigation. We conclude that Galanin controls cortical neuronal activity via the GalR2, since its blockade prevented all effects on CSD. The experiments with Bicuculline indicate that a GABAergic mechanism may be involved in the diminishing and slowing of CSD by Galanin.

Campus, Vanderbilt Univ., Nashville, TN; [6]Dept Physiol, Univ. of California Los Angeles Dept. of Physiol., Los Angeles, CA

Abstract: To survive, animals must generate appropriate behaviors in response to dynamic environmental stimuli and internal goals. How the brain evaluates external and internal evidence and changes behavioral strategies when necessary is an important but poorly understood problem in neuroscience. We study behavioral strategy switch in the case of futility-induced passivity in the larval zebrafish. Previous work demonstrated that larval zebrafish stop swimming when swims are ineffective and identified a hindbrain circuit consisting of both neurons and glia that integrates evidence of failure and inhibits swims. Here, further characterize this neural-glial circuit with a goal of understanding the molecular, cellular, and systems mechanisms through which it operates. To investigate the molecular mechanisms through which radial astrocytes integrate the previously characterized norepinephrinergic failure signal and communicate with downstream neurons, we employed simultaneous light-sheet imaging of intracellular astrocytic calcium levels and other astrocytic intercellular and extracellular signals, such as potassium concentration and ATP release. We identified correlates of futile swims, passivity, and recovery to activity in the ATP signal. To investigate the anatomical features of the futility-induced passivity circuit, we reconstructed noradrenergic hindbrain cells that signal futility, radial astrocytes that integrate the futility signal, and hindbrain GABAergic interneurons that inhibit swimming. By mapping connections between these medullary GABAergic neurons and their downstream partners, we uncovered anatomical evidence for how swimming is inhibited by futility.

Title: An in vitro model of human neural development indicates human specific astrocyte effects on neuronal network maturation

Authors: S. LIU[1], A. TAGA[2], A. JOHNS[1], N. J. MARAGAKIS[3], *C. W. HABELA[2]; [2]Neurol., [1]Johns Hopkins Univ., Baltimore, MD; [3]Dept Neurol, Johns Hopkins Univ. Dept. of Neurol. and Neurosurg., Baltimore, MD

Abstract: Neurodevelopmental disorders such as epilepsy and intellectual disability result from disruption of cortical neural development. This can occur due to changes in neural cell proliferation, migration, synaptic integration and network organization and may be a result of deficits in either neurons or glial cells or in the interactions between these cells. The study of cortical neurodevelopmental disorders with genetic causes has been facilitated by the development of human induced pluripotent stem cells (iPSC) which allow patient derived cells to be studied in the context of human genetic backgrounds. While there are numerous well characterized human cortical neuronal differentiation protocols from iPSCs, models in which both neurons and astrocytes are generated from a single progenitor are less well characterized and many studies of neuronal development rely on rodent astrocytes to facilitate synaptic development. To more closely approximate early neural development, we developed a protocol to generate astrocyte progenitors from forebrain neural progenitor cells previously validated to generate forebrain cortical neurons. When these astrocyte progenitor cells were matured until day in vitro (DIV) 95-100 and characterized by fluorescent immunocytochemistry, greater than 75% expressed the astrocytic markers GFAP and S100β indicating an astrocytic fate. Greater than 95% of cells expressed the cortical region-specific transcription factor OTX2 while only a small minority of the cells expressed the spinal specific transcription factor, HOXB4, indicating a cortical astrocyte fate. We subsequently cultured DIV 37 human cortical neurons (hCN) with either DIV 90 human cortical astrocytes (hCA), cortical rat astrocytes or no astrocytes on multielectrode array plates and recorded extracellular field potentials of the cocultures for 1 to 6

months. All co-cultures including hCA demonstrated robust spike activity within three days of plating, burst activity within 2 weeks, and synchronized bursts across the network between 1 and 2 months after plating. Interestingly, although hCN cultured with hCA all developed mature network burst patterns, this maturation occurred over a more protracted time course when compared to co-cultures including rat astrocytes. This is consistent with the slower rate of neural development in humans compared to rats and emphasizes important differences between fully human cultures and hybrid human-animal models. It also confirms the importance of astrocytes in neuronal development and network activity and supports the use of both astrocytes and neurons from patient iPSCs when studying neurodevelopmental disorders.

Abstract: At tripartite synapses, astrocytes enmesh synaptic contacts, but how astrocytes contribute to the formation, maturation and plasticity of synapses remains elusive. Here we show that both astrocytes and neurons abundantly express neurexin-1, a presynaptic adhesion molecule that controls synaptic properties. Using super-resolution imaging, we demonstrate that presynaptic neuronal and astrocytic neurexin-1 form discrete nanoclusters at excitatory synapses. We find that distinct patterns of heparan sulfate modification and alternative splicing confer onto astrocytic and neuronal neurexin-1 different ligand specificities, thereby enabling compartment-specific signaling by neurexin-1. At hippocampal Schaffer-collateral synapses, deletion of neurexin-1 from either astrocytes or neurons did not alter synapse numbers, but differentially impaired synapse function. Neuronal neurexin-1 was essential for NMDA-receptor-mediated synaptic responses, whereas astrocytic neurexin-1 was required for maturation of silent synapses,

AMPA-receptor recruitment, and long-term potentiation. Thus, astrocytes and neurons surprisingly use the same synaptic adhesion molecule to control distinct synapse properties.

Title: A neuron-glia signal strengthens inhibitory synaptic transmission to attain fly dim-light vision

Authors: *P. GUO, Z. LUAN, H.-S. LI;
Univ. Mass. Med. Sch., Worcester, MA

Abstract: Inhibitory neurotransmission participates in nearly every neural circuit and plays fundamental role in shaping and balancing neuronal signaling. Fast synaptic inhibition in the central nervous system is primarily mediated by the Cl^- influx through ligand-gated chloride channels. Therefore, the activation of these postsynaptic receptors has drawn most attention in previous regulation mechanism studies of inhibitory synaptic transmission. In *Drosophila*, visual information is relayed from photoreceptors to large monopolar cells (LMCs) through histamine-gated chloride channels. Here we report that this inhibitory synaptic transmission is strengthened by a glutamatergic neuron-glia signaling process to attain vision in dim conditions. Fly outer photoreceptors innervate LMCs in the first visual neuropil lamina, which also contains terminals of multiple types of interneurons. The epithelial glia (EG) spans the entire thickness of the lamina, extends processes into spaces between neurons and envelops synapses. We identified a glutamate-gated chloride channel (GluCl) that is localized on an EG membrane structure gnarl. Loss of glial GluCl significantly reduced the light-sensitivity of LMCs but not that of photoreceptors, and impaired the fly response to moving gratings in an optomotor assay when the background illuminance is below 100 lux. The visual defect was reversed by expressing a Cl^--extruding K^+-Cl^- cotransporter KCCB in glia, indicating that the activation of GluCl may release Cl^- from glia to increase the driving force for Cl^- flux into LMCs, thereby reinforcing the visual synapse in dim conditions. *in vivo* imaging using glutamate sensor and membrane potential sensor showed a laminar extracellular glutamate level ($[Glu]_o$) increase in dark that depends on

the depolarization of T1 interneuron. In the lamina, an electrogenic glutamate transporter EAAT1 is exclusively expressed in T1. Knockdown of EAAT1 in T1 cells completely abolished the light triggered $[Glu]_o$ change, and led to similar visual defects observed in GluCl knockdown flies, suggesting that the opening the GluCl-gated glial Cl^- pool is triggered by the EAAT1-mediated glutamate release from T1 cells. This work has demonstrated that the inhibitory neurotransmission can be rapidly modulated by glia under the control of a third neuron, which may represent a general glial regulation on the gain of inhibitory synapses.

Title: Ectopic action potential activation in regular-spiking neurons in the neocortex

Authors: *S. R. DOELFEL[1], B. W. CONNORS[1], B. B. THEYEL[2];
[1]Dept. of Neurosci., [2]Psychiatry and Human Behavior, Brown Univ., Providence, RI

Abstract: Objectives: This study aims to determine whether a form of backpropagating action potentials known as ectopic firing occurs in regular-spiking (RS) cells under non-pathological conditions. Prior work suggests that at least two types of inhibitory interneuron fire action potentials that originate in the axon (Elgueta et al., 2015; Imbrosci et al., 2015). There is a large body of evidence indicating that RS cells fire ectopic action potentials in seizure models, but we do not yet know whether they are capable of ectopic firing under non-pathological conditions. Here, we show preliminary data suggesting that ectopic firing occurs in mouse neocortical pyramidal cells.
Methods: We recorded from RS cells in layer 2/3 of the mouse orbitofrontal cortex utilizing the whole-cell patch clamp technique *in vitro* and attempted to induce ectopic firing using multiple protocols. To elicit ectopics, we ran 75, 60, 40, and 30 Hz protocols, as well as a protocol in which 600 ms current steps were incremented by +5 pA every 2 seconds. To quantify ectopic firing, we analyzed the number of evoked AP's that were required before the first ectopic, and determined how many ectopic APs were present in the most active sweep. An ectopic AP was defined as one that rose steeply from the baseline membrane potential and occurred greater than 3 milliseconds after the last evoked AP of that sweep.
Results: Among six RS neurons, 83% (n=5) fired ectopic APs. On average, it took 431 ± 455 APs before the arrival of the first ectopic. The most active run for cells one, three, and five

occurred during the 60 Hz protocol, while cell two's was at 75 Hz and cell four's was at 30 Hz. The average number of ectopics in the most active run was 8. Two of the five cells had 5 or less ectopics in their most active runs, while one cell had between 5 and 10. The other two cells had 20 or more ectopics during their most active runs. 100% of the cells had their first ectopic within 82 seconds of the first evoked action potential. The amplitude of the ectopics ranged from high amplitude (greater than the height of the evoked APs in that cell), medium amplitude (slightly lower than the evoked AP), and low amplitude (less than one-fourth of the evoked AP). **Conclusion:** Our data suggest that under non-pathological conditions, RS neurons are capable of firing ectopic APs after being sufficiently stimulated. Future work will determine the percentage of neocortical RS cells that are capable of ectopic firing, and determine the mechanism of ectopic firing.

Title: Evidence for an astrocytic role in somatosensory adaptation

Authors: *M. MACNAB, L. K. BEKAR;
Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Somatosensory cortical adaptation is the frequency-dependent inhibition of firing in response to background stimulation. At high frequency, this is largely a result of synaptic vesicle depletion. However, at lower frequencies, multiple systems may be at play. As part of the tripartite synapse, astrocytes interact closely with neurons and regulate many factors that influence firing. By regulating $[K^+]_e$, astrocytes can affect the membrane potential and thus neuronal excitability. Various gliotransmitters are also known to be involved in modulating synaptic release (glutamate, adenosine, endocannabinoids) and recruitment of interneuron-mediated inhibition (ATP, glutamate). As astrocytes are ideally positioned to respond to synaptic

activity, express a multitude of receptors, and release gliotransmitters to affect surrounding cells, we ***hypothesize*** that astrocytes play a role in cortical sensory adaptation. Live brain slices were stimulated in cortical layer IV with extracellular field recordings performed in layer II. Ten-pulse stimulation trains (25, 20 and 10 Hz) were used to assess pharmacological and technical manipulations on field EPSP adaptation. Initial patch electrode dialysis of astrocytes with the calcium chelator BAPTA demonstrates that astrocyte calcium signaling plays a prominent role. Lowering of extracellular K^+ from 3 to 1 mM in the artificial cerebral spinal fluid (aCSF) perfusing the slice to help reduce build-up in response to the stimulation train also reduced adaptation, supporting a role for astrocyte-mediated K^+ regulation. Subsequent assessment of pharmacological blockade of $GABA_A$, $GABA_B$, NMDA, P2Y1, and CB1 receptors all showed modest effects on adaptation. Surprisingly, mGluR5 and A1/A2a adenosine receptor blockade had no effect. The effects of astrocyte syncytium dialysis with BAPTA and perfusion with low K^+ aCSF demonstrate that astrocytes play a significant role in somatosensory adaptation. Pharmacological manipulation suggests that astrocytes may use ATP through P2Y1 receptors to recruit interneuron-mediated inhibition and that endocannabinoids from neurons and/or astrocytes also play a role.

Title: Examining BDNF/Astrocytic TrkB.T1 signaling as a mechanism underlying perisynaptic astrocyte process recruitment

Authors: *B. TORRES, L. M. HOLT, J. BROWNING, M. L. OLSEN;
Virginia Polytechnic Inst. and State Univ., Blacksburg, VA

Abstract: Perisynaptic astrocyte processes (PAPs) are fine terminal structures located on the distal processes of astrocytes. These PAPs contain numerous neurotransmitter receptors, ion channels, cell-adhesion molecules, and the ability to release synaptogenic molecules, allowing astrocytes to contribute to synapse homeostasis, development, and stabilization. Despite decades of research indicating astrocytes enwrap or contact synaptic elements, with increased coverage of mature glutamatergic synapses, there is little known regarding the molecular signals that recruit PAPs to synapses or induce structural PAP plasticity in response to neuronal signaling. Brain derived neurotrophic factor (BDNF) has been highly implicated as a molecule underlying both

synapse development and plasticity in neurons. In developing or highly active synapses, BDNF is released from pre- or post-synaptic elements and binds to its receptor TrkB to mediate synapse maturation. Interestingly, our recent published work demonstrates that astrocytes express high levels of TrkB. We identified that the truncated TrkB receptor, TrkB.T1, is the predominant TrkB receptor identified in cortex and is predominantly expressed in astrocytes relative to other CNS cell populations. Direct genetic manipulation of TrkB.T1 globally and in astrocytes alone is sufficient to reduce astrocyte morphological maturation both *in vitro* and *in vivo,* alters mature astrocyte gene expression *in vivo,* and reduces excitatory synapse formation *in vitro.* Our preliminary data indicate that TrkB.T1 knockout (KO) astrocytes fail to enwrap glutamatergic synapses *in vitro*. Ongoing studies using *in vitro* astrocyte neuron co-cultures and experience dependent plasticity in the mouse whisker barrel cortex *in vivo* are aimed at examining BDNF/TrkB.T1 signaling as a mechanism underlying PAP arrival and plasticity at developing synapses. Alterations in synaptic function and development have been implicated in multiple neurodevelopmental disorders. This work will advance the understanding of the role of astrocytes in synaptic development and offer new therapeutic targets where synapse development is implicated.

Title: Purinergic signaling in glia is necessary for foraging and food consumption in drosophila.

Authors: *J.-F. DE BACKER, T. KARGES, J. PAPS, I. C. GRUNWALD KADOW;
Neuronal Circuits and Metabolism, Tech. Univ. of Munich, Freising, Germany

Abstract: Like most animals, hungry flies have to start to seek for food supply. In order to find a food source, flies first use olfactory and visual cues. If successful, they then assess the type and the quality of the food and eventually start feeding. As foraging, feeding and digestion are also energy-costly activities, these behaviors must be repressed when the animal reaches satiation. This information is given by post-ingestive feedback over the quantity and the nutritive quality of the ingested food. All along an animal's life, internal resources such as energy stores must therefore be evaluated and allocated to the appropriate system according to the current metabolic state. In the central nervous system, glial cells seems to be good candidates to play that role. They are known to provide metabolic support to neurons but can also modulate their excitability as well as synaptic transmission. A recently increasing amount of data shows that glia activity can have a direct impact on various types of behavior in both vertebrates and invertebrates. Here,

we hypothesize that glial cells could sense the metabolic state of the animal and then promote and/or repress the decision of engaging food-seeking and feeding behavior. We are addressing this hypothesis in food-deprived *Drosophila* using food-odor tracking on a spherical treadmill and a single-fly feeding behavior assay. We observed that the expression of the adenosine receptor (AdoR) in glial cells is necessary in both cases. Interestingly, the role of AdoR seems to be different according to the cell types composing *Drosophila* glia population. Adenosine is often presented as a stress-signaling molecule and has for example been shown in flies to promote the allocation of internal energy stores to immune cells during an infection. Adenosine is also the product of ATP dephosphrylation and could then potentially be used by cells to sense energy level and/or consumption. As AdoR is an excitatory GPCR, we activated the different glia sub-types using optogenetics. Again, the activation of different cell-types inhibited or enhanced food-odor tracking behavior in starved flies. Together, our data suggest that different populations of glial cells could possibly sense the metabolic state of the fly and orient its behavior toward food-seeking or feeding.

Title: Mechanism of NMDA Receptor Potentiation by Lactate

Authors: *H. FIUMELLI[1], G. HERRERA-LOPÉZ[1], F. LEMTIRI-CHLIEH[2], N. CARRANO[3,4], F. GARDONI[3], M. DI LUCA[3], P. J. MAGISTRETTI[1];
[1]King Abdullah Univ. of Sci. and Technol., Thuwal, Saudi Arabia; [2]UConn Hlth., Farmington, CT; [3]Univ. of Milan, Milano, Italy; [4]KU Leuven, Leuven, Belgium

Abstract: Astrocyte-derived lactate is known to have multiple effects on neuronal cells, fueling high-energy demands as a metabolic substrate and acting as a trophic signaling molecule to promote synaptic plasticity and memory consolidation. Recent findings have shown that lactate regulates NMDA receptor activity through a NADH-dependent pathway and modulates gene expression related to synaptic plasticity and neuroprotection. To further elucidate the mechanism of NMDA receptor potentiation by lactate, we used patch clamp recordings in primary cultures of cortical neurons, and found that lactate rapidly enhanced both the amplitude and the inactivation time-constant of NMDA receptor currents (I_{NMDAR}) evoked by brief applications of glutamate and glycine. These effects were not observed by agonists of HCAR1/gpr81 receptors while the lactate-mediated increase in I_{NMDAR} amplitude was prevented by monocarboxylate

transporters and lactate dehydrogenase inhibitors. Moreover, intracellular infusion of specific CaMKII peptide inhibitors also abolished the potentiation of peak I_{NMDAR} responses by lactate, indicating a mechanism requiring entry of lactate into neurons, its oxidation to pyruvate, and involvement of CaMKII. Furthermore, interfering with the binding between CaMKII and GluN2B in a pharmaco-genetic model consisting of CaMKIIα-expressing HEK293 cells transiently transfected with functional NMDA receptors containing mutant GluN2B subunits prevented the potentiation of I_{NMDAR} responses by lactate. Interestingly, proximity ligation assays in cultured neurons between GluN2B and the postsynaptic density associated scaffolding protein PSD-95 revealed that lactate induced GluN2B accumulation in dendritic spines, an effect that was prevented by CaMKII inhibitors. Taken together, these observations suggest that lactate uptake stimulates synaptic plasticity by increasing the distribution of NMDA receptors in spines by a mechanism promoting the interaction between CaMKII and GluN2b subunits.

Med., Boston Children's Hosp., Boston, MA; [6]Ann Romney Ctr. for Neurologic Dis., Brigham & Women's Hosp., Boston, MA; [7]Harvard Med. Sch., Dept. of Neurol., Boston, MA

Abstract: The complement cascade modulates the innate immune system, which leads to the elimination of pathogens and dead or dying cells, as well as contributing to the extent and limit of the inflammatory immune response. Complement C3 is part of the innate immune system and participates in synapse elimination during normal brain development to refine neuronal networks. Further, this molecule may be detrimental in several neurodegenerative diseases, including Alzheimer's disease (AD). C3 levels in the brain are elevated during aging and AD.

Our group previously showed that lifelong C3-deficiency protected against hippocampal synapse loss in aged WT and APP/PS1dE9 mice, correlating with improved performance on cognitive tests. Recently, we developed an inducible conditional C3 knockout mouse model (C3iKO) by crossing C3 floxed ($C3^{fl/fl}$) mice with Rosa26-Cre-ERT2+/- mice on a C57BL/6J background. Our goal was to investigate whether C3 lowering in adulthood, after normal brain development, would still protect hippocampal function in these mice. First, 4-5-month-old male and female C3iKO mice were i.p. injected with tamoxifen (TAM) or corn oil (CO; control) daily for 5 days. Tamoxifen treatment of C3iKO mice led to a sustained ~95% lowering of serum C3 levels. Behavioral testing for hippocampal-dependent spatial memory, object memory, and object location were performed when TAM-treated and CO-treated mice reached 16-17 months of age. C3iKO+TAM mice performed significantly better than C3iKO+CO-treated mice in these behavioral tasks, indicating that C3 lowering after brain development protected mice from age-related cognitive decline. In another study, mice were treated with TAM or CO at 3-4 months of age and electrophysiological recording of long-term potentiation (LTP) was conducted 3 months later in hippocampal slices incubated with neurotoxic $(A\beta_{1\text{-}40}\ S26C)_2$. Remarkably, C3 lowering protected hippocampal synapses from $(A\beta_{1\text{-}40}\ S26C)_2$-mediated LTP impairment. In conclusion, global C3 lowering in C3iKO young adult mice protected against hippocampal dysfunction many months later, suggesting that targeting C3 may be an effective therapeutic strategy for AD.

Title: Impact of TREM2 in a Transgenic Mouse Model of Cerebral Amyloid Angiopathy

Authors: *R. ZHONG, A. GRAM, L. LI;
Exptl. and Clin. Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Cerebral amyloid angiopathy (CAA) is characterized by cerebral vascular deposition of pathological amyloid-beta protein (Aβ), triggering cerebrovascular inflammation,

hemorrhages, and cognitive impairment. CAA plays an important role in the multimorbidity of aging brains including Alzheimer's disease (AD), but it is less understood compared to the other more heavily studied Aβ pathology in AD, Aβ plaques. Currently, there is no approved therapeutic agent to specifically treat CAA. Triggering receptor expressed on myeloid cells 2 (TREM2), a key player in innate immune response, is exclusively expressed on microglia in the brain and mediates Aβ clearance by microglia and subsequently relieves neuroinflammation, among other neuroprotective effects. Recent studies on TREM2 function using TREM2 knockout (KO) in transgenic (Tg) AD mice have shown that TREM2 modulates parenchymal Aβ deposition in the brain, although the direction of the effect depends on the specific Tg background and the timing/stage of the disease development. However, the impact of TREM2 on CAA had not been investigated. In this study, we crossed TREM2 KO mice with APPswDI mice (C57BL/6-Tg(Thy1-APPSwDutIowa)BWevn/Mmjax), a model of CAA. We found that TREM2 deficiency markedly increased overall Aβ load in APPswDI/TREM2KO mice compared to APPswDI/TREM2WT or APPswDI/TREM2Het in cortex, hippocampus, and thalamus. Intriguingly, TREM2 deletion led to a dramatic decrease in CAA in vasculature-enriched regions, such as thalamus, in APPswDI mice. Moreover, overall microglial staining (IBA1) and CAA-associated microglia were significantly reduced in APPswDI/TREM2KO mice. Additional experiments are underway to explore the molecular mechanism underlying the changes in CAA and Aβ plaques upon TREM2 deletion. The results provide novel insights into the differential role of TREM2 in the regulation of parenchymal versus vascular deposition of Aβ in the brain.

Title: Delayed treatment with a brain-penetrating biologic TNF-α inhibitor in the APP/PS1 mouse model of human amyloidosis

Authors: *W. OU[1], Y. OHNO[2], M. CHOI[3], J. SUN[1], J. YANG[2], T. ABDULLAH[1], R. MURPHY[1], C. ROULES[1], M. CHOI[4], D. H. CRIBBS[5], R. SUMBRIA[1,5];
[1]Chapman Univ., Irvine, CA; [2]Keck graduate institute, Rancho Cucamonga, CA; [3]Claremont McKenna Collage, Claremont, CA; [4]New York Univ., New York, NY; [5]Neurol., Univ. of California Irvine Dept. of Neurol., Irvine, CA

Abstract: Tumor necrosis factor-α (TNF-α) plays a vital role in Alzheimer's Disease (AD) pathology and, TNF-α inhibitors (TNFIs), including Etanercept, modulate AD hallmark pathology (Aβ and tau pathology). We engineered a blood-brain barrier (BBB)-penetrating TNFI by fusing the type-II human TNF-α receptor (TNFR) to a transferrin receptor antibody (TfRMAb) that ferries TNFR into the brain non-invasively via receptor-mediated transcytosis. We previously showed that the BBB-penetrating TfRMAb-TNFR is protective when administered to 6-month-old APP/PS1 transgenic mice, however, the effects of delayed TfRMAb-TNFR treatment are not known. Herein, 10.7-month-old male APP/PS1 mice were injected intraperitoneally with saline (n=16), TfRMAb-TNFR (3 mg/kg; n=9), Etanercept (1.5 mg/kg; equimolar dose of TNFR; n=9) or TfRMAb (2.25 mg/kg; equimolar dose of TfRMAb; n=5) three days per week for 10 weeks. Blood was collected at 10 weeks for a complete blood count and white blood cell (WBC) differential. Spatial recognition memory was assessed using the modified Y-maze. Total brain Aβ peptide load was measured by 6E10 immunostaining and insoluble brain Aβ(1-42) was measured by ELISA. Markers of BBB function and amyloid precursor protein were measured by Western blotting in whole tissue homogenates. Biologic TNFIs did not alter hematologic parameters, however, TfRMAb decreased hematocrit ($p<0.0001$) and increased WBC ($p<0.01$) compared to saline-treated mice. Both TfRMAb-TNFR ($p<0.0001$) and Etanercept ($p<0.001$) significantly reduced brain insoluble Aβ(1-42); however, only TfRMAb-TNFR reduced both cortical and hippocampal 6E10-positive Aβ area ($p<0.05$) and number ($p<0.05$) in the APP/PS1 mice. The 6E10-positive Aβ area ($p<0.05$) and number ($p<0.05$) were significantly higher in the Etanercept-treated mice compared to the TfRMAb-TNFR-treated APP/PS1 mice. TfRMAb-TNFR-treated mice spent more time ($p<0.01$) in the novel arm and had reduced latency ($p<0.05$) to enter the novel arm compared to the APP/PS1 saline-treated mice. Etanercept treatment did not improve spatial memory of the APP/PS1 mice. Additionally, TfRMAb-TNFR-treated-, but not Etanercept-treated-mice, had higher BBB-tight junction protein expression ($p<0.05$) compared to saline-treated mice. Overall, delayed treatment with either Etanercept or TfRMAb-TNFR (BBB-penetrating TNFI) reduced insoluble brain Aβ(1-42), however, TfRMAb-TNFR resulted in better therapeutic indices and also reduced 6E10-positive total Aβ peptide load, increased BBB-tight junction protein levels, and improved spatial memory in the APP/PS1 mouse model of human amyloidosis.

Title: Investigating the role of cytotoxic t cells in alzheimer's disease pathogenesis

Authors: *J. SANCHEZ[1], J. BECK[1], L. MCINTYRE[2], S. KIANI SHABESTARI[2], M. INLAY[1], C. WALSH[1], H. DAVTYAN[1], M. BLURTON-JONES[1];
[1]Univ. of California Irvine, Irvine, CA; [2]Univ. of California, Irvine, Irvine, CA

Abstract: The innate immune system have been strongly implicated in Alzheimer's disease (AD) pathogenesis. In contrast the role of adaptive immunity remains poorly understood. My studies elucidate the specific role of T cell infiltration into the AD brain parenchyma. I have utilized both immune-deficient and immune-intact AD transgenic mouse models. I performed transplantation of either bone marrow hematopoietic stem cells (HSCs) or adoptive transfer of donor splenic T cells into our immune-deficient AD mouse model and wild-type controls. I found a significant increase in Helper T cells, and an even greater increase in memory Killer T cells within RAG2ɣc-/-5xfAD brain parenchyma. Interestingly, T cells were sometimes observed adjacent to plaque-associated microglia in the RAG2ɣc-/-5xfAD brain, suggesting that activated microglia may play a role in T cell recruitment and/or antigen presentation to T cells. I next sought to determine whether a similar effect can be observed within immune intact AD mice. I generated, aged, and examined four genotypes of immune intact mice: wild-type, 5xfAD, PS19 tau mice, and bigenic Tau-5x mice. I confirmed that beta-amyloid induces infiltration of CD8 T cells and that the combination of amyloid and tau pathology induces the most robust infiltration of CD8 T cells. Results also showed the subtypes of CD8 T cells that infiltrate the brains of AD mice are memory T cells, demonstrating that they respond to only a few highly specific brain-derived antigens. I next performed stereological quantification of neuronal numbers within these mice brains and compared these results to flow cytometry quantification of CD8 T cells. This analysis suggests a potential correlation between CD8 T cell infiltration and neuronal loss with greatest magnitude of neuronal loss observed in bigenic mice that concurrently exhibit the greatest increase in CD8 T cell infiltration. I hypothesize that protective effects may be mediated via direct interactions with microglia that beneficially modulate microglial activity to facilitate beta-amyloid clearance. Conversely I hypothesize that CD8 T cells may adversely promote neuronal death in AD mouse models. My ongoing experiments include utilizing a TCRalphaKO mouse model to investigate if a genetically-mediated absence of T cells alter AD neuropathology and microglial activation state, and 10x TCR scSeq will be used to examine differing subpopulations of brain infiltrating T cells and whether these subpopulations exhibit T cell receptor clonality. These studies aim to test the overarching hypothesis that CD8 T cells induce both protective and detrimental responses within the AD brain.

Title: Evidence that the gut microbiota regulates progression of neurodegeneration in a mouse model of tauopathy, in a sex- and ApoE isoform-dependent manner

Authors: *D.-O. SEO[1], D. O'DONNELL[1], J. STANLEY[1], N. JAIN[1], J. ULRICH[1], J. R. SERRANO[1], X. BAO[1], M. LEMIEUX[1], M. KARLSSON[1], M. MEIER[1], C. DESAI[1], J. LELWALA-GURUGE[1], K. ALVES DE LIMA[1], J. KIPNIS[1], S. S. SISODIA[2], J. I. GORDON[1], D. M. HOLTZMAN[1];
[1]Washington Univ. in St. Louis, Saint Louis, MO; [2]Univ. of Chicago, Chicago, IL

Abstract: Alzheimer’s disease (AD) is a fatal progressive neurodegenerative disease. Mounting evidence supports that perturbations in the gut microbiota (GM) may be causally linked to amyloid-β deposition, potentially via neuroinflammation and/or disrupted metabolic homeostasis. However, the contribution of the GM to tau aggregation and accumulation, which is strongly correlated with cognitive decline in AD and other tauopathies, is poorly characterized. ApoE4 allele is the strongest genetic risk factor for late-onset AD. Here, we use a mouse model of tauopathy to explore the hypothesis that the GM regulates tau-mediated neurodegeneration in a sex- and ApoE isoform- dependent manner. Male and female P301S tau transgenic mice were crossed with human ApoE knock-in mice (ApoE3 or ApoE4) or ApoE knockout mice (EKO) to generate P301S:ApoE3/E3, ApoE4/E4, or P301S/EKO mice (abbreviated TE3F, TE4F, and TEKO, respectively). The GM in each group was perturbed by gastric gavage of an antibiotic cocktail (ABX) from postnatal days 16-22; controls were gavaged with water. Mice were maintained in a specified pathogen-free facility and fed a standard mouse chow diet *ad libitum* until euthanasia at 9.5 months. In addition, germ-free male and female TE4F mice were characterized. Conventionally-raised (CONV-R), SPF male TE3F and TE4F mice not exposed to ABX showed significant hippocampal atrophy compared to their P301S counterparts lacking a functional ApoE gene (TEKO). However, CONV-R ABX-treated TE3F mice had significantly milder hippocampal atrophy compared to water-treated control. ABX treatment of TE4F animals was also associated with milder hippocampal atrophy, although the effect did not achieve statistical significance. There were no effects in CONV-R TEKO mice treated with ABX. Remarkably, these phenotypic effects of ABX treatment were not observed in females. Moreover, germ-free TE4F mice showed a marked decrease in brain atrophy compared to conventionally-raised animals; this was true for both sexes. We have examined immunological and signaling mechanisms that modulate the observed neurodegeneration. Our results indicate that tau-mediated neurodegeneration occurs in an ApoE- dependent manner and is influenced by the gut microbiota and sex.

Title: Microgliosis and peri-plaque tau pathologies following chronic TREM2 activation

Authors: *N. JAIN[1], I. TASSI[2], J. D. ULRICH[1], D. M. HOLTZMAN[1];
[1]Neurol. Dept., Washington Univ. in St. Louis, St. Louis, MO; [2]Alector, South San Francisco, CA

Abstract: Alzheimer's disease (AD) is the most common form of dementia and characterized by memory loss and progressive decline in cognitive function which ultimately leads to death. Variants in the triggering receptor expressed on myeloid cells 2 (TREM2) are associated with increased risk for sporadic, late-onset AD. Studies have shown that loss of TREM2 function impairs the microglial response to amyloid-β (Aβ) plaques which correlates with increased peri-plaque neurite damage. Importantly, microglia and TREM2 lay at the critical intersection of Aβ and tau pathologies in AD and it is hypothesized that loss of plaque-associated microglia in TREM2 variant carriers increases AD-risk and disease progression via increasing susceptibility to tau-seeding and spread. Through use of a 5XFAD amyloid mouse model induced to display neuritic plaque (NP) tau pathology, this study looks at the effect of chronic activation of TREM2 on microglia and the development of peri-plaque tau pathologies. 30 male and 30 female 5XFAD amyloid mice at 6 months of age were injected in the dentate gyrus and overlying cortex with sarkosyl insoluble tau isolated from human AD brain tissue and at this time received intraperitoneal injection of a murine agonist TREM2 antibody or a murine IgG control antibody

weekly for 3 months. At 9 months of age, we are assessing microglial and astrocytic activation, density and clustering around Aβ plaques within the cortex and hippocampus of these mice. Additionally, we are assessing the Aβ plaque burden and compaction along with assessing NP tau pathology after treatment. Finally, we are assessing neuritic dystrophy through BACE1 expression. We hypothesize that treatment with the TREM2 antibody will increase microglial density and clustering around Aβ plaques, decrease neuritic dystrophy and decrease NP tau pathology. Our study will provide further insight on TREM2 as a targetable treatment option in AD.

Title: Alterations of synaptic transmission at plaque-associated regions and glial responses in the presence of the TREM2^{R47H} mutation in APP knock-in mice

Authors: *K. S. VITANOVA[1], R. M. JOGHEE[1], K. M. STRINGER[1,2], D. M. CUMMINGS[1], F. A. EDWARDS[1];

Abstract: The role of glia in disease progression has become a central focus for Alzheimer’s disease research. Studies have shown that both microglia and astrocytes cluster around amyloid plaques, where microglia may phagocytose synapses. Therefore, this work aimed to explore if this is a protective mechanism to limit plaque-associated dysfunction and how impaired microglial function, as conferred by the TREM2^{R47H} mutation, affects synaptic function and glial clustering in plaque regions. Voltage-clamp recordings were made in brain slices from *APP*$^{NL-F}$ and *APP*$^{NL-F}$/*TREM2*^{R47H} mice. In particular, unitary excitatory postsynaptic currents (uEPSCs) were evoked at CA3-CA1 synapses in the hippocampus of male and female mice with moderate plaque pathology. Post-hoc analyses were performed to assess how synaptic activity is altered depending on whether plaques were present between the stimulation site and the recorded cell.

Furthermore, hippocampal sections obtained from the contralateral hemisphere of the same mice were stained using immunohistochemistry to examine the distribution of $IBA1^+$ microglia and $GFAP^+$ astrocytes in relation to their distance from plaques. While both *APP*$^{NL-F}$ and *APP*$^{NL-F}$/*TREM2*^{R47H} mice showed a tendency for increased glutamate release when a plaque was detected ($p=0.058$), reductions in uEPSC amplitudes in plaque conditions were found only in *APP*$^{NL-F}$ mice ($p<0.05$). Thus, the effects on amplitude but not release are dependent on microglial function. Interestingly, *APP*$^{NL-F}$/*TREM2*^{R47H} mice exhibited reduced microglial density in regions with higher plaque density and specifically immediately in the vicinity of plaques ($p<0.0001$). This was more prominent in the vicinity of plaques larger than $100\mu m^2$. These mice also demonstrated higher overall plaque load than *APP*$^{NL-F}$ mice ($p<0.01$). Furthermore, although these mice did not exhibit different astrocytic density in the whole hippocampus, astrocytic area was significantly reduced near plaques in *APP*$^{NL-F}$/*TREM2*^{R47H} mice compared to *APP*$^{NL-F}$ mice. This effect was lost further away from plaques. Altogether, this study demonstrates that functioning TREM2 is necessary for some but not all plaque-associated effects on synaptic transmission which may be dependent on appropriate microglial and astrocytic response to plaques. Such compromised microglial function could potentially contribute to the spread of damage in neuronal networks.

Title: Spatial transcriptomics reveals a plaque-specific microglial expression-type dependant on Trem2

Authors: *J. WOOD[1], E. WONG[1], A. VANSCHOIACK[3], S.-L. J. PHELAN[3], R. JOGHEE[2], K. S. VITANOVA[1], A. PATHAK[4], T. TRIPATHI[1], J. HARDY[1], D. M. CUMMINGS[1], F. A. EDWARDS[1];

Abstract: The response of microglia to accumulating amyloid-beta plaques has become a pertinent feature of Alzheimer’s disease. RNA-seq-based techniques used to describe this

response consistently report a disease-associated microglial (DAM) population characterised by an upregulation of genes associated with inflammatory and phagocytotic processes. However, finding whether the plaque association of microglia is paralleled by a DAM-like expression signature has been limited by the lack of spatial context and absence of cell-specificity when employing bulk RNA-seq. To overcome this problem, we have undertaken a preliminary study using the GeoMx Digital Spatial Profiler (DSP; NanoString, Seattle WA) to explore the hypothesis that genes classically associated with DAM will be upregulated specifically in plaque-associated microglia and reduced upon the introduction of the R47H mutation in the microglial hub gene *Trem2*.
Paraffin-embedded hippocampal 8-micron sections were prepared from 18-month App^{NL-F} knock-in mice, App^{NL-F} knock-in mice harboring the *Trem2*-R47H mutation (both n=4), and age-matched wild type and *Trem2*-R47H controls (n=2-3). After immunohistochemistry was performed to identify microglia, astrocytes and plaques, the sections were processed by the GeoMx DSP. Whole-transcriptome RNA-probes were collected from microglia-stained plaque-contacting, peri-plaque, and away-from-plaque regions. Bulk RNA-seq was also performed using RNA collected from 18-month APP^{NL-F} knock-in mice and age-matched wild type controls (n=10-12).
GeoMx DSP analysis revealed that many DAM-associated genes were increased only in plaque-contacting or peri-plaque regions (e.g., 2.5-fold increase ($P<0.05$) in *Tyrobp* expression in App^{NL-F} plaque-contacting versus peri-plaque regions). The introduction of the *Trem2*-R47H mutation into App^{NL-F} knock-in mice induced an intermediate microglial activation state that presented a reduced expression of many *Trem2*-associated genes. Furthermore, many DAM-associated genes that were not significantly increased in our bulk RNA-seq analysis showed a significant increase in expression around plaques in the GeoMx analysis for App^{NL-F} mice.
DAM populations are not homogenous throughout a plaque burdened hippocampus but rather show spatial specificity towards plaque regions. This plaque-induced expression-type is partially impaired in microglia harbouring the *Trem2*-R47H mutation, once again revealing the importance of TREM2 in controlling microglial activation.

Abstract: The advances in genetics of Alzheimer's disease (AD), particularly from Genome Wide Association Studies, have been pivotal in increasing understanding of the interacting factors that influence the progression of pathology and risk of eventual onset of the disease. The development of APP knock-in (KI) mice with familial AD genes has been an essential step in improving models for AD, without problems of overexpression and random transgene insertion. Here, we present genome-wide transcriptomic analysis, from 2 to 24 months, in the hippocampus of male and female APPKI mice with and without heterozygous human Tau (KI). We correlate changes in gene expression and consider development of pathology as well as comparing male and female mice. We then assess the differences caused by the presence of human Tau and investigate development of plaques and the interaction with human Tau, to assess Aβ-induced Tau pathology.Perhaps most notably we find that introduction of human Tau heterozygously into APPKI mice, results in decrease in expression of mitochondrial genes for Complex V of the respiratory chain, particularly ATP8, with increasing age, while nuclear expressed mitochondrial genes for Complex V tend to increase in expression. We suggest that human tau inclusion changes the interaction of tau with mitochondria possibly due to increased susceptibility to phosphorylation with the increased amyloid β and ageing. These effects are being further verified and assessed using qRT-PCR and immunohistochemistry.The preliminary network analysis of gene expression identifies microglial modules correlated to pathology development in the two APP KI lines (App^{NL-F} and App^{NL-G-F}), similar to what we previously reported in transgenic mice. We see a strong upregulation of microglial genes in App^{NL-G-F} mice and a weaker effect in the later-plaque-developing App^{NL-F} mice, that we hypothesise to be related to a protective effect of the microglia. Inclusion of heterozygous human Tau results in a small decrease in this correlation of genes of microglial modules in both lines suggesting that, with the inclusion of human Tau, the protective effect of the microglia is compromised. Addition of human Tau also results in inverse correlations for modules for protein synthesis compared to APPKI mice and in App^{NL-G-F} mice inclusion of human Tau similarly affects synaptic proteins modules. Hence, RNAseq genome-wide studies of APPKI mice confirm findings from previous transgenic studies, particularly for microglial modules, while inclusion of Tau causes additional alterations, not previously reported.

Abstract: Microglia, the resident macrophages of the central nervous system (CNS), play a crucial role in immune defense and in maintaining CNS homeostasis. Microglia continuously scan synapses, but active synaptic remodeling by these cells is rarely directly detected in mature healthy brains. Hence, we developed an approach to efficiently attract microglia to specific synaptic sites using targeted laser photoablation of single synapses. The photodamage temporally and focally elevated the frequency and duration of microglia-neuron interactions, and dramatically increased both the turnover of dendritic spines and presynaptic boutons as well as the appearance of new filopodia originating from spine heads or boutons. Microglia depletion experiments confirmed that elevated spine turnover and the generation of presynaptic filopodia are microglia-dependent processes. Since microglia activation plays an important role in neurodegeneration, we evaluated microglial dynamics in the context of systemic inflammation and AD pathology in adult mice. Systemic and local acute activation of microglial cells (with lipopolysaccharide or sarkosyl-insoluble fraction derived from AD patient brain) increased photodamage-related synaptic remodeling and generation of filopodia as compared to resting microglia. Noteworthy, the synaptic loss observed after both types of immune challenges was preceded by prolonged microglia contact and was partially mediated by microglia phagocytosis. Our results provide direct evidence that activated microglia is not only more active in pruning dendritic spines through phagocytosis but also actively promotes the formation of new spines.

Interestingly, both immune challenges decreased surveillance of synapses by increasing microglia contact duration with a fewer number of synapses under baseline conditions. Together, these results indicate that microglia play a critical role in synaptic remodeling which is modulated by their activation state in adult brains, and uncover new aspects of how the activation of the immune system may impact synaptic connectivity and cognitive function.

Title: Loss of spleen sympathetic innervation accelerates cognitive loss in Alzheimer’s disease animal model

Authors: *T. CROESE[1], M. ARAD[2], S. PINCHUK[1], G. CASTELLANI[1], J. M. PERALTA RAMOS[1], S. SUZZI[1], M. SCHWARTZ[1];
[2]Neurobio., [1]Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The immune system and the central nervous system are each in direct contact with the other organs of the body, although their interconnection is only starting to be appreciated. The periventricular nucleus of the hypothalamus (PVN) and the central nucleus of the amygdala (CeA) were shown to have an influence on immune responses via their innervation of the spleen, the major secondary lymphoid organ, through their connections with the Nucleus Tractus Solitarii (NTS) and the Vagus nerve. Both the PVN and the CeA suffer neuronal loss and Tau pathology during neurodegenerative disorders such as Alzheimer’s Disease (AD), nevertheless, to the best of our knowledge, the impact and consequences of impairment in this pathway in AD has never been studied. To test the role of splenic innervation in animal models of AD (5xFAD) and WT mice, we adapted a surgical denervation protocol treating splenic nerve plexuses with alcohol before they enter the spleen, selectively ablating the innervation of the spleen without affecting other organs. Sham-operated mice were used as controls in both groups. Subsequently, we tested the cognitive performance (Novel Object Recognition - NOR; Radial Arm Water Maze - RAWM) of all mice (4 groups, 8 mice per group), and we studied their immune landscape in both the spleen and blood through high-dimensional single-cell mass cytometry (CyTOF). Loss of the sympathetic innervation of the spleen significantly accelerated cognitive loss in 5xFAD but not in WT mice (NOR: $F(3, 24)=8.04$, $p<0.001$. RAWM: $F(3, 24)=32.02$, $p<0.001$). The cognitive loss was associated with significant immune alterations that were more pronounced in 5xFAD mice compared to WT mice. Specifically reduction of splenic and circulating B cells

(*p's*<0.05), reduction of splenic Dendritic cells (*p<0.05*), and increase in splenic CD8+ T cells (*p<0.05*). Overall, these results show that the integrity of the spleen and the immune system play an important role in the ability to cope with AD, and suggest that AD-related deterioration in the CeA and PVN might lead to immune dysfunction that further accelerates the disease.

Abstract: Most patients with advanced Parkinson's disease (PD) exhibit disturbances of gait, which severely affects their independence and quality of life. A commonly used therapy, deep brain stimulation (DBS) of the subthalamic nucleus (STN), has limited efficacy on severe gait deficits. We reasoned that the identification of STN neural dynamics during walking could guide the design of stimulation protocols specifically addressing gait deficits.
To deconstruct the neural dynamics underlying walking, we designed a well-controlled paradigm restricted to single joints of the legs. We recorded the local field potentials from DBS electrodes implanted in the STN of 20 PD patients as they produced varying isometric forces restricted to a single joint. Isometric force production led to low (~13-20Hz) and high beta (~20-35Hz) desynchronizations of STN LFPs that were time-locked to effort initiation, adaptation and termination, followed by a beta rebound. These modulations were present during passive and active movements. Surprisingly, these modulations were not only present in the STN ipsilateral to the active legs, but also on the contralateral side. Maintaining stronger efforts involved longer desynchronizations. This understanding allowed us to design a decoder based on a random-forest classifier that predicted the level of effort online.
We then leveraged these findings to design comparable conditions during gait. We found that gait initiation, adaptation and termination were marked by beta desynchronizations and could be decoded efficiently by our classifier. Additionally, the STN encoded changes in the length of the step, which allowed decoding of left versus right gait phases. Lastly, we identified increase in low beta power during freezing of gait, which supported the design of a freezing episode decoder.
These results may guide the decoding of abnormal gait patterns in PD, such as asymmetry,

shuffling steps or freezing of gait. Such biomarkers are critical for the development of adaptative DBS protocols targeting gait disorders.

Title: Alternating Neurophysiological States representing Parkinson's Tremor, Bradykinesia, and Optimal Motor Performance in the Subthalamic Nucleus and Sensorimotor Cortex

Authors: *P. LAURO[1], S. LEE[2], D. E. AMAYA[1], D. LIU[1], U. AKBAR[3], W. F. ASAAD[4]; [2]Neurosci., [3]Neurol., [4]Neurosurg., [1]Brown Univ., Providence, RI

Abstract: Neurophysiological biomarkers of disease expression can be used to monitor disease progression, assess therapeutic efficacy, and enable effective closed-loop neuromodulation. In the case of Parkinson's disease (PD), motor manifestations are heterogeneous and asynchronous. Thus, we examined neural activity in the subthalamic nucleus (STN) of 32 subjects (4 female, 47-78 years old) with PD to decode tremor and bradykinesia, two distinct, cardinal signs of this disease, and to discriminate these states from asymptomatic periods of behavior using a rigorous, quantitative visual-motor task. We also obtained electrocorticography along sensorimotor cortex from 10 of these subjects. Using support vector regression (SVR) with depth and electrocorticography signals, we found that tremor and bradykinesia had distinct, nearly opposite neural signatures, and that effective motor control without tremor or bradykinesia displayed unique, differentiating features.
Within the STN, we discovered that optimal tremor and bradykinesia decoding models leveraged distinct frequencies (theta-alpha; 3-12 Hz v. beta-gamma; 20-30/60-100 Hz, respectively) within the local field potential spectrum. We also found that each motor sign was more strongly

represented in a distinct subregion of the STN, with optimal tremor decoding sites (x = +14, y = +13, z = −5) found to be dorsolateral to optimal bradykinesia decoding sites (x = +11, y = +13, z = −8).
In addition, tremor and bradykinesia decoding from cortical recordings exhibited superior decoding performance relative to STN recordings for both tremor (ECoG v. STN, r = 0.275±0.226 v. 0.204±0.236, p = 0.002, Mann-Whitney U test) and bradykinesia (r = 0.249±0.222 v. 0.109±0.175, p < 0.001). While cortical decoding models for tremor and bradykinesia used similar frequency bands (beta and gamma), their model weights were applied in an opposing fashion between tremor and bradykinesia.
To dissociate optimal motor performance from symptomatic states, a measure of ”good performance“ was also calculated as the absence of tremor and bradykinesia for each patient. SVR models decoding good performance revealed distinct gamma frequency activity for both STN (30-45 Hz) and cortical (45-55 Hz) recordings.
Overall, tremor and bradykinesia were better decoded from different portions of the STN, and cortical decoding accuracy generally exceeded subcortical decoding. While tremor and bradykinesia exhibited opposing frequency profiles of spectral activity, optimal motor performance correlated with specific gamma frequencies. These results provide a roadmap to leverage real-time neurophysiology to understand and treat PD.

Title: Deep brain stimulation influences networks rather than individual neuron activity in the cortico-basal ganglia motor circuit

Authors: *A. C. GUEST[1], D. GRAHAM[2], H. SHILL[2], F. PONCE[2], B. GREGER[3];
[1]Univ. of Arizona Col. of Medicine--Phoenix, Phoenix, AZ; [2]Barrow Neurolog. Inst., Phoenix, AZ; [3]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Deep brain stimulation (DBS) is a well-established treatment for Parkinson’s disease (PD) and other movement disorders, where stimulation is delivered to particular anatomical targets in the brain to alleviate symptoms of the disease. Our goal is to investigate the network

dynamics of the cortico-basal ganglia circuit and local circuits within the subthalamic nucleus (STN) when applying DBS. This project is part of a larger effort to understand the neurophysiological mechanism of DBS, and how DBS changes motor processing in the human brain. There is a gap in our knowledge regarding if DBS affects the brain on a cellular versus a network level (McIntyre et al. 2004; Lozano et al. 2019). Here, we examine individual neurons, local circuits, and network relationships in the STN and cortex with DBS. Patients with PD underwent neurosurgery for DBS electrode placement. Intraoperatively, we recorded APs and LFPs from a microelectrode placed in STN, 2 mm anterior to the DBS lead. We simultaneously recorded LFP in the premotor cortex using a micro-electrocorticography (micro-ECoG) grid. DBS was performed in the anesthetized patient at various frequencies (30, 70, 140, and 250 Hz). Statistical significance was tested with ANOVA or t-tests and used a time-jittered "AP"-aligned LFP as a control. In our preliminary results, DBS does not change the firing rate of neurons in the STN. The LFP in the STN aligned on APs from a neuron in the STN shows increased power in the alpha frequency band when stimulated at a clinically relevant frequency (140 Hz). The cortex has a complex relationship with the neurons on the STN on subcentimeter scale, but it does not appear to be affected by DBS. Our results provide insight into the effects of DBS on neural tissue. This data suggests that DBS acts at the network level because of the lack of effect on STN neuron firing and the changes in AP-LFP relationship. Examining the cortex on a spatial scale relevant to cortical activity is critical to understanding the role of the cortex in the mechanism of DBS. LFPs on the cortex show a complex relationship with the STN and in response to DBS, perhaps reflecting multiple anatomic routes for stimulation propagation. Determining the electrophysiological changes in neural circuits with DBS will advance our mechanistic understanding of DBS in the cortico-thalamic-basal ganglia circuit and provide insight into DBS and neural pathology.

Title: Deep brain stimulation-induced local evoked potentials can guide intraoperative targeting and postoperative programming in Parkinson's disease.

Authors: *E. OPRI[1], F. ISBAINE[2], N. AU YONG[2], J. T. WILLIE[3], N. M. BOULIS[2], T. WICHMANN[1], R. E. GROSS[2], S. MIOCINOVIC[1];

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has become standard therapy for patients with Parkinson's disease (PD). Both accurate surgical implantation and optimal postoperative programming of the DBS device are required to realize the full therapeutic benefit, determining which parameters provide the best symptom suppression and the fewest side effects. This process is a time consuming trial and error approach, relying on clinical intuition and repeated patient exams. We studied whether the placement of leads and postoperative programming could instead be guided by measuring DBS local evoked potentials (DLEP) during the implantation surgery. DLEP is a strongly stereotyped stimulation-induced oscillatory activity measured from non-stimulating DBS lead contacts. We hypothesized that contacts whose stimulation produces the largest DLEP amplitude would be localized in the dorsal STN and would have the best therapeutic effect.We recorded intraoperatively DLEPs from leads implanted in the STN using low-frequency (1 and 3 mA, 10 Hz, 12 s blocks) stimulation in 16 patients with PD. We developed a post-processing artifact-suppression pipeline to reliably recover DLEP activity from a commercially available clinical amplifier (Neuro Omega), facilitating the deployment in routine surgery. DLEP activity was recovered after each stimulation pulse with multi-epoch averages. DLEP amplitude was estimated as the root-mean-square within 4-20ms after the pulse. Positions of the stimulating and recording contacts were determined from microelectrode mapping. We also recorded spontaneous local field potential activity at each contact to calculate peak beta power (within 13-30Hz). We surveyed clinical postoperative records to determine therapeutic efficacy of each contact (at initial programming and up to 1 year after surgery).We demonstrate that our pipeline reliably recovers DLEP from noisy recordings, due to the brief saturation recovery of the amplifier. The DLEP amplitude was indicative of the postoperatively determined therapeutic efficacy of the stimulating contact ($p<0.01$) and stimulating contact location, as it was the highest within the dorsal STN (in vs out-STN: $p<0.05$; dorsal vs ventral STN: $p<0.0001$). In contrast, contact's ability to record DLEP (as opposed to elicit DLEP) was not predictive of its location (in vs out-STN: $p>0.19$; dorsal vs ventral STN: $p>0.08$) or clinical efficacy ($p>0.5$). Beta power was less predictive of the location (in vs out-STN: $p<0.05$; dorsal vs ventral STN: $p>0.4$) or clinical efficacy ($p>0.2$). In conclusion, DLEP analysis is a promising method to guide lead placement and postoperative programming.

Title: Local Cell-Specific Pallidal Deep Brain Stimulation Ameliorates Parkinsonian Motor Deficits

Authors: *C. YU, H. LOUGHLIN, C. LOOMAN;
Michigan Tech. Univ., Houghton, MI

Abstract: Deep brain stimulation (DBS) is an established therapy for the motor symptoms of advanced Parkinson's disease (PD). The globus pallidus interna (GPi) is a commonly used anatomical target and clinically effective for DBS in PD therapy. The therapeutic effects of GPi DBS are frequency-dependent; high frequencies relieve PD motor symptoms, while low frequencies are not effective. Despite well-established clinical benefits, how GPi DBS exerts its therapeutic effects remains unclear. Here, we performed optogenetic stimulation in the entopeduncular nucleus (EP, rat homologue of GPi) using an ultrafast opsin (Chronos) in a unilateral 6-OHDA-lesioned rat model of PD. The Chronos construct was packaged into an adeno-associated virus serotype 5 (AAV5) under the control of the human synapsin neuron-specific promoter. We quantified the behavioral effects of different frequencies of optogenetic GPi DBS on motor deficits using circling behavior and adjusting steps test. We conducted single-unit recordings in GPi and ventral lateral motor thalamus (VL) to quantify changes in neural circuit activity during 130Hz optogenetic GPi DBS in the urethane-anesthetized PD rats (1.2g/kg, subcutaneous). We found that optogenetic stimulation of GPi local neurons exhibited a strong dependence on stimulation frequencies; high-frequency DBS (130Hz) alleviated pathological ipsilateral turning and corrected abnormal forelimb stepping while low frequency (20Hz) DBS was ineffective. Optogenetic activation of GPi at 130 Hz increased (45%) or decreased (38%) neural activity in the GPi. Similarly, neurons in the VL exhibited both increases (48%) and decrease (29%) in firing rate during 130 Hz optogenetic GPi DBS. Further, we conducted a spectral analysis of single-unit firing times to quantify the effects of optogenetic DBS on oscillatory activity. We found that GPi neurons (75%) exhibited decreased beta-band oscillatory activity (13-35Hz) during 130 Hz optogenetic GPI DBS. Similarly, the majority of VL neurons (71%) exhibited a reduced oscillatory peak in the beta band during 130 Hz optical DBS. Our results suggest that the neural firing rates within GPi and VL circuits were differentially modulated and could not explain the frequency-dependent behavioral effect of GPi DBS. Rather, high-frequency optogenetic GPi DBS could ameliorate parkinsonian motor symptoms through reduction of pathological oscillatory activity in the GPi-linked neural circuit.

Title: Deep brain stimulation in the subthalamic nucleus for Parkinson's disease can restore dynamics of striatal networks

Authors: *E. M. ADAM[1], E. N. BROWN[1], N. J. KOPELL[2], M. M. MCCARTHY[2]; [1]MIT, Cambridge, MA; [2]Boston Univ., Boston, MA

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) is highly effective in alleviating movement disability in patients with Parkinson's disease (PD). However, its therapeutic mechanism of action is unknown. The healthy striatum exhibits rich dynamics resulting from an interaction of beta, gamma and theta oscillations. These rhythms are at the heart of selection, initiation and execution of motor programs, and their loss or exaggeration due to dopamine (DA) depletion in PD is a major source of the behavioral deficits observed in PD patients. Interrupting abnormal rhythms and restoring the interaction of rhythms as observed in the healthy striatum may then be instrumental in the therapeutic action of DBS. We develop a biophysical networked model of a BG pathway to study how abnormal beta oscillations can emerge throughout the BG in PD, and how DBS can restore normal beta, gamma and theta striatal rhythms. Our model incorporates STN projections to the striatum, long known but understudied, that were recently shown to preferentially target fast spiking interneurons (FSI) in the striatum. We find that DBS in STN is able to normalize striatal medium spiny neuron (MSN) activity by recruiting FSI dynamics, and restoring the inhibitory potency of FSIs observed in normal conditions. We also find that DBS allows the re-expression of gamma and theta rhythms, thought to be dependent on high DA levels and thereby lost in PD, through cortical noise control. Our study shows how BG connectivity can amplify beta oscillations, and delineates the role of DBS in disrupting beta oscillations and providing corrective input to STN efferents to restore healthy striatal dynamics.

Title: Effects of levodopa and DBS on physiology of emotional conflict in Parkinson's disease patients implanted with a chronic sensing device

Authors: *B. WILT[1], R. PERRONE[1], P. A. STARR[2], S. LITTLE[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Neurosurg., Univ. of California San Francisco Dept. of Neurolog. Surgery, San Francisco, CA

Abstract: Parkinson's disease impairs emotion recognition and decision making due to dopaminergic denervation in mesocorticolimbic pathways. Levodopa and deep brain stimulation (DBS) have been known to modulate patient's affective states and decision making thresholds, but it remains unclear how this is indexed in neurophysiological brain signals. The objective of this study is to identify neural biomarkers and behavioral correlates of emotional conflict in Parkinson's patients with chronically implanted deep brain stimulation (DBS) electrodes and to assess the impact of levodopa and DBS on these biomarkers. Parkinson's patients (n = 4) with bilateral, chronically implanted Subthalamic Nucleus (STN) leads and a cortical sensori-motor electrocorticography 4 contact electrode strip, completed an emotional stroop task where they indicated the emotion expressed by a face while ignoring a word distractor. Patients also completed a gender-based control version of the task. Patients completed the task twice for each of the four conditions (off meds / off stim, off meds / on stim, on meds / off stim, and on meds / on stim) over 2 subsequent days. Invasive neurophysiology from the STN and motor cortex was recorded while patients performed the task using an investigational, sensing-enabled DBS stimulator. For DBS treatment conditions, patients were on their clinical monopolar DBS configuration. Across all conditions, patients made more errors for incongruent than congruent trials. The emotional stroop effect was higher for the levodopa condition than for the DBS condition with the largest stroop effect difference occurring between on/off levodopa without the presence of DBS. The control sub-task did not demonstrate an increased stroop effect when comparing levodopa on and off conditions. With DBS off, STN theta (3-7hz) power increased after stimulus presentation (300-600ms) in the on levodopa condition compared to the off levodopa condition. DBS increased STN theta power in the levodopa off condition, however theta power was decreased in the levodopa on condition. STN theta power in Parkinson's patients has been associated with conflict detection and plays a key role in decision making gating mechanisms. This study's behavioral and neurophysiological results suggest that dopamine and DBS modulate emotional conflict signals in the STN which may mediate their impact on behavior.

Title: Different Effects of Dopaminergic Medications on Subthalamic Beta Bursts and Non-Oscillatory Fractal Components in Parkinson's Disease: A Longitudinal Study

Abstract: Exaggerated beta power in the local field potentials (LFPs) recorded from the subthalamic nucleus (STN) is a hallmark of Parkinson's disease (PD). Longer durations and higher amplitudes of beta bursts are associated with motor impairment. STN- deep brain stimulation (DBS) and dopaminergic therapy attenuate beta power and shorten beta burst durations in PD patients. To date, little is known about the long-term effects of STN-DBS on beta oscillations and how it relates to disease progression after the stun effect of DBS placement has disappeared. The first aim of this study was to investigate the long-term effects of STN-DBS and levodopa on the beta band characteristics. In addition to oscillations, which are often identified as narrowband peaks in the spectrogram of the neurophysiological signals, brain activity entails a dominant fractal (non-oscillatory) component. There is ample evidence that fractal components carry critical physiological and pathophysiological characteristics closely linked to neural functions. The second aim of this longitudinal study was to separate oscillatory and fractal components, which are likely generated through different mechanisms. Here we used Irregular-Resampling Auto-Spectral Analysis (IRASA) to separate oscillatory and fractal components in the power spectrum of the STN-LFP signals and hypothesized that chronic STN-DBS and levodopa treatment not only change the oscillatory part of the beta band but also modulate the fractal component of beta-band signals. Ten patients with idiopathic PD participated in this study. Simultaneous bilateral STN-LFP recordings were conducted in five separate visits at 1, 2, 6, 12, and 18 months post-operation. Each visit was conducted over two days in the OFF and ON dopaminergic medication states. The results revealed a relatively stable benefit of dopaminergic medication for normalizing pathologic beta bursts over time with shorter burst durations and lower burst amplitudes in the ON medication compared to the OFF medication state. In contrast, fractal components were not significantly changed with dopaminergic medications. However, both the slope (exponent) and intercept (offset) of the beta band fractal components progressively increased over time. Since previous studies have shown

that global enhancement of the GABAergic transmission under general anesthetics resulted in larger slope of the fractal component, our findings suggest that long-term STN-DBS might have increased inhibition in the basal ganglia-cortical circuitries.

Title: 3d-ultrastructural analysis of gabaergic and glutamatergic synapses in the subthalamic nucleus of parkinsonian monkeys

Authors: *A.-C. MARTEL[1,2], R. M. VILLALBA[1,2], T. WICHMANN[3,1,2], A. GALVAN[1,2,3], Y. SMITH[1,2,3];
[1]Yerkes Natl. Primate Res. center, Atlanta, GA; [2]UDALL center of Excellence for Parkinson's Dis., Atlanta, GA; [3]Dept of Neurology, Emory Univ., Atlanta, GA

Abstract: The subthalamic nucleus (STN) is part of the indirect pathway of the basal ganglia, receiving its main glutamatergic and GABAergic innervation from the cerebral cortex and the external globus pallidus (GPe), respectively. Alterations of STN firing rates and patterns are linked to the severity of parkinsonian motor signs. Neuroplastic changes in the abundance, morphology and strength of GABAergic and glutamatergic synapses to the STN may contribute to the pathophysiology of parkinsonism. Severe cortical glutamatergic denervation of the STN has been described in primate and mouse models of parkinsonism (Mathai et al., 2015, Brain 138:946; Fan et al., 2012, JNS 32:13718). Additional changes in the strength and morphology of GPe-STN GABAergic synapses have been characterized in parkinsonian mice, but not in primates. To further characterize structural neuroplastic changes of GPe-STN terminals in parkinsonian monkeys, we undertook a quantitative morphometric 3D electron microscopy (3D-EM) analysis of these terminals and their synapses in the STN of MPTP-treated monkeys. The single block facing/scanning electron microscopy (SBF/SEM) approach combined with the *Reconstruct* software was used to address this issue. Preliminary data were collected from 55

3D-reconstructed GABAergic pallidal terminals in the STN of 2 MPTP-treated parkinsonian monkeys. The pallidal terminals were identified either by anterograde labeling from the GPe or using known ultrastructural features (large size, multiple symmetric synapses, two or more mitochondria). We collected morphometric data for each terminal, including its volume, the flat area of the post-synaptic densities (PSDs) formed by the terminal, and the number and size of mitochondria within the terminal. Our data show that the volume of GPe terminals ranged from 1.13-26.41μm^3 (mean ± SEM= 4.02 ± 0.47). Each terminal formed large and complex multi-fragmented synapses with flat areas varying from 0.04-2.67μm^2 (0.42 ± 0.05). The number of mitochondria per terminal ranged from 2-31 (5.15 ± 0.55), while the volume of individual mitochondria varied between 0.06-0.34μm^3 (0.15 ± 0.008). Studies in control monkeys are in progress. To determine the impact of the parkinsonism-associated breakdown of the cortico-STN projection on the pattern of synaptic innervation of STN neurons, 3D-EM approaches are being used to map the localization and quantify the abundance of glutamatergic and GABAergic terminals on STN dendrites in control and parkinsonian monkeys. Together, results of these studies will lead to a better understanding of the parkinsonism -associated changes of the synaptic innervation of STN neurons.

Title: Evaluation of marmoset as possible non-human primate model for HTT splicing modulation studies

Authors: *A. STRIJBOSCH[1], **M. E. HERVA MOYANO**[2], E. LORO[2], S. BRONKHORST[1], A. KYRIZAKI[1], J. SUTCLIFFE[2], P. MITCHELL[2], D. F. FISCHER[2], R. CHEN[3], G. MCALLISTER[4], L. LIU[4], V. KHETARPAL[3], C. DOMINGUEZ[4], I. MUNOZ-SANJUAN[4]; [1]Charles River, Leiden, Netherlands; [2]Charles River, Saffron Walden, United Kingdom; [3]CHDI Fndn., Princeton, NJ; [4]CHDI Fndn., Los Angeles, CA

Abstract: Several modalities aimed at lowering levels of pathogenic mutant HTT (mHTT) are currently in development for the treatment of Huntington’s Disease. Recently, small molecules have been identified targeting HTT mRNA splicing, that result in nonsense mediated decay (NMD) decreasing HTT mRNA and thus lowering HTT protein production. The use of orally bioavailable, brain penetrant small molecules for therapeutic intervention represents a potential advantage over other drug modalities currently in development.

One of the current small molecule splicing modulators appears to efficiently target a sequence in the human HTT gene (exon 49/50 and the intervening intron) that is poorly conserved in rodent HTT, thereby precluding the ability to directly test these compounds for on-target mechanisms (efficacy and safety) in standard rodent models.
The evaluation of a non-human primate (NHP) model would be beneficial towards progression of splicing modulating candidate molecules and assessment of possible off-target effects. Here we described the characterization of the Callithrix jacchus (common marmoset) as an NHP model given the strong similarity between marmoset and human HTT genomic sequences (95.1%) and the establishment of *in vitro* assays. Thereupon, a buccal cavity tumour and skin biopsies taken from common marmosets were used for the generation of immortalized marmoset fibroblast lines. Splicing modulation-mediated effects were assessed using a set of marmoset-specific Taqman assays to detect alternative splicing of HTT by the evaluation of exon 49-50 levels and iExon49b inclusion and additionally the effects on HTT protein levels were evaluated. Off-target effects were assessed by measurement of MADD exon 20-21 and FOXM1 exon 8-9 levels. Together the data demonstrate the evaluation of the common marmoset as model for HTT splicing modulation studies.

Abstract

In Huntington's Disease (HD), the uninterrupted CAG repeat length, but not polyglutamine length, predicts the disease onset yet the underlying pathology remains unclear. Here, we developed a human mutant huntingtin (mHTT) BAC transgenic mouse with long uninterrupted CAG repeats. This model (BAC-CAG) exhibits progressive behavioral deficits, striatal mHTT aggregation, synaptic pathology and astrogliosis. Interestingly, unlike previous human *HTT* BAC transgenic models with CAA interruptions in the polyglutamine coding region, BAC-CAG mice show robust and progressive striatal somatic repeat instability and transcriptomic dysregulation. We will present our current analysis of potential toxic entities that are associated with the distinct spatiotemporal patterns of neuropathogenesis elicited by human mHTT with or without long uninterrupted CAG repeats.

Abstract: Huntington's disease (HD) is a neurodegenerative disorder caused by an expansion in the number of glutamine-encoding CAG repeats in the huntingtin gene. The impact of mutant huntingtin (mHTT) on the brain's functional architecture is not fully understood. To address that, we sought the identification of functional imaging markers at the pre-manifest, early manifest, and advanced manifest stages in the Q175 heterozygous (HET) mouse model of HD. Resting-state (RS) functional MRI (1200 GE-EPI volumes, TR 0.5s) was performed at 9.4T (Bruker Biospec) using the cryo coil. 18 wild-type (WT) and 19 HET mice were scanned under anesthesia (0.5% isoflurane, 0.075mg/kg medetomidine, s.c. bolus followed by 0.15 mg/kg/h s.c. infusion), at 3 (pre-manifest), 6 (early manifest), and 10 (manifest stage) months of age. At each age, a range of 2-20 RS-co-activation patterns (CAPs) was identified based on the similarity of spatial distributions of voxel-wise z-scored BOLD signals. Data from all 39 subjects were concatenated before CAP extraction, thus enabling subsequent group comparisons. We compared WT and HET groups for voxel-level activation of each CAP as well as its duration, occurrence, and the transition entropy (a measure of systematicity of transitions to other CAPs). Finally, we assessed the predictive power of CAP features to distinguish HET from WT subjects at each age with cross-validation. Most robust inter-group differences were found in two prominent CAPs, which are human analogs. Duration and occurrence of the default-mode-like network (DMLN) CAP, displaying co-activation of DMLN and co-deactivation of the lateral-cortical network (LCN), and of its anti-correlated pair, the LCN CAP, were reduced in the HET group at the manifest stage. At the pre-, and early- manifest stages, HET animals showed lower occurrence and duration for LCN and DMLN CAP respectively. DMLN CAP's transition entropy was significantly reduced in the HET group at the manifest stage. While their durations and occurrences performed significantly better than the chance level accuracy of 50% in predicting the animal identity, the classification accuracy using voxel-wise activations of CAPs was significantly higher at nearly 80% at all stages. Our results suggest that the impact of mHTT on brain function is borne by biologically and translationally relevant transient states. Further, we find that RS-CAPs are powerful candidates for an early biomarker of Huntington's disease.

Title: Behaviour characterization of the Q175/B6 Huntington's disease mouse model

Authors: *J. CHENG[1], E. T. KOCH[2], L. A. RAYMOND[3];
[2]Psychiatry, [3]Dept Psychiatry and Ctr. for Brain Hlth., [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Q175/B6 is a knock-in mouse model of Huntington’s disease (HD), a neurodegenerative disorder characterized by chorea, loss of motor control and cognitive deficits. The primary site of neurodegeneration in HD is the striatum, a brain region important for motor learning. Studies have found hypoactivity and abnormal rearing behaviours in older HD mice during the open field. Other studies have revealed motor and cognitive deficits in Q175 mice on the accelerating rotarod and water T-maze tasks at around 10 months of age. This study aims to investigate behavioural changes in both 2-month-old (presymptomatic) and 10-month-old (symptomatic) Q175 mice while conducting more detailed analyses on the specific patterns of behaviour using the DeepLabCut tracking software and the new Behavioral Segmentation of Open Field in DeepLabCut (B-SOiD) machine learning program. 10-month-old Q175 mice showed differences in the frequency of locomotor, sniffing, grooming, and rearing behaviours as compared to wild-type (WT) during the open field. The older cohort also showed motor deficits on the rotarod, with a reduced latency to fall and a greater number of foot slips as analyzed with DeepLabCut. In the water T-maze, 2-month-old Q175 mice took significantly longer than WT to reach the hidden platform during the reversal phase. However, in the older group, only those that used a striatum-dependent response learning strategy during training showed a higher latency to reach the platform in both training and reversal phases. These findings reveal that Q175 mice show notable motor learning deficits at 10 months of age, as well as reduced exploratory behaviour and potentially increased anxiety-like behaviours in the open field. Our comparison between the two age groups suggests that younger Q175 mice may show early signs of impairment in cognitive flexibility, and that the specific strategy used during motor learning may be more relevant at the older age. Future studies that examine striatal signalling during performance of these tasks are needed for evaluation of potential therapeutic treatments in HD.

Title: Preclinical behavioral assessments of systemic, allele-specific transcriptional repression of mutant huntingtin as a therapeutic strategy for Huntington’s disease

Authors: *L.-Y. ZHANG, A. Y. KIM, I. GILDISH, S. ARONI, J. F. CHEER;
Anat. and Neurobio., Univ. of Maryland Sch. of Medicin Program In Neurosci., Baltimore, MD

Abstract: Huntington’s disease (HD) is an inherited monogenic progressive neurodegenerative disorder caused by a polyglutamine (CAG) expansion in the huntingtin gene. Resultant striatal and cortical dysfunction are the hallmark neuropathological features underlying dyskinesia (e.g. chorea) and akinesia at later stages. In addition, motivational and cognitive deficits commonly manifest concurrently with, or preceding, motor dysfunction. A recent study reported that engineered zinc finger protein transcription factors (ZFP-TFs), tuned to selectively target pathogenic CAG repeats for allele-selective repression, when locally administered into the striatum, efficiently suppressed mHTT production and ameliorated transcriptional and electrophysiological deficits in full length heterozygous knock-in Q175 mice. Expanding on these findings, we postulated that the systemic delivery of ZFP-TFs under the control of a synapsin promoter would permit broader transduction and consequent suppression of mHTT throughout the central nervous system. However, the efficacy and tolerability of systemic ZFP-TF-mediated suppression of mHTT has yet to be elucidated. We thus optimized systemic delivery of AAV_PHP.eB packaged ZFP-TFs, with its control lacking the ZFP DNA-binding domain, in 3-month and 6-month old male Q175 mice via retro orbital injection. We assessed the tolerability of ZFP-TFs by monitoring body weight, temperature, locomotor function in an open-field arena, and anxiety-like behavior in the elevated plus maze. Additionally, 3-month old WT mice treated with ZFP-TFs were trained on a fixed-ratio (FR) 5 and progressive ratio (PR) schedule of reinforcement. Here, we show that ZFP-TF administration induced a significant decrease in bodyweight in both WT and Q175 mice across age that led to an increase in mortality in both Q175 and WT animals. Mice of both genotypes failed to demonstrate any significant differences in locomotor function across viral treatment or age. However, both 6-month old WT and Q175 mice treated with ZFP-TFs exhibited a robust decrease in time spent in the closed arms in the elevated plus maze, suggesting that ZFP-TFs exert a non-specific, anxiolytic effect on all animals across the studied age range. WT mice treated with ZFP-TFs acquired significantly

fewer rewards in both FR5 and PR tasks, indicating that ZFP-TFs compromise reward-seeking behavior by a mechanism unrelated to mHTT suppression. Our findings suggest that further validation of the tolerability of systemically administered ZFP-TFs will critically inform preclinical development of this DNA-targeting approach to ameliorate HD pathogenesis.

Abstract: Huntington's disease (HD) is a genetically inherited progressive neurodegenerative disease caused by a mutation in the trinucleotide repeats of cytosine, adenine, and guanine (CAG) of the huntingtin (*HTT*) gene. The mutation in the *HTT* gene increases the number of CAG repeats, leading to an increased production of the mutant huntingtin protein. Healthy individuals typically exhibit 16 to 20 CAG repeats on the *HTT* gene, while those with HD exhibit 35 or greater CAG repeats, with an increase in CAG repeats corresponding to an increased severity in HD symptoms, including motor and cognitive declines, involuntary movements, weight loss, muscle loss, and a shorter lifespan. Currently, there is no treatment for Huntington's disease. The R6/2 mouse model of HD has a mutated exon 1 of the human huntingtin gene that exhibits 160 CAG repeats, serving as severe model for individuals with HD. R6/2 mice display similar symptoms to HD patients, such as severe weight loss, muscle loss, deficits in motor function, and reduced lifespan. Individuals with HD show a decrease in GM1 ganglioside levels,

severely affecting neurons and ultimately leading to a shorter lifespan in the affected individual. Treatment of mouse models of HD with bovine-sourced GM1 gangliosides leads to a decrease in disease symptoms. Bovine-sourced GM1 gangliosides are extracted from cow brains, while ovine-sourced GM1 gangliosides are extracted from sheep brains. Ovine-sourced GM1 gangliosides are one-fourth the cost and thus may serve as a cost-efficient alternative to bovine-sourced GM1 gangliosides. The aim of this project was to determine the effectiveness of ovine-sourced GM1 ganglioside treatment on R6/2 mouse models by studying survivability and quality of life of the mouse model. The results of our study indicated that HD mice treated with ovine-sourced GM1 ganglioside showed a significant increase in weight over their lifespan compared to bovine-sourced GM1 ganglioside treated HD mice and the control HD group. Ovine-sourced and bovine-sourced GM1 ganglioside-treated HD mice had a prolonged lifespan of nine and twelve days, respectively, compared to vehicle-treated HD mice. *Support for this study was provided by the Neuroscience program, College of Medicine, and the John G. Kulhavi Professorship in Neuroscience at CMU, and the Field Neurosciences Institute.*

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disease caused by mutations in the Huntington (*HTT*) gene containing a long polyglutamine (CAG) stretch. This mutation leads to excessive production and accumulation of mutant huntingtin protein (mHTT) in the brain. This excessive mHTT protein accumulation causes motor, psychiatric, cognitive impairments and, ultimately, neuronal death. Currently, no effective treatment has been approved for HD. However, a promising line of research in therapeutics for HD, involves the use of GM1 ganglioside, as levels of GM1 are reduced in HD patients, which is thought to contribute to the disease progression. GM1 ganglioside is a sialic acid-containing glycosphingolipid that is found abundantly in the outer leaflet of the neuronal membrane in the brain. The initial source for GM1 came from bovine brains, but new sources, including synthetic as well as those obtained from the ovine brain, have been developed subsequently. Treatments with synthetic- and bovine- sourced gangliosides have been shown to reduce motor dysfunction in HD rodent models. However, the efficacy of treatment using ovine-sourced GM1, which is much more economical, has yet to be tested. The goal of this study was to compare the efficacy of ovine-sourced GM1 with that obtained from bovine sources on the motor and cognitive dysfunctions in the R6/2 mouse model of HD. In the current study, we used intraventricular osmotic pumps to deliver the different-sourced GM1 gangliosides for four weeks in five-week-old R6/2 mice. Rotarod-, open field-, catwalk-, Barnes maze- and novel-object-recognition- tasks were used to measure motor and cognitive abilities in the treated and non-treated mice. Results indicated that ovine-sourced GM1 gangliosides significantly reduced behavioral deficits in R6/2 mice on the rotarod-, open field-, catwalk-, but not on Barnes maze-, and novel-object-recognition- tasks, compared to vehicle-treated and bovine-sourced-GM1-treated R6/2 mice.

Abstract: Huntington's disease (HD) is an autosomal dominant inherited neurodegenerative disease with a combination of motor, cognitive and behavioral impairments caused by an expanded CAG trinucleotide repeat (of variable length) in the huntingtin gene. To develop a more facile cell model, Induced Pluripotent Stem cell (iPSCs) derived from HD patient were immortalized and differentiated into highly homogeneous medium-spiny-neuron like cultures. These immortalized striatal precursor neurons (ISPNs) recapitulated HD-like phenotypes of the parental iPSCs including MAP2/DARPP32 positive immune staining (Akimov et al, 2021). Moreover, HD-ISPNs (180-CAG repeats) displayed greater mitochondrial depolarization and fragmentation than those of control ISPNs (33-CAG repeats). To develop a drug screening cellular platform, HD-ISPNs were placed in a 96-well plate format using CellTiter-Glo luminescent cell viability assay to measure ATP levels after BDNF withdrawal. There were significantly higher levels of toxicity in HD-ISPN lines compared with normal control lines after BDNF withdrawal. Replacement of BDNF (40-50 ng/ml) attenuated mutant HD-induced toxicity in both HD precursor and mature ISPNs. Earlier, we found that huntingtin (HTT) can interact with several protein arginine methyltransferases (PRMTs), and that arginine methylation of endogenous substrates is impaired in HD models (Ratovitski et al, 2015). To evaluate protein arginine methyltransferase (PRMT) as new potential therapeutic target for HD we tested if alterations of PRMT levels affects neuronal survival in our newly generated ISPN HD model. Overexpression of PRMT4, PRMT6, or PRMT8 showed partial protection against growth factor withdrawal-induces stress in ISPNs, whereas knockdown of PRMT6 enhanced mHTT toxicity. Concurrently, a specific PRMT4 inhibitor selectively exacerbated mHTT toxicity in 180CAG line, but not in 33CAG control ISPNs. Our data suggest that modulation of PRMT levels affects survival of HD ISPNs, and further validation of the role of arginine methylation in HD pathogenesis is under investigation. Moreover, we are performing screening tests using libraries of kinase inhibitors and diverse chemical compounds. Taken together, the ISPNs derived from HD iPSCs is a useful cellular model platform for drug screening to combat HD.

Abstract: Currently no treatment is available to slow, stop, or reverse the course of Huntington's disease (HD), neurodegenerative disorder caused by a CAG expansion. Physiologically relevant and scalable models of HD are needed to improve research outcomes and drug discovery efficiency. A robust source of human iPSC-derived neurons would offer disease-relevant in vitro model for research and high content drug screens, which could reduce costs, improve screen specificity, and accelerate drug development. Widespread use of human-induced, pluripotent stem cell (hiPSC)-derived, mature cell types however, is restricted by complex and lengthy directed differentiation protocols or cellular reprogramming methods lacking consistency. The novel opti-ox* cellular reprogramming technology, overcomes these restrictions by enabling the precisely controlled expression of transcription factors, and as a result, deterministic induction of a new cell identity. bit.bio ioGlutamatergic Neurons have been generated by NGN2-driven opti-ox reprogramming, which rapidly differentiate into consistent, functional and homogenous cultures of glutamatergic neurons (>80% VGLUT1/2-positive) with electrophysiological activity and 4R MAPT isoform expression after 2 weeks in culture.
Using CRISPR/Cas9-mediated genetic engineering, we have developed opti-ox based isogenic ioGlutamatergic Neurons models carrying heterozygous high CAG repeats in the HTT gene (>50 or >70 repeats), to study Huntington's Disease biology, allow drug screening and functional genomics.
We have performed immunocytochemistry (ICC) on the wild type and HD disease variant ioGlutamatergic Neurons using high content imaging, using pan neuronal (MAP2, TUBB3) and glutamatergic markers (VGLUT1 and VGLUT2) at different time of neuronal differentiation (up to 2 weeks post-revival). In addition, an HTRF® assay was performed in 384-well plate format for the detection of mutant and total HTT protein. CellTiter-Glo® (CTG) assay was performed to measure toxicity after compound treatment. Results demonstrate the suitability of ioGlutamatergic Neurons HTT 50CAG/WT and ioGlutamatergic Neurons HTT 70CAG/WT for high throughput screening.
Together with the wild type ioGlutamatergic Neurons isogenic control, these novel HD cell models offer new avenues into HD drug discovery, to accelerate research and the development of new therapeutics.

Abstract: DRG increased FTO is required for development of neuropathic PainBing Wang, Yize Li, Xinying Guo, Linlin Sun, Jifang Xiao, Shibin Du, Shaogen Wu, Daniel Denis, and Yuan-Xiang TaoDepartment of Anesthesiology, New Jersey Medical School, Rutgers, The State University of New Jersey, Newark, NJ07103, USA; Nerve injury-induced change in gene expression in primary sensory neurons of dorsal root ganglion (DRG) is critical for neuropathic pain genesis. N6-methyladenosine (m6A) modification of RNA represents an additional layer of gene regulation. m^6A is installed by a multi-subunit methyltransferase complex including the methyltransferase-like 3 and 14 (METTL3 and METTL14) and Wilms' tumor 1-associating protein (WTAP) and erased by at least two specific demethylases, fat-mass and obesity-associated proteins (FTO) and AlkB homolog 5 (ALKBH5). Our study showed that peripheral nerve injury increased the expression of FTO, but not METTL3, METTL4, WTTAP and AlkB in injured DRG. This increase occurred exclusively in DRG neurons. No change in expression of DRG FTO was seen after injection of complete Freund's adjuvant. Blocking the nerve injury-

induced increase in DRG FTO alleviated mechanical allodynia and thermal/cold hyperalgesia on days 3, 5, and 7 post-surgery. Mimicking this increase led to the enhanced responses to mechanical, thermal and cold stimuli in naive mice. Our findings indicate that FTO may participate in neuropathic pain development.This work was supported by NIH R01NS111553.

Abstract: Although neuropathic pain has been intensively investigated for several decades, how nerve injury produces nociceptive hypersensitivity is still incompletely understood. The evidence has demonstrated that changes in pain-associated gene expression in dorsal root ganglion (DRG) are critical for neuropathic pain. N^6-methyladenosine (m^6A) modification of RNA represents an additional layer of regulation of gene expression. Our pilot data indicated that nerve injury-induced increase in the expression of the m^6A demethylase fat-mass and obesity-associated proteins (FTO) in the injured DRG contributed to neuropathic pain genesis. However, the mechanism underlying this phenomenon is still unclear. We here showed that blocking this increase reversed a loss of m^6A sites in *Ehmt2* mRNA, destabilizing the nerve injury-induced increases in *Ehmt2* mRNA-coding the histone methyltransferase G9a and rescued G9a-controled opioid receptor downregulation. Mimicking nerve injury-induced DRG FTO increase erased m^6A in *Ehmt2* mRNA, elevated the level of G9a and reduced opioid receptor expression in injured DRG. FTO contributes to neuropathic pain likely through stabilizing nerve injury-induced upregulation of G9a, a neuropathic pain in initiator, in primary sensory neurons.

Ctr., [4]Anesthesia/ Pain Mgmt., [5]Dept. of Pediatrics/ Div. of Cancer Biol. and Exptl. Hematology, Cincinnati Children's Hosp. Med. Ctr., Cincinnatti, OH

Abstract: Neurofibromatosis type 1 (NF1) is a genetic disorder that predisposes individuals to benign tumors in the peripheral nervous system (PNS). NF1 patients display multiple clinical manifestations, (e.g., optic gliomas, cutaneous and plexiform neurofibromas and café au lait spots); however, neuropathic pain is one of the primary causes of decreased quality of life in NF1 patients. Specific loss of *Nf1* in SCs and SC precursors has been found to be responsible for neurofibroma formation in a genetically engineered mouse model, but the role of SCs in nociception and pain development in NF1 is not known. In the current study, we wanted to determine whether Schwann cells (SCs), sensory neurons, or both contributed to neuropathic pain-like behaviors in an animal model of NF1. With experimenters blinded to the conditions, we found that in male and female mice, *Nf1* deletion in SCs (Dhh;Nf1f/f) produced mechanical hypersensitivity while *Nf1* deletion in sensory neurons (Pirt;Nf1+/f) did not affect mechanical responsiveness. This was only observed when specifically performing non-evoked behavioral assessments (conflict avoidance). Behavioral hypersensitivity in the SC specific *Nf1* mutants, correlated with sensitization of myelinated A-fiber nociceptors and unmyelinated polymodal C-fibers (CPM) to mechanical stimuli compared to controls using an *ex vivo* skin/nerve/dorsal root ganglion (DRG)/spinal cord preparation. Electron microscopic analysis showed disruption of Remak bundles in SC specific *Nf1* mutants whereas no changes were found in the sensory neuron specific Nf1 mutants. Using transgenic animals with a GqDREADD receptor expressed specifically in SCs (Dhh;Chrm3), we found that chemo-genetic manipulation of SC calcium activity was able to effectively induce mechanical hypersensitivity at the behavioral level and produce sensitization of CPM neurons to mechanical stimuli compared to CNO treated controls. The observed peripheral sensitization correlated with an elevation of numerous cytokines and growth factors in the L2/L3 DRGs as assessed with realtime PCR. Together this suggests that alterations in SCs are directly responsible for changes in specific sensory neuron subtypes that modulate mechanical responsiveness and possibly neuropathic pain development in NF1. This

study has begun to elucidate the specific role of SCs and sensory neurons in the neuropathic pain and may help to identify novel cell-specific treatment strategies to ameliorate pain in NF1 patients.Funding: Grants to MPJ from the NIH (R01NS105715) and Cincinnati Children's Research Foundation.

Title: Loss of enrichment induces widespread muscle mechanical hypersensitivity

Authors: *L. F. QUEME[1,2,3], A. BUTTERFIELD[1], M. C. HOFMANN[1], M. P. JANKOWSKI[1,2,3,4];
[1]Dept. of Anesthesia, [2]Pediatric Pain Res. Ctr., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Dept. of Anesthesiol., [4]Dept. of Pediatrics, Univ. of Cincinnati, Cincinnati, OH

Abstract: The development of chronic musculoskeletal pain has been frequently associated with the presence of high levels of psychological stress. Multiple animal studies have previously shown that a variety of stress paradigms are effective at inducing deep tissue hyperalgesia and enhanced behavioral responses to subthreshold stimuli and injury. Nevertheless, the mechanisms behind stress-induced mechanical hyperalgesia are not clearly understood. Many of the current paradigms to induce stress in rodents fall into the common pitfall that they often utilize physical stimuli that are known to induce changes in sensory function, such as repeated cold exposure or electrical shock. Using non-invasive strategies to induce stress in animal models may uncover new mechanisms that drive stress related hyperalgesia. To address this issue, our lab has adapted a stress paradigm that utilizes environmental enhancement and subsequent loss of enrichment (LOE) to induce stress in mice. Enrichment consisted of 12-16 mice housed together for 3 weeks in a large cage with enrichment materials (e.g., increased bedding). Due to these housing requirements, experiments were performed in male mice only. We then paired this stress paradigm with fore limb ischemia/reperfusion injury (I/R) which served as a model of muscle

hypersensitivity. After 3 weeks of enrichment and 1 week of enrichment removal, our animals developed a prolonged immobility time in a forced swimming test, suggesting increased stress/anxiety-like behaviors. This result correlated with increased weight gain, which is another indicator of stress induction. At baseline (1 week after LOE), the mice also developed a bilateral decrease in mechanical withdrawal thresholds to plantar muscle squeezing, indicating stress related hypersensitivity. Immunohistochemical analysis of the plantar muscles showed increased macrophage infiltration one week after LOE. We then evaluated mice with I/R injury induced one week after LOE and found that these mice displayed a prolonged recovery time (up to 4 additional days to return to baseline levels), compared to normal housing controls that usually recover in approximately 3 days. All data were acquired with experimenters blinded to the various conditions. Our results suggests that LOE can significantly enhance the development of muscle pain after I/R. Together with the immunocytochemical data, results suggest that macrophages could play a role in the development of pain after LOE. These findings highlight the importance of stress in the development of long-lasting pain and may shed light in potential mechanisms behind chronic widespread muscle pain conditions like fibromyalgia.

Abstract: Cerebral palsy (CP) is the most prevalent motor disability in children, affecting 1:500 live births. CP is caused by injury to the developing fetal and infant central nervous system. The most common comorbidity associated with CP is pain, which is pervasively viewed as a

secondary effect of musculoskeletal abnormalities characteristic of the condition, such as spasticity, hip subluxation and joint contractures. Causal factors linked to CP include hypoxia-ischemia (HI), which could affect both motor and sensory systems. The effect of prenatal HI injury on nociception is entirely unexplored. We hypothesize that prenatal HI injury does not only affect parts of the nervous system involved in motor control, but also directly affects nociceptive sensory neurons, increasing their activity. Here, we investigate the link between prenatal HI injury and nociception in a rabbit model of CP. We evaluate nociceptive behavior in neonatal rabbits after intrauterine hypoxia and use immunohistochemistry to identify anatomical changes to spinal circuitry. We observe that HI-subjected rabbits exhibit mechanical allodynia, even in the absence of motor deficits. These findings indicate that developing sensory circuits may be *more* vulnerable than motor circuits to perturbation by prenatal injury, and that individuals with CP may experience pain as a result of alterations in nociceptive sensory neurons.

Title: Hyperpolarization of the VGluT2 neurons of spinal cord and dorsal root ganglion in mice

Authors: *A. ALEJO-MARTÍNEZ[1,2], R. GONZÁLEZ-RIVERA[3], E. RUÍZ RUÍZ[2], F. FERNÁNDEZ VALVERDE[4], F. A. MASSÓ-ROJAS[5], E. CHIQUETE ANAYA[2], F. J. LÓPEZ-MUÑOZ[1], J. J. ACEVES BUENDÍA[2];
[1]Pharmacobiology, CINVESTAV, Mexico City, Mexico; [2]Neurol. and Psychiatry, INCMNSZ, Mexico City, Mexico; [3]Fac. of Engin., UNAM, Mexico City, Mexico; [4]INNNMV, Mexico City, Mexico; [5]INCIC, Mexico City, Mexico

Abstract: Hyperpolarization of the VGluT2 neurons of spinal cord and dorsal rootganglion in mice Pain is an adaptive mechanism; it permits the detection of noxious stimuli throughthe sensory afferents, namely Aδ or C fibers. Some of this fibers colocalize with theVesicular of Glutamate Transporters (VGluTs), Aβ fibers colocalize with VGluT1,meanwhile C fibers colocalize with VGluT2 neurons, it is known that VGluT2 playsan important role in the physiopathology of pain, because its expression increasesin spinal cord after nerve injury. At presynaptic level, deletion of the gene thatcodificates for VGluT2 is related to a diminish in allodynia and hyperalgesia inducedby mechanical or thermal stimuli, without alterations of cold

hypersensitivity inexperimental models of neuropathic pain. **Hypothesis**: The transdermal activationof Arch in VGluT2 neurons of the DRG and their terminals will diminish painperception in a neuropathic pain model. **Objective:** The aim of this study was tocharacterize a subpopulation of the VGluT2 neurons in the DRG and to decreaseVGlut2 excitability in a chronic pain model. **Method:** VGluT2::Cre mice were sexuallymated with Ai35 transgenic mice (VGluT2-Ai35) of Arch. VGluT2-Ai35 and VGluT2hetecygotes (VGluT2 HET) mice with free access to water and food were used in achronic constriction injury (CCI) model of neuropathic pain. After the CCI, and beforesuturing the muscle and skin, 500 nl of virus were administered on the sciatic nerve.Fourteen days after the surgery, nocifensive responses were evaluated using thevon Frey test. Twenty one days after the viral transfection, both the VGluT2 HETand VGluT-Ai35 (constitutive strategy) were evaluated in a CPP model with lightstimulation. Briefly, in the CPP model we stimulate nociceptive fibers using a yellowLED matrix (560 nm). During the first 15 min of the recording (LIGHT OFF) therewas measured the time spent in every compartment of the acrylic box. After thisperiod, there was measured the time spent in the non-illuminated versus theilluminated compartment (LIGHT ON) to activate Arch in the C fibers. **Results:** Thevon Frey test showed that CCI group developed allodynia and hyperalgesia, and thiscondition can be reversed by the light stimulation of the nociceptive fibers usingyellow light in a CPP model in mice that expressed constitutively Arch and thosewere virally transfected. **Conclusions:** Light activation of Arch on VGluT2 neuronscan reduce the pain induced by the CCI and generates CPP in mice.

Title: Spike propagation through the dorsal root ganglion investigated using the modified working heart brainstem preparation

Authors: *V. K. LALL[1], P. MULLEN[2], H. HAO[3], X. DU[3], N. GAMPER[4];
[1]Univ. of Leeds, Leeds, United Kingdom; [2]St Andrews, Edinburgh, United Kingdom; [3]Hebei Med. Univ., Hebei, China; [4]Univ. Leeds, Leeds, United Kingdom

Abstract: Peripheral nerves convey versatile information about the body's environment to the brain, which is interpreted as haptic, somatic and visceral experiences, including pain. Healthy nerves conduct action potentials from their peripheral endings to the spinal cord, where synaptic transmission first takes place. The 'Gate Control' theory assumes that the peripheral somatosensory signals are first integrated in the spinal cord and subsequently analysed in higher brain centres. Here we show that the dorsal root ganglia (DRG) are able to modulate nociceptive signals before they enter the CNS. Simultaneous whole nerve recordings were obtained from the C8 dorsal root (DR) and spinal nerve (SN) in the decerebrate working heart brainstem preparation of the rat (18 day, Wistar rats of either sex). These nerves innervate the median nerve supplying the forepaw. C8 ventral roots were transected. Using in-house custom written scripts to enable spike sorting we were able to identify action potentials in the SN and match these to spikes propagated to the DR. Direct application of GABA (200 μM) into the DRG did not result in any changes in tonic activity in either aspect of the nerve. Noxious stimuli (Randall Selitto) applied directly to the forepaw of the rat resulted in increased firing in both, SN and DR. DRG application of GABA significantly reduced firing frequency in the DR but not in the SN, an effect we are interpreting as GABA-induced filtering of the conduction through the DRG. Spike sorting revealed that the extracellular action potentials traveling along C fibers were more likely to be filtered, in comparison to those in A-type fibers, suggesting that the DRG is able to selectively filter painful stimuli entering the spinal cord via GABAergic mechanisms. This notion was further confirmed in experiments with innocuous stimulation (cotton bud strokes, air puff) and proprioceptive stimulation. These stimuli also resulted in increased firing in both, SN and DR, however, direct application of GABA into the DRG during these circumstances was not able to reduce DR firing rate in the same manner seen with noxious stimulation. Taken together our findings indicate that peripheral somatosensory ganglia may represent a filter or even a 'gate' within the somatosensory system and may serve as a novel therapeutic target for pain relief. As DRGs are not well protected by the blood-brain or blood-nerve barriers, this offers a unique opportunity to target the DRG with BBB-impermeable drugs thereby reducing central nervous system related side effects.

Title: Neural mechanisms of exogenous and endogenous spatial attention in extrastriate visual cortex

Authors: *M. K. ERADATH[1], I. C. FIEBELKORN[3], S. KASTNER[1,2];
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ; [3]Univ. of Rochester Med. Ctr. Sch. of Med. and Dent., Univ. of Rochester, Rochester, NY

Abstract: Distinct mechanisms of spatial attention have been described based on whether the attention is directed to a spatial location by a salient external cue (exogenous attention) or by an internally generated signal (endogenous attention). Exogenous attention has been described as a bottom-up process, while endogenous attention has been associated with top-down mechanisms. In macaque extrastriate cortex (e.g. area V4), when exogenous cues are presented within a neuron's receptive field (RF), neuronal responses persist beyond the initial sensory response and are thus attention-related. However, it is not known whether this sustained attentional response in V4 can be initiated and maintained in the absence of an exogenous cue and also occurs in response to an endogenous cue. Here, we used a spatial attention task (Egly - Driver task), in which monkeys detected a near threshold contrast change by directing covert attention to a spatial location based on either a visual cue at the target location (exogeneous allocation of attention) or a symbolic cue (color change) at central fixation (endogenous allocation of attention). The symbolic cue (i.e., the endogenous cue) should not drive any sensory-evoked response, given that the cue is not presented in the RF of the V4 neuron. The target appeared after a variable delay period in a neuron's RF. We performed simultaneous multi-contact recordings from area V4 and the lateral intraparietal area (LIP). Significant delay period activity was observed in all V4 layers both for exogenous and endogenous conditions. In V4, neural responses evoked by exogenous cues were first observed in granular layers (51ms) followed by infra- and supragranular layers (57ms and 54ms, respectively). The endogenous cues on the other hand, evoked responses first in supragranular layers (53ms) of V4 followed by infra- and granular layers (60ms and 58ms, respectively). In LIP, the evoked response latency for exogenous cues was shorter in deeper layers (53ms) compared to superficial layers (56ms) while it was shorter in superficial layers (48ms) compared to deeper layers (58ms) for endogenous cues. Our results are consistent with bottom-up activation of attention-related delay activity in response to exogenous cues and top-down activation of attention-related delay activity in response to endogenous cues. Furthermore, the present findings provide evidence of different neural mechanisms leading to attention-related neural responses in extrastriate visual cortex, depending on whether attention is deployed in response to either an exogenous or an endogenous cue.

Title: Functional specificity of attentional modulation in the disparity domain

Authors: *Y. D. CHEN, M. KAESTNER, A. M. NORCIA;
Psychology, Stanford Univ., Palo Alto, CA

Abstract: It has been suggested that absolute disparity cues, unlike relative disparity cues, are perceptually inaccessible (Chopin et al., JVis, 2016). If so, processing of absolute disparity information should be less affected by manipulation of attention. Steady-state visual evoked potentials were recorded (N=20) in response to dynamic random dot stereograms (DRDS) alternating at 2 Hz between a flat plane at zero disparity and a 0.5 cpd crossed-disparity sine-wave grating. Disparity was measured at 10 equal log steps. In one condition, participants attended to monocular nonius lines at fixation and pressed a button when a color change occurred. In a free attend condition, participants attended to the DRDS stimulus while maintaining fixation with no button presses. Evoked responses were robust at the first four harmonics of the stimulus frequency (1F, 2F, 3F, 4F). The disparity response function at 1F in the free attend condition was leftward shifted relative to the attend nonius condition, consistent with an input-gain mechanism. The 3F and 4F responses showed no effect of attention. We hypothesized that the unmodulated 3F and 4F signals came from the leading edge of the response and conducted a follow-up experiment to determine the timing of the task effect and the relative timings of absolute and relative disparity encoding (N=9). The disparity grating response (relative disparity) started at around 100 ms and attention began to modulate the response around 50 ms later. Responses to a disparity plane (absolute disparity) and grating diverged at the same ~150 ms latency. Importantly, the task had no effect on the response to the absolute disparity condition at any latency. Our results suggest that the earliest disparity responses represent the encoding of absolute disparity and that responses to absolute disparity are unaffected by attention, whilst responses to relative disparity, once they have been extracted, are modulated by attention.

Title: Attentional modulation of spike count correlations among pairs of anatomically connected V1 neurons

Authors: *S. SHAH[1], B. CARR[1], J. R. HEMBROOK-SHORT[2], V. L. MOCK[2], F. BRIGGS[1,3]; [1]Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Physiol. & Neurobio. Dept., Geisel Sch. of Med. at Dartmouth, Lebanon, NH; [3]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Visual attention augments behaviorally relevant visual stimuli by modulating several aspects of neuronal activity among visual neurons, including altering firing rates, variability, and pairwise spike count correlations. Whereas attention was initially shown to reduce spike count correlations among pairs of simultaneously recorded visual cortical neurons, more recent evidence suggests that the effect of attention on pairwise spike count correlations varies dependent on cell type, laminar location, and whether neurons are located within the same visual area or spanning different visual areas. One factor that has not been considered is actual anatomical connectivity. i.e., does attentional modulation of spike count correlations among pairs of visual cortical neurons depend on whether or not they are connected? Additionally, many attention effects also depend on whether neurons encode task-relevant feature information. Here we examine the effect of attention on spike count correlations with respect to both anatomical connectivity and task-relevant feature selectivity of neuronal pairings. Specifically, we hypothesize that attention will reduce spike count correlations for neuronal pairs that are anatomically connected and tuned for task-relevant features. Furthermore, we predict that attention will not affect spike count correlations or even increase spike count correlations for neuronal pairings that are tuned for orthogonal features and/or are unconnected. To test this, we utilized multielectrode arrays inserted into V1 of macaque monkeys to simultaneously record from multiple neurons while monkeys performed an attention task. The attention task involved multiple visual discriminations of stimulus contrast, orientation, or color, all requiring shifts in covert visual spatial attention. We also measured neuronal tuning for visual stimulus features independent of the attention task. Preliminary data suggest that attention reduces spike count correlations among monosynaptically connected pairs of V1 neurons. However, attentional modulation of spike count correlations among unconnected pairings of V1 neurons was not significant. These data suggest that attentional modulation of correlated neuronal activity depends on actual connectivity.

Title: Tracking visual stimulus information across cortical layers in macaque's area V1 for identification of neuronal gating mechanisms

Authors: E. DREBITZ, L.-P. RAUSCH, E. DOMINGO GIL, R. BARTELS, *A. K. KREITER; Brain Res. Inst., Univ. of Bremen, Bremen, Germany

Abstract: Successful interaction with and within our environment requires the brain to deal with a large amount of visual information at once. Often that information represents multiple independent objects that are close together or even overlap. Therefore, the highly convergent neuronal connections along the visual processing pathways often provide inputs representing multiple separate objects to neurons located downstream. Nevertheless, these neurons respond as if only the currently relevant stimulus is present. The Routing by Synchrony hypothesis explains this selective processing by a selective synchronization of neuronal activity between neurons encoding relevant information. It has been shown that receiving neurons synchronize their activity with those input neurons representing the relevant stimulus within the gamma-band (30 - 100 Hz) while exhibiting almost no coherence with input neurons representing an irrelevant stimulus.Here we investigate whether a similar mechanism of dynamic information routing also exists between different layers of V1. Moreover, we tested whether effective information transfer between neurons in different cortical layers depends not only on the coherence of oscillatory activity but also on a particular instantaneous phase relation between sender and receiver neurons. These two aspects of synchronization (coherence, phase relation) are critical elements of a Routing by Synchrony mechanism.To this end, we recorded neuronal activity in two macaque monkeys (*Macaca mulatta*) striate cortex (V1). Neuronal recordings were conducted with linear multi-contact probes (100 µm spacing) while the animals performed a shape tracking task. On top, each visual stimulus changed semi-randomly in luminance, resulting in a stimulus-specific tagging of evoked neuronal activity. We calculated the spectral coherence between the current-source density (CSD) at different cortical layers and the time- and frequency-varying stimulus tags to quantify the stimulus information transfer. We found strong gamma-band coherence between neurons of different layers with comparably slight differences between conditions in which the processed stimulus was relevant vs. irrelevant. However, the transmission of stimulus-specific information depended on the instantaneous phase difference between the otherwise identical gamma-band oscillations of the neurons in granular and supragranular layers. In summary, our results deliver strong evidence for the proposed Routing by Synchrony mechanism by confirming that both coherence and specific phase relations determine the effectiveness of information transfer within a cortical column in V1.

Title: A machine vision approach to quantifying the effectiveness of cephalopod camouflage in natural scenes

Authors: *A. RISBUD[1], S. WANG[1], N. GOSWAMI[3], L. C. OSBORNE[4], K. BURESCH[5], C. CHUBB[6], R. HANLON[5], S. E. PALMER[2];

Abstract: Rapid adaptive camouflage is a critical defense mechanism for cephalopods. The characterization of cephalopod camouflage has thus far been restricted to qualitative descriptions or quantitative measures that rely only on a single low-dimensional factor, such as spatial frequency or color. While useful, these characterizations do not capture the multi-faceted nature of camouflage, nor do they provide a comprehensive metric by which the degree and effectiveness of cephalopod camouflage from the perspective of a given predator can be quantitatively measured in a given scene. Here, we propose a metric that integrates lower- and higher-dimensional visual features to read out the degree of texture matching in an image of a camouflaged cephalopod on a background texture. This metric is motivated by an algorithm in machine vision that decomposes an input image into its constituent artistic “style” and “content” components, using a cascade feedforward artificial neural network (VGG-19). The aforementioned integration of lower- and higher-dimensional visual features is made possible by the bank of visual filters of varying spatial scales present in the VGG-19 architecture. This next texture-distance metric will allow researchers to quantify camouflage in a variety of scenes, and possibly develop and test new camouflage designs based on these metrics. Pairing this metric with the results of high-resolution eye-tracking data might also allow researchers to better understand potential targets of visual fixation in natural scenes.

Nacional Autonoma De Mexico. Fac Psicologia, Mexico City, Mexico

Abstract: Historically in neuroscience, behavioral studies have been focused mainly in vertebrates, however, research on invertebrate behavior has been increasing because the potential for research that these models presents. Nowadays, when we talk about mollusk behavior, cephalopods are the first group that stand out, however, there is a lack of research with the endemic species from Mexico, particularly with *Octopus maya*. This octopus has shown to adapt well to laboratory conditions. Additionally, the breeding in captivity has been successfully achieved through several generations, giving it a great advantage as a research model. These characteristics, could reduce the number of variables that can affect the behavioral studies. In this way, with the aim of knowing the behaviors that this species can perform in controlled conditions and work properly with in the laboratory, the main objective of this study was carry out an ethogram that describes the behavioral repertoire that *O. maya* displays in controlled conditions. Individuals of *O. maya* (6-20g) were used and maintained in tanks with a closed circulation seawater system and illuminated with a red light of 30 lx in a 12:12 LD cycle. Nine of this individuals were used to an *ad libitum* sampling of behavioral repertoire to name, categorize and define operationally the recorded behaviors. Another four individuals were used to establish the day/night activity patterns, (length and frequency of the behaviors along the day). The obtained results showed that *O. maya* has a behavioral repertoire with eight postures and twenty behaviors, which we included in six behavioral different categories. Also, this species shows a differentiated activity patterns between day and night, with a peaks of activity, more distribution and frequencies of activity behaviors mainly in the light hours. This results showed that *O. maya* presents behaviors comparable with other octopus's species and support that it is an organism

that can be proposed as a research model. Also, knowing the behavioral repertoire of this species allows greater control in subsequent investigations related to behavior and provide a great tool to constantly monitor the health status of organisms and its use for research, being a precedent for future behavioral research in this species related to neuroscience and cognition.

Title: Female zebrafish (Danio rerio) Demonstrate Stronger Preference than Males for Established Shoals over Newly-Formed Shoals in the Three-Tank Open-Swim Preference Test

Authors: *I. DANSTROM[1], **C. KOON**[1], K. M. WIENS[2], *A. J. VELKEY, II[1];
[1]Neurosci., Christopher Newport Univ., Newport News, VA; [2]Sci. Dept., Baypath Univ., Longmeadow, MA

Abstract: Zebrafish (*Danio rerio*) display complex social behaviors such as shoaling and schooling, making them an attractive model for investigating normal social behavior as well as exploring conditions of impaired social function such as autism spectrum disorders. Recognizing group dynamics is an important aspect of successfully navigating social situations, and this capability may be impaired for individuals with autism. Several previous studies have examined the responses of fish in a test shoal with a novel conspecific and vice versa, but no published study has examined the response of a solitary test subject to shoals with different degrees of intra-group familiarity. Newly-formed and established shoals exhibit distinct behavior patterns and inter-member interactions that could convey the group's social stability. We used a three-chamber open-swim preference test to determine whether individual zebrafish show a preference for an established shoal over a newly-formed shoal. Results indicated that both sexes maintained greater proximity to arena zones nearest to the established shoal stimulus. However, there was a sex difference in movement patterns with males spending more time moving across all zones and demonstrating higher levels of behavioral diversity. This novel model using established versus newly-formed shoals can be used in future studies testing transgenics and pharmacological treatments that mimic autism spectrum disorder and other disorders that affect social interaction.

Title: Strategies of octopus arm control in the absence of visual feedback

Authors: *D. M. SIVITILLI[1], W. WEERTMAN[3], J. ULLMANN[2], J. R. SMITH[2], D. H. GIRE[1];
[1]Psychology, [2]Univ. of Washington, Seattle, WA; [3]Alaska Pacific Unversity, Anchorage, AK

Abstract: The octopus coordinates its multiple, highly flexible arms with the support of a complex distributed nervous system. The octopus' suckers, staggered along the length of each arm, are employed in a range of behaviors such as locomotion, exploration, foraging, and manipulation, for which the suckers serve as the primary medium of sensory transduction and as the primary motor effectors. In coordinating limbs with seemingly infinite degrees of freedom across a variety of adaptive behaviors, the octopus appears to have solved a significant control problem facing the field of soft-bodied robotics. To study the strategies that the octopus uses to coordinate its arms and suckers, we designed and 3D printed visually occluded single arm foraging tasks and tracked arm kinematics as the octopus attempted to find and retrieve a food reward. By varying the location of the food item within this task and the features of the task itself, we can characterize how the arms and suckers adapt to their environment. Our results suggest that the octopus relies on a contact-based navigation strategy that emerges from local sucker coordination within an arm to simplify the control of its soft, highly flexible limbs.

Title: B-soid, an open-source unsupervised algorithm for identification and fast prediction of behaviors.

Authors: *A. HSU, E. A. YTTRI;
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Studying naturalistic animal behavior remains a prohibitively difficult objective. Recent machine learning advances have enabled limb localization. Extracting behaviors, however, requires ascertaining the spatiotemporal patterns of these positions. To provide the missing bridge from poses to actions and their kinematics, we developed B-SOiD - an open-source, unsupervised algorithm that automatically identifies behavior without user bias (Nature Communications, 2021). By training a machine classifier on pose pattern statistics clustered using new methods, our approach achieves greatly improved processing speed and the ability to generalize across subjects or labs. By using a frameshift alignment paradigm, B-SOiD overcomes previous temporal resolution barriers that prevent the use of other algorithms with electrophysiological recordings, providing greater resolution for neural dynamics. With this behavioral segmentation paired with electrophysiological recordings, we demonstrate the representation of untrained, naturalistic movements, as well as how the selection of these actions and population dynamics change over time. Using only a single, off-the-shelf camera, B-SOiD provides sub-action categories and kinematics for trained or untrained behaviors in invertebrate, rodent, or primate models. These behavioral and kinematic measures are difficult but critical to obtain, particularly in the study of rodent and other models of pain, OCD, and movement disorders.

Title: Quantitative analysis of somersaulting in Hydra vulgaris

Authors: *W. YAMAMOTO, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Cnidarians are representatives of the first animals to evolve a nervous system, and use their simple nervous system, called a nerve net, to sense the external world, integrate information, and generate selective behaviors. Yet how the nerve net encodes these sensorimotor mechanisms and behaviors remains to be elucidated. In order to understand these mechanisms, it is important to first establish methods to detect and analyze different behaviors quantitatively. To explore this, we have studied the behavior of *Hydra vulgaris*. This fresh-water cnidarian is a small transparent polyp, 0.5-1.5 cm long, with 200 to 6,000 spiking neurons, organized into an ectodermic and an endodermic nerve net, and whose activity can be reconstructed with calcium imaging. We used DeepLabCut, based on deep convolutional networks, to track the position of the animal's body during free behavior. In those data, we were able to detect the *Hydra's* contractions and also somersaulting, acrobatic locomotion in which the animal fully rotates around a horizontal axis with the foot passing over the head. The results showed that contractions could be automatically detected by measuring changes in body length whereas somersaults could be detected by significant changes in the velocity of the basal disc. Furthermore, we found characteristic time scales for each of the five sequential components of somersaulting: (1) body elongation - tentacle attachment (508.6 ± 78.0 sec), (2) foot detachment (3.9 ± 0.8 sec), (3) body contraction (16.5 ± 1.3 sec), (4) foot attachment (19.1 ± 2.7 sec), and (5) tentacle detachment (162.6 ± 18.4 sec). The neural bases of these different components are being investigated. Characterizing quantitative behavior in primitive nervous systems is a first step toward understanding the neural code that relates neuronal activity to behavior, a code whose basic strategies may be conserved in other cnidarians and bilaterians.

Title: Molecular study of the structure and function of the octopus sucker ganglion

Authors: C. S. OLSON[1], N. G. SCHULZ[2], *C. W. RAGSDALE[3];
[1]Univ. of Chicago Committee On Computat. Neurosci., Chicago, IL; [2]Univ. of Chicago

Committee On Development, Regenerative and Stem Cell Biol., Chicago, IL; [3]Univ. of Chicago Committee On Neurobio., Chicago, IL

Abstract: Each sucker on the octopus arm has a dedicated ganglion positioned between the axial nerve cord, which runs down the center of the arm, and the base of the sucker. The functional purpose of these sucker ganglia remains obscure: some authors claim a primary motor function (Guérin, 1908), some argue for a mainly sensory role (Rowell, 1963), while Graziadei (1965) proposed a combination of the two. We examined the structural organization and molecular composition of the sucker ganglion in adult octopus arms (*Octopus bimaculoides*, n=5) with molecular methods including immunohistochemistry for acetylated alpha-tubulin, phalloidin and DAPI labelling, and in situ hybridization for pan-neuronal and neuronal subtype markers. The sucker ganglion is ellipsoid in shape and anchored in the stalk of the sucker by the acetabulo-brachial musculature. As demonstrated by acetylated alpha-tubulin immunostaining and pan-neuronal marker gene expression (*CPLX1*, *MUNC18*, *SYT1*), the sucker ganglion has an unusual organization for an invertebrate ganglion. The neuropil of the ganglion is dense aboral to the sucker, with neuronal cell bodies concentrated on the sucker (or oral) side of the ganglion. With neuronal subtype markers, we found clear districting within the ganglion's cell body layer. Cholinergic neuron markers, *VACHT* and *CHAT*, are localized to the outside edges of the ganglion as well as a region in the center. A potential motor neuron marker, *LHX3*, similarly labels the outside edges along with the aboral portion of the cell body layer. *PIEZO*, a mechanosensory ion channel gene, is detected heterogeneously throughout the ganglion, often forming clumps of cells. These results suggest that the sucker ganglion is composed of both motor and sensory components, and raise the possibility of a differential distribution of sensory and motor neurons within the ganglion.

Title: When speed is independent of size: quasi-static mechanics of cyclic Aplysia feeding

Authors: *V. FAN[1], A. SKALSKI DE CAMPOS[1], K. WANG[1], J. P. GILL[1], G. P. SUTTON[2], H. J. CHIEL[1];
[1]Case Western Reserve Univ., Cleveland, OH; [2]Univ. of Lincoln, Lincoln, United Kingdom

Abstract: How do rhythmic behaviors change with size? How can this affect neural control? In animals that primarily use inertial forces to generate rhythmic behaviors, smaller animals generate faster cycle times than larger animals. For example, in humans, children at the age of 5 years have faster step cycle times than adolescents at the age of 19 [Lythgo et al. Gait and Posture 2011]. Biomechanical analysis would predict this result: The resonant frequency of a system is proportional to the stiffness divided by the mass (i.e., $(k/m)^{(1/2)}$). Since stiffness is proportional to length L, and mass is proportional to the volume, L^3, the resonant frequency is proportional to $(L/L^3)^{(1/2)}$ which equals 1/L. In turn, this implies that the resonant frequency will decrease as mass increases, since L is proportional to $m^{(1/3)}$, and thus animals with larger masses will have lower resonant frequencies (i.e., 1/L will be smaller with larger mass). In contrast, when movement is dominated by elastic forces (i.e., when the system is quasi-static), displacement is primarily generated by storing energy in a spring. This scales differently: in these systems, force is proportional to stiffness times displacement (a spring equation), or F = k x. On the left-hand side of this equation, F is equal to the cross-sectional area of the muscle, which scales as L^2 times the muscle activation. On the right-hand side, the stiffness scales with the length of the muscle, and so the product k x scales as L^2. In turn, this predicts that the time to generate a motion will be scale *independent* (assuming the same activation). To test this prediction, we have measured the timing of biting and swallowing in the marine mollusk *Aplysia californica*, which grows over several orders of magnitude in mass over its lifetime. We observed that the durations of bites and swallows were essentially unchanged over a wide range of animal mass, consistent with the prediction of the theory. In contrast, peak forces are predicted to be proportional to the cross-sectional area of the muscle, which will increase with the mass of the animal (i.e., $m^{(2/3)}$). Measurements of the peak forces in *Aplysia* plotted on a log-log scale yielded a slope of approximately 0.7, consistent with the theory's predictions. Since muscles in *Aplysia*, in general, do not spike, muscle innervation must increase in proportion to the muscle's area as a function of the animal's mass. This hypothesis will be tested in future work.

Title: Astrocytes in the medial amygdala regulate playfulness in real time in juvenile rats

Authors: *J. VANRYZIN, A. E. MARQUARDT, M. M. MCCARTHY;
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The medial amygdala (MeA) is the site of masculinization of juvenile social play behavior in rats. We have established that during neonatal development, microglia in the male amygdala phagocytose more newborn astrocytes than in females. By the juvenile age, males have fewer astrocytes in the MeA. The sex difference in MeA astrocyte number is inversely related to both the activation of MeA neurons as well as the amount of play, as males display more frequent and vigorous rough-and-tumble play as juveniles and have more immediate early gene expression following a play bout (VanRyzin et al., Neuron, 2019). Whether the developmental determination of a sex difference in astrocyte number has direct implications on play as it is occurring has been unknown. Astrocytes are potent modulators of neural activity via gliotransmitter signaling, leading us to hypothesize that astrocytes in the MeA regulate rough-and-tumble play by influencing the activity of play-relevant neurons. To test this hypothesis, we selectively modulated these cells using astrocyte-specific DREADD viruses and found that HM3D stimulation of MeA astrocytes decreased juvenile play while HM4D stimulation increased play, in real time. Infusing an adenosine (a known gliotransmitter) receptor 1 (A1R) agonist directly into the MeA via bilateral cannulation similarly and immediately decreased play, suggesting that astrocytes may be regulating neural activity and behavior through this gliotransmitter. To determine the phenotype of play-active cells, we used RNAscope to identify the neurochemical phenotype of cells expressing the immediate early gene, Egr1, following a single play bout. Males had significantly more Egr1+ cells in the MeA than females, and the majority (>80%) of Egr1+ cells were also VGAT+ indicating that the play-active neurons are largely GABAergic. Future studies will determine the precise localization of adenosine receptors within the MeA, and determine the projection profile of play-active GABAergic cells. Together, these data suggest that astrocytes within the juvenile MeA provide real-time modulation of neural activity and play behavior.

Title: Lack of pattern decorrelation in the prelimbic circuit disables social discrimination in Mecp2-deficient mice

Authors: *P. XU, Y. YUE, J. SU, X. SUN, H. DU, Z. LIU, R. SIMHA, C. ZENG, H. LU; George Washington Univ., Washington, DC

Abstract: Social interactions involve a range of complex considerations, from awareness of one's internal state to assessment of myriad social cues and social memory. Much of the processing of socially relevant information takes place in the medial prefrontal cortex (mPFC) circuit, which supports cognition, memory, and decision-making. The mPFC responds to social stimuli and carries both social and spatial information, but it is unclear how its circuit activity encodes different stimuli to guide social discrimination. Because dysfunction of the prefrontal cortical circuit has been associated with social deficits demonstrated in Rett syndrome (RTT), which is caused by loss-of-function mutations in the X-linked gene Methyl-CpG-binding protein 2 (*MECP2*), we were able to compare mPFC function in both wild-type and mutant mice to examine circuit differences underlying a well-documented social deficit. Using a miniature microscope, we conducted calcium imaging of prelimbic mPFC pyramidal neurons in 5-month-old female heterozygous *Mecp2*$^{+/-}$ (RTT) mice and wild type (WT) mice while they were engaged in the three-chamber social interaction assay. We found that the mutant excitatory mPFC circuit is less responsive to both social and nonsocial stimuli in RTT mice, which limits its ability to decorrelate the activity patterns encoding different stimuli. Using simultaneous optogenetic manipulation and in vivo calcium imaging, we found that disinhibition of the mPFC excitatory circuit restored pattern decorrelation for social information coding and the social preference of RTT mice. Inhibition or over-activation of WT mPFC excitatory circuit causes a failure of pattern decorrelation in WT mice and caused them to exhibit the same deficit in social discrimination as RTT mice. Normal social behavior therefore depends on pattern decorrelation of mPFC circuit activity and normal E/I balance. Stimulation of the mPFC could serve as a potential strategy to mitigate some of the core symptoms of RTT patients.

Title: Sex differences in the transcriptional networks underlying playfulness suggest a distinct function for play in males compared to females

Authors: *A. E. MARQUARDT[1], J. W. VANRYZIN[2], S. A. AMENT[3], M. M. MCCARTHY[2]; [1]Program in Neurosci., [2]Dept. of Pharmacol., [3]Inst. for Genome Sci. and Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Social play, or rough-and-tumble play, is a dynamic behavior expressed by most juvenile mammals. While its function is debated, a prevailing hypothesis suggests play serves to sculpt and refine neural circuitry enabling expression of appropriate adult behavior. Importantly, in most species, males play more than females, a sex difference driven by the medial amygdala (MeA). To investigate whether the transcriptional signatures underlying play also differ by sex, we performed RNA-sequencing of MeA samples from high- and low-playing juvenile rats of both sexes. Using Weighted Gene Co-expression Network Analysis (WGCNA), we identified 22 co-expression modules, or networks of genes highly correlated in expression across samples. Of the 12 modules significantly associated with play (for $p<0.05$), almost all (11/12; ~92%) are sex-specific in expression, correlating with expression of play in one sex only. These data suggest there is a distinct transcriptomic profile associated with playfulness in the MeA of males compared to females, a noteworthy finding given the MeA regulates many sex-typical adult social behaviors. We propose that this is no coincidence: play-associated gene networks in the MeA are sex-specific because play modulates circuitry driving different adult behaviors depending on sex. To investigate this, we created perforated Plexiglass cage dividers to separate juvenile cagemates, preventing play while allowing for other forms of social interaction to occur. We hypothesized that preventing play would result in impairments in later-life behavior that differed in males compared to females. Supporting our hypothesis, preventing juvenile play impaired object memory and copulatory behavior and resulted in a hypersocial phenotype only in adult males. Surprisingly, we observed no effects on the same behaviors in females nor on maternal behavior, or on sex preference, social recognition, or anxiety-like behavior in either sex. Future studies will examine whether our identified sex-specific gene modules have a causal role in juvenile playfulness, an idea supported by preliminary siRNA experiments, and/or in later-life behavior, using a viral approach to determine if driving expression of modules of interest in the juvenile MeA can rescue behavioral deficits in animals prevented from playing. Together, these analyses will provide novel insight into the ultimate function of play and how and why this may differ by sex.

Title: Characterization of playfulness and social motivation in juvenile rats in a model of neuropsychiatric developmental disorders

Authors: *S. E. ASHTON[1], S. N. YAVASANI[3], S. PATTANAIK[3], K. E. KIGHT[2], M. M. MCCARTHY[2];
[1]Program in Neurosci., [2]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Poolesville High Sch., Poolesville, MD

Abstract: Juvenile social play is conserved across mammals, including humans, and is impaired in children with male-biased neuropsychiatric developmental disorders (NDDs) such as autism spectrum disorder, ADHD and possibly schizophrenia. Because play is thought to be important to development of later life social skills, it is plausible that the disrupted play in NDDs contributes to the lasting social impairments common in these disorders. Our lab has recently developed a "two-hit" rat model of NDDs by combining two established risk factors: haploinsufficiency of the candidate gene Nrxn1α (Sprague Dawley-Nrxn1^{tm1sage}) and early life inflammation, as modeled by PolyI:C injection on postnatal days 8 and 10. Interestingly, previous work in the lab has demonstrated that this "two-hit" model results in impaired playfulness in juvenile males but not females. We hypothesize that these deficits arise from reduced motivation for social interaction. We first optimized a novel assay for assessing social motivation in juvenile rats and found no sex differences in the willingness to push through a swinging door for access to a playmate in wildtype animals, even though males play more intensely than females. However, there was a positive correlation between the number of door entries and the number of play behaviors in males but not females, suggesting motivation for social interaction may be more closely related to playfulness in males. Contrary to our prediction, we found no reduction in the number of door entries following PolyI:C treatment in animals haploinsufficient for Nrxn1α compared to vehicle treatment, regardless of sex. This suggests that the impaired playfulness in the "two-hit" males is likely not due to reduced motivation to engage with a peer, but rather may be specific to play itself. To more thoroughly characterize juvenile social behavior in males and females of the "two-hit" model, we have employed DeepLabCut multi-animal pose estimation combined with SimBA classification. This machine learning approach has the potential to reveal subtle differences in the sequence and nature of playfulness that have thus far been difficult to identify by the traditional manual scoring of discrete behaviors. Together, this work provides insights into the origin of the lasting social deficits central to male-biased NDDs.

Title: The role of pair bonding and oxytocin receptor expression in partner-seeking behavior during loss in male prairie voles

Authors: *E. M. VITALE, S. A. SANCHEZ, L. H. HALE, A. S. SMITH;
Dept. of Pharmacol. & Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: In social species such as humans and the socially monogamous prairie vole, the dissolving of social bonds is disruptive and leads to increased stress responsivity and a strong desire for reunion with the lost individual. Indeed, male prairie voles that lose their partner are more anxious than those that maintain their partnership. Despite being separated from their partner for up to two weeks, males will retain a preference for their partner over an unfamiliar female. This suggests maintenance of partner recognition in the absence of physical contact and cohabitation. The oxytocin (OT) system is critical for the formation of pair bonds, and it is also involved in social recognition and social memory. Thus, long-term changes in the oxytocin system resulting from cohabitation and pair bonding may contribute to partner-seeking behavior. Additionally, if a bond is not robust enough to form the neural framework necessary for retaining social memory, this may inhibit partner-seeking behavior following loss. Here, we hypothesize that pair bonding is associated with OT receptor expression in brain regions which regulate pair bonding and social recognition. We predict that changes in the OT system are maintained after loss of a bonded partner, indicated by a strong partner preference, and preserves social memory to promote partner-seeking behavior. We used a social conditioned place preference test to assess the rewarding properties of the subjects' partner in pair-bonded animals that remained in an intact pair, pair bonded animals that lost their partner, and non-bonded animals that lost their partner. We found that pair bonded animals that lost their partner spent more time in the chamber associated with their partner than pair bonded intact animals and non-bonded animals that lost their companion. We are currently examining OTR binding in several brain regions associated with pair bonding and social recognition, including the prefrontal cortex, nucleus accumbens, lateral septum, amygdala, hippocampus, and ventral tegmental area.

Title: Bed nucleus of the stria terminalis corticotropin-releasing hormone and nucleus accumbens dopamine modulation of pair bonding in stress-naïve and socially defeated prairie voles (Microtus ochrogaster)

Authors: *M. TICKERHOOF, A. S. SMITH;
Dept. of Pharmacol. & Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: Social relationships and affiliation can provide a buffer against detrimental psychological and physical effects associated with severe or chronic stress. However, chronic stress can significantly impact an individual's ability to form and maintain relationships, negating the positive effects of these connections. Neurobiological systems responsible for relationship formation and maintenance, such as dopamine signaling within the nucleus accumbens (NAc), are susceptible to alteration following a stressful experience. Notably, corticotropin-releasing hormone (CRH) has been demonstrated to differentially modulate dopamine release within the NAc based on prior stress experience. That is, intra-NAc CRH release is appetitive and promotes intra-NAc dopamine release in a non-stressed state, but it becomes an aversive stimulus and uncouples from dopamine during chronic stress. The NAc receives CRHergic projections from the bed nucleus of the stria terminalis (BNST), which has been demonstrated to impact motivated behavior such as social interaction and fear aversion. In addition, it is well-documented that dopamine in the NAc promotes pair bonding in prairie voles (*Microtus ochrogaster*), and recently, we identified a role for BNST CRH in the regulation of pair bond formation. Therefore, BNST CRHergic activity may contribute to changes in both intra-NAc dopamine release and relationship formation, but a direct link has not been established. In this study, we utilized the social defeat model in the socially monogamous prairie vole to investigate the effect of social defeat on pair bond formation in both males and females and determine the role of BNST CRHergic activity in any changes observed. We observed that defeat leads to a sexually dimorphic, opposing effect on pair bond formation, in that defeat impaired bonding in males and accelerated bonding in females. We hypothesize that BNST CRHergic activity has both sex-dependent and stress-dependent effects on intra-NAc dopamine release and underlies the sex difference in pair bond abnormalities following defeat. The effect of the combination of defeat experience, bonding status, and BNST CRHergic activity using chemogenetic manipulation on NAc dopamine content is investigated with *in vivo* microdialysis and dopamine receptor activity through characterization of DARPP-32 levels and phosphorylation state. The results of this study may provide insight into the neurobiology contributing to the negative impact of stress on relationship formation.

Title: Social defeat regulation of oxytocin-related signaling proteins in female prairie voles (Microtus ochrogaster)

Authors: *L. NERIO MORALES[1], A. S. SMITH[2];
[1]Pharmacol. and toxicology, The Univ. of Kansas, Lawrence, KS; [2]Pharmacol. and toxicology, Lawrence, Lawrence, KS

Abstract: Social anxiety disorder (SAD) is one of the most common and disabling anxiety disorders. SAD is highly prevalent in female population and characterized by generalized social avoidance often comorbid with other psychiatric diseases. Despite its high prevalence and adverse prognosis, the molecular mechanism behind this condition is poorly understood. The social defeat (SD) paradigm is the most representative animal model to study SAD and the underlying neural mechanisms. Particularly, SD in prairie voles (*Microtus ochrogaster*) advantageously allows the study of female subjects due to their spontaneous display of aggression towards unfamiliar conspecifics after pair bond. Recently, we have documented that SD robustly decreases oxytocin receptor (OTR) levels in limbic brain regions relevant for affiliative behaviors and stress in female prairie voles, suggesting a role of this neuropeptide in the etiology of SAD. Oxytocin stimulation of its receptor leads to increased intracellular calcium levels and activation of the mitogen-activated protein kinase (MAPK) pathway, this last one being previously associated with the regulation of the anxiolytic effects of oxytocin. Here, we used female prairie voles to study the effect of SD on oxytocin-related signaling proteins and their response to a social encounter. Preliminary data obtained from regions where OTR was previously reported as downregulated, suggests that defeat increases the phosphorylation state of CREB, a transcription factor involved in the alleviation of anxiety-like behaviors. The continuation of this study will include measuring upstream signaling pathways associated with CREB that are responsive to changes in OTR expression, namely, the MAPK pathway and calcium-dependent signaling pathways.

Abstract: Aggression in the whole animal kingdom is strongly associated with acquisition and surveillance of resources such as food, territory, fight and mates. In both vertebrate and invertebrate, a number of genes have been identified as important players in aggression-associated behaviors. Most of them encode biogenic amines, neuropeptides, and their respective receptors with their second messenger cascades. In invertebrates, the majority of aggression-associated genes and signaling molecules were studied in the insect model *Drosophila melanogaster* via mutagenesis and direct labeling to allow for cellular analysis. The biogenic amine octopamine (OA), equivalent to norepinephrine in vertebrates, plays a key role in controlling aggression behavior. Two subpopulations of VUM/VPM neurons located in the gnathal ganglion have been shown to be required for regulation of aggression: (1) Three VUM/VPM neurons express the male specific transcription factor *fruM,* and (2) a small subset of 2-5 VMlb OA-expressing neurons. Here, we present a novel analytical approach to study the dynamics in up- and downregulation of OA on the single cell level in different behavioral contexts. For reliable VMlb cell identification, we used the Tdc2-GAL4 driver line crossed to a UAS-mCD8::GFP reporter line. First, individual VMlb-OA somata from both sexes at different ages were prepared for quantitative SC mass spectrometry as described in Diesner and Neupert (2018). Statistical analysis of OA titers in VMlbs revealed no differences between sexes and age groups. Next, we analyzed the OA titer in VMlbs between males reared in mixed groups, socially isolated males and pairwise regrouped flies. Statistical comparison of pairwise regrouped flies showed comparable OT titers as grouped males, while OA titers of isolated males were significantly lower. This novel analytical approach provides great potential for a quantitative analysis of the kinetics and functions of neurotransmitter signaling in neuronal circuits controlling behavior. Abstract: Social interactions in a group are comprised of multiple complex behaviors, and are crucial for the survival of most mammalian species. In recent years, groups of conspecific laboratory mice living together under semi-natural conditions have been studied by us and others, to examine the formation of social dominance hierarchy. In laboratory male mice, most researchers report the formation of solid, stable, hierarchies, while laboratory females present weaker and less stable organizations, if any.Here, we examine the role of pheromones detected through the vomeronasal system (i.e. TrpC2-mediated), in the formation of dominance hierarchies and phenotypic individuality in a group of mice, under ethologically relevant conditions, in both sexes. We analyzed social behaviors in groups of both lab and wild-derived mice using an automated semi-natural system. Moreover, we utilized our unique strain of backcrossed wild-derived TrpC2 knockout mice, which lack a functional vomeronasal organ (VNO). These mice possess a wild genetic background, and also cannot detect VNO-mediated pheromones, similar to laboratory TrpC2 knockouts, which do not present dyadic aggression.In inbred laboratory mice, we show that groups of males establish a solid dominance hierarchy within just 2 days, while females do not present any clear hierarchy throughout the experimental period. Surprisingly, TrpC2 knockout laboratory male mice also form a hierarchical structure, however it is delayed and appears to be more linear then despotic. In wild mice, we show for the first time that groups of female mice establish a strong, solid, dominance hierarchy, similar to that of males. We also show that in wild mice, genetic ablation of VNO-mediated pheromone processing in TrpC2 knockout mice does not seem to impair the construction of dominance hierarchy. Our results demonstrate the importance of examining social behaviors in wild mice, especially when for analysis of females and for deciphering sexual dimorphism. Moreover, our results indicate on further aspects of sensory perception in VNO-deficient mice, suggesting they utilize other pathways and/or modalities to detect social cues from conspecifics.

Title: Cellular substrates of a complex social behavior in cichlid fishes

Authors: *Z. V. JOHNSON, B. E. HEGARTY, G. W. GRUENHAGEN, T. J. LANCASTER, P. T. MCGRATH, J. T. STREELMAN;
Georgia Inst. of Technol., Atlanta, GA

Abstract: A central goal of neuroscience is to understand the biological basis of complex behaviors. Although many complex behaviors have been linked to natural genetic variation in humans and other species, we know little about how these gene-behavior effects are coordinated by specific cell populations and molecular signaling systems. To address this gap, we integrate comparative genomics with brain region-specific single nuclei RNA-sequencing to link natural genetic variation to cell populations to complex social behavior in Lake Malawi cichlid fishes, a powerful vertebrate system for understanding natural behavioral variation and evolution. About 200 Lake Malawi species exhibit bower construction behavior, a goal-directed social behavior whereby males manipulate sand into large structures for courtship and mating over the course of many days. Species variation in bower construction behavior has been linked to natural genetic variation within a concentrated region on a single chromosome. Here, we 1) transcriptionally map the cellular landscape of the cichlid telencephalon, 2) link behavior-associated genomic variation to specific cell populations, and 3) functionally profile these populations during active bower construction behavior in *Mchenga conophoros* males. We identify robust signals of behavior-associated evolution, neuromodulatory signaling, neuronal activation, neurogenesis, and gene regulatory network architecture in neuronal and non-neuronal cell populations. Further, we show that the same cell populations exhibiting signatures of behavioral evolution are selectively activated during behavior. Lastly, we identify candidate genes, cell populations, and molecular signaling systems whose causal role in behavior can be investigated. Taken together, our work shows how single nuclei RNA-sequencing can be used to link natural genetic variation to behaviorally-relevant cell populations in any species system with a suitable genome sequence.

Title: Maternal lineage diet-induced gut dysbiosis and social dysfunction propagate across generations

Authors: C. M. DI GESÙ, L. M. MATZ, I. J. BOLDING, R. S. FULTZ, ***S. A. BUFFINGTON**;
Neuroscience, Cell Biology, & Anat., Univ. of Texas Med. Br., Galveston, TX

Abstract: Gut microbiota are emerging as powerful regulators of host physiology, including brain function and behavior. Diet-driven westernization of the gut microbiota, or microbiome, commonly seen in industrialized countries, is characterized by a significant reduction in

microbial diversity and accompanying loss of beneficial functionalities afforded to the host by a rich microbial ecosystem. Given that the maternal gut microbiome modulates fetal and early postnatal brain development, it is essential to understand the impact of westernization of the maternal gut microbiome on offspring brain development and behavior. We previously showed that maternal Western-style diet (mWd) in mice induces long-term, functional changes in the gut microbiome of male offspring that are causally related to autism-like social dysfunction and underlying deficits in the hypothalamic oxytocinergic-mesocorticolimbic dopaminergic social reward circuit. Here, using metagenomic 16S ribosomal RNA gene amplicon sequencing, we found that mWd similarly induces long-term dysbiosis of the female offspring (F_1) gut microbiome, despite their being transitioned to a regular diet upon weaning. In light of these data, we hypothesized that the enduring dysbiosis of the F_1 female gut microbiome may negatively impact neurodevelopment and behavior in the subsequent generation (F_2). Interestingly, while we observed a partial recovery of the diversity of the F_2 mWd lineage gut microbiome, we observed a complete loss of social preference in male, but not female, F_2 offspring, consistent with our findings in the F_1 generation and the strong male bias in autism. Furthermore, oxytocin levels in the paraventricular nucleus of the hypothalamus were reduced in the F_2 male offspring. Notably, post-weaning dietary probiotic supplementation of the F_2 males rescued their social dysfunction. Our data provide critical insight into the potential for Western diet-inflicted scars on the gut microbiome, particularly within the maternal lineage, and related host phenotypes to propagate across generations. More importantly, they suggest antenatal targeting of the maternal gut microbiome during pregnancy may be an innovative prophylactic approach to improving mental health outcomes in children.

Abstract: Corresponding authors: aleruiz@unam.mx, alcauter@inb.unam.mx. Twin studies aim at comparing the similarity, with respect to a selected trait, between monozygotic twins (MZ), and dizygotic twins (DZ). The comparison of traits between twins allows us to analyze the relative contribution of genetic and environmental factors in various phenotypes (Craig JM et al., 2020). Mexico created the first national twin registry in 2017, TwinsMX (Leon-Apodaca et al., 2019), with which we aimed to estimate the heritability of different traits among the Mexican population, which presents a genetic admixture, different from that observed in other regions of the world (Moreno-Estrada et al., 2014). Here we show results of the Big Five Inventory (Extraversion, Agreeableness, Conscientiousness, Neuroticism and Openness) applied to twins currently registered in TwinsMX. **Methods**. Twin pairs were recruited through different media to remotely respond to the Big Five Inventory. **Results**. Currently, we have the response of 96 twins (MZ n = 74; DZ n = 22) who completed the inventory. In the sample, a higher proportion of female participants (78%) and young people between 21-30 years old (44%) is observed. It is a small sample from which preliminary conclusions about the population can be drawn. Here we present the correlation between MZ and DZ in the following traits: Extraversion:); Agreeableness:); Conscientiousness:); Neuroticism:); Openness:). **Conclusions**. These preliminary results represent a first advance in the study of personality trait heritability using TwisnMX data, showing that extraversion, neuroticism and openness seems to reflect a higher genetic component compared to the agreeableness and conscientiousness. However, it is necessary to increase the sample size to calculate a reliable index of heritability for each personality trait for Mexican population. Keywords: twins, big five, trait, personality, heritability. GRANT: CONACYT CF-2020-6390.

Title: Chronic isolation and acute restraint stress do not affect memory and affective behavior in 5XFAD mice

Authors: *S. DOMINGUEZ[1], A. LOCCI[3], H. DONG[2];
[2]Dept Psychiatry and Behavioral Sci., [1]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL;
[3]Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Introduction: Previous studies from our group and others suggest that physical and social stress are both risk factors of Alzheimer's Disease (AD). In this study, we aimed to determine whether cognitive decline, affective behavior, and biochemical markers of AD were significantly impacted in a sex-dependent manner by chronic isolation or acute physical restraint stress in an AD mouse model. **Methods:** Firstly: 5XFAD mice were either singly or group-housed (3-5/cage) beginning at wean age (21-23d) for 12 months. After isolation stress, all mice (n=12-14/sex/condition) underwent behavioral analyses for memory [Novel Object Recognition (NOR), Y-Maze, Morris Water Maze (MWM)], anxiety-like behavior [Open Field Test (OFT), Light Dark Test (LD)], and depressive-like behavior [Tail Suspension Test (TST)]. Secondly: 12m 5XFAD and wild-type (WT) littermates underwent one instance of 24h of restraint stress or no stress (n=10/sex/condition) prior to behavioral analyses for memory (Y-maze, MWM), anxiety-like behavior (OFT, LD), and depressive-like behavior (TST). Then, brain tissues were collected for biological analyses. **Results:** 12-month-old 5XFAD mice displayed memory deficits and depressive-like behavior, but neither chronic isolation nor 24h restraint stress resulted in significant differences compared to non-stressed groups. Specifically, Y-maze showed a significant effect of genotype ($p<0.0001$) regardless of stress condition, but isolation ($p=0.5206$) and 24h restraint ($p=0.6404$) had no effect on memory in either genotype. Latency to reach the hidden platform in MWM was significantly longer in 5XFAD mice ($p<0.0001$) with an effect of sex ($p=0.0084$) but not stress (isolation $p=0.4489$, 24h restraint $p=0.9360$). In OFT, WT male mice exposed to 24h restraint stress had a significant reduction in the time spent in the center ($p=0.0229$); however, isolated 5XFAD mice and non-isolated 5XFAD mice did not significantly differ (isolation $p=0.8853$). While 5XFAD mice spent significantly more time immobile during the TST ($p<0.0001$), neither isolation ($p=0.0875$) nor 24h restraint ($p=0.1865$) were significant. In the LD, isolated ($p=0.8985$) and 24h restraint ($p=0.7031$) mice had no significant differences compared to non-stressed mice. Biological analyses are underway. **Conclusions:** Our preliminary data has confirmed that 5XFAD mice display some memory deficits and depressive-like behavior at 12m, however, the chronic and acute stress paradigms we selected did not affect such behaviors. These results are unexpected and future studies are needed to confirm whether 5XFAD mice with the C57 genetic background are more resilient to physical and social stress.

Title: Social stress alters behavioral responses, synaptic properties and intrinsic excitability in nucleus accumbens of knock-in mice carrying the Parkinson's disease-linked LRRK2-G2019S mutation

Authors: *C. A. GUEVARA, B. A. MATIKAINEN-ANKNEY, S. J. RUSSO, D. L. BENSON, G. W. HUNTLEY;
Nash Family Dept. of Neurosci., The Friedman Brain Institute, Grad. Sch. fo Biomed. Sciences, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Parkinson's disease (PD) is associated with cognitive and psychiatric (anxiety, depression) non-motor symptoms that appear early, are initially independent of dopamine neuron loss and are poorly understood. The LRRK2-G2019S mutation is the most common genetic cause of late-onset PD. The risk for both PD and depression is increased by behavioral stress. To probe relationships between PD mutation, stress, and neural circuit modifications, we subjected young adult (2-3 mo) male wildtype (WT) and G2019S knockin mice to acute (1d) social defeat stress (SDS) followed by whole-cell recordings from striatal projection neurons in the nucleus accumbens (NAc)-- an area enriched in LRRK2 and known to regulate stress and depression-like responses--in order to interrogate the impact of 1d-SDS on synaptic function and intrinsic membrane properties. Following 1d-SDS, G2019S mice were significantly more socially avoidant compared to 1d-SDS WT mice. Subsequent whole-cell recordings in NAc revealed that mutant SPNs failed to exhibit changes in intrinsic excitability seen in 1d-SDS WT SPNs, but instead showed synaptic changes that WT SPNs lacked. Together, these data indicate that G2019S drives a temporally-evolving set of cellular and synaptic adaptations to behavioral stress that differ from WT and may impact onset of psychiatric symptoms in human PD patients. Identifying synaptic and cellular adaptations to stress may reveal novel targets for ameliorating mood-related and cognitive symptoms associated with PD.

Title: Neurobiological differences between laboratory and wild-trapped Rattus Norvegicus: Implications for translational value of preclinical psychiatric models and therapeutic interventions

Authors: J. JACOB[1], S. WATANABE[1], N. GONZALES[1], J. RICHARDSON[1], E. G. PLOPPERT[1], G. LAHVIS[2], A. B. SHIELS[3], S. WENGER[1], K. SAVERINO[1], J. BHALERAO[1], B. CROCKETT[1], E. BURNS[1], O. HARDING[1], K. STENGER[1], ***K. LAMBERT**[1]; [1]Univ. of Richmond, Richmond, VA; [2]Harvard Law Sch., Boston, MA; [3]Natl. Wildlife Res. Ctr., Fort Collins, CO

Abstract: For over a century, preclinical research has utilized numerous laboratory-bred strains of *Rattus norvegicus*. Although research with these models has produced valuable information, in biomedical disciplines such as psychiatric research, rodent models continue to lack predictive validity. Despite the annual use of tens of millions of rodents in U.S. laboratories, few studies have compared laboratory rodent strains with their wild counterparts. Recognizing the importance of environmental influences on neural functions, laboratory habitats are severely restricted in comparison to the dynamic, sensory-rich habitats of wild rats. In the current study, we compared two wild rat populations (i.e., each from an urban and rural environment) to a common outbred laboratory strain, the Long Evans (LE) rat (Envigo, Inc). Laboratory rats were weight-and sex-matched to the wild urban rats. Wild urban rats were live-trapped in Richmond, VA, and were euthanized so their brains could be immediately extracted and post-fixed. Additional morphological measures were collected including spleen, adrenal, and body weights; further, fecal boli were collected for corticosterone and DHEA analyses. Brains were dissected and prepared for histological analysis, including isotropic fractionation, to determine cell counts in the cell-dense cerebellum, with ongoing assessments of cytoarchitectural profiles in the hippocampus and amygdala as well as cytokine levels in spleen tissue. Whole brains of the rural/farm rats were post-fixed and sent to our lab for histological analyses. LE rats were acclimated to the vivarium for one week in standard laboratory conditions before tissue collection as described for the wild rats. Fecal samples were collected from the lab rats immediately upon arrival to capture transport stress to compare to trap-related stress of wild rats. Wild rat adrenal glands were 3x larger than the lab rats ($p=.001$) and, focusing on the spleen weights, a significant interaction ($p=.045$) indicated that the 4x increase in female wild spleen weights compared to female lab rat spleens was larger than the 2x increase observed in wild male spleen weights compared to lab rats. LE cerebella ($N = 10$) contained significantly fewer cells than both urban ($N = 11$, $p = 0.00002$) and farm rats ($N = 14$, $p = 0.002$) rats (i.e., 20% and 15% fewer, respectively). Of specific relevance for stress-related preclinical models, stressed corticosterone levels were 5x higher in urban rats compared to laboratory rats ($p=.025$).

Additional research is necessary to explore the clinical relevance of laboratory and wild rat comparisons to determine the translational value of rodent neuropsychiatric models.

Title: Behavioral consequences of a traumatic experience in mice

Authors: *I. D. B. WEBER[1], R. HEN[2], G. F. TURI[1];
[1]Systems Neurosci., New York State Psychiatric Inst., New York, NY; [2]Neurosci. and Psychiatry, Columbia Univ., New York, NY

Abstract: Though fear is an adaptive behavior essential for survival, overexpressed fear can cause anxiety in situations where it is not called for and reduce quality of life. Patients with post-traumatic stress disorder (PTSD) have difficulties distinguishing similar contexts containing cues related to a traumatic experience and are less able to determine which are safe or threatening. The hippocampus and specifically the dentate gyrus subarea have long been implicated in the pathogenesis of PTSD, possibly due to its role in pattern separation, the network-level process which underlies the ability to distinguish highly similar contexts. Thus, we hypothesized that mice which experience trauma and develop PTSD-like behavior will also have impairments in behaviors that depend on intact hippocampal function. To test this idea, our first aim was to develop a high-throughput behavioral profiling pipeline which can be used to characterize PTSD-like and hippocampal dependent mouse behavior before and after the traumatic experience with the least amount of human interference and bias. To subject mice to trauma, we used the stress-enhanced fear learning (SEFL) footshock protocol. Our behavioral profiling battery included the open field task and elevated plus maze to assess anxiety-like behavior, as well as object recognition and spontaneous alternation tests for assessing memory and the functional integrity of the hippocampus. To subject mice to a traumatic experience, we used the stress-enhanced fear learning (SEFL) footshock protocol. To analyze how trauma affects

behavior in these tasks, we implemented the DeepLabCut package for tracking mouse body parts in recorded video and wrote additional code to analyze the tracking results. In spite of the frequent occurrence of negative experiences in humans, the overall lifetime prevalence of PTSD in the US population is about 10%, which suggests that factors other than trauma are also involved in the pathogenesis of PTSD. Thus, we identified a subset of SEFL treated mice exhibiting pronounced freezing in a fear conditioned context even after repeated exposure to the context without shock. These mice freeze 40% of the time after 4 exposures, as opposed to the resilient population which freezes only 10% of the time. We are planning experiments to investigate network-level disruptions of contextual discrimination in the dentate gyrus of mice expressing this behavioral phenotype. A characterization of the network properties underlying pattern separation and contextual discrimination which are disturbed in a PTSD-like state will improve our understanding and ability to find endophenotypes of PTSD based on circuit components.

Title: Role of the ventral hippocampal circuit in the responses to chronic stress, acetylcarnitine and ketamine

Authors: *B. BIGIO[1], J. DOBBIN[1], O. BARNHILL[1], D. MILLER[1], R. HEN[4], E. J. NESTLER[5], B. S. MCEWEN[2], C. NASCA[3];

Abstract: Chronic stress is a main risk factor for major psychiatric disorders, including depression. In rodent models, administration of acetylcarnitine (LAC) leads to a rapid and persistent antidepressant-like response by increasing a chronic stress-induced suppression of acetylation of specific histone markers and the related expression of key genes for synaptic plasticity in ventral dentate gyrus (vDG). In patients with depression, LAC levels are decreased. Yet, the circuit level mechanisms underlying the rapid antidepressant-like responses of LAC remains to be determined. Here, we used a chemogenetic, behavioral and pharmacological approach to test the role of the ventral hippocampal circuit in the responses to LAC as compared

to ketamine at chronic stress models. Our preliminary data showed that either administration of ketamine (10 mg/kg, i.p. injection) or LAC (100 mg/kg, i.p. injection) rescues depressive-like phenotypes at both the chronic restraint stress (CRS) and social defeat stress (SDS). Next, we used Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) approaches to suppress neuronal firing of the ventral hippocampal circuit in transgenic mice expressing Cre recombinase under the control of the mouse calcium/calmodulin-dependent protein kinase II alpha (Camk2a) promoter (Camk2a-Cre+ mice). Preliminary data showed that chemogenetic silencing of neuronal firing of the ventral hippocampal circuit blunted the action of LAC on the amelioration of CRS-induced behavioral deficits. In all, these findings support the critical role of the ventral hippocampus in stress responses and in the responses to the novel epigenetic modulator of glutamatergic function.

Medicine at Mount Sinai New York, NY
Major depressive disorder (MDD) is the leading cause of disability and a leading contributor to suicide according to the World Health Organization. Unfortunately, close to half of all patients diagnosed with MDD are at least partly resistant to antidepressant treatment. Notably, both genetic and environmental factors, including exposure to chronic social stress, play a role in the development of MDD and related syndromes. The chronic social defeat stress (CSDS) paradigm in mice has proven to be a highly useful animal model for studying depression-related behavioral abnormalities. Importantly, this paradigm allows for the identification of animals that succumb to the effects of the stress, termed susceptible, from those that do not, termed resilient. To better understand the potential genes underlying the resilient phenotype, we performed RNA-sequencing on mice exposed to CSDS and compared gene expression changes within the nucleus accumbens (NAc) between resilient and susceptible mice. Using weighted gene co-expression network analysis (WGCNA), we identified gene expression patterns that are associated uniquely with resilience. These data were then evaluated using an undirected key driver analysis that allows for the reconstruction of accurate cellular networks (ARACNE) based on gene-gene correlations. We identified three genes (*Gprin1*, *Bcr*, and *Stx1a*) that were predicted to be key drivers (predicted to regulate other genes) within a highly significant, resilient-specific module. We are now investigating how changes in the expression of these genes could lead to changes in depressive-like behavior. To test this, multiple cohorts of mice were exposed to CSDS or another stress paradigm, chronic variable stress, and mRNA expression levels of these target genes were assessed. We also tested the functional consequences of virally manipulating these genes following prior to CSDS. Evidence from these studies suggests that overexpression of each of these genes in NAc neurons produces a pro-resilient effect. Current work is investigating these molecular mechanisms in a cell-type-specific manner within the NAc. Together, these studies are providing novel insight into the molecular basis of stress resilience.

Abstract: Major depressive disorder involves changes in synaptic structure and function, but the molecular underpinnings of these changes are still not established. In an initial pilot experiment, whole-brain synaptosome screening with quantitative western blotting was performed to identify synaptic proteins that may show concentration changes in a congenital rat learned helplessness model of depression. We found that the N-methyl-D-aspartate receptor (NMDAR) subunits GluN2A/GluN2B, activity-regulated cytoskeleton-associated protein (Arc) and syntaxin-1 showed significant concentration differences between congenitally learned helpless (LH) and nonlearned helpless (NLH) rats. Having identified these three proteins, we then performed more elaborate quantitative immunogold electron microscopic analyses of the proteins in a specific synapse type in the dorsal hippocampus: the Schaffer collateral synapse in the CA1 region. We expanded the setup to include also unstressed wild-type (WT) rats. The concentrations of the proteins in the LH and NLH groups were compared to WT animals. In this specific synapse, we found that the concentration of NMDARs was increased in postsynaptic spines in both LH and NLH rats. The concentration of Arc was significantly increased in postsynaptic densities in LH animals as well as in presynaptic cytoplasm of NLH rats. The concentration of syntaxin-1 was significantly increased in both presynaptic terminals and postsynaptic spines in LH animals, while pre- and postsynaptic syntaxin-1 concentrations were significantly decreased in NLH animals. These protein changes suggest pathways by which synaptic plasticity may be increased in dorsal hippocampal Schaffer collateral synapses during depression, corresponding to decreased synaptic stability.

Title: A novel fatty acid amide hydrolase inhibitor as a potential antidepressant and its effect on gene expression in BALB/c mice acute stress model

Authors: *C. MEDINA-SALDIVAR, S. CRUZ-VISALAYA, G. E. PARDO, J. M. IGLESIAS-PEDRAZ, L. F. PACHECO-OTALORA;
Univ. Andina del Cusco, Cusco, Peru

Abstract: Background Endocannabinoid modulators has recently gained relevance as a potential treatment of depression due to its particular mechanism of action that differs from the classic antidepressants. Inhibitors of the fatty acid amide hydrolase (FAAH) have demonstrated antidepressant effects in the murine model by increasing the bioavailability of anandamide in the central nervous system. In the present study, we have used a novel compound (MCH1) derivate from the Peruvian plant *Lepidium meyenii* (maca) that shown an *in vitro* FAAH inhibitory activity. Our goal was to evaluate the antidepressant effect of different MCH1 doses i.p administered in mice that were then exposed to acute stress using shawn mice as controls. Also, we evaluate the effect of the optimal dose of MCH1 on the gene expression levels of *FAAH*, *Cnr1* and *NAPE-PLD* in the dentate gyrus of treatment and controls mice. **Methods** 25 male BALB/c mice (2-month-old) were randomly assigned in groups of 5. Each group received a single dose of vehicle (1: 1: 18 DMSO / polyethylene glycol 600 / 0.9% saline (shawn)), 3 mg/kg MCH1, 10mg/kg MCH1, 30mg/kg MCH1 or 20mg/kg fluoxetine. After one hour, mice were exposed to a forced swim test (acute stressor) and the immobility and latency time evaluated. One hour after the test, the brains were collected, freeze at -80°C and cryostate-cutted at 500 µm. The hippocampus was 16G micropunched at dentate gyrus of both sides, and RNA was extracted by TRIzol method. Genomic DNA was removed by DNase I before cDNA generation. Freshly prepared cDNA was used to perform qPCR. **Results** Tukey's post-hoc analysis showed that the administration of 10mg/kg (59 sec, $p < 0.01$) and 30mg/kg (77.40sec, $p < 0.05$ MCH1 vs 151.8 sec vehicle) of MCH1 reduced the immobility time of mice significantly, reaching the maximum effect with 10mg/kg. Though the administration of MCH1 showed a trend of increasing immobility latency in the three MCH1 groups, this was not significant ($p = 0.2107$). Thus, 10mg/kg MCH1 group was selected for gene expression analysis. Our preliminary qPCR data reveals that, after MCH1 treatment there is a significant increase in *FAAH* expression while observing a reduction in *Cnr1* and *NAPE-PLD* expression levels compared to vehicles. **Conclusion** The administrations of MCH1 have antidepressant activity in an acute model. The MCH1 dose of 10 mg/kg showed the most significant antidepressant effects. This antidepressant effect could be linked with the inhibitory effect of MCH1 on FAAH activity. The expression levels of *Cnr1* and *NAPE-PLD* was significantly reduced, suggesting a negative feedback

possible as an over signaling of anandamide as consequence of FAAH inhibition, irrespective of mRNA upregulation.

Title: Predator odor (TMT) exposure modifies alcohol interoceptive sensitivity and differential gene expression in the insular cortex

Authors: *R. E. TYLER[1], S. MAGEE[1], M. BLUITT[1], J. BESHEER[2];
[1]UNC Chapel Hill, CHAPEL HILL, NC; [2]Psychiatry; Bowles Ctr. for Alcohol Studies, Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Post-traumatic stress disorder (PTSD) confers enhanced vulnerability to develop problem drinking or AUD co-morbidity. Alcohol produces interoceptive (subjective) stimulus effects that likely inform drug intake by driving drinking or signaling satiety. Therefore, understanding the role of stress on alcohol interoceptive sensitivity is a clinically relevant question. The present studies used exposure to the predator odor 2,5-dihydro-2,4,5-trimethylthiazoline (TMT) to model aspects of a stressor relevant to PTSD. A Pavlovian drug discrimination procedure was employed to train rats to respond to a conditioned stimulus (light) to procure a sucrose reward (unconditioned stimulus) conditional on the interoceptive effects of alcohol. That is, male, Long-Evans rats were trained to discriminate the interoceptive effects of alcohol (2.0 g/kg, i.g.) from water. Upon stable discrimination, rats received a single, inescapable TMT exposure and then remained undisturbed in their home cage for 2 weeks prior to interoceptive sensitivity testing. Prior TMT exposure did not affect interoceptive effects of alcohol at 2 g/kg but potentiated the stimulus effects of 1 g/kg of alcohol. Because the interoceptive effects of 1 g/kg alcohol are predominantly mediated by GABA receptor potentiation, a substitution experiment using pentobarbital was conducted and showed potentiated alcohol-like stimulus effects in the TMT group compared to controls, confirming a GABAergic adaptation. Next, rats underwent extinction training by removing the sucrose reward, uncoupling the unconditioned stimulus (sucrose) from the conditioned stimulus (light) while under the alcohol interoceptive state at the training dose (2 g/kg). Both the TMT and control groups showed identical within-session extinction, but the TMT group showed persistence in responding to the first light presentation between sessions compared to controls that showed normal between-session extinction. Gene expression analyses 2 weeks after a TMT

exposure in a separate group showed that the inhibitory cell marker *GAD1* gene expression was elevated in the insular cortex, suggesting some GABA receptor adaptation, which may underlie the potentiated sensitivity of 1 g/kg alcohol and pentobarbital in the TMT group. Together, these data begin to elucidate mechanisms that may underlie stressor-induced adaptations to alcohol interoceptive sensitivity. Supported by: AA026537

Title: Prefrontal cortex norepinephrine represents predictability of aversive events.

Authors: *A. BASU[1], A. YU[2], Y. LI[4], A. P. KAYE[3];
[1]Yale Univ. Interdepartmental Neurosci. Program, New Haven, CT; [2]Psychiatry, [3]Dept. of Psychiatry, Yale Univ., New Haven, CT; [4]Peking Univ., Beijing, China

Abstract: Animals must learn to predict levels of threat in environments containing uncertainty to respond with appropriate defensive behaviors. Neuromodulators such as norepinephrine (NE) have been proposed to mediate predictions under uncertain conditions as well as stress-related disorders such as anxiety disorders and post-traumatic stress disorder, which arise from irresolvable uncertainty. Both acetylcholine and dopamine have been shown to represent predictive signals during both appetitive and aversive learning. However, investigation of the role of norepinephrine in threat prediction has been limited by the lack of high-resolution measurements of NE. Models in which NE release in PFC represents threat, threat prediction errors, or valence-independent uncertainty may help to resolve the role of NE in this structure. To that end, we expressed the fluorescent norepinephrine sensor GRAB-NE2h is the dorsomedial prefrontal cortex (dmPFC) or in multiple brain regions simultaneously and measured norepinephrine release via fiber photometry. We measured norepinephrine release during fear conditioning while varying the temporal delay between cues and aversive outcomes. NE release transients are synchronous with footshock, and NE release during threat-predictive cues increases across multiple cue presentations regardless of temporal delay. However, amplitude and temporal characteristics of NE release are modulated by temporal delay. Cue-evoked NE

persists in the absence of cue-shock pairings but extinguishes over repeated cue presentations, which may be consistent with plasticity in the locus coeruleus. Cue-evoked NE release amplitude scales with time-discounted magnitude of predicted aversive events supporting a hypothesis in which NE release may correspond to threat level. Multi-region fiber photometry shows heterogeneous NE dynamics in several brain regions, but consistent shock and cue evoked elevations in release. Ongoing studies will examine the role of cue and shock evoked dmPFC NE in aversive learning, as well as the role of temporal and probabilistic unpredictability. Determining the role of norepinephrine in prediction of threats of varying certainty will illuminate computational processes underlying anxiety and anxiety disorders.

Title: Behavioral and dopaminergic signatures during chronic social defeat stress that predict resilience

Authors: *L. WILLMORE[1], I. B. WITTEN[1], A. L. FALKNER[2];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ

Abstract: Chronic stress can have lasting adverse consequences in some individuals, yet others exhibit resilience. While molecular and intrinsic neural properties of the midbrain dopamine (DA) system differ in susceptible and resilient individuals following stress, if and how DA activity during the stressful experience itself differentiates susceptible and resilient individuals is an open question. To address this gap, we chronically record behavior and DA neural activity in the projections to the nucleus accumbens (NAc, signal reward) and tail of the striatum (TS, signals threat) during chronic social defeat stress. We find distinct behavioral and neural signatures of resilience and susceptibility. During stress, susceptible mice have lower NAc DA activity at the onset of aggressor encounters and higher NAc DA at the offsets during and after stress. In contrast, resilient mice exhibit higher NAc DA in proximity to the aggressor during and after defeat, exhibit more fighting back behavior during defeat, and have increased NAc DA

activity during this specific behavior. To test whether this specific timing of NAc DA activity is sufficient for producing resilience, we perform closed-loop (fight-back-triggered) and open-loop optogenetic stimulation of NAc DA neurons during stress. We find that both closed- and open-loop stimulation are pro-resilient, which suggests that increasing DA and positive valence generally in the aggressor interaction context is enough to protect against stress-susceptibility.

Title: Orexinergic projections to VTA and amygdala promote active avoidance

Authors: C. SILLER PÉREZ[1], S. SAMELS[2], E. ANDRADE[2], C. CAIN[2,3], *R. SEARS[2,3]; [1]Emotional Brain Inst., The Nathan Kline Inst., Orangeburg, NY; [2]Emotional Brain Inst., Nathan Kline Inst., Orangeburg, NY; [3]Dept. of Child and Adolescent Psychiatry, NYU Langone Med. Ctr., New York, NY

Abstract: Proactive strategies for coping with threats are essential to survival. Identifying the neuromodulatory mechanisms that orchestrate survival behaviors is of critical importance to understanding fear- and stress-coping in health and disease. Perifornical (PFH) and lateral hypothalamus (LH) neurons expressing orexin (hypocretin) peptides project throughout the brain and mediate functions critical for survival behaviors including vigilance, attention, and action selection. Here we delineate the role of two targets of the hypothalamic orexin system using a model of proactive threat-coping behavior—signaled active avoidance (SigAA). Based on appetitive instrumental studies and physiology findings, we hypothesized that orexin projections to the central nucleus of the amygdala (CeA) would oppose restrictive freezing reactions, thus permitting proactive SigAA responses, and projections to the ventral tegmental area (VTA) would invigorate SigAA. Sprague Dawley rats received infusions of an orexin-specific viral vector containing an inhibitory opsin (AAV1-Ple112-Arch3.0-eYFP) into the PFH/LH, and optic fibers were implanted in the CeA or VTA. Following a 6-8 week incubation, rats were trained in the SigAA task. Animals received one Pavlovian trial (60 s white noise warning signal (WS) paired with an inescapable foot-shock (1.0/0.7 mA males/females; 0.5 s). For all remaining trials, if animals shuttled during the WS (an avoidance response), a feedback (FB) tone was delivered

(5 s, 80 dB), which served as a safety signal. Rats received 15 trials per day until reaching 80% avoidance responses per session. During test sessions, orexin-->CeA or orexin--> VTA axon terminals were inhibited either during the WS or the FB. Photoinhibition (green laser 532 nm, 10 mW) occurred during shock-free extinction tests. Impairments were observed in avoidance responses and avoidance latency when inhibiting orexin-->CeA or orexin-->VTA axon terminals. These results suggest that the orexin system suppresses passive reactions (freezing) and promotes adaptive instrumental actions (active avoidance) via two separate neural pathways, highlighting a novel role for the orexin system as a 'master modulator' of proactive coping behavior.

Title: The amygdala's role in learning from gains and losses

Authors: *M. A. JANSSEN, C. A. TASWELL, E. A. MURRAY, B. B. AVERBECK;
Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Adaptable behavior requires animals to learn the values of different stimuli to gain rewards and avoid losses. Most prior work has studied learning from rewarding outcomes. However, different learning environments, such as environments with aversive outcomes, may affect the animal's ability to learn. Therefore, we developed a task that allowed us to examine the neural systems involved with learning from both gains and losses. Previous research using this task has found that animals with ventral striatum (VS) lesions had deficits only when choosing between two rewarded outcomes, suggesting that different neural circuitry may underlie learning from losses. The amygdala is a prime candidate for this role because it plays a role in aversive learning, conditioned reinforcement, and visual stimulus-based reinforcement learning. Additionally, the amygdala projects to additional areas that are involved with coding value representations, driving motivated behavior, and processing aversive emotions. To investigate the role of the amygdala in learning from gains and losses, we compared rhesus monkeys (*Macaca mulatta*) with excitotoxic amygdala lesions (n = 4) with unoperated controls (n = 4) on a task in which monkeys chose between two pictures with associated gains and losses of tokens, which were presented visually on the screen. These tokens were conditioned reinforcers that

were periodically cashed out for a juice reward. They learned to choose cues associated with gains and avoid cues associated with losses of tokens. We ran four experiments. In the first, we introduced four images with deterministic outcomes of +2, +1, -1, and -2 tokens. The second task had an additional cue with a value of 0, resulting in five deterministic outcomes of +2, +1, 0, -1, and -2 tokens. The third task was a stochastic task with the four original cues. There was a 75% chance of receiving the original tokens and a 25% of not receiving any tokens. The fourth task resembled the first experiment but with -2 tokens substituted with -4 tokens, which acted as a large token loss. We found that token gains were appetitive and token losses were aversive, and that monkeys performed well on conditions with gains paired with losses. Additionally, monkeys learned to select the 0 token cue when it was paired with a loss cue. On the 0 token task, monkeys with amygdala lesions performed better than controls. Further, a reinforcement learning model with one parameter for each cue best fit the data. With this model, we found that lesion animals performed better with the +1 cue in the 0 token experiment, and this drove the significant difference between groups.

Title: Hippocampal-hypothalamic circuit controls context-dependent innate defensive responses

Authors: *J. BANG[1], J. SUNSTRUM[4], D. GARAND[2], M. A. WOODIN[1], W. INOUE[4], J. KIM[3];
[2]Cell and Systems Biol., [3]Psychology, [1]Univ. of Toronto, Toronto, ON, Canada; [4]Univ. of Western Ontario, London, ON, Canada

Abstract: Preys use their memory - where they sensed a predatory threat and whether a safe shelter is nearby - to dynamically control their survival instinct to avoid harm and reach safety. However, it remains unknown which brain regions are involved, and how such top-down control of innate behavior is implemented at the circuit level. Here, we show that the anterior hypothalamic nucleus (AHN) is best positioned to perform this task as an exclusive target of the hippocampus (HPC) within the medial hypothalamic defense system. Direct AHN activation is

sufficient to evoke robust defensive responses (running, jumping, freezing) in the absence of threat and can act as an unconditioned stimulus in the conditioned place aversion test. In contrast, the HPC-AHN activation induced escape-associated locomotion in the absence of threat yet induced goal-directed escape when a shelter is available. Next, we inhibited HPC-AHN to test whether the pathway is necessary for context-dependent escape responses. Inhibition of HPC-AHN impaired avoidance of predator associated context and reduced escape runs to the safe context. When escape response is dependent on the availability of a shelter, we found that the HPC-AHN inhibition impaired efficiency (i.e. speed, escape linearity) and accuracy of shelter-oriented escapes upon ultrasound cue. Selective optogenetic stimulation and inhibition of hippocampal inputs to the AHN revealed that the HPC→AHN pathway not only mediates the contextual memory of predator threats but also controls the goal-directed escape flight by transmitting information about the surrounding environment. These results reveal a new mechanism for experience-dependent, top-down control of innate defensive behaviors.

Abstract: The mechanistic theory of neural information storage speculates that neural representation activated during memory encoding is preferentially recruited during memory retrieval. Recent developments in network science are offering an excellent set of tools to analyze complex neural processes associated with learning and memory. Current studies use one-photon calcium imaging in freely behaving mice to assess large network dynamics and aim at identifying the neural representations of contextual fear memories and assess circuit dynamics underlying disambiguating safety and danger. Alterations of prefrontal network activity during fear modulation associated with context-dependent fear discrimination learning are evaluated via

real-time network activity assessment using miniaturized head-mounted microscopes followed by computational analysis of large-scale neuronal activity patterns. Head-mounted miniaturized microscopes are capable of measuring calcium transients reflecting neuronal activity from more than thousands of neurons in freely behaving mice. To evaluate large-scale circuit dynamics associated with fear discrimination learning, the calcium-sensitive fluorescent protein GCaMP6f is expressed in the prelimbic subdivision (PL) of the mPFC followed by assessment of real-time prefrontal network changes in response to dangerous and safe context stimuli across the behavioral testing. Our data indicate that PL local network is required for safety learning. To better understand these large and complex network dynamics, we use an unsupervised Tensor Decomposition in order to track neuronal populations involved in network learning across the temporal component of the behavioral sessions and across multiple days of stimuli (context) presentation. In addition, using the spike data of the calcium traces we constructed a new graph-theory-based computational model to better understand the overall network dynamics, population coding, and predictive properties of neural interactions. Our computation model revealed discrete alteration of global parameters of the large-scale network underlying safety learning and explains how these measures relate to the neural information-theoretic measure of predictive analysis. Understanding how fear memories are encoded and kept resistant to confusion is clinically relevant as fear memory overgeneralization is a hallmark of phobias, PTSD, and generalized anxiety disorder.

Title: Infralimbic prefrontal cortex neural activity associated with diurnal rhythms in auditory conditioned fear extinction in male rats

Authors: *M. J. HARTSOCK, M. J. NAVARRO, C. T. LEVY, M. P. SADDORIS, R. L. SPENCER;
Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Neurobiological mechanisms of memory are pervasively regulated by the circadian system. Individuals with post-traumatic stress disorder and related conditions show impairments

in fear extinction, a memory process by which a subject learns that cues that once predicted danger no longer do. Understanding how the circadian system regulates extinction memory may point to new approaches for optimizing extinction-based therapies in the clinic. Using rats, we have previously demonstrated that diurnal rhythms in fear extinction recall require normal circadian clock gene expression in the infralimbic prefrontal cortex (IL) (Woodruff et al. 2018, eNeuro). How the IL clock coordinates diurnal rhythms in extinction recall remains unknown. Here, we assessed IL neural activity during fear extinction at different times of day in adult male Sprague-Dawley rats maintained on a 12h:12h light-dark cycle. First, we bilaterally implanted 8-channel electrode arrays in the IL. Then, at either ZT4 (inactive phase) or ZT16 (active phase), rats underwent fear conditioning (Day 1: 3 tone-shock pairings in Context A), extinction learning (Day 2: 15 tone presentations in Context B), extinction recall (Day 3: 15 tone presentations in Context B), and fear relapse (Day 7: 15 tone presentations in Context B). We recorded neural activity in the IL on Day 2, Day 3, and Day 7 and subsequently time-locked freezing behavior to neural recordings by manually placing freeze onset and offset markers in videos captured with the Plexon Cineplex software. ZT4 and ZT16 rats showed comparable freezing behavior during the first three sessions, but ZT16 rats froze significantly less during the fear relapse session on Day 7. Our initial analyses of the neural data show changes in single-unit activity and local field potential power corresponding to tone onset, tone offset, freeze onset, and freeze offset. In our ongoing work, we will examine burst firing, identify putative excitatory versus inhibitory neurons, track isolated units and populations within and between sessions, and characterize potential time-of-day differences in neural activity.

Title: Nmda receptors in signal transmission: a computational perspective

Authors: *G. GLICKERT[1], B. LATIMER[1], P. SAH[2], S. NAIR[1];
[1]Univ. of Missouri, Columbia, Columbia, MO; [2]Queensland Brain Inst., Univ. of Queensland, Brisbane, Australia

Abstract: NMDA receptors in signal transmission: a computational perspective
Greg Glickert[1], Benjamin Latimer[1], Pankaj Sah[2], and Satish S. Nair[1]

1 – Dept. of Electrical Engineering and Computer Science, Univ. of Missouri, Columbia, MO USA2 – Queensland Brain Institute, University of Queensland, Brisbane, Queensland AU
Hebbian, N-methyl-D-aspartate (NMDA) receptor-dependent long-term potentiation (LTP) is believed to underpin many forms of learning and memory. The Hebbian model of fear conditioning posits that repeated pairing of a conditioned stimulus (CS) with an aversive unconditioned stimulus (US) leads to LTP of synapses carrying CS information to the amygdala, and activation of these enhanced synapses evokes the conditioned response (CR). Fear learning and the associated synaptic plasticity has been shown to involve NMDA receptors. However, it is unclear whether in addition to facilitating potentiation of the CS pathway NMDA receptors also have a role in signal transmission itself. In particular, the role of these effects in fear discrimination remains to be explored. An interesting possibility is that intrinsic circuits may play an important role in engendering such plasticity, including via a recently discovered reverberatory circuit involving chandelier neurons in the amygdala. We analyze single unit recordings from the rodent basolateral amygdala during fear conditioning that show application of (7)-3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP), an NMDA antagonist, shifted the excitation-inhibition balance toward inhibition during auditory stimulus presentation. CPP application impaired recruitment of putative inhibitory neurons during tone presentation. In this computo-experimental model, we construct a large-scale biophysically realistic network model to show how the dynamics of NMDA receptors facilitates both intrinsic neural activity and long-term potentiation in the basolateral amygdala during fear discrimination.

Title: A thalamo-amygdalar CGRP circuit encoding aversive information

Authors: *S. KANG, S. LIU, M. YE, D.-I. KIM, J. KIM, S. HAN;
Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The perception of noxious stimuli motivates animals to perform immediate avoidance behaviors and to form aversive memories so that tissue-damaging stimuli can be avoided in the future. Thus, electrical footshock is often used as the unconditioned stimulus (US) in the classical associative threat learning paradigm. The amygdala plays a key role in this type of aversive learning. However, neural pathways by which nociceptive signals are conveyed to the

amygdala are not fully understood. Here, we identify that neurons expressing calcitonin gene-related peptide (CGRP) in the thalamus relay nociceptive information from the spinal cord to the lateral amygdala (LA). Using cutting-edge circuit dissection tools, such as fiber photometry, optogenetics, chemogenetics, and viral circuit tracing, we show that these neurons are activated by various nociceptive stimuli and form the spino-thalamo-amygdaloid pathway that is necessary and sufficient for affective-motivational pain perception. Furthermore, we find that this pathway is critical for conveying the US during the Pavlovian threat learning. The discovery of the cell-type-specific US pathway that transmits noxious inputs to the LA during associative threat learning provides critical circuit-based insights into developing therapeutic interventions for pain and threat-related disorders.

Title: Medial prefrontal cortical dynorphin-containing neurons constrain emotional memories

Authors: *H. WANG[1], H. YARUR CASTILLO[1], R. FLORES GARCIA[1], N. LOOMBA[1], S. CASELLO[1], Q. WANG[1], G. OR[2], K. MAHE[2], L. TIAN[2], H. A. TEJEDA[1];

Abstract: The medial prefrontal cortex (mPFC) is implicated in modulation of stress and anxiety. Dysfunction of mPFC circuitry is associated with several common symptoms in neuropsychiatric disorders, including cognitive deficits, anhedonia, and anxiety. The dynorphin (DYN) / kappa-opioid receptor (KOR) system has been implicated in mediating stress-induced adaptive and mal-adaptive behavior and is highly expressed within mPFC. However, our understanding of how the DYN / KOR system is embedded in mPFC networks and regulates circuit function is extremely limited. Here, by utilizing *in situ* hybridization we found that prodynorphin (PDyn) mRNA is expressed in subpopulation of mPFC glutamatergic and GABAergic somatostatin (SST) neurons. We then utilized *in-vivo* fiber photometry and single

cell imaging to demonstrate that mPFC DYN-expressing neurons are recruited during processing of threats and during retrieval of these memories. mPFC DYN neurons are not only activated by the threat itself but also tuned to respond to the cues that predict the threat upon associative learning. By using intersectional transgenic and viral approaches, we examined the activity of glutamatergic DYN neurons and GABAergic SST DYN neurons. We demonstrated that distinct DYN-containing cell types differentially encode threats and the cues that predict them. Moreover, we used a novel, fluorescence-based KOR sensor to probe the *in-vivo* dynamics of DYN / KOR transmission during fear conditioning. Similar to the activity of PDyn neurons, the KOR sensor signal is increased by threats and the cues that predict them, while responses to on-going threats are modulated in a dynamic manner. These results demonstrate the involvement of local DYN / KOR signaling during the Pavlovian threat conditioning. Finally, we demonstrated that manipulating DYN / KOR signaling via viral-mediated knockdown of PDyn expression using small hairpin RNA (shRNA) modifies Pavlovian threat conditioning. We find that PDyn knock-down mice exhibit enhanced freezing to threat-associated cues compared to control group during Pavlovian threat conditioning, without impacting expression of long-term memories or their extinction. In summary, we address the anatomical organization of DYN / KOR system in mPFC and demonstrate the role of mPFC DYN neurons and DYN / KOR signaling in formation of emotional memories. As dysregulation of mPFC circuits and DYN / KOR signaling therein have been implicated in various neuropsychiatric disorders, these results may provide a framework to inform the development of therapeutic targets focused on these systems.

Abstract: One diagnostic criterion for post-traumatic stress disorder (PTSD) is exposure to a traumatic event. However, experiencing a traumatic event will not necessarily result in PTSD. The molecular mechanisms that underlie protection against traumatic sequels remain unclear. The single prolonged stress (SPS) is an animal model of PTSD recently develop that induces a PTSD-like behavior in rodents 7 days after exposure to three different stressors. This model consisting of restraint stress, forced swim test and ether-induced loss of consciousness has proven to induce behavioral and molecular characteristics similar to humans with PTSD. Still, similar to humans, rats exposed to SPS show variability in their behavior. Not all rats exposed to SPS end up developing a PTSD-like phenotype. It should be noted that although the prevalence of PTSD is twice in women than men, few studies include female rats in their research. The few studies including female rats suggest that they are not sensitive to the effects of SPS. Thus, in this study we aim to investigate the molecular mechanisms underlying the variability in behavior in SPS exposed animals. To this end, we exposed male and female Sprague Dawley rats (p60) to the SPS. Seven days after we analyzed anxiety-like behavior using the open field test and animals were trained in fear conditioning. Results showed no difference in anxiety like behavior between SPS animals or sex. Fear conditioning results showed variability in the ability to extinguish the fear memory. From a pool of 8 male and female SPS exposed animals' half of them presented impairment in fear memory extinction. The other half were able to recall the extinction memory. Classification of fear extinction deficits was determined based on the number of freezing percent the animals exhibited during the extinction training recall test. Animals with a freezing percent above 50 were considered to have impaired fear memory extinction, whereas animals with a freezing percent below 50 were considered to have extinguished the fear memory. Since the infralimbic cortex has been reported to have a role in fear memory extinction, we collected infralimbic cortex tissue for a proteomic analysis of membrane associated proteins of those animals with impaired or enhanced fear memory extinction. Proteomic analysis is undergoing, we expect our results to provide a better insight of the molecular mechanisms associated with fear memory extinction deficits. Our main goal is to identify potential therapeutic targets for pharmacological treatment of this disease. As well as to understand what factors might be providing protection to individuals individual whom to not develop this disease.

Title: Reducing FKBP5 expression in the ventral hippocampus of adult male rats reduces conditioned fear

Authors: *N. IRIZARRY-MÉNDEZ, A. HERNANDEZ, M. COLON, J. T. PORTER;

Abstract: Reducing FKBP5 expression in the ventral hippocampus of adult male rats reduces conditioned fear

Nashaly Irizarry-Mendez, Anixa Hernandez, Maria Colon, & James Porter,Ponce Health Sciences University. Ponce Research Institute, Ponce Puerto Rico

Post-traumatic stress disorder (PTSD) is a neuropsychiatric disorder that may develop after exposure to an overwhelming traumatic event, such as rape, war or an accident. Memories of traumatic events are reinforced by glucocorticoid signaling which can induce changes in ventral hippocampal (VH) neurons to regulate memory consolidation. The hippocampus is involved in both learning and memory processes and endocrine regulation, and its function is susceptible to disruption by stress. Excessive glucocorticoid signaling induced by stress is inhibited by FKBP5 protein, which decreases glucocorticoid receptor affinity for glucocorticoids. Human postmortem investigations imply that increased FKBP5 expression may play a role in psychiatric phenotypes. Also studies in rodents suggest that abnormal glucocorticoid signaling in the fear circuits may play a role in the development of PTSD-like phenotypes. Despite the association of FKBP5 with PTSD, it is unclear if altering FKBP5 expression contributes to the susceptibility or resiliency to PTSD. This study aims to examine if modulation of FKBP5 expression in the VH is sufficient to affect fear acquisition or extinction. We hypothesized that reducing FKBP5 protein expression in the VH would increase glucocorticoid signaling to enhance auditory fear memory and reduce extinction. To test this, an AAV5 vector expressing 4 different shRNAs that target FKBP5 and the fluorescent marker mCherry was infused into the VH to reduce FKBP5 levels in adult male rats. One month later, rats were exposed to auditory fear conditioning and extinction and then sacrificed for brain tissue collection. The infusion site and viral efficiency were verified with immunofluorescence labeling of mCherry and FKBP5. In contrast to our hypothesis, we found that reducing FKBP5 in VH decreased fear acquisition and facilitated fear extinction memory. Our findings suggest that people with lower the expression of hippocampal FKBP5 might acquire less fear during trauma exposure and show resiliency to PTSD.

Title: Bdnf bioavailability differentially impacts adolescent and adult safety learning

Authors: *H. C. MEYER, F. S. LEE;
Psychiatry, Weill Cornell Med., New York, NY

Abstract: A prevailing molecular framework thought to underlie mood and anxiety disorders is the neurotrophic hypothesis, which postulates that reductions in neurotrophic support can alter neural plasticity in key regions implicated in anxiety and fear responses. In line with this, to examine how the neurotrophin BDNF contributes to the pathophysiology of anxiety disorders our lab has utilized a knock-in mouse line carrying the human Val66Met polymorphism, which leads to decreased BDNF bioavailability. We have previously shown that adult mice expressing the Met allele recapitulate the phenotypic hallmarks of humans with this polymorphism, especially with regard to altered anxiety- and fear-related behaviors. While substantially less is known about the impact of BDNF signaling on the development of fear-related circuits, our lab has shown that genotypic differences observed in adulthood are not apparent for extinction in adolescent mice expressing either the Val or Met allele, although both groups exhibit blunted extinction learning. These findings indicate the need for novel methods of fear regulation that can be utilized both during adolescence and also during adulthood in populations with disrupted neurotrophic signaling. To address this, we examined the capacity for Val66Met mice and age-matched controls to utilize a conditioned safety signal to directly inhibit fear responding. Wild-type adolescent mice and adult mice of both genotypes were able to acquire and use (i.e., conditioned inhibition) a safety signal to inhibit fear. In contrast, adolescent mice expressing the Met allele exhibited impaired conditioned inhibition. Our data suggest a developmental dissociation in the impact of BDNF bioavailability on the neural circuitry underlying extinction learning and conditioned inhibition. Ongoing studies are investigating how the relative distribution of BDNF throughout fear regulation circuitry across development (focusing on the ventral hippocampus and medial prefrontal cortex) directly relates to fear expression profiles. In sum, this line of research will provide insight into both age- and genotype-informed treatments for anxiety disorders.

Title: Anatomical Connectivity of the Intercalated Cells of the Amygdala

Authors: *D. STERN[1], C. M. ROOT[2];
[1]UCSD Dept. of Neurosciences, San Diego, CA; [2]Neurobio., Univ. of California San Diego, La Jolla, CA

Abstract: The Intercalated Cells of the Amygdala (ITCs) represent a unique, understudied subset of exclusively inhibitory neurons within the amygdala that are phylogenetically conserved and share developmental, morphological, and biochemical similarities with cells of the striatum. ITCs reside within the intermediate and external capsules surrounding the BLA and can be grouped into three separate nuclei that extend nearly the entire rostro-caudal extent of the amygdala: the main, caudal, and lateral nuclei. The transcription factor FoxP2 is a known genetic marker of the ITCs, and the FoxP2-cre mouse was recently used to refine our understanding of their role in fear conditioning, extinction, and recall. We used FoxP2-cre mice and small iontophoretic injections of cre dependent viruses to investigate the upstream and downstream connectivity of the three ITC nuclei. For downstream connectivity, we used a synaptophysin virus that expresses tdTomato cytoplasmically and a synaptophysin-GFP conjugate that shows putative synapses (n=18 mice, 9 male / 9 female, 3-9 months old). The three ITC nuclei project ipsilaterally in overlapping but distinct patterns to large areas within the basal forebrain, bed nucleus of the stria terminalis, and amygdala. The densest projections are sent to the basal forebrain, medial amygdala, cortical amygdala, and other ITC nuclei. Contrary to prior thinking, there are relatively sparse projections to the basolateral and central amygdalae. For upstream connectivity, we used a cre-dependent monosynaptic rabies approach to reveal neurons that project to the ITCs (n=18 mice, 9 male / 9 female, 3-9 months old). All presynaptic projections are ipsilateral and include dense clusters in the insular cortices, paraventricular thalamic nucleus, posteromedial cortical amygdala, entorhinal cortex, hippocampus, ethmoid nucleus, substantia nigra and posterior thalamic nuclei. Additionally, there are numerous but diffuse presynaptic neurons throughout the basal forebrain and amygdalar nuclei. Surprisingly, we see only a few presynaptic neurons within the BLA, and none in the prelimbic and infralimbic cortex, challenging prior work on the hypothesized network underlying fear conditioning, extinction, and recall. This work makes clear the comparative projections to and from the separate ITC

nuclei, demonstrates significantly more abundant projections than prior work, and suggests that the ITCs are well positioned to influence a broad range of amygdala and basal forebrain mediated behaviors by integrating information from a wider range of structures than previously known.

Title: Role of PP1 in conditioned inhibition related reductions in type B photoreceptor excitability

Authors: *J. B. ANDERSON[1,2], J. S. CAVALLO[1,2], J. FARLEY[1,2];
[1]Psychological and Brain Sci., [2]Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Explicitly unpaired (EU) presentations of light and rotation produce behavioral changes (e.g., increased phototaxis) in the sea snail Hermissenda crassicornis that satisfy the behavioral criteria for conditioned inhibition (CI) learning. This is accompanied by decreased excitability of type B photoreceptors (B cells) due to corresponding increases in potassium (K^+) currents. We've previously shown that protein phosphatase 1 (PP1) inhibitors (e.g., Calyculin A): 1) depolarize Untrained B cells and reduce somatic K^+ currents, partially mimicking the effects of associative conditioning (light - rotation pairings), 2) contribute to the excitability (spike frequency) decreases produced by extinction training (a form of learning that overlaps mechanistically with EU conditioning). Conversely, injection of catalytically-active PP1 (caPP1) into Untrained B cells partially mimicked the spike frequency declines produced by extinction training, and occluded further reductions in spiking by additional extinction training. Thus, we hypothesized that PP1 activity may also contribute to EU-training effects on B cells. To test this, we measured B cell photoresponses from Untrained and EU-trained animals following treatment with caPP1. B cells showed marked reductions in steady state generator potentials (SSGPs) and spike frequencies over the course of five 30-sec test lights, mimicking EU training. Prior EU training the effects of caPP1 injection. Additional measurements showed that caPP1 increased both the transient (I_A) and delayed ($I_{K\text{-}Ca}$) components of K^+ current, previously shown to mediate the EU-related decrease in B cell excitability. We next injected B cells from Untrained and EU-trained animals with the core peptide fragment of the PP1 regulatory G subunit (GM), which acts as a competitive inhibitor of PP1. Iontophoresis of 25uM GM increased B cell SSGPs from untrained (14.3%, n.s.) and EU-trained (45.7%; $p = 0.0332$) animals. Whereas EU training resulted in a 41.6% reduction in B cell SSGP ($p < 0.001$), SSGPs of GM treated B cells were not

significantly different from untreated B cells of Untrained animals. Thus, GM treatment abolished the EU-related decrease in B cell excitability. Our results suggest that: 1) upregulation of PP1 activity is an important component of the EU-mediated decrease in B cell SSGP, 2) PP1 is constitutively active in B cells of Untrained animals. These data indicate that EU training increases PP1 activity in B cells, decreasing excitability through effects on downstream K^+ currents.

Title: Endocannabinoid Regulation of Predator Odor Avoidance

Authors: *V. KONDEV[1], A. MORGAN[1], **M. NAJEED**[1], S. PATEL[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Anxiety disorders are the most common mental illness in the United States and symptoms characteristic of these disorders include hyperarousal, excess fear, and enhanced avoidance even in the absence of immediate threat. The endocannabinoid (eCB) system regulates fear responsivity and stress adaptivity and thus has been identified as an emerging therapeutic target to treat the underlying pathology. Importantly, eCB signaling has been found to potently modulate avoidance behaviors, especially under conditions of high environmental aversiveness. However, the role that the eCB system plays in mediating avoidance during an innate predator odor stress exposure has not been thoroughly investigated. Here, we have determined a reliable, dose-dependent protocol that induces avoidance in both CD-1 and C57 strains of mice to 2-methylthiazoline (2-MT), a synthetic analog of the highly volatile molecule found in fox odor. Given that the eCB system plays a prominent role in approach-avoidance conflicts, we demonstrate that 2-arachinoylglycerol (2-AG), but not anandamide, regulates avoidance to this innate stressor. Specifically, pharmacologically enhancing 2-AG levels with treatment with the MAG lipase inhibitor, JZL-184, mitigates avoidance of the odor source. This data sheds light onto the therapeutic potential of eCB modulators in treating the hypervigilant state associated with pathological fear and anxiety.

Title: Cued fear conditioning inhibits neurons of the bed nucleus of the stria terminalis (BNST) to the central amygdala

Authors: *V. OLIVERA-PASILIO[1], J. DABROWSKA[2];
[1]Rosalind Franklin Univ. Sch. of Grad. and Postdoctoral Studies, North Chicago, IL; [2]Rosalind Franklin Univ., North Chicago, IL

Abstract: The dorsolateral bed nucleus of the stria terminalis ($BNST_{DL}$) contains GABA-ergic neurons co-expressing various neuropeptides. $BNST_{DL}$ sends inhibitory projection to the central amygdala (CeA), and activation of this projection increases anxiety-like behavior. However, based on the dominant role of the CeA in cued fear acquisition, the inhibitory BNST-CeA neurons might also suppress cued fear. This is also supported by our recent results demonstrating that activation of oxytocin receptors (OTR) in the $BNST_{DL}$ inhibits BNST-CeA neurons and facilitates cued fear. To determine the phenotype of the BNST-CeA neurons, adult male Sprague-Dawley rats (SD; n=4) were injected with retrograde pENN.AAV.hSyn.GFP-Cre into the CeA. BNST-CeA neurons expressing eGFP were co-labeled with antibodies against protein kinase C δ (PKCδ), striatal-enriched protein tyrosine phosphatase, calbindin, somatostatin, and cholecystokinin 8. BNST-CeA neurons co-express all these markers at specific sub-nuclei of the $BNST_{DL}$, suggesting diverse content of the projection. As the majority of the BNST-CeA neurons in the oval nucleus of the $BNST_{DL}$ co-expressed PKCδ, we next determined if PKCδ neurons were recruited during fear conditioning. Male SD rats (n=18) were subjected to 10 foot shocks (un-signaled or signaled by a discrete cue) or were placed in chambers as controls; 45 min after injection of non-peptide OTR antagonist (L-368,899, 5 mg/kg) or vehicle. Neurons expressing PKCδ or cFos and co-expressing both markers were counted in the $BNST_{DL}$ using ImageJ. Here, cued fear conditioning tended to reduce the percentage of neurons co-expressing PKCδ+cFos per total number of cFos neurons, an effect reversed by L-368,899 (treatment $F(1,30)=3.593$ $p=0.0677$, interaction between fear and treatment $F(2,30)=3.302$ $p=0.0506$), suggesting that cued fear conditioning inhibits $BNST_{DL}$-PKCδ neurons via OTR-dependent mechanism. To determine the recruitment of BNST-CeA neurons in fear acquisition, male SD rats (n=9) were injected with the retrograde AAV-eGFP into the CeA and 2 weeks later were subjected to 10 predictable foot shocks (paired with cue as above), or 10 un-paired foot shocks, or 10 visual cues alone. Exposure to foot shocks paired with cue reduced the percentage of

BNST-CeA-eGFP neurons expressing cFos per total of eGFP neurons (fear effect F (2, 26) = 5.696 p=0.0089, in comparison to control, p<0.01). Overall, our results suggest that cued fear conditioning inhibits BNST-CeA neurons via OTR-dependent fashion. This might be an important mechanism by which OTR attenuates the inhibitory influence of the BNST over the CeA and facilitates cued fear.

Title: The role of serotonin 5-HT2C receptors at the RMTg in cocaine conditioned avoidance

Authors: *Y. CHAO[1], J. PARILLA CARRERO[1], M. EID[1], P. J. VENTO[2], T. C. JHOU[1]; [1]Med. Univ. of South Carolina, Charleston, SC; [2]Univ. of South Carolina, Columbia, SC

Abstract: Relatively little is known about the processes that underlie cocaine's aversive effects. Aversive responses to cocaine are significant because they may modulate both the acquisition of drug-seeking, and later behaviors such as relapse in experienced animals, and may underlie individual differences in susceptibility to cocaine addiction. Prior work from our lab showed that activation of the rostromedial tegmental nucleus (RMTg) by cocaine critically drives cocaine conditioned avoidance. While some of this cocaine-induced RMTg activation is due to glutamatergic inputs from the lateral habenula, a majority arises from unknown mechanisms. Using RNAseq we made the unexpected discovery that the RMTg expresses robust and enriched levels of mRNA for the serotonin 2C receptor (gene name *htr2c*) relative to surrounding regions. Because cocaine binds to both serotonin and dopamine uptake transporters, we postulate that 5-HT_{2C}R activation at the RMTg might be a novel mechanism by which cocaine activates the RMTg and drives aversive response. Using in situ hybridization technique, we find 80% of RMTg neurons are *htr2c* positive. Most of these *htr2c* positive neurons express putative markers of RMTg neurons *gad1* and *foxp1*, and a significant proportion of them responds with elevated *cfos* to a diverse array of aversive stimuli. Next, using behavior paradigms that have been established to be sensitive to the aversive properties of cocaine, we find injection of Ro60-0175, a specific 5-HT_{2C}R agonist, is sufficient to induce conditioned place aversion and enhance anxiety-like behavior, while both intra-RMTg injection of SB-242084, a specific 5-HT_{2C}R antagonist, and RMTg site-specific shRNA knockdown of the *htr2c* gene, reduce cocaine-

induced anxiety like behavior, block cocaine conditioned place aversion, and attenuate cocaine conditioned avoidance. Using Sprague Dawley rats that have been trained to develop divergent low versus high avoidance response to cocaine, we find knockdown of *htr2c* at the RMTg increases cocaine self-administration and reinstatement in high-avoider but not low-avoider animals. Further, using slice electrophysiology techniques, we find both cocaine and 5-HT_{2C}R agonist induce depolarization of RMTg neurons that can be blocked by specific antagonist and *htr2c* specific shRNA. These evidences support an important role of RMTg 5-HT_{2C}R in the aversive effects of cocaine, and the notion that aversive effects of cocaine modulate subsequent relapse drug seeking. The current studies may identify a valid target for treating cocaine's aversive effects and relapse drug seeking.

Title: The interplay between vanilloid and endocannabinoid signalling in the hippocampus is modulated by the intensity of the contextual fear conditioning

Authors: *L. P. IGLESIAS[1], H. B. FERNANDES[2], A. S. DE MIRANDA[2], C. A. SORGI[3], F. A. MOREIRA[1];
[1]Pharmacol., Univ. Federal De Minas Gerais, Belo Horizonte, Brazil; [2]Morphology, Univ. Federal de Minas Gerais, Belo Horizonte, Brazil; [3]Univ. de São Paulo, Ribeirão Preto, Brazil

Abstract: The TRPV1 channel has been proposed as potential target for the modulation of fear memories. TRPV1 is activated by anandamide (AEA), which also binds to the CB1 receptor. It remains unclear in which circumstances anandamide and TRPV1 signalling is recruited in contextual fear conditioning (CFC). Here, we tested the hypothesis that TRPV1 blockers prevent CFC retrieval under specific intensities of aversive stimuli. We also investigated the underlying mechanisms. Male C57BL/6J mice (n=5-8/group) were submitted to different shock intensities in the CFC paradigm and received local administration of SB366791 (SB, 3nmol), a TRPV1 blocker, into the dorsal hippocampus (dHPC) before fear memory retrieval. The hippocampus was removed for PCR quantification of selected genes and for mass spectrometry analysis of AEA levels. To study the involvement of CB1 and AEA, a subeffective dose of AM251, a CB1 antagonist, was administered prior to SB. Double immunofluorescence staining was used to

evaluate TRPV1-CB1 co-localization. The data was analysed by ANOVA followed by Bonferroni post-hoc test. SB prevented CFC retrieval in animals conditioned under aversive stimuli of moderate (MI) and high (HI), but not low intensity (LI). The genes related to neural plasticity, Arc, Zif and Trkb, were upregulated after SB treatment in the MI but not in the HI group. In addition, the animals treated with SB in the MI, but not in the HI protocol, were resistant to CFC reinstatement. The local levels of AEA positively correlated with freezing levels. Finally, we found that TRPV1 and CB1 are co-localized in the dHPC and that AM251 prevented SB effects. In conclusion, dHPC TRPV1 channels are recruited as a function of the aversive stimulus intensity. At low-intensity aversive stimulus, AEA levels may not be sufficient to recruit TRPV1 channels. However, at medium and high intensity aversive stimuli, AEA levels are increased to facilitate TRPV1-mediated CFC. Under this circumstance, TRPV1 blockade prevents fear retrieval by shifting AEA signalling to CB1-mediated mechanisms and possibly recruiting Arc, Zif and Trkb transcription. The recruitment of this pathway was associated with reinstatement resistance, which was not observed at the highest intensity. Acknowledgement: CAPES

Title: Astrocytic GluN2C-containing NMDA receptors in the basolateral amygdala facilitate fear extinction

Authors: *G. P. SHELKAR, J. LIU, S. M. DRAVID;
Pharmacol. and Neurosci., Creighton Univ., Omaha, NE

Abstract: Abstract: Fear extinction is a learned inhibitory response to a conditioned fear when the initially noxious conditioned responses are no longer associated with aversive outcomes, and it is an important model of cognitive-behavioral therapy for human anxiety disorders. The basolateral amygdala (BLA) is one of the brain nuclei that play an essential role in fear extinction. Recently we have identified predominant expression of GluN2C-containing NMDA receptors in astrocytes in BLA; however, their functional roles remain poorly understood. Herein, we took advantage of the novel highly potentGluN1/GluN2C NMDA receptors selective co-agonist, AICP, to assess the functional role of GluN2C subunits in fear extinction. We found that intracerebroventricular injection of AICP produced robust facilitation of fear extinction in WT mice. However, this effect was absent in GluN2C KO mice. Further, local injection of AICP

in BLAfacilitated fear extinction in WT but not in GluN2C KO mice, suggesting that AICPproduces its effect via GluN2C-containing receptors in the BLA. Knowing the astrocytic expression of GluN2C subunit in the BLA, we used conditional knockout strategy to delete obligatory GluN1 subunits from astrocytes. Intra-BLA injection of AICP did not facilitate fear extinction in mice with conditional deletion of obligatory GluN1 subunit from astrocytes. Notably, chemogenetic activation of astrocytes in the BLA facilitated fear extinction. In electrophysiological studies, bath application of AICP facilitates excitatory neurotransmission in the BLA via a presynaptic GluN2C-dependent mechanism. Furthermore, in immunohistochemical analyses, AICP treatment showed significant upregulation of GluA1 AMPA receptors and their colocalization with PSD 95. Together, our results showed an essential role of astrocytic GluN2C-containing NMDA receptors in the extinction of conditioned fear memory and propose that further development of superagonists of GluN2C-containing receptors may offer a novel therapy for PTSD and anxiety-like disorders.

Title: A novel FABP5 inhibitor modulates anxiety-related signaling patterns in the basolateral amygdala-prefrontal cortical-hippocampal circuitry

Authors: *M. J. JONES[1], T. C. UZUNESER[1], M. KACZOCHA[2], I. OJIMA[2], S. R. LAVIOLETTE[1];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Stony Brook Univ., Stony Brook, NY

Abstract: Anxiety disorders are a class of disorders characterized by pathological anxiety and stress symptoms, impacting one in three people throughout their lifetime. Currently available medications for the treatment of anxiety-related symptoms are associated with significant side-effects such as dependence, withdrawal, and cognitive problems. This calls for the development of alternative pharmacotherapies. The endocannabinoid (eCB) signaling system is critically involved in anxiety-related neural processing. We have previously reported that CB1 receptor transmission within the basolateral amygdala (BLA) can strongly modulate emotional sensory information salience and associative memory formation via modulation of neuronal activity patterns in the prefrontal cortex (PFC) and ventral hippocampus (vHIPP)[1]. Anandamide, a key

eCB ligand, has limited ability for diffusion, causing transport for degradation to be largely reliant on Fatty Acid Binding Proteins (FABPs) — with the FABP5 subtype displaying one of the highest affinities. We hypothesized that FABP5 inhibition with a novel FABP5 pharmacological inhibitor (SBFI-103) in the BLA would increase localized anandamide levels leading to suppression of anxiety-related activation of BLA neurons and functional outputs to neuronal populations in the PFC and vHIPP, resulting in anxiolytic outcomes. Using *in vivo* single-unit recordings in rats, we found that FABP5 inhibition in the BLA produced a significant increase in the spontaneous firing and bursting rate of PFC neurons, accompanied by an increase in gamma oscillatory activity, both of which are associated with anxiolytic and cognitive processing phenotypes. Furthermore, we observed significant changes in vHIPP neuronal activity dynamics following intra-BLA FABP5 inhibition, most notably associated with increased theta oscillatory activity, suggesting potential modulation of fear memory processing. Remarkably, these effects in the PFC and vHIPP were blocked when the FABP5 inhibitor was co-administered with a selective CB2 receptor antagonist, suggesting a novel functional role for CB2 receptor transmission in these phenomena. Future studies will investigate the behavioural effects of FABP5 inhibitors in the BLA on anxiety-related behaviours. Together, these findings demonstrate a novel, FABP5-dependent mechanism directly in the BLA regulating anxiety-like phenotypes and identify a novel pharmacotherapeutic role for this FABP5 inhibitor within anxiety-related neural circuitry.

Title: Induction and sensitivity to apprehensive expectation, a model of chronic trait anxiety in mice.

Authors: *D. W. CRAWFORD, K. M. MCKEEN, H. M. PATEL, L. D. MATZEL;
Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: The use of animal models to assess characteristics of human psychological disorders is predicated on the presumption that the model is analogous to the human condition in symptomology, duration, differentiation from disparate disorders, etiology, and sensitivity to known treatments. Unlike those of some notable other disorders (e.g., depression), current rodent models of anxiety fail to satisfy these requirements, instead serving as simple measurements of

variations in the expression of an “anxious” response when the animal is placed in a state of temporary conflict. While these current models (e.g., the elevated plus maze) *are* sensitive to anxiolytic drugs, they fail to induce a chronic state of behavior, i.e., a trait, and do not differentiate between related states (e.g., fear, acute stress). Relatedly, common models make little contact with theories of the etiology of anxiety. In the present study, we propose a novel operantly-induced model of chronic anxiety in mice aimed at overcoming these pervasive limitations. Here, genetically heterogeneous mice were exposed to environmental conditions which induce a state of “apprehensive expectation,” a fundamental characteristic of human anxiety disorders as described by the DSM-V. Mice were subjected to a 15 day treatment of unpredictably interspersed food reinforcement *or* mild shock after entering the terminal goal area of a straight alley. A one-way ANOVA with planned comparisons revealed that mice exposed to this treatment exhibited significantly elevated levels of anxiety-like behaviors compared to mice that received either consistent food or shock in the maze ($t = 2.41$, $p = .02$). No significant differences in anxiety-like behaviors were observed between groups prior to these treatments ($F = .04$, $p = .96$). These results suggest this novel apprehensive expectation manipulation had induced a chronic anxiety-like trait in the mice exposed to the emotionally conflicting outcomes (i.e., food or shock). This anxiety-like trait may have an etiology more aligned with that of the human disorder and is empirically separable from simple fear (i.e., shock-only control). Furthermore, there was a significant correlation between the pre- and post-treatment measures of anxiety-like behaviors in the emotional conflict group ($r = .45$, $p = .04$), suggesting that pre-treatment measures of state anxiety capture a predisposition for induction of trait anxiety. Future studies are underway to assess the induction of this model using a classical conditioning paradigm, as well as to test the model’s susceptibility to anxiolytic drug intervention to ensure the model retains the predictive validity expressed by current models.

Title: Encoding of anxiety learning and diazepam treatment by rodent prefrontal cortex and VTA neurons

Authors: *D. S. JACOBS[1], M. C. ALLEN[1], M. L. KIELHOLD[1], J. PARK[2], B. MOGHADDAM[1];

[1]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Neurosci., HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Background: Learning that routine reward motivated actions are associated with the risk of an aversive event is critical for development and expression of anxiety. To model this real-life scenario, we designed a task where instrumental actions taken toward obtaining a reward were probabilistically punished with a mild footshock. We addressed the outstanding questions of whether the ventral tegmental area (VTA) and rodent medial prefrontal cortex (mPFC) adapt to learning of punishment risk in correlation with behavior, and how diazepam influences these neural responses.
Methods: Fiber photometry was used to measure pan-neural activity in mPFC and VTA in adult male and female rats. This method allowed us to quantify mPFC and VTA neural response to the shock itself as well as during cue and action encoding epochs which is critical to distinguish how neural responses adapt to receiving versus expecting an aversive experience.
Results: We find that selective suppression of male and female behavior developed after 2-3 sessions of exposure to punishment risk. This change, or learning, was accompanied by a reduction of phasic neural activity in mPFC and an upward shift in VTA activity, primarily during the peri-action period. Footshock produced a robust activation of neural activity in mPFC and VTA that remained consistent in magnitude after learning. Diazepam did not change the phasic neural response of mPFC or VTA to the shock nor did it influence mPFC responses to task events. Diazepam did, however, significantly and selectively produce a peri-action ramping response in the VTA and enhanced correlative VTA-mPFC activity.
Conclusions: These findings characterize the adaptive neural responses of mPFC and VTA during the learning of anxiogenic contingencies that are independent from the aversive experience itself. They also identify peri-action ramping of VTA activity as a potential marker for anxiolytic properties of diazepam. This ramping signal has been linked to preparatory attention and goal driven states, potentiation of this response may lead to attentional disengagement from harm probability and provide a mechanism for how diazepam influences action selection under anxiety.

Title: Moderate prenatal alcohol exposure on gestational day 12 produces sex-specific social impairments and alters prelimbic cortex physiology

Authors: *K. R. PRZYBYSZ[1], E. I. VARLINSKAYA[2], M. R. DIAZ[2];
[1]Psychology - Behavioral Neurosci., [2]Psychology, Binghamton Univ., Binghamton, NY

Abstract: Prenatal alcohol exposure (PAE) is capable of producing many psychological, cognitive, and behavioral deficits, and social impairment is the most common behavioral problem associated with PAE. Rodent models examining PAE have identified gestational day (G) 12 as a critical developmental point for producing social impairments across the lifespan. Importantly, in the human population, low-moderate PAE (mPAE) is more prevalent than binge-level PAE; despite this, whether mPAE on G12 can also produce similar social impairments as binge-level exposure, and the potential neuroadaptations that may underlie them, has not been examined. Two brain regions that modulate social behaviors are the basolateral amygdala (BLA) and prelimbic cortex (PL). The PL specifically is involved in producing negative social behaviors, such as social avoidance, and stimulation of the neural projection from the BLA to the PL (BLA-PL) decreases social interaction. However, whether these structures are altered by PAE, and whether they play a role in PAE-induced social impairments, is unknown. To examine these questions, we exposed pregnant Sprague-Dawley rats to vaporized ethanol or room air for 6 hours on G12 (blood ethanol concentration: 60-90 mg/dL) and tested their male and female offspring on the modified social interaction paradigm. This resulted in sex-specific social impairments that lasted into adulthood. Specifically, we found that both mPAE-exposed males and females exhibited reduced social investigation, while only males had reduced social preference. We then performed whole cell patch clamp electrophysiology experiments on PL pyramidal cells from a separate set of adult male and female offspring and found that, while there was no effect of mPAE on basal glutamate transmission, cells from mPAE-exposed males and females had significantly reduced intrinsic excitability. Finally, to examine the role of the BLA-PL pathway in mPAE-induced social deficits, we used a chemogenetic approach to inhibit the BLA-PL during social behavior testing with the hypothesis that inhibiting the BLA-PL would recover normal social behavior in mPAE offspring. Our preliminary data suggest that this projection, and its role in modulating social behavior, are potentially altered following mPAE in a sex-dependent manner. Taken together, we have identified multiple neural mechanisms that may play a role in PAE-induced social impairments, as this work is among the first to examine mPAE-induced changes to PL physiology and to probe neural circuits in the context of PAE. This will be highly valuable in furthering our understanding of the neuroadaptations underlying PAE-induced social dysfunction.

Title: Cell-type-specific dopamine signaling in ventral hippocampus tracks anxiety-related behavior

Authors: *A. GODINO[1], M. SALERY[1], A. M. MINIER-TORIBIO[1], J. F. FULLARD[2], E. M. PARISE[1], F. J. MARTÍNEZ-RIVERA[1], C. MOREL[1], S. E. MONTGOMERY[1], M.-H. HAN[1], P. ROUSSOS[2], E. J. NESTLER[1];

Abstract: Anxiety is an emotional response that, under normal conditions, promotes adaptive avoidance behaviors, but, when inappropriate to the level of threat, can contribute to several psychiatric disorders. Despite accumulating evidence for a role of both the ventral hippocampus (vHipp) and the mesocorticolimbic dopamine system in encoding anxiety-relevant information, surprisingly little is known about how dopamine signaling selectively affects vHipp representations of emotionally-salient stimuli to guide innate approach/avoidance behaviors. To address this knowledge gap, we here study dopamine release and dopaminoceptive neurons in mouse vHipp – which can be segregated based on their expression of either the dopamine D1 or D2 receptor – as performed routinely for striatum – to delineate a model of dopamine action in vHipp. At the histological level, D1- and D2-expressing cells exhibit a precise topographical organization across vHipp subfields. We further dissected their transcriptional profiles and cell-type identity using RNA-sequencing of single, sorted nuclei from D1- and D2-cells. Functionally, using fluorescent probes for *in vivo* dopamine sensing, we showed that anxiogenic environments trigger higher dopamine release in vHipp and assessed the postsynaptic consequences of these changes in dopamine levels by coupling dopamine imaging with fiber photometry recordings of calcium signals in D1- or D2-expressing vHipp neurons. Bidirectional chemogenetic and optogenetic manipulation of D1- or of D2-neurons' activity causally demonstrated their distinct roles in mediating anxiety and approach/avoidance behaviors. Intriguingly, cocaine exposure modified vHipp dopamine dynamics, with D1- and D2-expressing neurons differently modulating drug-related behaviors, suggesting drug-induced plastic changes in this circuit. Together, we propose that dopamine dynamics in vHipp operate as a feedback loop that bidirectionally tracks anxiety levels to gate exploratory behaviors through differential recruitment of vHipp D1- and D2-neurons, which in turn mediate opposite anxiety-like responses. This work paves the way for further studies of dopamine signal processing in limbic regions, and underscores the complexity of the circuit mechanisms that govern affective states.

Title: Effect of central oxytocin administration on anxiety- and depression-like behavior in C57Bl/6J mice: preliminary evidence for sex-differences

Authors: *K. E. NISBETT[1,2,3], M. TEREUL[3], L. F. VENDRUSCOLO[1], M. E. RAGOZZINO[3], G. F. KOOB[1];
[1]Integrative Neurosci. Res. Br., NIH Natl. Inst. on Drug Abuse IRP, Baltimore, MD; [2]Grad. Program in Neurosci., [3]Dept. of Psychology, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Anxiety and depression are highly prevalent psychiatric disorders worldwide. Evidence indicates that central oxytocin ameliorates social deficits in studies examining social bonding and social anxiety. Although these studies suggest that the therapeutic effects of oxytocin are reliant on social contexts, we hypothesize that the positive effects of oxytocin observed in social contexts are due to intrinsic effects of oxytocin on the neural systems that are related to emotion regulation. The present experiments investigate whether an intracerebroventricular (ICV) infusion of oxytocin (i.e., central action) would reduce anxiety- and/or depression-like behavior in C57Bl/6J mice. Male and female mice received an ICV infusion of vehicle or oxytocin (100, 200 or 500 ng), then they were tested on non-social tests of anxiety and depression, the elevated zero maze (EZM) and the tail suspension test (TST). In males, findings indicate that oxytocin dose-dependently increased the open zone occupancy in the EZM and reduced immobility in the TST, with statistically significant effects at 200 & 500 ng doses. In intact females, oxytocin slightly increased the open zone occupancy in the EZM, whereas it significantly reduced immobility in the TST, having a similar effect at all 3 doses. These initial results demonstrate that central oxytocin is effective in both male and female mice, but these effects vary across sexes and behavioral tests. Further, given the interaction between the oxytocin and estrogen receptor systems, we are exploring whether there is an effect of ovariectomy combined with estrogen replacement therapy on female mice in our mouse model.

Future studies will target specific emotional-related brain regions to help elucidating potential neural mechanisms that underlie the effects of oxytocin on behavior and the observed sex differences.

Title: Sex differences in common rodent assays of anxiety-like behavior following single exposure to predator odor

Authors: *S. R. PITCAIRN[1], J. L. WEINER[2];
[2]Physiol. and Pharmacol., [1]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Despite the high prevalence of anxiety disorders in women, many preclinical studies focused on anxiety have utilized only male animals in their experiments. The current study sought to characterize potential sex differences in common assays of anxiety-like behavior following a 30-min exposure to either saline or fox urine, a well-validated stressor for rodents. Immediately following exposure to the stressor, male and female Long-Evans rats (n=8/group) underwent behavioral testing using three assays of anxiety-like behavior that were run consecutively, where subjects were first placed in the open field test, followed by the elevated plus-maze, and concluding with the successive alleys test. 90 minutes following completion of the successive alleys test, animals were deeply anesthetized with isoflurane and sacrificed before tissue was collected in order to examine c-fos activity in the basolateral amygdala and ventral hippocampus, two stress-sensitive brain regions known to play a role in anxiety-like behaviors. Results of the behavioral studies demonstrated complex, sexually dimorphic responses. For example, in the open field test there were no effects of odor exposure on anxiety-like behavior (time in center of arena) in either sex but, independent of stressor exposure, females showed a trend of less anxiety-like behavior (p=.06). On the elevated plus-maze, odor-exposed females showed an expected anxiogenic effect while males did not (p=.043). Studies are currently in

progress to quantify c-fos activity as a proxy for neural activation. Although preliminary, the findings from this study suggest that acute exposure to predator odor gives rise to sexually dimorphic behaviors in different assays of anxiety-like behavior, possibly reflecting sex differences in coping strategies employed on these tests.

Title: Evidence for a synergistic effect of an edible CBD:THC formulation in reducing anxiety and depressive-like symptoms following chronic stress

Authors: *E. PÉREZ-VALENZUELA, W. RUSHLOW, S. LAVIOLETTE;
Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: Cannabis has shown therapeutic potential in neuropsychiatric pathologies associated with mood and anxiety. The two main phytochemicals in cannabis, cannabidiol (CBD) and delta9-tetrahydrocannabinol (THC), produce distinct effects on a variety of molecular and neuronal pathways associated with anxiety-related disorders. Given the distinct molecular targets of CBD and THC, it has been proposed that combined formulations of THC:CBD have synergistic properties. Nevertheless, evidence for the synergy between CBD and THC in the treatment of mood/anxiety disorders is limited. The aim of this research is to characterize the effects of a 1:100 THC:CBD ratio formulation in anxiety/depressive phenotypes, comparing naïve vs. chronically stressed rats, and to determine the neuronal and molecular mechanisms associated with these effects. Male Sprague-Dawley rats were exposed to unpredictable stress for 14 days. Then, to determine treatment effects on anxiety or depressive-like behaviours, elevated plus-maze test, social interaction task, open field exploration, sucrose preference test, and forced swimming tests were carried out 90 minutes after intake of THC 0.3mg/kg: CBD 30 mg/kg vs. vehicle. After testing, rats were assigned for western blot or electrophysiology experiments. Tissue extractions were taken from prefrontal cortex (PFC), nucleus accumbens (NAc), basolateral amygdala (BLA), and hippocampus. Then, expression and phosphorylation of biomarkers for mood/anxiety disorders including: extracellular-signal-related kinase (ERK1-2), protein kinase B (AKT), and glycogen synthase kinase-3 (GSK-3) were analyzed. For electrophysiological studies, the PFC and ventral tegmental area dopamine neurons were recorded and local field potential (LFP) and single unit activity were analyzed. The oral

formulation of THC:CBD produced an anxiolytic effect in the EPM test and in the social interaction test in stressed-rats. In addition, the edible formulation reversed depressive phenotypes induced by chronic stress. Remarkably, the combination of THC:CBD was superior to either THC or CBD alone, strongly suggesting a synergistic therapeutic potential for this formulation. These changes were also associated with significant expression changes in AKT/GSK-3 signaling pathways mainly in PFC, NAc and hippocampus. Furthermore, the oral formulation of THC:CBD showed differential effects in LFP patterns in the PFC of stressed rats in the Theta and Gamma oscillatory bands. These results show the therapeutic potential of the combination between CBD and THC in pathologies associated with chronic stress such as generalized anxiety disorder or major depression

Title: Type-1 corticotropin releasing factor receptor (CRF-R1) expression and neurotransmitter balance in the nucleus accumbens of juvenile rats exposed to social isolation stress

Authors: *F. CALDERON, J. A. ZEGERS, J. A. NOVOA, C. BLANLOT, H. E. YARUR, C. BASTIAS, K. GYSLING;
Dept. of Cell. and Mol. Biol., Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: Rat social isolation is a model of stress commonly used in early stages of life. It has been shown that early and long-lasting intervals of isolation induce anxiety-like behaviors and aberrant neurotransmitter balance in some brain areas during adulthood. Nevertheless, there are a few studies evaluating short periods of isolation, therefore characterization of the latter is scarce and needed. Previous studies of our laboratory have shown that rat social isolation between days 21-32 PND induces an increase in anxiety-like behavior and changes in the balance of neurotransmitter levels. Briefly, isolation induces an increase of dopamine (DA) levels in nucleus accumbens (Nac) in response to a depolarizing potassium stimulus. Interestingly, there are no changes in glutamate (GLU) levels induced by isolation. Furthermore, the effects of a CRF-R1 antagonist upon DA and GLU levels were lost when rats were isolated. The mechanism underlying these changes remains unknown. Preliminary results of our laboratory suggest that these changes rely on the decrease of CRF-R1 expression in Nac. To evaluate this, we used synaptosomes, depleted of their postsynaptic densities, extracted from Nac of isolated and non-

isolated juvenile rats. We performed immunofluorescence in these synaptosomes and measure the expression of CRF-R1 with synapsin I as control. Further studies are needed to strengthen this hypothesis. Funded by FONDECYT grant N° 1191274

Abstract: Comorbidity is more the norm than the exception and is strong amongst psychiatric disorders. Anxiety and depression, the highest burden of disability amongst psychiatric disorders, present a high rate of comorbidity, such that 62% of patients with anxiety disorders also experience depressive episodes. This detrimental interplay between anxiety and depression results in the exacerbation of the negative symptoms from one to the other. However, the shared or segregated mechanisms remain largely unknown. Clinical and preclinical studies implicate the dopaminergic system in the emergence of anxiety disorders and depression. In particular, ventral tegmental area (VTA) dopamine neurons which encode rewarding, salient and aversive stimuli, project heavily to emotion-related brain regions, including the medial prefrontal cortex (mPFC), the nucleus accumbens (NAc), and the amygdala to support adaptive behaviors and healthy brain

functions. Here, utilizing the chronic social defeat stress (CSDS) paradigm that induces singular or combined anxiety- and depression-like phenotypes - A group and AD group respectively, we dissect the role of the dopamine subcircuits in the expression of anxiety- or depression-like phenotypes. Utilizing neural circuit-probing techniques, we previously established that the maladaptive firing activity of VTA dopamine neurons projecting to mPFC and projecting to NAc regulates the depressive-like behaviors selectively occurring in AD mice, but not in A mice. In contrast, our current results show that the firing activity of VTA-basolateral amygdala (BLA) neurons is dramatically decreased in both A and AD mice after CSDS. Additionally, using *in vivo* calcium imaging in freely behaving mice, we correlate VTA-BLA circuit activity with the expression of anxiety- but not depressive-related behavioral outcomes. Finally, our optogenetic studies establish bi-directionally the causal link between VTA-BLA subcircuit dysfunction and the anxiety phenotype. Overall, our study identify a novel functional role for VTA-BLA dopamine neurons in controlling anxiety-related behaviors not only in anxiety-alone, but also in anxious-depressive comorbid subjects.

Title: Late positive potential indexes baseline and treatment-related changes in anxiety sensitivity and is modulated by treatment content

Authors: *D. BUTLER[1], A. PAVULURI[2], A. A. VIVINO[2], F. BAUTISTA[3], N. B. SCHMIDT[4], E. M. BERNAT[2];
[1]Psychology, [2]Univ. of Maryland, Col. Park Neurosci. and Cognitive Sci. Program, College Park, MD; [3]Texas A&M Univ., College Station, TX; [4]Florida State Univ., Tallahassee, FL

Abstract: Background. Anxiety sensitivity (AS) refers to an individual's tendency to be fearful of anxiety-related bodily sensations, or symptoms that accompany feelings of anxiety (Reiss et al., 1986). These symptoms can be cognitive (i.e., fear of mental dyscontrol), physical (fear of catastrophic physiological outcomes such as heart attack or stroke), or social (concern about negative social judgment and subsequent observable symptoms of anxiety). Cognitive Anxiety

Sensitivity Treatment (CAST) (Schmidt et al., 2014) is a technology-based intervention shown to be efficacious in reducing AS. In recent work by Schmidt (2014), nontreatment seeking participants with elevated AS cognitive concerns participated in one session of CAST and showed significant reductions in AS posttreatment, relative to controls. Current Study. The primary purpose of this study is to assess the late positive potential (LPP) event-related potential (ERP) component, recognized as a marker of motivated attention, as an index of baseline AS, as well as treatment-related change in AS in response to CAST. Methods. In this study 263 participants (with complete EEG data at 1-month follow-up) received either an anxiety reduction intervention of CAST alone (N = 65), a mood intervention of cognitive bias modification interpretation (CBM-I) (N = 66), or a combined CAST and CBM-I interventions (N = 68), as well a repeated contact control group (N= 64). Prior to the intervention, baseline LPP was measured via exposure to affective stimuli (neutral, unpleasant, and pleasant images), and baseline AS recorded using the ASI-3. Results. Across all groups, increased LPP amplitude in response to unpleasant stimuli (UP) was positively correlated with baseline AS ($r=.20$, $p <.001$), but not LPP in response to pleasant or neutral images. At the 1-month follow up, there were different treatment effects based on treatment content: in the CBM-I group, there was an effect in that greater AS reduction at month 1 correlated with early frontal LPP amplitude ($r = -.328$ during our n2 @ Fz, $r = -.387$ during P3 @ Fz, $p < .001$), whereas that effect did not exist frontally in the CAST treatment group ($r = .065$, $p > .05$). The CAST group instead showed AS reduction being related to later parietal LPP effects. Taken together, the Combined group's findings showed a combination of CAST and CBM-I group effects with both early frontal LPP ($r = -.2980$, $p < .05$) and the later LPP effects relating to AS reduction ($r = -.33$, $p < .001$). Discussion. Overall, treatment effects were modulated by treatment content, as CAST yielded one pattern, CBM-I another, and combined CAST + CBM-I displayed an amalgamation of the two in terms of relating AS reduction to EEG amplitude.

Title: Structure-activity relationship of novel synthetic cathinones. Selective DAT inhibitors and hybrid compounds at monoamine transporters.

Authors: *N. NADAL-GRATACOS[1,2,3], A. S. SILVA[4], K. JÄNTSCH[4], M. HOLY[4], E. URQUIZU[1,2], M. BUENROSTRO-JÁUREGUI[1], X. BATLLORI[3], X. BERZOSA[3], H. H. SITTE[4], D. PUBILL[2], J. CAMARASA[2], E. ESCUBEDO[2], R. LOPEZ-ARNAU[2];
[1]Univ. Iberoamericana, Álvaro Obregón, Mexico; [2]Dept. of Pharmacology, Toxicology and Therapeut. Chem., Univ. of Barcelona, Barcelona, Spain; [3]IQS Sch. of Engineering, Univ. Ramon Llull, Barcelona, Spain; [4]Med. Univ. Vienna, Ctr. for Physiol. and Pharmacology, Inst. of Pharmacol., Vienna, Austria

Abstract: Several new synthetic cathinones have appeared in the global illicit drug market in the last decades. Synthetic cathinones are designed in order to mimic the effect of already considered illicit compounds such as cocaine, MDMA and methamphetamine. However, the illicit drug market is continually evolving by constantly adding small structural modifications to the common chemical structure of synthetic cathinones. Moreover, and despite the lack of information of their effects, it is widely known that this class of compounds interact with dopamine and serotonin transporters (DAT and SERT) through different mechanisms of action. Thus, the aim of this study was to investigate the *in vitro* structure-activity relationship (SAR) of six novel synthetic cathinones with current popularity as recreational drugs; Pentedrone, Pentylone, N-ethyl-pentedrone (NEPD), N-ethyl-pentylone (NEP), 4-methyl-pentedrone (4-MPD) and 4-methyl-ethylaminopentedrone (4-MeAP), which structurally differ in the absence or presence of different aromatic substituents as well as in the amino terminal group. Human embryonic kidney cells (HEK293) expressing the human isoforms of SERT (hSERT) and DAT (hDAT) were used for the uptake inhibition and release assays. All tested synthetic cathinones presented low IC_{50} values for hDAT and low or negligible activity at hSERT, resulting in high hDAT/hSERT ratio values. At hDAT, the capacity to inhibit [^{3}H]MPP^+ uptake increased with the presence of ethyl amine substitution. When studying [^{3}H]serotonin uptake inhibition at hSERT, ring-substituted cathinones showed higher inhibition potency than their no ring-substituted analogues. Surprisingly, and regarding their releasing properties, besides NEP, all tested compounds evoked serotonin release but negligible effect as DAT substrates. In summary, the present study provides new information about the *in vitro* potency and mechanism of action of some novel synthetic cathinones, which showed “hybrid” properties, acting as DAT blockers but SERT substrates. Moreover, a lack of ring-substitution in the structure of these novel synthetic cathinones together with an increased bulk of the amino terminal group results in higher DAT/SERT ratios, and therefore, higher risk of abuse liability.

Title: Role of organic cation transporter 3 in ethanol and cocaine co-abuse

Authors: *N. CLAUSS[1], A. OWENS[1], M. VITELA[1], M. A. BOWMAN[1], G. GOULD[1], W. KOEK[2], L. C. DAWS[1];
[1]Cell. and Integrative Physiol., [2]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Concurrent use of cocaine and alcohol is a major cause for emergency hospitalization, underscoring a vital need to understand the mechanistic basis of this highly addictive, and dangerous drug combination. Both cocaine (blocker of dopamine, norepinephrine and serotonin transporters, DAT, NET and SERT, respectively) and ethanol (EtOH) increase extracellular dopamine (DA), norepinephrine and serotonin. However, we and others, find no evidence for EtOH interacting with DAT, NET or SERT, suggesting that EtOH may be acting elsewhere to inhibit uptake of these monoamines. Organic cation transporter 3 (OCT3) is emerging as an important player in regulation of monoamine signaling. However, whether OCT3 contributes to actions of abused drugs that act primarily by increasing extracellular levels of monoamines, remains unclear. To establish proof-of-principle for this idea, we conducted studies to determine the ability of EtOH to inhibit uptake of the prototypical cation [^{3}H]1-methyl-4-phenylpyridinium ([^{3}H]MPP$^+$) into cultured HEK293 cells stably overexpressing human OCT3, and found the IC_{50} to be 4 mM, supporting a role for OCT3-dependent actions of EtOH, and showing that concentrations of EtOH reaching brain following behaviorally relevant doses may be sufficient to engage OCT3. We also found that cocaine does not have activity at OCT3 (Mayer et al., 2018, PMID: 29773909) raising the possibility that EtOH may interact with OCT3 to inhibit uptake of monoamines, potentially increasing the addictive properties of cocaine and propagating the concurrent use of these drugs. To this end we used high-speed chronoamperometry to interrogate the effects of local application of EtOH, cocaine, and their combination on clearance of exogenously applied DA from extracellular fluid in striatum of male and female constitutive OCT3+/+ and OCT3-/- mice *in vivo*. We found that in both male and female OCT3+/+ mice, EtOH inhibited DA clearance and enhanced the ability of cocaine to inhibit DA clearance, effects that were lost in OCT3-/- mice. Behavioral data in male and female OCT3+/+ mice reveal that the combination of EtOH (1000 mg/kg) and cocaine (3.2 mg/kg), doses which by themselves did not induce conditioned place preference (CPP), produced robust CPP. CPP studies in OCT3-/- mice are ongoing, but so far demonstrate no development of CPP, regardless of treatment. Taken together, results suggest that potentiation of the neurochemical and behavioral effects of cocaine by EtOH are OCT3 dependent. OCT3 may be a putative target for therapeutic intervention in the treatment of EtOH and cocaine co-abuse.

Title: Benzofuran derivatives are potent serotonin releasers and substitute for the discriminative stimulus effects of MDMA in rats.

Authors: C. B. JOHNSON[1], D. WALTHER[2], M. J. BAGGOTT[3], M. H. BAUMANN[2], *L. E. BAKER[1];
[1]Psychology, Western Michigan Univ., Kalamazoo, MI; [2]Designer Drug Res. Unit, IRP, NIDA, NIH, DHHS, Baltimore, MD; [3]Tactogen, Palo Alto, CA

Abstract: 3, 4-Methylenedioxymethamphetamine (MDMA) is currently under evaluation in phase III clinical trials for the treatment of post-traumatic stress disorder (PTSD) and is expected to be approved by the FDA for clinical use in the near future. MDMA is also a popular abused substance with risks for cardiovascular toxicity and neurotoxicity, particularly when misused at higher doses. Characterization of the behavioral and neurochemical effects of novel psychoactive substances is an essential step in the development of safer alternative therapeutic agents. Drug discrimination is a preclinical behavioral assay with pharmacological specificity for characterizing *in vivo* drug actions in the central nervous system. This project implemented rodent drug discrimination studies and serotonin transporter assays to characterize the enantiomers of 5-(2-methylaminopropyl) benzofuran (5-MAPB) and 5-(2-methylaminobutyl)benzofuran (5-MBPB), two benzofuran derivatives with potential MDMA-like effects. Eight male Sprague-Dawley rats were trained in a standard two-lever operant drug discrimination procedure under a fixed ratio 20 schedule of food reinforcement to discriminate MDMA (1.5 mg/kg) from saline. Once criteria for stimulus control were established, stimulus substitution tests were conducted with (RS) 5-MAPB, (R)-5-MAPB, (S)-5-MAPB, (R)-5-MBPB, and (S)-5-MBPB. All substances produced dose-dependent increases in MDMA-lever responding and full substitution at the highest dose assessed with minimal effects on response rate. The 5-MAPB and 5-MBPB enantiomers differed slightly in potency. Serotonin release assays using rat synaptosomes and [3H]serotonin indicated all substances are substrate-type releasers of serotonin with nanomolar potency. S-enantiomers appeared to have a somewhat higher potency than their corresponding R-enantiomers. The benzofuran scaffold may allow the development of substances that retain MDMA-like therapeutic effects while reducing toxicities associated with MDMA.

Title: Gene expression of Vesicular Glutamate Transporter 2 in the rat ventral tegmental area after episodic adolescent exposure to nicotine and alcohol

Authors: *M. VRETTOU[1], S. THALHAMMER[1], A.-L. K. SVENSSON[2], K. W. NILSSON[3], Å. WALLÉN-MACKENZIE[4], R. FREDRIKSSON[2], I. NYLANDER[2], E. COMASCO[1]; [1]Neuroscience, Sci. for Life Lab., Uppsala Univ., Uppsala, Sweden; [2]Pharmaceut. Biosci., [3]Ctr. for Clin. Res., [4]Organismal Bology, Uppsala university, Uppsala, Sweden

Abstract: Adolescence is a highly sensitive period, during which initiation of use/co-use of alcohol and nicotine commonly occurs in an episodic manner and can imprint vulnerability to the developing brain. Alterations in glutamatergic neurotransmission have been implicated in various phases of addiction cycle, yet little is known about the interactive effect of both nicotine

and alcohol on it. A marker of the glutamatergic phenotype is the Vesicular Glutamate Transporter 2 (VGLUT2) which is expressed in the ventral tegmental area (VTA), in glutamatergic-only but also in dopaminergic neurons. Differential VTA *VGLUT2* expression has been observed after chronic nicotine use and co-abuse with alcohol in human post-mortem brains. The present study aimed to investigate whether *Vglut2* gene expression in the VTA of adolescent outbred male rats is affected by prolonged episodic nicotine and/or alcohol administration. A total of forty animals were used, randomly assigned to four experimental groups (n = 10, per group) exposed to either: i) alcohol-only; ii) nicotine-only; iii) combination of alcohol and nicotine; or iv) control (water and saline) for three consecutive days per week for six weeks during adolescence. *Vglut2* mRNA was assessed in the anterior and the posterior VTA by use of double fluorescent or combined fluorescent/chromogenic *in situ* hybridization followed by automated cell counting. Differences on *Vglut2*-positive cells (%) among groups were assessed using one-way ANOVA, followed by Tukey *post-hoc* tests. Between-group comparisons on glutamatergic and dopaminergic neuronal subpopulations were performed using the independent student t-test. The profile of glutamatergic and dopaminergic neurons varied among the sub-nuclei of the VTA. *Vglut2* expression in the glutamatergic neurons was borderline upregulated in the lateral anterior, but not the posterior, VTA of rats exposed to both nicotine and alcohol compared to the control group. Contrariwise, alcohol alone and the combination of drugs borderline affected the glutamate-releasing dopaminergic neurons towards the opposite direction. The present preliminary results support the VTA heterogeneity, with different effects of alcohol and nicotine in the anterior compared to the posterior VTA. Furthermore, they hint towards an early effect of prolonged episodic alcohol and nicotine adolescent exposure on the distinct VTA glutamatergic/dopaminergic subpopulations. Determining genetic signatures of key-neuronal markers such as *Vglut2*, in key reward brain regions can contribute to further understanding of the biological underpinnings of drug addiction.

Title: Fluoxetine potentiates gene regulation by chronic oral methylphenidate treatment in the rat striatum

Authors: C. MOON[1], M. MARION[2], P. K. THANOS[2], ***H. STEINER**[3];
[1]Stanson Toshok Ctr. for Brain Function and Repair, Rosalind Franklin Univ., North Chicago, IL; [2]Res. Inst. on Addictions, Univ. at Buffalo, Buffalo, NY; [3]Chicago Med. School/RFUMS, North Chicago, IL

Abstract: The psychostimulant methylphenidate (MP, Ritalin) is used in the treatment of attention-deficit hyperactivity disorder (ADHD) and as a cognitive enhancer in the healthy. MP, like cocaine, acts by blocking the reuptake of dopamine. However, unlike cocaine, MP does not affect serotonin. Serotonin contributes to addiction-related gene regulation by cocaine. Thus, the lack of a serotonin effect may explain MP's more moderate impact on gene regulation and addiction liability. Previously, we showed that enhancing serotonin action by adding a selective serotonin reuptake inhibitor (SSRI), fluoxetine (FLX), to MP indeed potentiates MP-induced gene regulation in the striatum in rats. However, these studies used intraperitoneal (IP) drug administration, which is more relevant for MP abuse. IP administration produces drug spikes that are known to have a greater impact on gene regulation. In clinical treatments, however, MP and FLX are typically taken orally, which produces a slower bioavailability of the drugs and avoids spikes. In the present study, we investigated whether chronic oral administration of MP and FLX altered gene regulation in the striatum. MP (30/60 mg/kg/day), FLX (20 mg/kg/day) and MP+FLX were administered in rats' drinking water for 8h/day over 4 weeks. We assessed the expression of the neuropeptides dynorphin and substance P (both markers for striatal direct pathway neurons) and enkephalin (indirect pathway) by in situ hybridization histochemistry. Chronic oral MP alone produced a tendency for increased dynorphin and substance P expression and no changes in enkephalin expression. Oral FLX alone did not increase gene expression. In contrast, when given together, FLX greatly enhanced oral MP-induced expression of dynorphin and substance P and to a lesser degree enkephalin. Thus, FLX potentiated oral MP-induced gene regulation predominantly in direct pathway neurons, mimicking cocaine effects. The three functional domains of the striatum were differentially affected: While present throughout the striatum, MP+FLX-induced increases in dynorphin and substance P expression were maximal in sensorimotor sectors and minimal in limbic sectors. In contrast, increases in enkephalin expression occurred in associative sectors. MP+SSRI concomitant therapies are indicated in ADHD/depression comorbidity and other disorders, and co-exposure also occurs with MP misuse as a cognitive enhancer by patients on SSRIs. Our findings indicate that chronic MP+SSRI combinations, even given orally, may enhance addiction-related gene regulation.

Title: Sex, but not chronic cocaine administration, alters allopregnanolone levels in rat brain tissue and serum

Authors: *M. H. MCFARLAND[1], M. M. MACHADO[3], C. C. CARR[1], G. M. SANSBURY[1], K. C. MUSSELMAN[1], G. BOERO[4], T. K. O'BUCKLEY[1], A. MORROW[5], D. L. ROBINSON[2]; [2]Bowles Ctr. for Alcohol Studies, [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Univ. Federal De Sao Paulo, Diadema, Brazil; [4]Dept. of Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [5]Psych, Pharmacol & Ctr. Alcohol, UNC Sch. of Med., Chapel Hill, NC

Abstract: Neurosteroids are compounds synthesized within the brain that influence neuronal activity, in part, via actions at γ-aminobutyric acid (GABA) type A receptors. Multiple psychiatric disorders are associated with altered brain and serum levels of neurosteroids. Furthermore, the endogenous GABAergic steroid (3α,5α)-3-hydroxy-5-pregnan-20-one, or allopregnanolone, a metabolite of progesterone, has emerged as a clinically beneficial therapeutic for the treatment of psychiatric disorders, such as post-partum depression and substance use disorders. Although allopregnanolone can reduce cocaine-seeking and reinstatement in rats, the mechanism by which it exerts its effects remains unclear. Clinically, chronic cocaine use was correlated with decreased levels of pregnenolone, a precursor to allopregnanolone, and increasing allopregnanolone levels via progesterone administration in humans with a history of cocaine use resulted in reduced cocaine craving and stress arousal. The present study tested the hypothesis that chronic cocaine exposure in male and female rats would reduce levels of allopregnanolone in serum and brain regions involved in dopaminergic transmission and neurosteroidogenesis, such as olfactory tubercle, cortex, dorsal and ventral striatum, and midbrain. To test this hypothesis, we administered 15 mg/kg cocaine or saline to Sprague-Dawley female and male rats daily for 14 days consecutively. We recorded locomotor activity and stereotyped behavior each day to assess for cocaine sensitization. We observed typical behavioral neuroadaptations consistent with cocaine sensitization, including increased locomotion and stereotyped behavior in cocaine-exposed animals over the 14 days of administration. After allopregnanolone extraction from brain tissue and serum, we observed no significant differences in allopregnanolone levels between cocaine and saline groups in serum or any brain regions analyzed. We did, however, identify a main effect of sex in serum, olfactory tubercle, and cortex, but not in midbrain or ventral and dorsal striatum. These findings revealed that allopregnanolone levels vary across brain regions and by sex, which may play a part in sex differential responses to stress.

Abstract: Toluene is the most misused solvent. It can be found as part of multiple products such as thinner, adhesives, gasoline, and cleaning products. The abuse of this solvent is considered a public health problem, mainly between children and adolescents. Toluene is known to affect the function of the pronociceptive purinergic $P2X_{2/3}$ and $P2X_3$ receptors by activating or inhibiting them, respectively. There is evidence indicating that exposure to toluene can cause an increase in nociception through neurotransmitter systems such as serotonergic system. However, it is unknown whether other neurotransmitter systems are involved in the pronociceptive effect of toluene. The purpose of this study was to assess the participation of the local peripheral purinergic $P2X_{2/3}$ and $P2X_3$ receptors in the effect of toluene exposure on nociception, hyperalgesia and allodynia. Female Wistar rats were acutely exposed to toluene (6000 ppm) or air and some groups were treated with a $P2X_{2/3}$ and $P2X_3$ receptor antagonist (A-317491). Acute nociception was assessed using the formalin test and subsequently hyperalgesia and allodynia were evaluated with von Frey filaments in the same test. Acute solvent exposure increased

formalin-induced acute and chronic nociception in rats. Toluene pronociceptive acute and chronic effects were blocked in a dose-dependent fashion with A-317491. Data suggest that peripheral $P2X_{2/3}$ and $P2X_3$ receptors participate in the development of toluene-induced pronociceptive effects in rats.

Abstract: Raman spectroscopy is a powerful, *label free* technique to probe the molecular composition of a specimen. Recent studies have shown the potential of Raman spectroscopy to investigate the onset of neuropathological conditions emerging from brain tumors or traumatic brain injury. To exploit the full potential of this approach, it is crucial to access deep brain regions that lay beyond the reach of conventional Raman micro-spectroscopy. However, even the most advanced Raman probes, which are designed to provide intraoperative surgical guidance in humans, are bulky and expensive and are unsuited to retrieve Raman signals from deep brain regions in small animals, e.g. the mouse. To circumvent these limitations, we propose the use of a minimally invasive, disposable tapered optical fiber as an implantable probe to collect volumetric Raman signal at depth. We show that our approach not only can resolve the cytoarchitectonic layering of the mouse cerebral cortex, but also provides novel information on biochemical alterations linked with traumatic brain injuries and with the formation of brain

metastasis from different primary tumor (e.g. melanoma or lung). We believe our work is a significant contribution towards the future establishment of novel strategies for multimodal evaluation of the brain with a broad array of applications compatible with the study of the physiological state as well as the impact of any disorder affecting this organ.

Title: Wearable high-density diffuse optical tomography (WHD-DOT) instrument for mapping human brain activity

Authors: *A. S. AGATO[1], H. E. DEVORE[2], M. J. HEDLUND[1], A. C. O'SULLIVAN[1], W. T. HAMIC[1], C. F. SVOBODA[1], A. L. MAGEE[2], B. A. BURKE[1], A. T. EGGEBRECHT[1], E. J. RICHTER[1], J. P. CULVER[1];

Abstract: In recent years, functional neuroimaging has gone beyond the field of cognitive neuroscience and is increasingly being used in clinical applications for diagnosis and treatment planning. Its expanding application outside traditional research lab settings requires instruments with the flexibility to accommodate various clinical populations and allow a wide range of behavioral paradigms in naturalistic environments. The logistics of traditional neuroimaging technologies (such as fMRI, PET and MEG) exclude participants with metal implants or movement disorders and those who are unable to lie still in the scanner. Optical neuroimaging provides alternative methods for human brain mapping where gold-standard imaging modalities are contraindicated. Functional near-infrared spectroscopy (fNIRS) is one such method that is safe, lightweight, and portable. However, most fNIRS systems have low channel counts that limit resolution, field of view, and depth sensitivity. High-density diffuse optical tomography (HD-DOT), a form of fNIRS with high spatial density and increased channel count, provides

improved image quality and brain specificity but uses bulky optical fibers, which restrict subject movement and portability. We developed a wearable HD-DOT (WHD-DOT) instrument that combines the portability of fNIRS and the image quality of HD-DOT. Our design replaces fibers and rackmount hardware with modules that integrate the electronics for optical sources and detectors into tiny packages that fit on the head. Each module works like a smart comb with cylindrical tips that brush through hair and maintain stable optode-scalp coupling for optimal light detection. Multiple modules are combined using a custom FPGA board, which simultaneously controls sources and decodes signals from detectors. Real-time data from the WHD array is transmitted to a laptop via WiFi. Compact rechargeable batteries, stored in a small backpack, powers the whole system. We created a WHD-DOT instrument with 32 sources and 32 detectors at 13 mm optode spacing. The modular structure of the WHD patches facilitates scaling to a whole-head field of view with up to 144 sources and 144 detectors. In-vivo measurements were conducted to characterize system performance, resulting in dynamic range, cross talk and effective noise levels similar to fiber-based HD-DOT. To establish imaging feasibility, we validated mapping performance using retinotopic mapping of the visual cortex.

Title: Imaging Cerebral Blood Flow Using Speckle Contrast Optical Tomography: Simulation in a Human Head Model

Authors: *C. P. LIN[1,2], I. E. ORUKARI[2], L. K. FRISK[4], M. VERMA[4], S. CHETIA[4], A. T. EGGEBRECHT[5], T. DURDURAN[4,6], J. P. CULVER[2], J. W. TROBAUGH[3];

Sch. of Med., Saint Louis, MO; [6]Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain

Abstract: The development of real-time measures of cerebral blood flow (CBF) in clinics is desired since CBF is a crucial biomarker for brain diseases. Speckle contrast optical tomography

(SCOT) is a non-invasive imaging modality for mapping CBF via analysis of dynamic speckles; moreover, it has the potential for imaging at the bedside and has cost advantages and improved signal-to-noise ratio (SNR) compared to diffuse correlation spectroscopy (DCS), a popular optical method for imaging CBF. It also solves the limitations of positron emission tomography, the gold standard of imaging CBF, by enabling continuous measurements without ionizing radiation. High-density SCOT (HD-SCOT) has been studied in rodents, but the current free-space design of SCOT is not ideal for large-area brain imaging in humans. A fiber-based HD-SCOT is considered a potential solution where the fibers can comb through the hair and the fiber cap can be conformed to the complex surface of the human head. However, anatomical based reconstructions for HD-SCOT system on a human head have yet to be fully developed. In this study, we developed a pipeline for simulating HD-SCOT measurements and reconstructed images, and then we used the simulations to investigate the CBF imaging performance. Our pipeline is based on NIRFASTer and NeuroDOT modeling packages, and we simulated imaging with an array of 24 sources by 28 detectors and an anatomical head model. We studied the imaging depth sensitivity under varied source-detector distances and system exposure times with a simulated perturbation of CBF and demonstrated that the superficial cortical region of the brain can be measured with second nearest neighbors (source-detector distance = 29 mm). Simulated images showed spatial resolution of approximately 12 mm full-width-half-maximum at the depth of 10 mm, and reduced localization error when including larger source-detector distances. However, noise in an imaging optical system can prohibit the goal to use larger source-detector distances because of the attenuated signal-to-noise ratio (SNR). The system exposure time plays an important role in SNR since both the measurement amplitude and noise of an HD-SCOT system are strongly dependent on the exposure time. We evaluated SNR vs exposure time and found that the measurement SNR is approximately 1000x greater for an exposure time of 1ms relative to 1 μs. These results can be used to guide future instrument designs, including the optimal exposure time and available source-detector distances, and it is a powerful tool for studying the performance of HD-SCOT since different noise models can be easily incorporated into the pipeline.

Title: Measuring simultaneous neural activity and blood flow in awake freely behaving animals

Authors: *S. GULATI, O. MILLER, D. CHENG, S. MALEK, S. NOGUCHI, N. ADIL, B. BOIVIN, S. NEUFELD, A. M. STAMATAKIS;
Inscopix, Palo Alto, CA

Abstract: Neurovascular coupling, the process of localized change in blood flow following neuronal activity, ensures active regions of the brain are supplied with abundant levels of oxygen, glucose and substrates in a timely manner. Pathological conditions such as stroke, tumor, hypertension, Vascular Cognitive Impairment and Dementia (VCID) and Alzheimer's disease disrupt this intricate process impacting brain function. The complex nature of how this disruption occurs, however, remains elusive. Studying neurovascular coupling requires precise measurements of the spatial and temporal relationships of neuronal activity and changes in blood flow. We have developed a dual color miniscope, the nVueTM system, that allows simultaneous imaging of the neural activity and blood flow in animals during free behavior, enabling the investigation of neurovascular coupling. The nVue system acquires dual color data by multiplexing two LEDs at a high frame rate enabling direct visualization of both blood flow and calcium activity. We have also developed analysis algorithms for accurate and precise measurement of changes in vessel diameter and red blood cell (RBC) velocity. To validate that we could detect changes in blood flow alongside changes in neural activity, we injected a blood plasma labeling dye, Rhodamine-dextran, in GCaMP expressing mice via the tail vein. We then simultaneously imaged GCaMP and Rhodamine-dextran signals using the nVue system in freely behaving animals in baseline and amphetamine conditions. We observed 1) changes in blood flow correlated with increased neuronal firing and 2) vasodilation and increased blood flow following amphetamine administration compared to saline controls. This new application of the nVue miniscope system opens up new ways to study functional circuit data with vascular dynamics in cortical and deep brain regions in awake animal paradigms for both basic and translational neuroscience areas.

Title: High-throughput automated cages for longitudinal monitoring of neurovascular coupling in mice

Authors: *I. DJEROUROU[1], E. DELAMARRE[2], S. TISSIER[3], M. PTITO[5], M. P. VANNI[4]; [1]Univ. De Montréal, Montréal, QC, Canada; [2]Polytechnique Montréal, Montréal, QC, Canada; [3]École d'optométrie, Univ. de Montréal, Montréal, QC, Canada; [4]Univ. de Montréal, Montreal, QC, Canada; [5]Univ. Montreal, Montreal, QC, Canada

Abstract: In neuroscience, wide-field optical imaging in awake mice is an efficient technique to monitor the neural dynamic in the neocortex. It is usually performed on head-fixed awake mice implanted with a titanium bar and a chronic cranial window giving access to the brain. Mice are manually fixed to the apparatus via the bar to perform various tasks related to observing or manipulating brain activity through optogenetics. These protocols are very time-consuming for the experimenter and cause a lot of variabilities. A new strategy that emerged recently was to design a device able to automate this process, where mice set themselves to perform tasks while allowing massive data acquisition (Murphy et al. 2020 eLife). Automation also helps to increase the reproducibility of the experiments. Our goal was to optimize this technology and combine it with visual discrimination tasks and visual stimulation paradigms in the context of a longitudinal study exploring stroke. We created an automatic cage composed of two compartments, a weighing tunnel and a fixation tunnel having the only source of water, the wide-field optical imaging system, and a LCD screen. RFID readers are located on the two tunnels to identify the mice. When the mice enter into the fixation tunnel, the fixation system locks the head and starts the imaging and visual tasks, while the water is given. Besides the technical development of the device, the main challenge lies in the learning procedure of this task by the mice. Seven mice were implanted and then placed in a training cage where they were accustomed to drinking at the end of a passive tunnel. Then the mice were placed in the real automatic cage where the fixation sound was activated on the fourth day. After getting used to it and successful drinking, partial fixation was introduced, then hard fixation to stabilize the heads of mice for mesoscopic imaging. Widefield intrinsic signals imaging was introduced while the mice were head-fixed during 45s, using red, green and orange light focused on the dorsal cortex. Within the automatic cage, 6 mice out of 7 performed voluntary head fixations at an average rate of 27 fixations per day and per mouse. Considering the fixation time of 45s, it represents around 20min/day/mouse. Furthermore, over 5000 fixations with intrinsic signal imaging were registered. This system has great potential for longitudinal optical imaging studies in awake mice. It can then improve the research on the evolution of neurological disorders such as stroke in the visual cortex, their effect on cognition and the search for new treatments. The large amount of data generated can easily be shared and thus accelerate discoveries in the field of vision neurosciences.

Title: Simple movement correction method for laser speckle contrast imaging of cerebral blood flow in cranial windows in rodents

Authors: *J. GUILBERT, V. CHOUINARD, M. DESJARDINS;
Dept. de physique, de génie physique et d'optique, Univ. Laval, Quebec, QC, Canada

Abstract: Laser speckle contrast imaging (LSCI) is a widely used method to monitor blood flow in biological tissue. One of its main research applications is the mapping of cerebral activity by the measurement of changes in cerebral blood flow (CBF), which serve as a proxy for neuronal activation through neurovascular coupling. A major drawback of LSCI is its susceptibility to movement artifacts, a problem that is seldom considered despite the technique's large adoption. Movement artifacts are especially prevalent in stimulus response experiments, in which the hemodynamic response to a sensory stimulus is to be measured. In such studies, movement makes it hard to use LSCI to study the temporal and spatial dynamics of the CBF response, which are crucial to understand how functional imaging signals relate to neuronal activity. Here, we demonstrate a simple motion correction method that allows to describe both spatially and temporally the onset of the CBF response using LSCI, which is usually obscured by motion artifacts. The method is based on identifying a scattering region inside the imaged field of view in which the speckle contrast varies independently of CBF and then regressing out the mean-subtracted signal from this region. In a mouse cranial window preparation in which the edges of the window are fixed with dental cement, a common preparation in awake animal studies, we show that the average signal outside the exposed brain correlates strongly with head movement and hence forms an appropriate movement regressor. We demonstrate that the regression method corrects stimulus-locked motion artifacts, increases the signal-to-noise ratio, and makes CBF responses more physiologically plausible, revealing the hemodynamic lag that was masked by movement. We further validate the method by simultaneously measuring relative changes in cerebral blood volume (CBV) using intrinsic optical imaging and show that correcting the speckle contrast response increases its concordance with the CBV response, consistent with the fact that the two are physiologically linked. Finally, we show that the regression method performs better than alternative methods including image realignment and global signal regression. Our work highlights the importance of having a proper movement correction strategy when performing LSCI in awake animals and identifies the regression of flow-independent speckle contrast variations as a simple and accessible way to improve the quality of LSCI data.

Title: Blood glucose regulation by magnetogenetic stimulation of pancreatic nerves

Authors: R. Y. LI[1], M. JIMENEZ GONZALEZ[1], L. POMERANZ[2], G. J. SCHWARTZ[3], J. FRIEDMAN[2], *S. STANLEY[1];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Dept. of Mol. Genet., The Rockefeller Univ., New York, NY; [3]Medicine/ Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: There is substantial evidence that neural regulation plays a critical role in glucose metabolism and hormone release. Targeting neural populations innervating the pancreas could provide therapies for diabetes and other metabolic conditions. However, our understanding of the precise physiological roles of pancreatic nerves is incomplete because we lack tools to study these populations in a non-invasive, targeted, temporally controlled manner. Here, we validated and applied a novel magnetogenetic neuromodulatory construct *in vitro* and *in vivo* to discern the roles of defined pancreatic nerves in glucose metabolism.
The construct, coding for the TRPV1 ion channel fused to a nanobody binding endogenous ferritin (NbTRPV1), was transfected into Neuro2A cells and primary mouse DRG neurons. Magnetic stimulation significantly increased intracellular calcium in cells expressing NbTRPV1. For *in vivo* delivery, cre-dependent NbTRPV1 was packaged into AAV8; *ex vivo* calcium imaging of celiac ganglia confirmed magnet activation of pancreas-projecting neurons expressing NbTRPV1.
In vivo, magnet treatment of mice expressing NbTRPV1 in β cells increased plasma insulin and improved glucose tolerance in males and females, validating the efficacy of this construct to regulate cell activity in the pancreas of freely moving mice.
When NbTRPV1 was delivered to all pancreas-projecting efferent neurons, glucose clearance was significantly improved, mediated by suppression of glucagon secretion. Next, we targeted expression to pancreatic parasympathetic efferent innervation; magnet treatment of mice expressing NbTRPV1 in parasympathetic efferent pancreatic neurons significantly improved

glucose tolerance via increased insulin secretion, without impact on plasma glucagon. Finally, NbTRPV1 was targeted to pancreatic vagal sensory neurons in either the left or right nodose ganglion. With magnet treatment, these mice showed impaired glucose tolerance, reduced insulin secretion and increased glucagon secretion in the face of glucose challenge. These data demonstrate for the first time a method for remote, temporally controlled, targeted modulation of pancreatic islets and nerves to regulate blood glucose. These are also the first studies to begin parsing out the physiological roles of vagal sensory neurons projecting *specifically* to the pancreas, without off-target effects resulting from stimulation or ablation of the entire vagus nerve. This approach can be used to study the contribution of pancreatic nerves in a wide range of diseases, from diabetes to pancreatic cancer, as well as other peripheral nerves and conditions relevant to their pathophysiology.

Abstract: STEM engagement in U.S. K-12 classrooms has increased over the past decade thanks to efforts from the National Science Foundation and the National Institute of Health and the adoption of Next Generation Science Standards (NGSS) into the classroom. While NGSS has embedded engineering, neuroscience, and computer science skills and topics into traditional K-12 course requirements, the integration of these skills and topics by schools and teachers is not

standardized. Teachers and schools are experiencing an increasing pressure to incorporate these STEM concepts in a way that students can understand and enjoy but lack both resources and adequate STEM expertise. While many programs, lessons, and activities used to embed STEM into K-12 exist, many of these resources are unavailable to low-income schools due to factors including cost and classroom space requirements. We introduce an open-source eBook complete with freely accessible STEM lessons that introduce students to concepts that are relevant to the new K-12 standards related to engineering and neuroscience. These lessons are aligned with NGSS, Common Core, and state standards, and each lesson includes a set of lecture slides, assessments, and an engaging, hands-on activity.

Title: Fiola: an accelerated pipeline for fluorescence imaging online analysis

Authors: *C. CAI[1], C. DONG[2], M. ROZSA[3], E. PNEVMATIKAKIS[4], A. GIOVANNUCCI[1]; [1]Biomed. Engin., Univ. of North Carolina Chapel Hill and North Carolina State Univ., Chapel Hill, NC; [2]Computer Sci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [4]Ctr. for Computat. Biol., Flatiron Institute, Simons Fndn., New York, NY

Abstract: Optical microscopy methods such as calcium and voltage imaging already enable fast activity readout (30-1000Hz) of large neuronal populations using light. However, the lack of corresponding advances in online algorithms has slowed progress in retrieving information about neural activity during or shortly after an experiment. This technological gap not only prevents the execution of novel real-time closed-loop experiments, but also hampers fast experiment-analysis-theory turnover for high-throughput imaging modalities. The fundamental challenge is to reliably extract neural activity from fluorescence imaging frames at speeds compatible with new indicator dynamics and imaging modalities. To meet these challenges and requirements, we propose a framework for Fluorescence Imaging OnLine Analysis (FIOLA). FIOLA exploits computational graphs and accelerated hardware to preprocess fluorescence imaging movies to extract neural activity at speeds in excess of 300Hz on standard fields of view for calcium imaging and at over 400Hz for voltage imaging movies. We evaluate FIOLA on ground truth

data and real datasets, demonstrating reliable and scalable performance. Our methods provide the computational substrate required to interface precisely large neuronal populations and machines in real-time, enabling new applications in neuroprosthetics, brain-machine interfaces, and experimental neuroscience. Moreover, this new set of tools is poised to dramatically shorten the experiment-data-theory cycle by providing immediate feedback on the activity of large neuronal populations at experimental time.

Title: Parameter estimation and uncertainty quantification of Hodgkin-Huxley style neuron models using the Markov chain Monte Carlo method

Authors: J. VELASCO[1], N. SINHA[2], G. IDUMAH[4], C. HECKMAN[3], J. RUDI[5], *Y. WANG[1], **M. K. CHARDON**[3];
[1]Electrical and Computer Engin., California State University, Los Angeles, Los Angeles, CA; [2]Interdepartmental Neurosci., [3]Physiol., Northwestern Univ., Chicago, IL; [4]Case Western Reserve Univ., Cleveland, OH; [5]Argonne Natl. Lab., Lemont, IL

Abstract: Experimental data based parameter search for Hodgkin-Huxley style neuron (HHN) models is a major challenge for neuroscientists. Current search strategies are often computationally expensive, slow to converge, poorly handle nonlinearities in the objective function or require good initial guesses. Most importantly, none of the existing approaches offer quantification of uncertainties in parameter estimates even though such uncertainties are of immense biological significance. We propose a novel state-of-the-art method for uncertainty quantification in a Bayesian framework using the Markov chain Monte Carlo (MCMC) approach. This approach incorporates prior knowledge about model parameters (as probability distributions) and aims to map the prior to a posterior distribution of parameters informed by both the model and the data. Furthermore, using the adaptive parallel tempering strategy for MCMC, we tackle the highly non-linear and noisy HHN cost-function. We tested the robustness of our approach using the voltage trace data generated from a well studied 9-parameter HHN model using four levels of injected currents (0.0, 0.1, 0.2 and 0.3 nA). Each test consisted of

running the ground truth with their respective currents to estimate the model parameters. Each training run used 24 to 32 chains and generating 10000 to 14000 samples.We found that the MCMC algorithm was able to converge to an optimal parameter set with a loss value of 0.0008, 0.0002, 0.0348, 0.0013 for each of the four injected currents respectively. Our search strategy also produced other solutions with acceptable losses (e.g., for 0.0 nA, 889 solutions were within 0.5% of the best solution and 1595 solutions with 1% of the best solution). Thus, in addition to producing a single optimal solution, the MCMC search provided a "landscape" of the possible parameters sets with acceptable loss values in a tractable manner. Our approach, for the first time, is able to obtain an intelligently sampled global view of the solution distributions within a search range in a single swoop. Furthermore, we also demonstrate a practical strategy to unravel hitherto 'unseen' solution spaces which can serve to better inform and guide future experiments.

Title: Convergent mapping dominates cerebro cerebellar connectivity

Authors: M. KING[1], ***L. SHAHSHAHANI**[2], R. IVRY[3], J. DIEDRICHSEN[4];
[1]UC Berkeley, Berkeley, CA; [2]Univ. of Western ontario, London, ON, Canada; [3]Univ. California, Berkeley, CA; [4]Brain and Mind Inst., Western Univ., London, ON, Canada

Abstract: The cerebro-ponto-cerebellar system entails aseries of closed loops, creating anetwork inwhich cerebral and cerebellar regions are organized inaone-to-one mapping (Schmahmann&Pandya, 1995;Buckner et al. 2011). However, other lines of evidence suggest that corticalprojections tothe cerebellum may be more convergent. Here, we quantitatively compared anillustrative one-to-one model and amany-to-one convergent model, asking which provides amore accurate representationof cerebro-cerebellar connectivity. Using amulti-domainfMRIdataset (King et al. 2019), we built regularized linear regressionmodels using cerebral regionsas model features and thenused the weights from these models topredict cerebellar activitypatterns. We used arange of cortical parcellations as model features, resulting indivisions ofthe cortical surface for each hemisphere into7to2000regions. We compared twomodels ofcerebro-cerebellar connectivity:1) Winner-take-all which assumes aone-to-one mapping andkeeps the cortical regionwith the highest connectivity weight, setting all other

weights tozero. 2)Ridge regressionwhich assumes aconvergent many-to-one model and uses L2-normregularizationtoconstrainconnectivity weights tobe close tozero. The estimated connectivityweights from each model were used tomake predictions for cerebellar activity profiles inanoveltask set. The convergent “many-to-one”model outperformed the sparse “one-to-one”model forall cortical parcellations. As the granularity of the parcellationincreased, the predictive accuracyof the convergent model showed amodest increase. The opposite patternwas observed for thesparse one-to-one model, although the decrease inaccuracy with increasing granularity wasmore marked. We alsofound differences across the cerebellar cortex interms of predictiveaccuracy. Specifically, the one-to-one models performed best insensorimotor regions of thecerebellum (e.g lobules I-V), whereas the many-to-one model alsoperformed well incerebellarareas associated with more cognitive tasks (e.g., lobules VII), suggesting that aconvergentcerebro-cerebellar mapping is more likely for cognitive circuits. One limitationwith the currentanalyses is that all of the models underperformed relative tothe noise ceiling, demonstratingthat there is still potential for better predictive models. However, the results todate, derived fromarich set of functional data, challenges the view of one-to-one closed loopcircuitry as the corearchitectural feature of cortical-cerebellar connectivity.

Title: Machine Learning Pattern Recognition for Identifying and Detecting Spontaneous IPSCs

Authors: *E. WHITE[1], J. BRUNDAGE[2], H. WADSWORTH[3], C. MASON[3], D. HEDGES[5], J. T. YORGASON[4];
[1]Brigham Young Univ., Holladay, UT; [2]Neurosci., [4]Cell. Biol. and Physiol., [3]Brigham Young Univ., Provo, UT; [5]Billings Clin., Univ. of Utah, Bozeman, MT

Abstract: Analysis of patch clamp electrophysiology data can be a time consuming and error-prone task, with limited ways of controlling variation introduced during analysis. The analysis of spontaneously occurring events, such as spontaneous inhibitory post synaptic currents (sIPSCs), introduces an additional layer of complexity because these signals are typically smaller in amplitude, occur infrequently and can vary greatly from one laboratory to another. Many laboratories use a simple amplitude thresholding algorithm or signal matching tools for sIPSC

detection, and the detected events are then confirmed by a researcher. The present work developed and tested machine learning tools for sIPSC detection, with the goal of reducing error introduced through researcher input bias and computational time. Different model architectures and data input types are compared to determine which machine learning methods are best suited for the detection of sIPSCs. Manually defined sIPSCs were used as initial training sets (input features) for the created architectures. An XGBoost model—using standardized, raw waves as inputs—had the best performance for event detection, with an accuracy of 74.9% and an ROC-AUC of 0.82. Using feature reduction techniques, the number of input features for training was reduced from 4000 to 100 inputs with no drop in performance, thus lowering the computational burden of training. Finally, the trained model was validated in an analytic workflow, where it was used to identify and classify events in a new dataset. This validation demonstrated that a semi-automated approach using the machine learning powered peak detector was able to process raw recording data with comparable results to a manual workflow. To ensure the generalizability of this technique, the XGBoost model was given to various laboratories to implement on different types of data. The architecture's performance and analysis of different datasets proved to be successful and easy to use. Importantly, in all experiments, the machine learning detector was much quicker, with the manual method requiring an estimated 66 work hours to determine all peak locations, compared to just minutes for the machine learning method. These data indicate that an XGBoost model trained on standardized raw traces as inputs, rather than extracted features, is well suited for peak detection for sIPSCs and could greatly decrease analysis time and experimenter bias.

Title: Comparing Denoising Approaches in Ultra-High Field Resting State fMRI

Authors: *M. MEHTA[1,3], Y. JACOB[2], L. MORRIS[1];
[1]Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]BioMedical Engin.

Abstract: Background: One of the biggest challenges in functional Magnetic Resonance Imaging (fMRI) research has been parsing brain activation (BOLD signal) from artifact noise. Multi-echo (ME) acquisition of fMRI data facilitates BOLD separation by capturing every slice at multiple echo times. The use of ME 7 Tesla data allows examination of more detailed signal at a high spatial resolution. Currently there are several mathematical approaches to combining and denoising ME data to obtain BOLD signal but the optimal method for high-resolution data is unknown.**Methods:** In this project, we aim to compare the predominant ME preprocessing pipelines: AFNI and MEICA. We also analyze individual echo images using SE AFNI preprocessing approach. We evaluate the quality of the denoised BOLD signal using global and regional temporal Signal-to-Noise Ratio (tSNR) and functional connectivity measures in healthy individuals (N=9).**Results:** Our preliminary data suggest that with minimal processing with smoothing a 6 mm full width at half maximum (FWHM) kernel in the MNI space, there was significant effect of combining and denoising method on the whole-brain tSNR [$F(7,63)=44.85$, $p<0.001$] and functional connectivity of key nodes of the default mode network (DMN) [$F(7, 63) = 10.59$, $p<0.001$], motor network [$F(7, 63)=2.68$, $p=0.017$] and reward network [$F(7, 63)=3.52$, $p=0.003$].**Conclusion:** Our preliminary results suggests that denoising and multi-echo combining approaches significantly impact the pre-processed BOLD signal. MEICA based denoising approach offers better tSNR, while AFNI based approaches seem better at conserving functional connectivity. However, visualization of seed-to-voxel connectivity showed presence of high but localized connectivity in the MEICA-based output. These results indicate a need for a global measure for signal quality of ME resting state (rs)-fMRI data.

Title: Bayesian Inference in High-Dimensional Time-Series with the Orthogonal Stochastic Linear Mixing Model

Authors: *R. MENG, K. BOUCHARD;
lawrence berkeley national laboratory, Berkeley, CA

Abstract: Many modern neuroscience datasets are time-series that contain large numbers of output response variables sampled for prolonged periods of time. For example, the neurophysiology of 100s-1000's of neurons are recorded during behaviors and in response to sensory stimuli. While several latent-variable methods exist for analysis of such data, each has benefits and shortcomings from a computational or interpretational perspective. Within the class of Bayesian methods, an outstanding challenge is scalability of inference for datasets with large numbers of output responses and many samples.
We propose a new regression framework, the orthogonal stochastic linear mixing model (OSLMM), that enables inference in large time-series datasets. Multi-output Gaussian process models capture structure across multiple outputs, however they typically assume correlations between the output response variables are invariant in the input space. Stochastic linear mixing models assume the mixture coefficients depend on input, however, the inference is intractable for large datasets. Here, we propose the orthogonal stochastic linear mixing model (OSLMM) that introduces an orthogonal constraint amongst the mixing coefficients. This constraint reduces the computational burden of inference while retaining the capability to handle complex output dependence. We provide Markov chain Monte Carlo inference procedures for both SLMM and OSLMM. In neurophysiology recordings, we use the inferred latent functions for compact visualization of population responses to auditory stimuli, and demonstrate superior results compared to a competing method (GPFA). Specifically, compared to GPFA, OSLMM has better data-predictive performance (e.gcross-validated R2), and the structure of neural activity in the inferred latent states more accurately matches the parametric relationships of the amplitude and frequency of the stimuli. Thus, the interpretation of the latent variables is easier.
Together, these results demonstrate that OSLMM will be useful for the analysis of diverse, large-scale time-series datasets commonly found in neuroscience. More broadly, the results highlight the importance of continued development of methods to reveal latent structure in high-dimensional neuroscience datasets.

Title: Modeling neuronal engagement in rhythmic network activity

Authors: *P. D. RIVIERE[1], G. SCHAMBERG[2], T. P. COLEMAN[3], L. M. RANGEL[4]; [1]Cognitive Sci., Univ. of California San Diego, La Jolla, CA; [2]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [3]Bioengineering, UCSD, La Jolla, CA; [4]Cognitive Sci., UCSD, San Diego, CA

Abstract: Neural spiking activity exhibits exquisite temporal structure that emerges from the interplay of various intrinsic and synaptic currents, requiring methods that can evaluate specific contributions to this structure from various possible neural influences. Spike timing is systematically constrained by stereotyped membrane responses and neuronal interactions, including refractory periods (milliseconds) during which neurons are unlikely or unable to fire action potentials, and rhythmic currents that create temporal windows of excitability (hundreds of milliseconds). Here, we offer a novel approach to (1) represent the relationship between neuronal spike timing and the phase of any network local field potential (LFP) oscillation, and (2) weigh the relative contributions of longer-timescale rhythmic constraints and shorter-timescale ones, such as the refractory period. Specifically, we use kernel density estimation to directly model the likelihood of observing particular phases when spikes occur, and subsequently compute the posterior probability of spiking over time given a phase time series. To model refractory constraints on neuronal spiking, we apply logistic regression to predict upcoming spiking from the immediately preceding spike history (3 ms). Within this logistic regression framework, we combine phase and short history information to generate a comprehensive model that explicitly tests the hypothesis that neurons are engaged in a given rhythmic network process, while still accounting for intrinsic refractory constraints on spiking. We compare this comprehensive model against models that capture long-term (250 ms) autocorrelations in spike trains, in order to assess whether temporal structure in spike trains is in fact predominantly related to network dynamics reflected in the LFP, rather than a variety of alternative influences that would contribute to autocorrelations (e.g. spike-frequency adaptation, alternative rhythmic modulation). We first validate the models in simulated neurons, and subsequently apply the models to assess the relationship between hippocampal CA1 inhibitory interneuron spiking and the phase of the theta (4-12 Hz) rhythm. For most interneurons, models that combined immediate history (capturing refractory periods) and phase (reflecting rhythmic current influences) most accurately described the temporal structure of neuronal spike trains. With this modeling suite, we model variability in spike trains, and specifically test the relationship between network-level rhythmic currents and neuronal spike timing.

Title: A novel method to account for temporal variability in EEG: Bump-related potentials

Authors: *H. S. BERBERYAN[1], H. VAN RIJN[2], J. P. BORST[1];
[1]Bernoulli Inst., [2]Dept. of Exptl. Psychology, Univ. of Groningen, Groningen, Netherlands

Abstract: Over the past century, different recording techniques have been used to measure brain activity. One of these techniques, electroencephalography (EEG), has the undoubted advantage of a very high temporal resolution that allows for recording brain activity at a millisecond timescale. This advantage, however, also presents a challenge in the analysis because cognitive processes are not aligned precisely between participants, and between trials within a participant. When applying the traditional event-related potential technique – that is, averaging the signal over trials and participants – part of the information that is present in single trials is lost due to the averaging procedure. In particular further away from a fixed time point such as stimulus or response, the average signal tends to become blurry and uninformative. To overcome this limitation, we applied a novel machine learning algorithm called Hidden semi-Markov Model multivariate pattern analysis (HsMM-MVPA; Anderson, Zhang, Borst, & Walsh, 2016). This algorithm was developed to identify processing stages on a trial-by-trial basis by searching for the peaks across the scalp (so-called bumps) that signify critical events. In the current project, the results of HsMM-MVPA were applied to calculate bump-related potentials (BRPs). BRPs are extensions of classical ERP analysis that are calculated by aligning EEG data to the locations of the peaks identified with HsMM-MVPA. BRPs were calculated on data from a lexical decision task in which the frequency of words (high frequency and low frequency) and "wordness" of non-words (pseudo words and random letter strings) were varied (Berberyan, van Rijn, Borst, 2021). The results of analysis revealed clear early peaks present in both ERPs (Figure 1A) and BRPs (Figure 1B). While in ERPs the information from about 400 ms was less clear, BRPs could successfully recover the precise location of the later peaks for each condition. Taken together, the results suggest that BRP technique is a promising approach for gaining new insights into cognitive processing.

Title: Comparing age trajectories of MRI cortical markers and myelin: An exploratory study

Authors: *O. PARENT[1,2], E. OLAFSON[6,1], A. BUSSY[1,2], S. TULLO[1,2], A. SALACIAK[1], S. FARZIN[1], S. A. BEDFORD[1,3], M.-L. BÉLAND[1], C. L. TARDIF[4,7,5], G. A. DEVENYI[1,3], M. CHAKRAVARTY[1,2,3,4];
[1]Computat. Brain Anat. Lab., Douglas Mental Hlth. Univ. Inst., Montréal, QC, Canada; [2]Integrated Program in Neurosci., [3]Dept. of Psychiatry, [4]Dept. of Biol. and Biomed. Engin., [5]Dept. of Neurol. and Neurosurg., McGill Univ., Montréal, QC, Canada; [6]Dept. of Radiology, Weill Cornell Med., New York, NY, Canada; [7]McConnell Brain Imaging Ctr., Montreal Neurolog. Inst., Montréal, QC, Canada

Abstract: The biological interpretations of neuroanatomical magnetic resonance imaging (MRI) are challenging. While MRI indices such as cortical thickness (CT) relate to macrostructural organization of the cortical mantle, there is evidence that CT estimates are impacted by cortical myelin and other microstructural properties. Here, we compare the spatial organization and age effects of CT to 3 measures of cortical microstructure (gray-white matter contrast [GWC], the newly developed boundary sharpness coefficient [BSC] from our group, gray matter [GM] T1w/T2w ratio and superficial white matter [SWM] T1w/T2w ratio), and probe their specificity to cellular organization using the histological reconstruction of BigBrain.
T1-weighted MPRAGE (1 mm3 voxels) and T2-weighted SPACE (0.64 mm3 voxels) images from 127 healthy subjects (aged 18-81, 76F, 51M) were used. Cortical surfaces were generated and CT estimates were derived using the CIVET 2.1.0 pipeline (see Fig 1A for derivation of microstructural metrics). For each marker and vertex, the mean value across subjects was computed and a linear model with age and sex as predictors was fitted. The correlation of the surface maps was assessed and significance tested via spin tests.
Results included a significant spatial relationship of the mean values between the GM T1w/T2w ratio and the GWC, BSC and CT, and between SWM T1w/T2w ratio and the BSC (Fig 1B). There was a positive spatial correlation between the age effect of the GWC and SWM T1w/T2w ratio (Fig 1C). A significant relationship was found between the BSC and GWC calculated on BigBrain and their MRI equivalent, although it is likely that the BSC correlation is mediated by CT (Fig 1D).
Our finding of spatial correlations being higher for mean values than for age effect indicates that

some measures tend to covary at the cortex-wide level, but age trajectories are likely influenced by different interactions of microstructural changes. Our BigBrain results indicate a general trend of GM T1w signal and myelin being inversely related to the density of cells, although that relationship is weak to moderate.

A. The GWC was calculated by dividing the intensity of the T1w image at 25% of CT translated in SWM by the intensity at 25% of CT in GM. The BSC was defined as the growth parameter of a sigmoid curve fitted to 10 intensities sampled across the gray-white matter boundary. A sharper gray-white matter transition is reflected by a high BSC value. GM T1w/T2w ratio was sampled at 25% of CT in GM, and SWM T1w/T2w ratio was sampled at 25% of CT translated in SWM. B. Correlations between cortical maps of the mean values between the markers. P-values are corrected for false discovery rate. Correlations at p<0.05 are highlighted in green. C. Correlations between cortical maps of the betas of the age term between the markers. D. Correlations between cortical maps of the markers computed on BigBrain (top row) and markers computed on MRI images (bottom row)*.
* The T1w/T2w markers on MRI images are compared with the intensities on BigBrain at the same sampling distance

Title: Temporal profile of genomic imprinting of the E6-AP ubiquitin ligase (Ube3a) gene in developing GABAergic neurons in vivo

Authors: *K. GUTHRIE[1], S. MIRI[2], M. AMIR[2], A. VISAVADIYA[2];
[2]Biomed. Sci., [1]Florida Atlantic Univ., Boca Raton, FL

Abstract: Angelman Syndrome (AS) is a severe neurodevelopmental disorder characterized by developmental delay, intellectual disability, seizures, lack of speech, and motor impairment. AS is caused by maternally inherited deletions/mutations in the gene encoding the HECT E3 ubiquitin ligase Ube3a. This eliminates functional Ube3a during early brain development as the paternal Ube3a allele undergoes epigenetic silencing in neurons. In AS model mice, almost all neuronal Ube3a protein is lost by birth. Exceptions include immature neurons born during late fetal stages, which retain some paternal Ube3a expression, and progenitor cells in forebrain neurogenic niches. Differential splicing generates multiple Ube3a isoforms with distinct patterns of intracellular localization in neurons (nuclear vs cytosolic) thought to reflect multiple functions. Shifts in localization occur with increasing neuron maturation in vitro, and during early postnatal development. However, a complete profile of Ube3a expression and paternal silencing during neuron development in vivo, from cell birth, neuroblast migration and later maturation, has yet to be characterized. Using adult AS model mice, and adult mice expressing Ube3a-YFP from the paternal allele, we tracked the expression and localization of Ube3a in SVZ-generated GABAergic olfactory granule cells over the course of their development using bromodeoxyuridine (BrdU) and markers indicative of maturational stage. We found that SVZ progenitors and migrating neuroblasts expressed Ube3a in AS and wild-type (WT) mice, and Ube3a-YFP in this strain. In these populations, Ube3a localization was predominantly cytosolic. As they matured in the olfactory bulb, transitioning from doublecortin to new NeuN expression while extending an apical process at 7-9 days post BrdU, Ube3a and Ube3a-YFP shifted to nuclear localization, with cytosolic Ube3a maintained. Some BrdU+ neurons exhibited nuclear NeuN and Ube3a colocalization in both WT and AS mice, with Ube3a disappearing from nuclei in AS neurons rapidly thereafter. Similarly, Ube3a-YFP disappeared soon after the shift to the nucleus, indicating that at this early developmental stage, potential nuclear functions of Ube3a isoform 3, which predominates in this compartment, are permanently lost from AS neurons. Quantitative analysis of labeled granule cell counts in WT mice at 14 days post-BrdU confirmed this as 93.8% of Brdu+ cells were also NeuN+/Ube3a+, whereas in AS mice, 2.2% of BrdU+ cells were Ube3a+, with 93.8% of cells BrdU+/NeuN+ only. In contrast to a report of disrupted adult hippocampal neurogenesis in AS mice, we found no evidence of altered olfactory neurogenesis.

Title: RNA interference to treat neurological genetic disorders

Authors: *R. K. BUTLER[1], H. KANG[2], V. ZARIC[1], A. RAHIM[1], S. P. DEVRIES[1], Y. MA[1], S. J. GRAY[2];
[1]Psychiatry, [2]Pediatrics, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: RNA interference could potentially treat numerous genetic disorders by indirectly elevating healthy protein levels genotypically present on a silenced allele or on a duplicated gene. Deficits in neuronal UBE3A protein result in Angelman Syndrome (AS). UBE3A is regulated through genetic imprinting whereby the maternal allele is expressed and the paternal allele is silenced. Paternal silencing is induced with a portion of a large, non-coding antisense transcript specific to UBE3A (UBE3A-ATS). Previously it has been demonstrated that anti-sense oligonucleotides targeting the region between SNORD115 and upstream of UBE3A-ATS elevate paternal expression of UBE3A and improve behavior deficits in an AS mouse model. Using a similar transgenic model, targeting SNORD115 with CRISPR/Cas9 also elevated UBE3A and improved behavior deficits. We explored whether small interfering RNAs (siRNA) targeting the region encompassing SNORD115 and upstream of UBE3A-ATS elevated UBE3A transcript in human cultured neurons. Furthermore, we administered intrathecally at P7-P10 an adeno-associated virus type 9 (AAV9) with a short-hairpin RNA (shRNA) targeting the same transcript region in the AS mouse model. *In vitro* screens (N=3) of 46 siRNA candidates (10 nM; 24 hour incubation) indicate that several candidates reduce UBE3A-ATS and increase UBE3A in human cultured M17 neuroblastoma cells. Preliminary data suggest that shRNA/AAV9 delivered intrathecally induces paternal expression of UBE3A in Purkinje cells of the cerebellum and rescues nest building behavior deficits in the AS mouse model at 8 and 12-weeks post-injection. No sex differences were observed. Similar siRNA and shRNA/AAV9 approaches are being performed concurrently in human cells and animal models of Prader-Willi Syndrome and Spinal Muscular Atrophy. Taken together, this study demonstrates the potential for a vector-mediated and permanent RNA interference approach to treat neurological disorders.

Title: Genome-wide significant identification of novel neurodevelopmental candidate proteins through a two-stage CLUMP analysis workflow

Authors: T. M. AKINWE, E. MEHINOVIC, J. K. NG, T. N. TURNER;
Washington Univ. in St. Louis, St. Louis, MO

Abstract: Genes associated with neurodevelopmental disorders (NDDs) have been previously identified with an excess of protein-coding *de novo* variants (DNVs). Most of the emphasis thus far has been on likely gene-disruptive DNVs. Missense DNVs, have been less studied because their functional consequence on protein function is more difficult to interpret. Nonetheless, there have been efforts made to look at rare missense variants in high-impact risk genes and observe functional effects to the encoded protein. One area that has been examined is whether missense variants are present in a domain, as presence in a domain may have a more severe impact. However, the assumption that rare missense mutations of large effect will only occur in protein domains may obscure functionally important regions outside of known domains. To assess clustering of mutations in an unbiased manner, we use the CLUstering by Mutation Position (CLUMP) algorithm. CLUMP has previously been applied to rare missense NDD-associated variants., but we now present an updated two-stage workflow that allows CLUMP to test for genome-wide significant (GWS) clustering. Using CLUMP, we tested 45,221 protein-coding DNVs within 13,353 proteins (18,762 genes) from 31,058 NDD families against two negative controls: the 1000 Genomes Project (1000G, n = 670) and the Genome Aggregation Database (gnomAD, n = 76,156). We began with Phase I where we applied a low number of permutations (z = 100), and proteins that met nominal significance ($p < 0.01$) proceeded to Phase II at a higher permutation ($z = p < 1 \times 10\text{-}7$). Proteins that reached multiple-test correction significance ($p < 2.6 \times 10\text{-}6$) had GWS mutation clusters. After generating CLUMP results, we visualized clusters and compared them to previously mapped protein domains and regions using 3D protein structure analysis. We identified three GWS CLUMPed proteins (GNA01, PPP1CB, CREBBP) in comparison to the 1000G dataset. CLUMP analysis with gnomAD as a control dataset is underway, but we have identified four significant proteins (GNAO1, PSMC5, DDX23, and COG4), thus far. By updating the CLUMP workflow, we have been able to find six GWS CLUMPed proteins, two of which (PSMC5 and DDX23) are new candidate proteins that require functional assessment beyond the *in silico* approach. Overall, CLUMP allows for a method to assess clustering of rare missense mutations beyond the context of established protein domains. Significant mutation clusters can be further analyzed to identify new functional or therapeutic targets for NDDs.

Title: MECP2 gene replacement therapy shows efficacy in patient cell lines and a mouse model of Pitt Hopkins Syndrome

Authors: *C. DENNYS[1], K. RICH[2], J. SIERRA DELGADI[1], J. ZHANG[1], P. ANDRES CORNEJO[3], P. FRANCISCO FERNANDEZ[3], S. POWERS[1], R. RODRIGO[2], A. HARTLAUB[1], R. PINEDA[1], P. COGRAM[3], K. C. MEYER[4];
[1]Nationwide Children's Hosp., Columbus, OH; [2]The Ohio State Univ., Columbus, OH; [3]Univ. of Chile, Santiago, Chile; [4]Ctr. for Genetherapy, Res. Inst. Nationwide Childrens Hosp., Columbus, OH

Abstract: Pitt Hopkins Syndrome (PTHS) is a neurological disorder caused by mutations in the TCF4 gene leading to haploinsufficiency affecting 1 in 34,000 to 41,000 individuals. Patients present with developmental delays, intellectual disabilities, microcephaly and seizures along with a broad spectrum of behavioral symptoms. Unfortunately, the large size and number of different isoforms of TCF4 limits the use of gene replacement therapy for the treatment of PTHS. Furthermore, while neurons and oligodendrocytes are heavily implicated in disease pathology, little research has been performed on other non-cell autonomous contributions. Thus, identifying the roles of other cell types, such as astrocytes, in disease pathology is critical as gene therapy approaches must target disease relevant cell types. We have previously developed a rapid reprogramming method to convert patient skin fibroblasts to neuronal progenitor cells (NPCs). These cells can subsequently be differentiated into induced astrocytes (iAs) to investigate the contributions of iAs to PTHS. To evaluate the impact of TCF4 mutations on fibroblasts, NPCs, and iAs we used western blot, co-cultures, qPCR and immunostaining. Co-culture analysis demonstrated that PTHS iAs have a negative impact on neuron morphology and survival. Interestingly, we also observed that NPCs with deletion mutations have difficulty differentiating into iAs. Further proteomic analysis identified down regulation of MeCP2 protein levels in these patient lines. AAV9 mediated restoration of MECP2 in NPCs containing a TCF4 deletion restored differentiation defects previously observed. Given that TCF4 mutations are known to cause aberrant differentiation, these findings suggest that an MECP2 gene therapy approach may be an effective treatment strategy for PTHS. To evaluate this, we injected AAV9.MECP2 intracerebroventricularly (ICV) to P0-P1 TCF4 knockout mice. Behavioral analysis indicated amelioration of the aberrant phenotype in AAV9.MECP2 injected mice demonstrating that

MECP2 gene therapy might be a promising therapeutic strategy for PTHS. Combined, for the first time, this data demonstrates that astrocytes play a critical role in PTHS disease pathology. Furthermore, current limitations to PTHS gene therapy may be circumvented by utilizing an alternative, MECP2 gene replacement approach. Thus, we have discovered a new disease mechanism for PTHS in addition to identifying a novel therapeutic approach.

Title: Molecular changes in Prader-Willi syndrome neurons reveals clues about increased autism susceptibility.

Authors: *A. VICTOR[1], M. DONALDSON[2], D. JOHNSON[3], W. MILLER[3], L. T. REITER[4]; [1]Univ. of Tennessee Hlth. Sci. C Neurosci. Grad. Program, Memphis, TN; [2]Dept. of Pediatric Dent., [3]Mol. Bioinformatics Core, [4]Neurol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Prader-Willi syndrome (PWS) is a neurodevelopmental disorder characterized by hormonal dysregulation, obesity, intellectual disability, and behavioral problems. Most PWS cases are caused by paternal interstitial deletions of 15q11.2-q13, while a smaller number of cases are caused by maternal uniparental disomy (UPD), where only maternal copies of the PWS critical region are present. The PWS critical region is imprinted, meaning certain genes on the maternal chromosome are silent in neurons, resulting in a phenotype that is milder than, but equivalent to PWS cases where the paternal copies are deleted. There are, however, notable phenotypic differences between PWS Deletion (PW-del) and PWS UPD (PW-UPD). PW-UPD cases show milder phenotypes but are associated with an increased risk of developing autism spectrum disorder (ASD) and cycloid psychosis. Understanding the molecular differences

between PW-del versus UPD cases may provide clues to this increased risk for ASD. We have established a large collection of dental pulp stem cell (DPSC) lines derived from the teeth of subjects with various neurogenetic disorders. We regularly differentiate these stem cell lines into cortical-like neuronal cultures. Using neuronal cultures derived directly from DPSC of affected individuals and neurotypical controls, we preformed RNAseq studies to investigate differential gene expression changes associated with PWS subtypes and increased ASD risk. We found key molecular differences between PW-del and UPD both within and outside of the 15q region. In addition to genes that are specific to each class, we found 9 transcripts outside of the 15q critical region that may contribute to a core PWS phenotype, including *SNTB2*, which is involved in the regulation of secretory granules. In the PW-UPD +ASD group, we found 380 transcripts significantly differentially expressed versus the -ASD groups. Enrichment analysis revealed a strong decrease in mitochondrial-associated transcripts in this transcript set. Immunocytochemistry revealed not only a significant reduction in mitochondrial volume, but also a mitochondrial aggregation phenotype in the UPD +ASD neurons. Decreased mitochondrial metabolism in PWS neurons may cause changes in synaptic function that underlie the increased risk for ASD in PW-UPD individuals.

Title: Effect of the combination of β-caryophyllene and cannabidiol in a murine model of Dravet syndrome

Authors: C. ALONSO[1,2,3], V. SATTA[1,2,3], I. HERNÁNDEZ[4], J. FERNÁNDEZ-RUIZ[1,2,3], ***O. SAGREDO**[1,2,3];

Ramón y Cajal de Investigación Sanitaria (IRYCIS), Madrid, Spain; [4]Dept. de Bioquímica y Biología Molecular, Facultad de Medicina, Madrid, Spain

Abstract: Dravet syndrome (DS) is a genetic epileptic encephalopathy usually caused by mutations in the Scn1a gene, which encodes the α1 subunit of the voltage-gated sodium channel

$Na_V1.1$. Clinically, patients are affected by multiple types of seizures that begin at very early ages of development and generate several behavioural comorbidities that accompany individuals throughout their lives. Patients are currently resistant to treatment with antiepileptic drugs, and lack of efficacious disease-modifying therapies. Recent clinical evidences have demonstrated that the cannabidiol (CBD), formulated and licenced as Epidiolex, has potential to reduce seizure frequency and intensity in these patients, and might serve as a disease modifier too. The objective of this study was to investigate whether β-caryophyllene (BCP), a terpenoid with a broad-spectrum profile abundantly found in the *Cannabis sativa* plant, is also a good candidate both for controlling seizures and for attenuating/delaying the progression of associated comorbidities. As a second objective, we also investigated the potential of the combination of CBD and BCP to improve the therapeutic management in DS. To this end, we used a new experimental model of DS, which consisted of heterozygous conditional knock-in mice carrying a missense mutation (A1783V) in *Scn1a* gene expressed exclusively in neurons of the CNS (Syn-Cre/Scn1a$^{WT/A1783V}$), using two different experimental approaches. In a first approach, we evaluated the anticonvulsant effect of BCP against the proconvulsant agent pentylenetetrazol (PTZ). Our data proved that Syn-Cre/Scn1a$^{WT/A1783V}$ mice are more susceptible than wildtype animals to PTZ, whereas BCP reduced its proconvulsant activity in both genotypes. In a second approach, we investigated the effect of a chronic treatment with BCP, CBD and their combination on various behavioural comorbidities associated with the progression of DS in Syn-Cre/Scn1a$^{WT/A1783V}$ mice. The three treatments corrected the behavioural alterations observed in these mice and delayed their premature mortality, with the combined treatment being the most effective. The reactive astrogliosis and observed in the prefrontal cortex and the hippocampal dentate gyrus of Syn-Cre/Scn1a$^{WT/A1783V}$ mice was also reduced after the three treatments and once again the combined treatment was the best option. In conclusion, this study confirms the potential of CBD as a disease modifier in DS, proposes an additional phytocannabinoid, BCP, as an alternative symptom-alleviating and disease-modifying agent, and provides the first evidence that their combination may be a promising therapeutic strategy for the treatment of DS.

Title: Delta EEG rhythms are increased in Angelman syndrome during overnight sleep

Authors: *N. HOSAMANE[1], Y. LEVIN[1], B. D. PHILPOT[2], Z. FAN[2], M. S. SIDOROV[1]; [1]Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., Washington DC, DC; [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: Angelman syndrome (AS) is a neurodevelopmental disorder resulting from decreased expression of the maternal copy of the paternally imprinted *UBE3A* gene on chromosome 15. AS is characterized by intellectual disability, impaired speech and motor skills, and sleep abnormalities but currently lacks any treatment. However, mouse models have shown that unsilencing the dormant paternal copy of *Ube3a* has been an effective mechanism to restore the functionality of the UBE3A protein, thus clinical trials using this approach are on the near horizon. Developing biomarkers is essential for assessing responses to treatment when clinical trials begin, and our prior work quantifying clinical EEGs has defined promising biomarkers for AS. Here, we sought to extend analyses to periods of overnight sleep, as sleep impairments affect ~90% of individuals with AS. We retrospectively analyzed twelve overnight sleep studies from patients with AS with age and sex matched Down syndrome and neurotypical controls. We specifically examined low-frequency (2-4 Hz) delta rhythms and sleep spindles during NREM sleep. Delta rhythms were increased during overnight sleep in AS, and the magnitude of delta abnormalities was comparable between periods of wake and periods of sleep. There were no changes in the number or duration of sleep spindles in AS, but spindles did occur at slightly higher frequencies. Overall, we conclude that periods of wakefulness are sufficient, and perhaps ideal, to quantify delta rhythms for use as biomarkers.

Title: Functional and structural differences in the brains of one-year-old infants with Turner Syndrome in comparison to typically developing children

Authors: *R. BLANCHETT[1], H. CHEN[2], E. CORNEA[3], M. DAVENPORT[4], D. REINHARTSEN[5], M. DERAMUS[5], R. PRETZEL[5], J. H. GILMORE[7], S. HOOPER[6], M. A. STYNER[8], W. GAO[9], R. KNICKMEYER[1];

Sci., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Turner syndrome (TS), or X monosomy, is often accompanied by deficits in executive function, visuospatial reasoning, and social cognition. Magnetic resonance imaging studies of adults and school-age children with TS suggest these deficits may reflect differences in anatomical and functional connectivity. However, no imaging studies have explored anatomical and functional connectivity in infants with TS. Consequently, it is unclear at what point in development connectivity differences emerge. To address this gap, we compared functional and structural connectivity of one-year-old infants with TS to typically developing boys and girls of the same age. We examined functional connectivity between the right precentral gyrus and the following regions: right and left calcarine cortex, right and left lingual cortex, and right supramarginal cortex. Regions were selected because they show reduced volume in 1-year old infants with TS compared to either male or female controls. To assess anatomical connectivity, we examined diffusivity indices along the superior longitudinal fasciculus (SLF). We focused on the SLF because DTI studies of adults and school-age children with TS have revealed differences in white matter microstructure of this tract. An exploratory analysis of 31 additional white matter tracts was also performed. TS and control groups did not differ in radial, axial, and mean diffusivity, or fractional anisotropy along the SLF. However, exploratory analyses revealed significant group differences in axial, radial, and mean diffusivity along the temporoparietal segments of the left and right arcuate fasciculi. Results indicate that some connectivity differences observed later in development of TS individuals are not present at one year, suggesting early intervention could prevent some of these differences and, by extension, some of the cognitive challenges associated with TS. However, significant differences in the left and right arcuate fasciculi appear to arise very early in development and could have implications for cognitive processes related to these tracts including auditory spatial attention, visuospatial cognition, and mathematical operations.

Title: Using automated, objective facial measurements to characterize facial dysmorphology as a potential risk factors in psychosis.

Authors: *M. KRALL[1], D. R. ROALF[2], J. JEE[3], D. MCDONALD-MCGINN[4], R. T. SHINOHARA[1], L. WHITE[4], E. MCCLELLAN[4], A. CROW[1], T. B. CROWLEY[4], A. BAILEY[4], R. S. GALLAGHER[4], V. GONZENBACH[1], P. J. MOBERG[1], B. I. TURETSKY[1], C. KOHLER[1], R. C. GUR[5], E. CHEN[4], R. E. GUR[1], K. GAISER[1], D. Pennsylvania, Philadelphia, PA

Abstract: Background. Psychosis is a brain disorder that typically develops during adolescence or young adulthood and 22q11.2 deletion syndrome (22q11DS) is a chromosomal deletion that is highly associated with psychosis-spectrum (PS) disorders. Individuals with 22q11DS are known to have facial dysmorphology while these features have been documented in individuals with schizophrenia, which are likely due to disruptions of prenatal development. These minor physical abnormalities (MPA) of the face may be informative in understanding the nature and timing of risk factors for brain disorders like psychosis. Thus, the aim of the current study is to compare facial features among four groups (22q11DS; schizophrenia (SZ); clinical high risk for psychosis (CHR); and healthy individuals) to determine whether people with psychosis spectrum disorders and 22q11DS exhibit similar MPAs. **Methods.** 2D facial images were collected from patients with 22q11DS (n=171), SZ (n=37), CHR (n=16) and HC (n=94). Images were analyzed using the software Emotrics, a newly developed, machine-learning algorithm that provides automated, objective facial measurements using 68 facial coordinates that are automatically placed. Facial landmarking in Emotrics outlines the superior border of the brow, the free margin of the upper and lower eyelids, the nasal midline, the nasal base, the mucosal edge and vermillion-cutaneous junction of the upper and lower lips, and the lower two-thirds of the face. The outcome measures from Emotrics included eyebrow height, marginal reflex distance (MRD), and palpebral fissure (PFH). **Results.** As expected, we found that across all features, those with 22q11DS differed the most from the HC group, however SZ and CHR showed similar patterns as those with 22q11DS. As compared to HC, 22q11DS and SZ showed smaller MRD ($p<0.001$) and PFH ($p<0.001$), while CHR only showed lower MRD ($p<0.008$). Specificity analysis indicated that MRD differences were most prominent from the pupil to top eyelid. There were no differences in brow height. **Conclusion** These preliminary results suggest overlap in facial dysmorphogenesis between 22q11DS and psychosis. Results are promising and suggest that individuals with psychosis exhibit a similar pattern of facial MPAs to those with 22q11DS, which may help understand the developmental basis for this complex brain disorder.

Title: Differential expression of plasticity of the medial and lateral perforant path input to the dentate gyrus in a neurodevelopment model of schizophrenia

Authors: *L. A. MÁRQUEZ, C. LÓPEZ-RUBALCAVA, E. J. GALVÁN;
Pharmacobiology, CINVESTAV, Ciudad de Mexico, Mexico

Abstract: Differential expression of plasticity of the medial and lateral perforant path input to the dentate gyrus in a neurodevelopment model of schizophrenia
Transient hypofunction of the NMDA receptor-mediated synaptic transmission during early postnatal development induces schizophrenia-like behavior. Despite the growing effort to understand the role of the hippocampus on the pathophysiology of schizophrenia, little is known about alterations in the synaptic transmission conveyed by the entorhinal cortex and the dentate gyrus (DG). We performed extracellular recordings (fEPSPs) on juvenile acute hippocampal slices (P30-P35) to explore alterations in synaptic transmission of the medial perforant path (MPP) and lateral perforant path (LPP) to the DG in animals treated with MK-801 (0.2 mg/kg s.c; P7-P11). We found that synaptic strength is decreased in the MPP – DG synapse, whereas the opposite occurs in the LPP – DG synapse. When comparing the paired-pulse ratio (PPR), we found that only LPP-DG synapses of MK-801 slices showed a reduction in neurotransmitter release probability. In addition, theta-burst stimulation failed to induce stable LTP in the LPP – DG synapse and induced a blunted response in the MPP – DG synapse of the MK-801 treated animals, indicating that the somatosensorial processing of the DG (spatial information for MPP and contextual information for LPP) exhibit dysregulation and likely, cognitive impairment. Therefore, we evaluated the performance of MK-801 treated rats in the Barnes maze, a hippocampus-dependent task. Compared to control, the MK-801 treated animals exhibited impaired performance. Collectively, these results indicate altered information transfer from the entorhinal cortex to DG that is reflected in altered synaptic transmission and impaired DG-related cognitive capabilities.

Title: Selective GSK3α and β inhibition alters working memory-related behavior in a mouse model of 22q11.2 deletion syndrome

Authors: *C. M. ALOIMONOS[1], J. PASSECKER[2,1,3], C.-Y. CHANG[3], A. DAGUNTS[1], D. A. KUPFERSCHMIDT[1], J. A. GOGOS[3], J. A. GORDON[4];

Abstract: Overactivation of the Glycogen Synthase Kinase (GSK3) pathway has been implicated in a variety of neurological and psychiatric disorders. Non-selective GSK3 (α and β isoform) inhibitors have been found to rescue cognitive deficits in a variety of preclinical models, but their non-selective profiles hamper their preclinical research utility. Recently developed selective inhibitors allow targeted inhibition of each isoform, but their impacts on cognition and disease-relevant cognitive dysfunction are unresolved. Here, we tested their potential to rescue spatial working memory deficits in the *Df(16)A*$^{+/-}$ mouse model relevant to the 22q11.2 deletion syndrome. The selective GSK3β inhibitor BRD3731 administered in early postnatal development (P7-P28) rescues acquisition deficits in spatial working memory in male but not female *Df(16)A*$^{+/-}$ mice (n = 121, p=0.01, 3-way ANOVA). GSK3β inhibition also rescued deficits in theta frequency (4-12 Hz) coherence between ventral hippocampus and medial prefrontal cortex, a neurophysiological correlate of spatial working memory performance, in *Df(16)A*$^{+/-}$ mice (n=98, p=0.02, 3-way ANOVA). By contrast, selective postnatal GSK3α inhibition with BRD0705 failed to rescue task acquisition deficits, while it did reverse deficits in task performance under conditions of increased memory demand in both male and female *Df(16)A*$^{+/-}$ mice (n=109, p=0.003, 3-way ANOVA). Detailed behavioral tracking revealed no evidence of differences in locomotor behavior that could explain these effects. Overall, this work indicates differential roles of GSK3α and β isoforms in the development of the neural circuits that support spatial working memory and its disease-relevant dysfunction in mice. Ongoing transcriptomic analysis of the medial prefrontal cortex and ventral hippocampus of wildtype and *Df(16)A*$^{+/-}$ mice at various developmental stages stands to inform the molecular basis of our behavioral and neurophysiological findings.

Title: Alterations in neural circuit function during working memory task acquisition in Setd1a-deficient mice

Authors: *M. J. RAILING[1], S. HUPALO[1,2], M. V. MYROSHNYCHENKO[1], J. A. GOGOS[3], D. A. KUPFERSCHMIDT[1], J. A. GORDON[4,1];
[1]Integrative Neurosci. Section, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD; [2]Postdoctoral Res. Associate Training Program, Natl. Inst. of Gen. Med. Sci., Bethesda, MD; [3]Zuckerman Inst., Columbia Univ., New York City, NY; [4]Office of the Director, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Heterozygous null mutations of *SETD1A* are definitively linked to an increase in schizophrenia risk. Mice carrying a heterozygous loss-of-function mutation in *Setd1a* have been shown to exhibit deficits in working memory, a cognitive function disrupted in schizophrenia. To explore the neurobiological consequences of SETD1A haploinsufficiency, we examined connectivity within a circuit including the ventral hippocampus (vHPC), medial prefrontal cortex (mPFC) and nucleus reuniens (Re) of the thalamus, three regions necessary for successful working memory performance in rodents, in *Setd1a*-deficient mice. Adult male and female *Setd1a*$^{+/-}$ and C57/BJ wildtype (WT) littermate controls were trained in a delayed non-match-to-sample test of spatial working memory. Local field potentials were recorded in the mPFC, Re, and the CA1 region of the vHPC before and throughout task training. Experimenters were blinded to genotype. We observed that *Setd1a*$^{+/-}$ mice acquired the working memory task comparably to WT controls (p=0.633, WT, n=28; *Setd1a*$^{+/-}$, n=24, two-way ANOVA). We examined coherence, a measure of neural synchrony, prior to working memory training. *Setd1a*$^{+/-}$ mice displayed significantly lower mPFC-Re theta (4-12 Hz, p=0.02, two-way ANOVA) synchrony and non-significant decreases in gamma (30-80 Hz, p=0.09) synchrony relative to controls (WT, n=14; *Setd1a*$^{+/-}$, n=8). Conversely, among the vHPC-mPFC and vHPC-Re circuits, we observed trends toward an increase in gamma (vHPC-mPFC, p=0.27; vHPC-Re, p=0.08) and theta (vHPC-mPFC, p=0.15; vHPC-Re, p=0.21) synchrony before training. During task training, *Setd1a*$^{+/-}$ mice (WT, n=12; *Setd1a*$^{+/-}$, n=9) exhibited significant decreases in mPFC-Re theta

neural synchrony (p=0.001) while displaying no significant changes in gamma synchrony (p=0.15) compared to WT mice, similar to that seen before task learning. Moreover, we found no differences in vHPC-mPFC (WT, n=11; *Setd1a*$^{+/-}$, n=11) and vHPC-Re (WT, n=8; *Setd1a*$^{+/}$, n=11) theta (vHPC-mPFC, p=0.29; vHPC-Re, p=0.6) and gamma coherence (vHPC-mPFC, p=0.058; vHPC-Re, p=0.06) between *Setd1a*$^{+/-}$ mice and WT controls. These data suggest that alterations in synchrony among *Setd1a*$^{+/-}$ mice reflect stable alterations in connectivity within the mPFC-Re circuitry that exist prior to task training. Future studies aimed at validating these results will examine how vHPC and Re theta and gamma oscillations modulate mPFC neuronal spiking. Finally, understanding the neurophysiological consequences of haploinsufficiency of a definitive schizophrenia risk gene will provide insights into the neural mechanisms underlying the cognitive processes that are altered in this disorder.

Title: Schizophrenia risk gene FXR1 maintains prefrontal parvalbumin interneuron functions through enhancing Cav3.2 expression

Authors: *M. SHEN[1], Y. GUO[1], Q. DONG[2], Q. CHANG[4], X. ZHAO[3];
[1]UW-Madison, Madison, WI; [2]Waisman Ctr., [3]Dept Neurosci, Univ. of Wisconsin-Madison, Madison, WI; [4]Genet & Neurol, Univ. Wisconsin-Madison, Madison, WI

Abstract: FXR1, a mutation-intolerant and high confident risk gene for schizophrenia, encodes a brain-enriched RNA binding protein, but its function in the brain remains unclear. Parvalbumin interneurons (PVI) are essential for sensory processing, working memory, and cognition and are impaired in psychiatric disorders including schizophrenia. We show that FXR1 has important roles in PVIs. Deletion of FXR1 from PVIs leads to reduced PVI excitability and synaptic transmission, impaired prefrontal cortical gamma oscillation and synchronization, and behavioral deficits resembling psychiatric disorders. PVI-specific translational profiling reveals that FXR1 binds Cacna1h encoding a T-type calcium channel Cav3.2. Inhibition of Cav3.2 phenocopies

FXR1 deficiency whereas elevation of Cav3.2 in PVIs or stimulation of PVI activities rescues behavioral deficits of mice with FXR1 deficiency. We have unveiled the function of a newly identified schizophrenia risk gene FXR1 in PVI excitability, circuit function, and behavior. We have identified Cav3.2 as a potential target for treating psychiatric disorders.

Title: Longitudinal assessment of developmental changes in the structure and function of white matter tracts in adolescent minipigs

Authors: *P. KOCHUNOV[1], A. T. SUMMERFELT[1], P. L. BROWN[1], M. C. TERZI[2], K. YACHERA[2], K. V. SATHYASAIKUMAR[1], X. DU[1], L. E. HONG[1], R. SCHWARCZ[1], *P. D. SHEPARD[1];
[1]Dept. of Psychiatry/MPRC, [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Most translational animal models used to study structural and functional alterations in the organization of cerebral white matter in schizophrenia have serious limitations. Rodents have a lissencephalic cortex and a grey:white matter ratio that differs from humans; ferrets undergo gyrification after birth; and use of non-human primates is constrained by ethical and economic considerations. By contrast, Sinclair miniature pigs are born with a fully gyrencephalic brain and have a grey:white matter volume ratio similar to humans. Pigs mature over a 4-6 month interval which is more extensive than rodents but compressed relative to primates, making them well suited for longitudinal studies of adolescent brain development. In the present series of experiments, we used quantitative diffusion weighted imaging (DWI) and evoked potential (EP) recording to assess the maturation of cerebral white matter in adolescent Sinclair miniature pigs. Animals underwent four EEG/MRI sessions on PND 98, 138, 166 and 194. Imaging was conducted in a Siemens 3 Tesla Prisma scanner and a 15-channel knee coil. A higher resolution anatomical (0.5mm isotropic) DWI protocol (1.25mm isotropic), proportionally scaled to the resolution used in humans, consisted of 15 b-shells (b = 0-3500 s/mm2) with 32-directions/shell. Data were analyzed using diffusion kurtosis and bi-exponential modeling that provide fractional anisotropy radial kurtosis, kurtosis anisotropy, axial kurtosis, tortuosity, and permeability-diffusivity index of cerebral white matter. EEG recordings were acquired with a Neuroscan

Synamp2 (5 kHz sampling rate; bandpass of 0.1-200 Hz) immediately before imaging from subdermal platinum-iridium needles. Following a 5-minute resting EEG recording, monocular visual EPs were elicited by light flashes (300 stimuli @ 1 Hz, 10 - 500 ms duration) generated by a Lifelines photic stimulator. Auditory EPs were recorded in duration mismatch (80% standard, 60-ms 1000 Hz tones and 20% deviant 100 ms, tones presented in pseudorandom order) and auditory steady-state (75 click trains presented at 2.5 Hz and 40 Hz) procedures. All stimuli were applied at 72 dB through inserted earphones (Etymotic ER-1). We expect to observe significant changes in DWI parameters consistent with the structural maturation of cerebral white matter during adolescence. We further anticipate that these changes will be reflected by coincident changes in the amplitude and conduction speed of visual and auditory EPs. These studies provide foundational experiments for assessing the role of elevated kynurenic acid in white matter abnormalities and related cognitive impairments in people with schizophrenia.

Title: Dopamine neuron-specific manipulation of GRIN2A or GRIN2B influences adolescent behavior and psychostimulant sensitivity

Authors: M. L. KIELHOLD[1], D. S. JACOBS[1], A. P. BOGACHUK[1], A. HUNKER[2], L. ZWEIFEL[3], B. MOGHADDAM[1];
[1]Behavioral and Systems Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Allen Brain Inst., Seattle, WA; [3]Univ. of Washington, Seattle, WA

Abstract: Background: NMDA receptor dysfunction has long been implicated in the etiology of schizophrenia and other neurodevelopmental disorders. Recent whole exome/genome sequencing studies have further associated variants in genes encoding the GluN2A and GluN2B subunits of the NMDA receptor (GRIN2A and GRIN2B respectively) with schizophrenia diagnosis.

Critically, levels of these subunits continue to be dynamically regulated through adolescence and early adulthood, when symptoms of schizophrenia manifest. We are interested in studying the effect of cell-specific disruption of GluN2A or GluN2B during adolescence on behaviors and related functions that are relevant to symptoms of schizophrenia. Our focus here is on levels of GluN2A and GluN2B in dopamine neurons within the VTA as these neurons have been historically implicated in the pathophysiology of schizophrenia.
Methods: Cre-dependent CRISPR/SaCas9 viruses for GRIN2A and GRIN2B were injected into the VTA of th::cre male and female rats after weaning. Adolescent animals were tested on a battery of behavioral tasks and for sensitivity to psychostimulants. Postmortem tissue was analyzed by IHC or western blotting for GluN2A or GluN2B abundance.
Results: Treatment with virus led to a partial reduction of GluN2A (40%) and GluN2B (60%) in the VTA. Knockout (KO) of either GRIN2A or 2B in dopamine neurons of adolescent male or female rats did not influence baseline motor behavior in the open field or simple associative learning. Differences began to emerge in more complex paradigms such as the progressive ratio schedule of reinforcement, where response rates were disrupted in different ways for GRIN2A and GRIN2B KO groups suggesting that these manipulations cause hyperactivity and changes in incentive value of reward, respectively. In addition, we observed sex-specific effects of propsychotic drugs with amphetamine producing an exaggerated response in GRIN2B KO males and MK801 producing an exaggerated response selectively in GRIN2A KO females.
Conclusion: While further characterization is necessary, our results suggest that selective KO of GRIN2A and GRIN2B in adolescent dopamine neurons may provide useful models for some aspects of genetic vulnerability to schizophrenia.

Title: Evidence for a potential role of an increased copy number of the gene encoding glycine decarboxylase (GLDC) in the pathophysiology of psychosis

Authors: *M. KAMBALI[1], M. WANG[1,2], R. NAGARAJAN[1], J. LYU[2,1], J. LIU[3,4], E. ENGIN[3,4], G. HOMANICS[5], U. RUDOLPH[1,3,4];

Abstract: Genomic copy number variants (CNVs) have been implicated in the etiology of schizophrenia (SCZ) and bipolar disorder. In two patients with psychosis, a rare 9p24.1 CNV, a 1.8 Mb duplication/triplication involving multiple genes, including the GLDC gene encoding the glycine-degrading enzyme glycine decarboxylase, has been found by others. Our goal was to determine whether this CNV is sufficient to induce biochemical or behavioral phenotypes in mice and which gene(s) would be underlying these phenotypes. We hypothesized that an increased copy number of Gldc would lead to increased degradation of glycine, eventually resulting in NMDA receptor hypofunction and schizophrenia-like phenotypes. To address this, we developed mouse models with a triplication (4 copies) of the 9p24.1 genes, or a duplication (3 copies) or a triplication (4 copies) of Gldc alone or of all other 9p24.1 genes. These mice were subjected to qRT-PCR (n=5 each genotype), Western blot (n=10 each genotype) and behavioral studies (n=10 each genotype) at 2-4-month of age. In all genetic mouse models with increased copy numbers of Gldc we found an increase in GLDC protein in hippocampus (Hip), prefrontal cortex (PFC) and amygdala. The microRNA mir132 which has been linked to density of dendritic spines and which is downregulated in patients with schizophrenia was reduced in Hip and increased in PFC. In addition, BDNF mRNA was reduced in Hip and PFC of mice with 4 Gldc copies. However, expression of CREB, p-CREB and BDNF proteins was unaltered. MicroRNA mir137, the product of a risk gene for SCZ as evidenced by GWAS studies was increased in PFC. Furthermore, only in mice with increased Gldc copy number but not in mice with increased copy numbers of the other 9p24.1 genes, we found key behavioral deficits, i.e., startle habituation impairment, absence of latent inhibition to conditioned freezing, working memory deficits in both the Y- maze spontaneous alternation test and T- maze forced alternation tests and sociability deficits, along with social novelty preference deficits. Thus, an increase in the copy number of the Gldc gene is sufficient to induce molecular and behavioral features consistent with a schizophrenia-like phenotype. Our results suggest that in the patients with the 9p24.1 duplication/triplication the increase in GLDC copy number may be an important contributing factor to pathophysiology. The results are in line with our still to be tested overall hypothesis that an increased copy number of Gldc results in increased glycine degradation in astrocytes, leading to deficits in glycine-dependent activation of excitatory glutamate receptors of the NMDA type in neurons and NMDA receptor hypofunction.

Title: Vulnerability of parvalbumin circuits in basolateral amygdala following neonatal hippocampal damage in a monkey model of neurodevelopmental disorders

Authors: G. BAROKAS[1], P. E. MOON[2], J. BACHEVALIER[3], ***H. RODMAN**[2];
[1]Neurosci. & Behavioral Biol. Undergraduate Program, [2]Dept. of Psychology, [3]Yerkes Primate Ctr., Emory Univ., Atlanta, GA

Abstract: Schizophrenia (SCZ) and related neurodevelopmental disorders are associated with alterations in circuits involving the hippocampus, amygdala, and prefrontal cortex. In particular, early damage to the hippocampus may contribute to the pathophysiology of SCZ by inducing maldevelopment of GABAergic circuits within the fronto-limbic system. In monkeys, damage to the hippocampus early in life produces alterations in socioemotional behavior, underscoring a possible contribution of shifts in maturation of the amygdala. Finally, parvalbumin (PV) is a calcium-binding protein characteristic of subpopulations of GABA neurons that have been implicated in SCZ. Thus, we predicted that a neonatal hippocampal lesion would disrupt the maturation of PV cell populations within the amygdala. We used tissue from adult rhesus monkeys (*M. mulatta*) that had sustained bilateral ibotenic acid lesions of the hippocampus as neonates (Neo-H, n = 5) or sham controls (n= 6) to analyze the morphologies of PV+ interneurons and relative density of PV+ neuropil in the basal amygdala. PV cells were classified based on the descriptions of Pitkanen & Amaral (1993) in which Type I ('simple' in our terminology) neurons are mainly small and round, whereas Types II and III have more elaborate morphologies. We classified all PV+ neurons at three levels within the dorsal and ventral portions of the basal nucleus and the paralaminar nucleus to obtain a ratio of neurons with simple vs. elaborate morphologies. PV+ fibers were counted using a stereological strategy and expressed as a ratio of mean fiber density in DB:VB. Amygdalae from Neo-H cases had lower ratios of simple: elaborate neurons in both subdivisions of the basal nucleus, suggesting that early hippocampal lesions interfere with normal maturational processes of inhibitory cell morphology in the primate amygdala. Amygdalae from Neo-H cases also showed a strikingly lower density of PV+ fibers in the dorsal basal relative to the ventral basal in comparison with the equivalent ratio in controls, suggesting a redistribution of PV+, GABAergic connections from the dorsal to the ventral portion of the basal nucleus. Together, the results indicate that early lesions of the hippocampus in monkeys produce significant alterations in the internal inhibitory circuitry of the amygdala, and highlight the vulnerability of this PV+ population to

early-life perturbation. These results indicate that the effects of neonatal hippocampal lesions on behavior and frontal lobe function may include disruptions of the development of specific amygdala circuitry as part of a broader profile of limbic-frontal disconnection in neurodevelopmental disorders.

Title: Perinatal omega-3 fatty acid supplementation rescues the aberrant cognitive and affective symptomology in a prenatal cannabis exposure model of schizophrenia

Authors: *M. SARIKAHYA[1], S. L. COUSINEAU[2], M. DE FELICE[1], M. G. NASHED[1], H. SZKUDLAREK[1], K. K.-C. YEUNG[2], D. HARDY[3], W. J. RUSHLOW[4], S. LAVIOLETTE[4]; [1]Anat. and Cell Biol., [2]Chem. and Biochem., [3]Obstetrics and Gynaecology and Physiol. and Pharmacol., [4]Anat. and Cell Biology, and Psychiatry, Univ. of Western Ontario, London, ON, Canada

Abstract: Clinical and preclinical studies indicate prenatal cannabis exposure (PCE) pathologically effects fetal brain development and may increase vulnerability to neuropsychiatric disorders, including schizophrenia, cognitive and mood/anxiety disorders. However, the underlying mechanisms remain unknown. Research in our lab suggests that fetal exposure to Δ9-tetrahydrocannabinol (THC) impairs neurodevelopment, in part, through the alteration of cortical fatty acids. Considerable evidence demonstrates that abnormal omega-3 (N3) fatty acid signaling may underlie various neuropsychiatric disorders. In addition, evidence has shown that dietary interventions with N3 fatty acids may prevent or ameliorate neuropsychiatric symptom profiles. The present study examined if perinatal supplementation with N3-fatty acids may rescue neuronal, behavioural and molecular neuropsychiatric phenotypes induced by pre-natal THC exposure. Pregnant Wistar rats were assigned to saline (VEH) or 3mg/kg THC (daily, *i.p.*) from gestational day (GD) 7-22. Dams were given an N3 enriched diet vs. standard control diet (control: CT) *ad libitum* from GD 7 to postnatal day (PND) 21 of the offspring. Treatment groups were: VEH/CT, VEH/N3, THC/CT and THC/N3. On PND 21, a subset of male and

female offspring was sacrificed for molecular analyses. Between PND 35-45, and PND 90-120, subsets of male/female offspring underwent behavioural tests for memory, social and novelty-induced anxiety, sensory integration, and depression. The subsets were later used for *in vivo* electrophysiology or molecular analyses and Matrix-Assisted Laser Desorption/Ionization Imaging Mass Spectrometry. Our adolescent behavioural data indicated a sex-specific N3-mediated therapeutic effect on PCE-induced behavioural phenotypes. For the male rats, VEH/N3s exhibited significantly less anxiety than either the VEH/CT or THC/CT groups, but the THC/N3 group showed a similar level of anxiety as the THC/CT group. However, the N3 diet prevented memory and sociability impairments seen in the male THC/CT group. The female VEH/N3 and THC/N3 groups exhibited significantly lower anxiety and improved social and working memory compared to their THC/CT group. Thus, female rats experience a broader therapeutic effect than males. Given that N3's interact with estrogen receptors, this interaction will be further explored. Behavioral, electrophysiological, molecular, and fatty acid profile analyses are currently ongoing. These findings suggest that dietary interventions aimed at N3-fatty acid normalization may be a promising therapeutic option for cannabis-induced neurodevelopmental pathologies.

Title: Adolescent thalamic inhibition leads to long-lasting impairments in prefrontal cortex function

Authors: *L. J. BENOIT[1], E. HOLT[1], L. POSANI[1], S. FUSI[2], A. HARRIS[1], S. E. CANETTA[3], C. KELLENDONK[4];
[2]Neurosci., [3]Div. of Mol. Therapeut., [1]Columbia Univ., New York, NY; [4]Columbia Univ. Press, New York, NY

Abstract: Impaired cortical maturation is postulated as a mechanism in the etiology of neurodevelopmental disorders, including schizophrenia. In sensory cortex, activity relayed by the thalamus during a sensitive postnatal time window is essential for proper cortical maturation. Whether thalamic activity also shapes prefrontal cortical maturation is unknown. Here, we show

that inhibiting the midline thalamus during adolescence leads to a long-lasting decrease in the density of thalamo-prefrontal projections and attenuated cortical excitation. Thalamic inhibition during adolescence also causes prefrontal-dependent cognitive deficits during adulthood that are associated with disrupted single unit cross-correlations and impaired task outcome encoding in the prefrontal cortex. In contrast, inhibiting the thalamus during a comparable time window in adulthood has no long-lasting consequences. Strikingly, exciting the thalamus in adulthood during a cognitive task rescues prefrontal cross-correlations, task outcome encoding, and the cognitive deficit. These data point to adolescence as a sensitive time window of thalamo-cortical circuit maturation. Furthermore, by supporting prefrontal network activity and encoding, boosting thalamic activity provides a potential therapeutic strategy for rescuing cognitive deficits in neurodevelopmental disorders.

Title: Mechanisms of cerebellar microglia dynamics

Authors: *M. B. STOESSEL, R. D. STOWELL, A. K. MAJEWSKA;
Neurosci., Univ. of Rochester, Rochester, NY

Abstract: Synaptic plasticity allows the central nervous system (CNS) to incorporate new sensory experiences and information, and its disruption is associated with many neurological and psychiatric disorders. Much recent work has focused on the contribution of non-neuronal CNS cells, especially microglia, to synaptic plasticity. Though classically thought of in their immune capacities, microglia are vital to many homeostatic processes, including synaptic plasticity of nascent and adult neuronal networks. Despite the emerging consensus that microglial dynamics are critical to brain function during physiological as well as pathological conditions, it is unclear whether these microglial roles and their underlying mechanisms are universal or differ between

brain regions. There is a growing body evidence to suggest microglia exhibit a high degree of regional specialization; existing on a continuum from homeostatic (cortex) to immune vigilant (cerebellum) even in the absence of pathological stimuli. Indeed, microglia in the cerebellum represent a distinct population, exhibiting unique transcriptional and epigenetic profiles, along with distinct functional properties, such as being more phagocytic, morphologically less ramified and less densely distributed. As a consequence, cerebellar microglia survey less of parenchyma than cortical microglia, but compensate for this by undergoing frequent somatic translocations under homeostatic conditions, a phenomenon not observed in cortex. Despite these differences, cerebellar microglia maintain common microglial functions, exhibiting a robust injury response and dynamic interactions with surrounding neural elements. Two pathways of interest to cortical microglial mediated synaptic plasticity include noradrenergic signaling through the β_2 adrenergic receptor (β_2-AR) and purinergic signaling through the P2Y12 receptor, both of which have been shown to be critically involved in microglial roles in synaptic remodeling and rapid chemotaxis to sites of injury. We used time-lapse *in vivo* imaging through a chronic cranial window preparation to visualize cerebellar microglial dynamics while β_2-AR and P2Y12 signaling were manipulated. We found that β_2-AR stimulation reduced microglial surveillance in both the cortex can cerebellum but slightly reduced cerebellar soma migration. Lastly, we demonstrated that P2Y12 deficiency did not alter the response of cerebellar microglia to focal injury, unlike what is seen in cortical microglia. These findings show that cerebellar microglia likely use a distinct set of molecular cues to guide dynamic responses in both homeostatic and pathological conditions.

Title: Dissecting the regulation of a spatiotemporally distinct microglial state in postnatal development

Authors: *Y. DE SOYSA[1,3,4], A. C. WALKER[1], A. J. WALKER[1,3,4], B. STEVENS[1,3,4,2];

Abstract: Microglia are brain-resident macrophages that regulate critical processes in neurodevelopment; dysregulation of microglial identity has been linked to neurodevelopmental disorders. Single-cell transcriptomics studies have identified dynamic microglial states throughout life, with the greatest heterogeneity appearing during the embryonic and early postnatal period. These states express a core gene signature defining their microglial identity, but also exhibit unique transcriptional programs indicative of discrete behaviors and functions. A critical gap in knowledge centers on how these states are transcriptionally regulated in distinct developmental contexts. Precisely mapping the mechanisms of microglial state regulation during normal development provides a framework for understanding how their perturbation contributes to neurodevelopmental disease progression and informing the development of therapeutic strategies. Axon Tract-associated Microglia (ATM) are a highly dynamic state with a distinct transcriptional profile that appears in the white matter axon tracts of the corpus callosum and cerebellum during the first postnatal week in mice, and in late gestation in humans. Due to their distinct gene signature and defined spatiotemporal window of emergence, ATM represent a powerful *in vivo* paradigm to interrogate how the intersection of developmental origin, intrinsic gene regulatory programs and environmental signals shapes the transcriptional signature of a microglial state. In this work, we combined ATAC-sequencing with ATM-specific cre ablation and fate-mapping reporter models to dissect how ATM emergence and attrition are regulated. First, we identified candidate transcription factors that drive and distinguish the ATM gene signature from that of canonical microglia at P5, the peak of their emergence, with ATAC-seq analysis. Second, developmental ablation of these cells revealed that a compensatory population with a distinct chromatin accessibility profile upregulated the ATM signature to repopulate the compartment. Finally, fate mapping analysis revealed that ATM attrition does not occur by apoptosis, but that ATM downregulate their defining gene signature, become reintegrated into the broader homeostatic microglia pool and persist in the white matter into adulthood. Capture of ATM chromatin profiles during this transition revealed putative signaling and transcriptional drivers underlying this dynamic reintegration process. Overall, this work uncovers novel insights into the transcriptional dynamics and context-specific regulatory mechanisms of a distinct *in vivo* microglial state.

Title: Pharmacologic microglial depletion disrupts breathing and body temperature regulation during torpor in 13-lined ground squirrels

Authors: R. J. SPRENGER[1], A. B. RADCLIFF[2], A. L. MEZA[2], C. R. MICKELSON[2], A. WATTERS[2], W. MILSOM[1], H. V. CAREY[2], *J. WATTERS[2], T. BAKER[2];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Comparative Biosci., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Mammalian hibernation initiates dramatic changes in physiology that include large reductions in ventilation ($\dot{V}_E$), heart rate, oxygen consumption rate ($\dot{V}o_2$), and body temperature (T_b) upon entrance into torpor, effects that reverse upon arousal. Several physiologic processes must maintain function throughout a wide range of temperatures. Recent evidence indicates that neuronal synapses loosen and retract in regions of the brain that are silenced during a torpor bout, although little is understood yet about how these connections are regulated during hibernation. Microglia, brain resident immune cells, are potential facilitators of these essential neural homeostatic activities due to their critical roles in neuronal support and synaptic strengthening and pruning. Thus, we hypothesized that microglia are required for maintaining normal ventilatory neural control during hibernation. To test this, we treated 13-lined ground squirrels with either vehicle or colony-stimulating factor receptor-1 (CSF1R) antagonist, PLX3397 (80mg/kg, po), a receptor whose activation is necessary for microglial survival in the adult nervous system, and measured $\dot{V}_E$, $\dot{V}o_2$, and T_b throughout a torpor bout. During entrance, PLX-treated squirrels took ~1.5 hours longer to reach their minimum torpor temperature (T_b; 12°C) compared to control animals (T_b; 9.3°C) (ambient temperature; 5-6°C). Similarly, arousal time in microglia-depleted animals was as much as 1 hour longer relative to controls, despite starting at a higher minimum T_b. In both treatment groups, $\dot{V}o_2$ during entrance fell and spiked periodically. However, in PLX-treated animals, these spikes were much greater and more frequent. Minimum $\dot{V}o_2$ in torpor was ~3 times greater in PLX-treated animals compared to control animals. Upon arousal from torpor, $\dot{V}o_2$ remained elevated, longer, in PLX-treated squirrels. Total $\dot{V}_E$ tended to be elevated in PLX-treated animals through entrance, steady state torpor, and arousal, but it was most striking during steady state torpor, where $\dot{V}_E$ in PLX-treated animals was as high as 15-fold greater than control animals. The net result in torpor was an elevated air convection requirement, thus microglia-depleted animals hyperventilated throughout the torpor bout. Together, these results suggest that microglia play an important regulatory role in normal ventilatory and temperature control throughout torpor and influence the rate at which animals enter into and arouse from torpor. Mechanisms whereby microglia contribute to hibernation neurophysiology are currently under investigation. (Funded by NIH R01HL142752 (JJW and TLB), NSF IOS1558044 (HVC), and NSERC 22R87150 (WKM)).

Abstract: Microglia are the immune cells of the brain and expert phagocytes of harmful content for parenchymal homeostasis. Apoptotic neurons generated during development, in adult neurogenic niches, and neurodegenerative conditions leak toxic intracellular content compromising surrounding cells. Microglial phagocytosis avoids the spillover of toxic content and exerts immunomodulatory effects. However, we still do not know the molecular, metabolic, and functional effects of engulfing and degrading an apoptotic cell. To address this question, we first performed a global transcriptomic analysis of primary microglia exposed to apoptotic cells. The analysis showed that phagocytosis induced changes in metabolic gene expression, suggesting a positive regulation of glycolytic genes and a negative regulation of oxidative phosphorylation genes. We used Seahorse extracellular analyzer to confirm the reduction of mitochondrial metabolism, although we did not detect increased glycolysis. Phagocytosis-

induced metabolic changes were related to a strong remodeling of the mitochondrial network, with fewer and less complex mitochondria. These metabolic and mitochondrial changes compromised cell function, leading to a reduced engulfing capacity of microglia 24 hours after phagocytosis. Furthermore, to study phagocytosis-induced changes in vivo, we developed a "superphagocytosis" model using low cranial irradiation (2Gy), which induced apoptosis of newborn cells in the dentate gyrus and subsequent increase in microglial phagocytosis. This model offers several advantages to study phagocytosis in vivo, as it considerably increases the number of phagocytic microglia without damaging them or disrupting the blood-brain barrier (BBB). We are currently examining the transcriptome, ultrastructure, and function of phagocytic microglia by performing single-cell RNA-sequencing, electron microscopy, and functional analysis. This data will provide us with more information about the complex process of phagocytosis, a necessary knowledge to use microglia as a therapeutic target in diseases where phagocytosis is impaired.

Title: Differences in microglia and macrophage interaction with extracellular matrix environment

Authors: *S. PAULSON, M. STINSON, J. ROTTY;
Uniformed Services Univ., Bethesda, MD

Abstract: Microglia are becoming the forefront of neurodisease research as more studies develop the link between chronic microglial inflammation and disease pathways. To better understand what potential role these cells play in disease progression, it is important to first determine their interactions with the central nervous system (CNS) extracellular matrix (ECM). The ECM microenvironment is complex, containing at least two different types of cues: ECM composition and ECM stiffness. Our overarching hypothesis is that these two components will shift the behavior of microglia. Understanding the underlying mechanisms will help us appreciate how these components of the microenvironment influence microglia function. This

understanding can then potentially be translated to human disease settings. Previous research in our lab has established that the ECM microenvironment alters the migrational velocity and morphology of immortalized bone marrow derived murine macrophages without the presence of an extracellular gradient cue. We wondered whether we would replicate these results with immortalized murine microglia (BV2) cells and set out to compare their responses to those already established in macrophages. Findings that support similarities between microglia and macrophages would demonstrate that response to different ECM components is conserved across cell-types, while a divergent response would reveal important differences that might explain underlying physiological responses. We observed a morphological difference in microglia plated on the two ECM proteins fibronectin and laminin, as well as differences in velocity and directional persistence. BV2s demonstrated higher velocities on laminin, proceeding in a balled-up morphological state; BV2s plated on fibronectin demonstrated slower speeds and a more spread-out morphological state. These changes were similar to those we observed in macrophages. In addition, we performed motility experiments on variable stiffness polyacrylamide gels to more closely replicate the soft environment of the CNS compared to the glass dishes used in initial motility tests. Polyacrylamide gels at softer densities closer to that of the brain displayed increased velocity and directional persistence over gels with stiffer densities closer to that of glass. Ongoing experiments in the lab will continue to assess ECM context effects on microglia after they are activated by inflammatory cues. Future studies will determine the mechanistic character of the microglia ECM discrimination and mechanosensing pathways, and their in vivo relevance.

Title: Effect of neuronal cell adhesion molecule L1 on microglia grown on nanoparticle modified surfaces

Authors: *N. KUSHWAH, K. WOEPPEL, X. TRACY CUI;
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: ***Background:*** Neural recording electrodes often suffer from low recording yield and stability, which have been partly associated with the inflammatory host tissue responses to neural

probe implantation. The neuronal cell adhesion molecule L1 has been used as biomimetic coating for neural electrodes and demonstrated significant benefit in reducing glial scar formation, promoting electrode-neuron integration, and improving recording performance. Coating probes with L1 on a nanoparticle (NP) base layer further increased these beneficial effects. Two photon microscopy studies revealed that the L1 coating inhibits microglial spreading on neural probes at 2- and 6-hours post-implantation suggesting a specific interaction between the surface bound protein and microglia. However, the exact mechanism of L1-microglia interaction has not been understood. In this study we cultured primary microglia cells on various L1 modified surfaces (with and without nanoparticle base layer) in an effort to illustrate the exact effects of L1 and nanoparticle on microglia activation. ***Method:*** Microglial cells were extracted from E-18 fetus and grown on smooth and NP coated surfaces with and without L1. After stimulating with phorbol myristate acetate (PMA), Dihydrorhodamine 123 (DHR) staining and cytochrome c assay were performed to characterize the production of superoxide. ELISA for inflammatory markers was also performed following stimulation with lipopolysaccharide (LPS), to study inflammation. ***Results:*** Results showed reduced superoxide production, decreased pro-inflammatory cytokines (TNF alpha, IL-6, IL-1 beta) and increased level of anti-inflammatory markers (TGF beta 1 and IL-10) in L1 treated samples. Furthermore, microglia phagocytosis was studied and L1 significantly increased the number of phagocytic cells, which may translate to enhanced ability for removing the cellular debris caused by implantation injury. ***Conclusion:*** From these observations it can be concluded that L1 protein significantly reduces superoxide production and inflammatory response of microglial cells in response to insults and promote wound healing.

Title: Microglial culture shift: Finding factors to drive in vitro microglia towards an in vivo phenotype

Authors: *R. MISSALL, F. GIGASE, R. KUBLER, G. SNIJDERS, E. J. GARCIA REINO, L. DE WITTE;
Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Primary adult microglia rapidly lose their microglial-specific phenotype when they are isolated from the central nervous system (CNS) and put in culture. The sensitivity of microglia to even small environmental changes creates difficulty in extending *in vitro* results into *in vivo*

hypotheses and makes comparisons between experimental outcomes inconclusive and even contradictory. These problems are exacerbated by the lack of a standardized microglia culture protocol accurately representing the *in vivo* CNS environment. To address this issue, we first define a multi-faceted target phenotype, which we term the mature homeostatic microglial (MHM) phenotype. This includes a radially ramified morphology, motile processes with low overall cell mobility, and an RNAseq-based human microglial gene signature. Notably, this gene signature makes up a subset of genes in previously published microglia-specific gene signatures, and includes commonly seen genes such as *p2ry12*, *cx3cr1*, and complement factors, as well as genes such as *folr2* and *insr*. We next performed a consensus weighted gene correlation network analysis (WGCNA) on RNAseq data of 410 human microglia samples from one published dataset and two of our own unpublished, a significant improvement on the strength of *ex vivo* vs. *in vitro* comparisons done to date. Key gene networks identified include those enriched for GO terms associated with myeloid differentiation and signaling, cell migration, and intracellular transport. Alongside WGCNA, we perform a structural literature review, and combine these results to build a list of factors that have been shown or are predicted to drive the MHM phenotype. This list includes factors already in use, such as CSF1 and IL-34, along with lesser investigated factors such as cholesterol and semaphorins. Lastly, we perform experiments to assess the effects of the identified factors on human primary microglia *in vitro*. Together, this will contribute to development of a standardized culture protocol that mimics the *in vivo* CNS environment, thereby better enabling molecular and cellular studies of adult primary microglia.

Title: Minimizing the ex vivo confounds of cell-isolation techniques on transcriptomic profiles of purified microglia

Authors: *S. R. OCAÑAS[1], K. D. PHAM[2], H. E. BLANKENSHIP[1], A. H. MACHALINSKI[3], A. J. CHUCAIR-ELLIOTT[2], W. M. FREEMAN[2];
[1]Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [2]Genes and Human Dis., [3]Oklahoma Med. Res. Fndn., Oklahoma City, OK

Abstract: Modern molecular neuroscience studies require analysis of specific cellular populations derived from brain tissue samples to disambiguate cell-type specific events. This is particularly true in the analysis of minority glial populations in the brain, such as microglia, which may be obscured in whole tissue analyses. Microglia have central functions in development, aging, and neurodegeneration and are a current focus of neuroscience research. A long-standing concern for glial biologists using *in vivo* models is whether cell isolation from CNS tissue could introduce *ex vivo* artifacts in microglia, which respond quickly to changes in the environment. Mouse microglia were purified by magnetic-activated cell sorting (MACS), as well as cytometer- and cartridge-based fluorescence-activated cell sorting (FACS) approaches to compare and contrast performance. The Cx3cr1-NuTRAP mouse model was used here to provide an endogenous fluorescent microglial marker and a microglial-specific translatome profile as a baseline comparison lacking cell isolation artifacts. All methods performed similarly for microglial purity with main differences being in cell yield and time of isolation. *Ex vivo* activation signatures occurred principally during the initial tissue dissociation and cell preparation and not the microglial cell sorting. Utilizing transcriptional and translational inhibitors during the cell preparation prevented the activational phenotype. These data demonstrate that a variety of microglial isolation approaches can be used, depending on experimental needs, and that inhibitor cocktails are effective at reducing cell preparation artifacts.

Abstract: Identification and characterization of UCI MODEL-AD mouse models using single-cell and single-nucleus Split-seq
Authors: Heidi Y. Liang, Magdalena Gantuz, Narges Rezaie, Gabriela Balderrama-Gutierrez, MODEL-AD Consortium**,** Ali Mortazavi
Alzheimer's Disease (AD) is a progressive neurodegenerative disease that affects over 5 million Americans and is the 6th leading cause of death in the US. Scientists have been using the mouse brain as a pre-clinical model of human brain, but no existing mouse models of AD are able to recapitulate fully human AD pathology. The MODEL-AD consortium seeks to generate more realistic mouse models of AD using human GWAS variants to further understand the disease as well as to develop more effective therapeutics.
One of the core activities of MODEL-AD is to characterize the mouse models using transcriptomics, primarily using bulk RNA-seq. Here, we investigated the performance of the Split-seq (split-pool ligation-based transcriptome sequencing) protocol for single-cell and single-nucleus RNA-seq in mouse hippocampus and cortex. As a proof of concept, we compared 5xFAD, which shows heavy plaque load, and 3xTgAD, which have both plaques and tangles, using Split-seq. Specifically, we capture microglial cells from right half of the brain tissues, and isolate nuclei from the left half of the same brain, then profile the combined samples using Split-seq in the same sequencing run.
We discuss our current experimental pipelines and preliminary results which show that we can distinguish populations of activated microglia as well as distinct neuronal populations in the two mouse models. This suggests that Split-seq will be a useful platform of the late-onset models that MODEL-AD is in the process of releasing.

Title: Metabolomics Profiling Reveals Distinct Signatures in the Serum and Brain Metabolites in Mouse Models of Alzheimer's Disease

Authors: *R. PANDEY[1], M. ARNOLD[2,3], R. KADDURAH-DAOUK[4], G. W. CARTER[1]; [1]The Jackson Lab., Bar Harbor, ME; [2]Helmholtz Zentrum München, German Res. Ctr. for Envrn. Health,, Inst. of Computat. Biology,, Neuherberg, Germany; [3]Dept. of Psychiatry and Behavioral Sci., Duke University,, Durham, NC; [4]Psychiatry, Duke Univ. Med. Ctr., Durham, NC

Abstract: Progress in development of efficacious therapies for Alzheimer's disease (AD) is halted limited understanding of underlying pathological mechanisms. Increasing evidence suggests that metabolic impairments prior to symptom development can contribute to disease mechanisms and subsequent dementia. Signals in conserved metabolomic pathways could provide a method to translate experimental findings in preclinical mouse models to humans. In this study, we systematically investigated the sex-stratified associations of serum and brain metabolites with sample-matched APOE4.Trem2^{R47H}and 5xFAD mouse models at six months of age. Metabolites were measured withthe targeted metabolomics platform AbsoluteIDQ®-p180 (Biocrates AG, Innsbruck, Austria). We next investigated whether blood and brain metabolites significantly associated with AD biomarkers in the ADNI cohort and the ROSMAP cohort, respectively. We identified a sex-specific increase of glycerophospholipids levels in male mice, while levels of sphingolipids were more abundant in females. Further, we identified that serum levels of glycerophospholipidswere reduced in APOE4.Trem2^{R47H}mice compared to C57BL/6J controls, while levels of these metabolites in the same animals were greater in both male and female brains of APOE4.Trem2^{R47H} and 5XFAD mice. Several of these findings were consistent with recent results from the ADNI cohort, which suggested a similar decrease in the same metabolites in serum of APOE4 carriers compared to non-carriers and indicates a serum-based effect of APOE genotype. Metabolomic signatures were notably different between brain and serum in mouse models. The 5xFAD mice exhibited stronger effects in the brain, whereas the APOE4.Trem2^{R47H} mouse showed more pronounced effects in serum with reversed effects in the brain. These findings are consistent with high levels of amyloid pathology in 5xFAD mouse brains and the modifications of serum biomarkers in APOE4.Trem2^{R47H} mice, and demonstrate an important mismatch between serum and brain metabolite abundances.

Title: Analyzing gene expression during neurodegeneration in a 3xTgAD mouse model at transcriptome level

Authors: *N. REZAIE, G. BALDERRAMA-GUTIERREZ, H. LIANG, C. MODEL-AD, A. MORTAZAVI;
Univ. of California, Irvine, Irvine, CA

Abstract: Clinical trials for potential Alzheimer disease (AD) drugs have a high failure rate since most drugs are successful in mouse models but are not translatable to humans. Mouse models fail to fully recapitulate the pathology, especially presenting plaques, and tangles at the same time.
The 3xTg mouse model contains three mutations associated with familial AD (APP Swedish, MAPT P301L, and PSEN1 M146V), and it is the only AD model that presents plaques and tangles. While the 3xTg shows changes in behavior, the transcriptomic response of the different subtypes of neurons and glia during neurodegeneration has not been comprehensively characterized.
As part of the MODEL-AD consortium phenotypic characterization of existing models of familial AD, we use bulk RNA-seq in the female hippocampus of 3xTg mice at different time points (4,12 and 18 months) to identify distinct gene modules associated with microglia and oligodendrocytes that increase with ageing and pathology. We further investigate the changes in cell populations using matching single-nucleus RNA-seq of the hippocampus and cortex of 3xTg (12, 18 and 24 months) and 5xFAD (18 months) mice to detect major changes in astrocytes and oligodendrocytes groups. We recover a common path of astrocyte activation with the 5xFAD mouse and find that 3xTg derived astrocytes seem to be at an earlier stage of activation. To investigate the activation of microglia in 3xTG, we also generated a single-cell RNA-seq dataset of microglial cells and found multiple subtypes, including a set of microglia with distinct transcription factor expression profiles that are associated with an early increase in CSF1 expression before the full onset of DAM gene expression. Finally, scATAC-seq reveals a set of chromatin accessible areas shared across multiple activation states found in the scRNA-seq that matches glial activation processes. Overall, differences between the main glial groups point to a slower activation process in the 3xTg model when compared to the 5xFAD. Our study contributes to identifying progressive transcriptional changes of glial cells in a model with plaques and tangles.

Title: Improved mouse models of the Alzheimer's disease risk variant Trem2*R47H

Authors: *M. SASNER[1], G. MACGREGOR[2], A. OBLAK[3], D. GARCEAU[1], K. KOTREDES[1], C. PREUSS[1], A. UYAR[1], R. PANDEY[1], P. B.-C. LIN[3], A. P.-Y. TSAI[3], S. KAWAUCHI[2], G. BALDERRAMA-GUTIERREZ[2], J. ALCANTARA[2], J. NEUMANN[2], A. MORTAZAVI[2], K. N. GREEN[2], G. R. HOWELL[1], G. CARTER[1], A. J. TENNER[2], F. M. LAFERLA[2], B. T. LAMB[3]; [1]The Jackson Lab., Bar Harbor, ME; [2]Univ. California Irvine, Irvine, CA; [3]Stark Neurosciences Res. Inst., Indianapolis, IN

Abstract: TREM2 (triggering receptor expressed on myeloid cells 2) is expressed by microglia in the brain and plays a key role in modulating microglial activity. TREM2 expression is increased in AD and is associated with recruitment of microglia to amyloid plaques. The TREM2*R47H allele is one of the strongest genetic risk factors for developing late-onset Alzheimer's disease; patients exhibit both earlier onset of symptoms and rapid cognitive decline. We used CRISPR to engineer the R47H variant into the mouse *Trem2* locus; this model is available as JAX #27918. This, as well as two other CRISPR-generated *Trem2**R47H models, displays a splicing event seen in mouse, but not humans, that leads to a novel splice form with a deletion of 119bp at the 5' end of exon 2 (Xiang et al, *Molecular Neurodegeneration,* 2018). This leads to a decrease in ~50% of both transcript and protein levels in brain homogenate in the mouse, indicating that the model expresses mutant *Trem2*, but is also a hypomorph. To generate a more clinically relevant model, MODEL-AD has undertaken two complementary approaches. One approach has modified the existing Trem2*R47H mouse allele by using CRISPR to humanize the exon 2 splice site. This model, which we are calling Trem2*R47H^{HSS} for **h**umanized **s**plice **s**ite (JAX #33781), was analyzed by RNA-seq of brain homogenate. Relative to B6J controls, this new model expresses normal levels of each of the four transcripts. No truncated transcript was detected.As a second approach, we used a CRISPR-based strategy to engineer the R47H variant into the *Trem2* locus in B6J mice, accompanied by a different set of synonymous base changes. RNA-seq analysis of hippocampus and cortex indicates that transcript levels are similar to the wild-type *Trem2* allele, with no evidence of cryptic splicing products from the mutant allele. This model, named Trem2*R47H^{NSS} for **n**ormal **s**plice **s**ites is also available (JAX # 34036). We expect that these newly available models will facilitate research into the mechanisms and pathways related to *TREM2* genetic risk in late-onset AD.For more information see www.model-ad.org .

Title: Inpp5d regulates the amyloid pathology in alzheimer's disease

Authors: *P. B.-C. LIN[1], A. P.-Y. TSAI[1], K. NHO[2], B. T. LAMB[1], A. OBLAK[3];
[1]Stark Neurosciences Res. Inst., Indianapolis, IN; [2]Dept. of Radiology & Imaging Sci., Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Stark Neurosci. Res. Inst., Indianapolis, IN

Abstract: Background Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by cognitive decline, robust microgliosis, neuroinflammation, and neuronal loss. Genome-wide association studies highlighted a prominent role for microglia in late-onset AD (LOAD). Specifically, inositol polyphosphate-5-phosphatase (*INPP5D*) is selectively expressed in brain microglia and one of its common intronic variants (rs35349669; OR=1.08, 95%CI=1.06-1.11) has been reported to be associated with increased risk of LOAD. INPP5D is linked to the triggering receptor expressed on myeloid cells 2 (TREM2) signaling, but little is known about the function of INPP5D in microglia and how INPP5D regulates TREM2-related AD pathogenesis. Therefore, we aim to understand the role of INPP5D in microglia and AD pathology. **Methods** We performed differential gene expression analysis to investigate INPP5D expression in LOAD and its association with plaque density using transcriptomic (RNA-Seq) data from the Accelerating Medicines Partnership for Alzheimer's Disease (AMP-AD) cohort. We also performed quantitative real-time PCR, immunoblotting, and immunofluorescence assays to assess INPP5D expression and microglial markers in the 5xFAD amyloid mouse model with INPP5D deficiency. Using the INPP5D knockout animal crossed with the 5xFAD, we performed behavioral assays and IHC staining to reveal how the INPP5D regulates amyloid pathology. **Results** *INPP5D* gene expression is upregulated in LOAD and positively correlated with the amyloid plaque density. *Inpp5d* expression increased along with increasing disease progression in 5xFAD mice, and is selectively expressed in plaque-associated microglia. Furthermore, reducing Inpp5d expression *in vivo* mitigates plaque burden in 5xFAD mice and further protected against behavioral deficits induced by amyloid pathology. **Conclusions** We have demonstrated that INPP5D expression increases throughout the AD progression and is predominantly in plaque-associated microglia. Importantly, inhibiting INPP5D expression reduces amyloid pathology and protects against amyloid-induced behavioral deficits, thus highlighting INPP5D as a potential therapeutic target.

Institute, NB214C, [3]Indiana Univ. Sch. of Med., Indianapolis, IN; [7]Med. and Mol. Genet., Indiana University-Purdue University,Indianapolis, Indianapolis, IN

Abstract: Signaling via microglial Cx3CR1and its neuronal ligand (Cx3CL1) has been long associated with 'protective' activation of brain resident glia, as well as protection against neuronal excitotoxicity. Recently, Cx3CR1-V429I, a putative loss-of-function variant, previously associated with macular generation has been associated with worsened tau pathology, Braak staging and neurodegeneration in AD and ALS. Despite its identification as a key checkpoint regulator of microglial activation in Alzheimer’s disease, the overarching role of CX3CR1 signaling in modulating mechanisms of Aβ driven neurodegeneration is not well understood. In this study we investigate accumulation and phagocytosis of soluble and insoluble Aβ species, plaque associated microglial activation, synaptic dysregulation and neurodegeneration with disease progression in 5xFAD;*Cx3cr1*$^{+/+}$ and 5xFAD;*Cx3cr1*$^{-/-}$ mice. Lastly, we use Y-maze testing to analyze the effects of *Cx3cr1* deficiency on working memory in 5xFAD mice. Disease progression in 5xFAD;*Cx3cr1*$^{-/-}$ mice is characterized by increased deposition of filamentous plaques that display defective microglial plaque engagement, along with impaired microglial Aβ phagocytosis and lysosomal acidification *in-vivo*. Interestingly, *Cx3cr1* deficiency resulted in heighted accumulation of neurotoxic, oligomeric Aβ, which correlated with severe neuritic dystrophy, preferential loss of post-synaptic densities, exacerbated tau pathology, neuronal loss and cognitive impairment. Transcriptomic analyses using cortical lysates revealed that biological pathways regulating apoptotic signaling, TGFb signaling, ROS production and responses to ER

stress are differentially altered in 5xFAD;*Cx3cr1*$^{-/-}$ mice. Interestingly, microglia purified from 6 month-old 5xFAD;*Cx3cr1*-/- mice show increased mRNA levels of pro-inflammatory cytokines CCL2, CCL5 and IL1b while TNF and IL6 levels were significantly downregulated as compared to microglia from age-matched 5xFAD;*Cx3cr1*$^{+/+}$ mice. Lastly, Cx3cr1 deficient microglia show a significant downregulation of TGFb1 mRNA with elevated transcript levels of PTEN and Cybb. Thus, *Cx3cr1* deficiency impairs microglial uptake and degradation of fibrillar Aβ, thereby triggering an accumulation of neurotoxic Aβ species. Furthermore, loss of Cx3CR1 also results in a largely pro-inflammatory microglial activation phenotype, with a dysregulation in TGFb signaling, ER/oxidative stress and ROS metabolism. Our results indicate that Aβ-driven microglial dysfunction in *Cx3cr1*$^{-/-}$ mice aggravates tau hyperphosphorylation, neurodegeneration, synaptic dysregulation and impairs working memory.

Abstract: High Fat Diet Exacerbates the Neuroinflammatory Signature in Mouse Models relevant to Late-Onset Alzheimer’s Disease
Adrian L. Oblak, Kevin Kotredes, Ravi Pandey, Michael Sasner, Stacey Rizzo, Greg Carter, Bruce Lamb, Gareth Howell
Age, genetic variants, and environmental factors such as consumption of a high fat diet contribute to Alzheimer’s disease (AD) risk. Diets high in fat and sugar also increase disease neuropathology and/or cognitive deficits in mouse models relevant to early-onset or familial AD. However, the effect of a high-fat diet on biometrics, neuropathology and cognitive impairments

in novel knock-in models of late-onset AD (LOAD) is unknown. The IU/JAX/PITT MODEL-AD Center is focused on developing improved mouse models for LOAD by combining genetic risk variants such as *APOE^{E4}*, *Trem2*R47H*, and *Plcg2*M28L* initially on a C57BL/6J (B6) background. Here, we examine the effect of incorporating a diet high in fat and sugar as an environmental risk factor to improve alignment of novel mouse models to LOAD. A high fat diet (45% high fat/high sugar, HFD) was provided *ad libitum* to B6.APOE^{E4}TREM2^{R47H} (LOAD1), and LOAD1.Plcg2^{M28L} mice from two to 12 months of age. Control mice from each strain were fed standard chow diet (6% fat). Metabolic assays, including weight and blood glucose, were performed throughout the study. Cholesterol, liver enzymes, cytokines, transcriptomics and AD-relevant neuropathology were performed at terminal timepoints. As expected, consumption of a HFD exacerbated age-related increases in body weight in both LOAD1 and LOAD1.*Plcg2^{M28L}* mice. Further, HFD increased glucose, cholesterol, triglycerides and liver enzymes regardless of genotype. Interestingly, HFD had different effects in the periphery compared to the CNS. In HFD LOAD animals, we found an increase in plasma proinflammatory cytokines TNFα and CXCL1, but reduced IL2 and IFNγ. In brain, IFNγ and IL2 are increased in LOAD1 and LOAD1.Plcg2^{M28L} animals. Transcriptomic analysis of brain samples revealed that the presence of the *Plcg2^{M28L}* risk variant in combination with HFD caused an elevation of human AD-relevant inflammatory genes that didn't occur in LOAD1 on HFD or in LOAD1.*Plcg2^{M28L}* mice on control diet. Our multi-analyte approach suggests that changes in inflammatory signature is exacerbated by the interaction of genetic risk factors for LOAD and HFD. These findings provide a platform to combine LOAD variants and environmental influences, providing more relevant models for preclinical studies.

Title: Analysis of CNS disorders using active kinome profiles

Authors: *A. JOYCE, K. ALGANEM, A. S. IMAMI, J. CREEDEN, A. HAMOUD, W. RYAN, R. SHUKLA, R. MCCULLUMSMITH;
Neurosci. & Neurolog. Disorders, Univ. of Toledo Col. of Med., Toledo, OH

Abstract: Central nervous system (CNS) disorders such as AD (Alzheimer's dementia) and schizophrenia are often caused by a variety of pathophysiological processes, many of which involve abnormal protein kinase signaling. The active kinome is the set of kinases actively regulating cellular functions through phosphorylation. The active kinome can be profiled using protein kinase activity arrays. Using these profiles, we can empirically determine the phosphorylation state of peptide targets and find commonalities between the mechanisms of CNS disorders. To determine how the active kinome regulates the mechanisms underlying CNS disorders, we will first identify peptides that are differentially phosphorylated in AD and schizophrenia postmortem brain samples versus control subjects. We will then use deconvolution methods to identify the top dysregulated kinasesTo determine how the active kinome regulates the mechanisms underlying CNS disorders, we will first validate kinases that have been implicated in CNS disorders by our kinome array profile. We will identify peptides on the array that are differentially phosphorylated in Alzhemier's dementia and schizophrenia. Next, techniques such as BLAST will be used to assign these peptides to their respective proteins and identify homologous sequences mapped to other proteins. We will use perform an in-silico data exploration of databases such as BrainAtlas to determine the regional and cell level protein expression patterns of both the kinases and targets in the brain. We will use Enrichr to perform a pathway analysis on the final list of proteins to determine their functional implications.To have a more thorough understanding of the effects of the active kinome and the downstream effects of its protein targets, we will compare the two sets of pathways generated from ADAlzheimers and schizophrenia. Finally, we will curate publicly available CNS datasets from phosphoproteomic databases of CNS datasets disorders and explore the overlapping pathways using these data sets to get a more complete picture of the commonalities between these disorders regarding dysregulated kinases. We believe that this dysregulation plays an important role in CNS disorders and that common pathways regarding these dysregulated kinases could provide a unique insight into the mechanisms of CNS disorders and their methods of treatment.

Title: Protein Kinase B Expression and Activity in Schizophrenia and Alzheimer's Dementia

Authors: *P. PULVENDER, N. D. HENKEL, E. A. DEVINE, R. E. MCCULLUMSMITH;
Univ. of Toledo, Toledo, OH

Abstract: Protein Kinase B (AKT) Expression and Activity in Schizophrenia and Alzheimer's Dementia Authors: Priyanka Pulvender, Nicholas Henkel, Emily A. Devine and Robert McCullumsmith.Schizophrenia (SCZ) and Alzheimer's dementia (AD) are devastating illnesses that impact millionsworldwide. SCZ, a severe psychiatric disorder characterized by psychotic and delusional symptoms as wellas cognitive impairment, affects over 2 million in the United States and 50 million worldwide. AD, themost common cause of dementia, impacts over 5.7 million people in United Sates, and 50 millionworldwide.AKT, or Protein Kinase B, is a serine/threonine-specific protein kinase that plays a key role inmultiple cellular processes such as glucose metabolism, apoptosis, cell proliferation, transcription, andcell migration. Using the PamGene12 Kinome Array platform, we identified AKT as a signaling node inAD dorsolateral prefrontal cortex (DLPFC). We hypothesize that AKT activity is altered in this disorder.Using the DLPFC from postmortem brain, the expression and the activity of AKT isoforms (AKT1,AKT2, AKT3) will be assayed in AD and SCZ using biochemical activity assays plus and minus specificAKT inhibitors. AKT expression will also be measured at the transcript and the protein level.The results of these experiments are expected to serve as validation of the Kinome Array platformas well as provide valuable insight into how AKT is perturbed in these neuropsychiatric disorders. Tofurther probe AKT's role in AD and SCZ, this research will also encompass interacting biochemicalpathways in which AKT is a key player, which will provide novel pathophysiological insights into thesediseases.

Title: Quantitative assessment of the perception of movement in humans

Authors: *E. CARRANZA, A. BOOS, M. CAPOGROSSO, G. F. WITTENBERG, E. PIRONDINI;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: A key sensory component for volitional movement is proprioception, which relies on a sense of muscle and tendon stretch to indicate position, motion, and force. Since proprioception updates the spatial properties of body parts to plan motor commands, its loss can affect all

aspects of force production, positioning and dynamics during voluntary movement. Proprioception is typically tested passively by assessing the perception of limb position in space. However, proprioceptive afferents largely convey information on movement and movement velocity that are modulated during active movement. Here we developed a battery of robotic tasks to assess position sense, kinesthesia, and force and evaluate proprioception during volitional movement. These tasks were designed to obtain metrics that distinguish proprioceptive and motor control skills. To isolate motor from proprioceptive skills, we evaluate the participant's ability to reach to targets while moving in a horizontal plane. For this, the subject is asked to perform a visually guided reaching (VGR) task in which eight targets have to be reached quickly and accurately. Three targets with the straightest and smoothest movement trajectories are chosen for further testing. With vision of the arm occluded, subjects are asked to actively reach these targets and report when they perceive they have been reached. The shift between the position reached and the real target location is then calculated to assess active sense of position. For the second task, we studied the participant's active kinesthetic sense. First the robot moves the participants affected limb, then the participant is asked to perform a reaching or pulling motion matching the sensed speed. The subject's ability to match the speed, direction, and length of the dynamic target is then measured for each trial. To determine the proprioceptive and motor control components of movement, each task is evaluated with and without visual feedback. We tested these tasks in able-bodied subjects and a group of stroke participants. The latter showed increased errors when trying to match the target's final location in contrast to healthy participants, but not during VGR tasks. In the kinesthetic task, stroke participants show impaired control trying to match the speed of the dynamic target only when relaying on proprioception (without visual feedback). Our results demonstrate that our tasks can reliably dissociate motor control from proprioception during volitional movements. These tasks will help to understand the importance of active proprioception in motor control and support the development of novel stroke rehabilitation techniques.

Title: Spinal cord stimulation requires inhibitory mechanisms to enable voluntary motor control after paralysis

Authors: J.-M. BALAGUER[1], M. CAPOGROSSO[2];
[1]Dept. of Bioengineering, [2]Dept. of Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Epidural spinal cord stimulation (SCS) improves voluntary motor control after spinal cord injury (SCI). It has been proposed that SCS increases the excitability of spinal motoneurons thus amplifying residual supra-spinal inputs that enable volitional movement. However, no studies to date have directly measured how SCS interacts with residual voluntary commands within the spinal cord. Understanding these mechanisms would be critical to optimizing SCS for clinical use. Addressing this interaction can be lengthy and costly through experimental models without neurophysiological guidance. In silico models can unveil latent insights optimizing the experimental design. Thus, we implemented a realistic computational model of spinal motoneurons. Our model included inputs both from proprioceptive afferents that were recruited by SCS and residual excitatory cortico-spinal axons, which are rarely completely abolished after SCI. We simulated subthreshold or suprathreshold SCS pulses as synchronous synaptic inputs and subthreshold cortico-spinal inputs as stochastic. Simulations revealed two types of interactions as a function of the stimulation amplitude. Natural asynchronous cortico-spinal inputs increased the motoneurons membrane potentials, amplifying subthreshold postsynaptic potentials induced by SCS. However, this led to firing rates that were too low to generate movement. In contrast, suprathreshold SCS completely dominated motoneurons responses, uninfluenced by cortico-spinal inputs. Our results contradicted the leading hypothesis for the generation of voluntary movement. Residual supra-spinal inputs increased the responsiveness of motoneurons to subthreshold SCS responses, contradicting the leading hypothesis for the generation of voluntary movement through SCS. Conversely, when SCS parameters delivered a suprathreshold response, our simulations suggest that this modulation may not be sufficient to explain the experimental results of SCS after SCI. Therefore, we now propose that mechanisms related to the regulation of spinal excitability such as presynaptic inhibition may play a critical role in this context. In particular, residual supra-spinal axons could exploit surviving GABAergic interneurons to reduce unwanted motoneuron firing caused by suprathreshold SCS pulses. In this work, we present these hypotheses in the form of simulations of alternative spinal circuit structures exploring the effects of presynaptic inhibition during SCS. We believe that future work should start from our proposal to validate and explore the role of voluntary sensory gating during SCS rather than direct cortico-spinal excitation.

Title: Spinal Cord Stimulation of the Cervical Spinal Cord Improves Both Gross Strength and Fine Force Control of the Upper Limb in Post-Stroke Hemiparesis

Authors: *E. SORENSEN[1], M. P. POWELL[2], N. VERMA[5], E. CARRANZA[1], A. F. BOOS[3], L. E. FISHER[4], D. J. WEBER[5], P. GERSZTEN[2], G. F. WITTENBERG[3], E. PIRONDINI[4], J. W. KRAKAUER[6], M. CAPOGROSSO[2];

Abstract: In strokes involving subcortical brain structures, damage to the corticospinal tracts often leads to severe deficits of volitional motor control. There is currently no effective therapy for such cases. Importantly though, spinal cord circuits responsible for movement remain intact and supraspinal connections are not completely severed. Here we seek to understand if these residual connections are sufficient to synergistically interact with epidural spinal cord stimulation (SCS) to restore volitional upper limb motor control. In a participant with chronic stroke of the internal capsule, we implanted two percutaneous linear SCS leads spanning the C4 to T1 dorsal roots. Continuous stimulation was delivered through these leads to evoke motor potentials in the deltoids, biceps, triceps, or forearm. Compared to the no-SCS condition, we observed marked improvements in force production when the participant was asked to produce isometric force of the shoulder, elbow, and wrist with some joints demonstrating over a two-fold increase when volitional effort was paired with SCS. Notably, SCS alone did not induce any measurable force output. This suggests that it is the interaction of stimulation and supraspinal inputs that enables the observed increase in strength. We then asked the participant to perform an isometric roadway test, in which they were tasked with following a thresholded pathway to gradually increase, sustain, and decrease force in a controlled manner. The maximum force required to complete the test was within the ability of the participant without stimulation. The participant accurately followed the roadway during SCS, demonstrating that volitional input can regulate stimulation induced excitation. Furthermore, the participant's performance during SCS compared to no-SCS improved dramatically as assessed by a significant improvement in accuracy. This suggests that SCS improved not only gross muscle strength, but also fine force control. We have begun investigating how an individual with hemiparesis might regulate motor outputs during continuous stimulation in this manner by directly comparing evoked muscle responses during continual passive motion as opposed to matched volitional isokinetic motion. This should demonstrate effects of SCS and volitional muscle activation independently from sensory dependent modulation of motoneuron excitability. In conclusion, we showed that SCS not only improves force production, but also fine force control in a participant with moderate post-stroke hemiparesis. In the future we aim to investigate the mechanisms of volitional motor control during SCS in subjects with stroke.

Abstract: Stroke is the 5th leading cause of death and the leading cause of permanent disability in the United States. There are more than 7 million stroke survivors living in the US, two-thirds of whom have motor deficits. Even though physical exercise can improve motor function in this population, outcomes are highly variable across patients and a large fraction of the population is left with permanent motor deficits. Here we show that epidural cervical spinal cord stimulation (SCS) improved motor control of the arm and hand by restoring synergistic muscle activation in a person with chronic hemiparesis post-stroke. The study participant was implanted with 2 percutaneous spinal cord stimulator leads in the lateral epidural space of the cervical spinal cord for a duration of 30 days. SCS was delivered using a custom-built stimulation system that allowed stimulation on multiple contacts, either continuously or upon movement onset, detected through EMG signals. The participant performed planar and 3D reaching and grasping movements with her affected limb with and without SCS. Stimulation was applied on three monopolar contacts that were found to facilitate the recruitment of muscles at the shoulder, elbow, and hand. Tonic and phasic modes of stimulation were tested. During tonic SCS, the stimulation parameters were fixed and delivered continuously throughout the entire movement. During phasic stimulation, an increase in volitional EMG at the shoulder triggered stimulation bursts of fixed duration, linked to the phase of the motion (reach, grasp or retract) while the participant performed the task. The participant was able to perform the task faster with SCS on, than it being off, with smoother trajectories and a higher range of motion in the shoulder, elbow, and hand, leading to overall better task performance. The muscle activations were higher during the trials where the stimulation bursts were linked to the phase of movement than with continuous and no-stimulation conditions. EMG from 14 major muscles of the arm were analyzed using dimensionality reduction methods to identify patterns of correlated activity across subgroups of muscles. We found that both tonic and phasic stimulation decreased aberrant synergies and led to more typical synergistic activation of muscle groups during different phases

of the movement. These results show the potential of SCS of cervical spinal cord to improve motor control in the upper limb in people with post-stroke hemiparesis and how targeted stimulation burst linked to a specific movement phase increases its efficacy.

Abstract: Stroke is a major cause of permanent upper limb disability. Impairments caused by damage to cortico-spinal axons do not respond well to physical methods of therapy, leaving hundreds of thousands of people every year with unsatisfactory clinical outcomes. However, the spinal circuits that control movement of the arm and hand remain fully intact after stroke. Here we demonstrate that epidural electrical stimulation of the cervical spinal cord can be used to immediately improve muscle strength and motor control in a person with chronic stroke, 9 years after insult. An internal capsule lesion resulted in moderate upper limb impairment with a pre-study Fugl-Meyer Assessment for upper extremity (FMA-UE) motor score of 36/66. Two 8-contact percutaneous spinal leads were surgically implanted in the lateral epidural space spanning the C4 to T1 dorsal roots. The subject participated in a 30-day clinical trial in which we systematically evaluated the efficacy of spinal cord stimulation (SCS) to improve single joint strength and range of motion in the arm and hand, functional planar kinematics and 3D reaching movements, and performance during activities of daily living (ADL). Continuous monopolar 60 Hz stimulation was temporally interleaved between 3 electrical contacts which, combined, could elicit motor evoked potentials in the shoulder, arm, and hand. Marked improvements in isometric force production and range of motion in the shoulder, elbow, wrist, and hand were observed as

immediate effects of stimulation, with some joints demonstrating over 100% improvements in generated force. SCS-assisted planar and 3D reaching movements were smoother, faster, and more accurate than unassisted controls and allowed the subject to reach distal targets that could not be reached without stimulation. Functional movement was also evaluated using a series of common tasks ranging from drinking from a glass to cutting food with a fork and knife. In all cases, movements had better quality and amplitude with SCS. Remarkably, we observed immediate improvement in impairment, without any training as demonstrated by an SCS-assisted 13 point increase in FMA-UE score from pre-study baseline at the beginning of the trial. We also observed therapeutic effects. After the 30-day trial, the subject scored an SCS-unassisted 11 point improvement in FMA-UE score which has remained robustly elevated for at least 4 weeks after explant. Importantly, spinal stimulation did not aggravate muscle spasticity. These results demonstrate the exciting possibility that SCS can be used to improve clinical outcomes and functional independence of stroke patients with moderate upper limb impairment.

Abstract: Studying subcortical structures such as the internal capsule and thalamus in non-human primates has proven to be extremely difficult and requires extensive planning. There currently exist very few anatomical atlases and landmarks to provide accurate coordinates of specific brain structures, and they often vary significantly between each animal. The ROSA One® Brain surgical robot has already been implemented to provide neurosurgeons with a magnetic resonance imaging (MRI) guided and minimally invasive platform for procedures such

as stereo-electroencephalography and deep brain stimulation for patients. Here, we sought to leverage this robotic platform for non-human primate surgeries to more accurately and efficiently reach subcortical targets of interest to accelerate deep brain research. Specifically, we used the ROSA One® Robot Assistance Platform to position a stimulation probe in the internal capsule, a white matter structure in the inferomedial part of each cerebral hemisphere harboring every single cortico-spinal projection. We also placed a probe in the ventralis intermedius, a thalamic relay for incoming cerebellar projections with outgoing connectivity to the premotor and motor regions of the cortex. For this, we acquired T1-weighted MRI and CT images of the macaques in a customized plastic stereotactic frame with fiducials implanted in the skull. We subsequently co-registered these images in the ROSA robot and calibrated the robot with the implanted skull fiducials. We also utilized 3-D printed skulls of the animals from the CT images to simulate the implantation of our probes, the positions of which we later confirmed with a post-implantation CT image. Our results in the 3D printed skulls and the animal showed that our technique allowed ultra-high precise implantation of the probes (0.39 mm registration error) and electrical stimulation of internal capsule axons and the ventralis intermedius as demonstrated with intra-spinal and electromyographic recordings. In conclusion, we were able to use the ROSA robot in non-human primates as a minimally invasive, high-precision stereotactic approach to access subcortical structures of interest.

Title: Post-stroke postural abnormalities in the arm and their relationship to loss of motor control

Authors: *A. M. HADJIOSIF[1], K. KITA[1], S. T. ALBERT[2], R. A. SCHEIDT[3], R. SHADMEHR[2], J. W. KRAKAUER[1,4];
[1]Neurol., [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Biomed. Eng, Marquette Univ., Milwaukee, WI; [4]Santa Fe Inst., Santa Fe, NM

Abstract: Abnormal resting postures are one of the most common and recognizable motor symptoms after stroke. For example, the typical hemiparetic arm posture consists of flexion at

the fingers, wrist, and elbow. This pattern appears to parallel the abnormal muscle synergies during movement, like the abnormal coupling of muscles that move the shoulder vs. the elbow joint. Whether these synergies are generated by the same mechanism as abnormal resting postures remains an open question; it might instead be that resting abnormalities are inactive during movement. Also unknown is the degree to which abnormal resting posture influences active moving and holding.
Here, we investigated resting postural abnormalities in stroke patients (N=16) and healthy, age-matched controls (N=6). We measured resting postural forces by passively moving the arm to different locations on a plane. Stroke patients showed remarkably stronger resting postural force biases in their paretic arm compared to the non-paretic arm and controls. These resting force biases were greater in more distal positions, when measured without weight-bearing arm support, and for patients with increased impairment based on the Fugl-Meyer scale - a measure primarily designed to assess abnormal synergies active during movement. These observations suggest a common mechanism underlying abnormal resting postures and abnormal movement synergies. We then examined the interplay between resting posture abnormalities and the control of reaching and holding actions in the same workspace. The same participants made repeated, arm-supported 2D reaches between 5 different targets. Patients' (unperturbed) movements were impaired compared to the non-paretic arm and controls: they were slower and took a longer path to reach the target. Since postural abnormalities may differentially affect regular vs. perturbed movement, we also examined patients' responses to perturbing forces applied during reaching; these were also impaired. When we compared unperturbed and perturbed movement performance against resting posture, however, we did not find any systematic effects of resting postural forces either across patients with different resting postural force magnitudes, nor between high- vs. low-resting postural force regions for the same patient. This suggests a dissociation between abnormal resting posture and reaching dexterity. Finally, we examined perturbations during active holding. Patients' ability to recover from these perturbations tended to improve when the resting postural force was in a direction that would resist the perturbation, suggesting that resting postural forces influence holding control in stroke.

Title: Quantifying the effect of trunk postural control deficits on arm reaching in hemiparetic stroke

Authors: *K. SUVADA, J. DEOL, J. DEWALD, A. ACOSTA;
Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: The trunk provides a stable base of support and facilitates interaction of the limbs with the environment. Post hemiparetic stroke, damage to descending corticospinal pathways impacts motor control and activities of daily life. In the arm, impairments include weakness, hyperactive stretch reflexes, and involuntary coupling of shoulder abduction with elbow, wrist, and finger flexion, or flexion synergy. Previous studies suggest that the flexion synergy is a result of increased reliance on reticulospinal pathways, also responsible for maintenance of posture. In the trunk, studies found excessive trunk movements, larger sway area during sitting, weakness, and altered coordination compared to controls. Yet, little is known about the role of the flexion synergy in trunk-arm coordination.This study provides evidence of the impact of stroke on trunk-arm coordination presumably due to increased use of the reticulospinal system wherein the arm and trunk are utilizing the same pathways. We designed a novel experimental paradigm that uses a haptic robotic device to create virtual environments, a motion capture system measuring trunk and arm kinematics, surface EMGs to measure trunk and arm musculature activity, and pressure mats on the seat and back to quantify trunk center of pressure.Four controls and eight stroke participants provided informed consent prior to enrolling in the study. Participants were seated with their arm coupled to the robotic device, allowing motion on a plane while supported on a virtual table or generating 25% or 50% of their maximum shoulder abduction torque (SABT). Participants were instructed to reach as fast and as far as possible for all conditions. For controls, regardless of restrained vs. unrestrained in the table (95±8 vs. 96.96±5), 25% (95 ±5 vs. 90±7), and 50% (93±3 vs. .93±4 % limb length) conditions, the reaching distances (mean±std normalized to limb length) were comparable. For stroke and trunk restrained vs. unrestrained in the table (92±9 vs. 90±8), 25% (86.±1 vs. 82±9) and 50% (86±9 vs. 84±10) conditions we saw an effect of trunk restraint. In addition, in stroke, there was increased trunk movement with the trunk unrestrained vs. restrained across conditions (mean±std mm): table (25.3±13.3 vs. 12.6±7.8), 25% (38.7± 13.6 vs. 26.8±10.8) and 50% (39.0±20.2 vs. 24.6±8.3).Results show the detrimental effect of impaired trunk control on reaching ability, compounding the effect of the flexion synergy. While additional participants are needed to show statistical significance, the data shows clear trends of decreased reaching distance during unrestrained with loading conditions and the effect of stroke on trunk-arm motor control.

Title: Physiological Response and Tissue Damage Following Different Depths of Impact in a Rodent Model of Mild Traumatic Brain Injury

Authors: *H. K. PREDALE[1], C. KNAPP[1], R. RAGHUPATHI[2], B. D. WATERHOUSE[1], R. L. NAVARRA[3];

Abstract: Mild traumatic brain injury (mTBI) is a serious public health concern that can result in neurological and behavioral deficit. mTBI results from impact to the head and can be repetitive in nature, especially in sports and domestic violence. Our laboratory studies the effects of repetitive mTBI (rmTBI) on risky choice behavior in rodents using a closed-head controlled cortical impact (CH-CCI) model of injury and a probabilistic discounting task that assesses risk-based decision-making behavior. We found that females, but not males, display transient increases in risky choice behavior following three CH-CCI's delivered at 5.5m/s velocity and 2.5mm impact depth. These findings suggest that our injury parameters may yield marginally threshold influences on behavior that do not allow observation of the extent of rmTBI-induced effects and have prompted us to expand our model to include greater depths of injury. In the present work we subjected rats to a series of three repetitive fixed velocity impacts at depths of 2.5mm, 3.0mm, or 3.5mm. The goal was to compare physical indicators of injury in male and female rats following different depths of injury. We posited that these indices of injury would be more prominent as injury depth increased. The survival rate, righting reflex time, skull observations, and animal weights were evaluated post-injury. All animals survived all three injuries at all impact depths. We found that the average righting reflex time increased as the injury depth increased for both males and females. Males exhibited overall longer righting reflex times as compared to females at the 3.5mm impact depth. In comparison to the 2.5mm group, a greater percentage of animals in the 3.0mm and 3.5mm groups had moderate and significant skull fractures and hematomas, and a greater incidence of skull indentation. Weight gain post-injury did not differ amongst injury depths. Nissl staining showed that structural damage of tissue within the region under the impact site increased as the depth of injury increased. Studies using silver and glial fibrillary acidic protein (GFAP) stains to examine axonal injury and the astrocytic response to injury, respectively, supported these findings. The current results show that physiological measures of injury are positively correlated with depth of impact in the CH-CCI model of TBI. These data will be used to guide selection of CH-CCI impact depth in future studies designed to reveal changes in behavior following rmTBI. Based upon these findings we predict that greater depths of impact will produce greater post-injury deficits in behavioral tests of executive function and that these deficits will be greater in female vs male animals.

Title: Mild traumatic brain injury produces transient increases in risk taking behavior in female rodents

Authors: *C. P. KNAPP[1], S. B. FLORESCO[2], R. RAGHUPATHI[3], B. D. WATERHOUSE[4], R. L. NAVARRA[5];
[1]Rowan Univ. Grad. Sch. of Biomed. Sci., Stratford, NJ; [2]Univ. British Columbia, Vancouver, BC, Canada; [3]Drexel Univ. Col. of Med., Philadelphia, PA; [4]Cell Biol. and Neurosci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ; [5]Cell Biol. and Neurosci., Rowan Univ. Sch. of Med., Stratford, NJ

Abstract: Mild traumatic brain injury (mTBI) is the most common form of TBI. Many individuals, such as athletes, often experience repetitive mTBIs over the course of their athletic careers. Consequences of mTBIs include impairments to higher order cognitive processes such as decision making. Risk-based decisions involve choices that have probabilistic outcomes. Increased risk taking behavior has been reported for TBI patients following a single TBI event; however, little information is available regarding the effects of repetitive mTBIs on risk-based decision making. Here, we examined how single and repetitive mTBI affects risk-based decision making in rodents using a well-established probabilistic discounting task (PDT). Age-matched male and female rats were trained on the PDT and then exposed to either a single or a series of three closed head control cortical impact (CH-CCI) injuries over the course of one week. Rats then returned to the PDT for testing for four weeks. We observed no changes in risky choice behavior across all four weeks of testing in male rats following either single or repetitive mTBI. In contrast, mTBIs, specifically repetitive injuries, increased risky choice behavior in female rats at one week and two weeks post injury. Increased risky choice behavior was more prominent two weeks post injury with effects being driven by a reduced sensitivity to non-rewarded outcomes following a risk-based decision, demonstrated by a decrease in lose-shift responses. When evaluated three and four weeks post injury, choice behavior was no longer significantly different from uninjured animals indicating that the observed effects of mild head injuries in female rats are transient. These results indicate that females are more susceptible to changes in risk-based

decision making following repetitive mild TBIs in comparison to males of the same age. Overall, when used together, the CH-CCI model of repetitive mTBI and the PDT are useful tools for experimentally evaluating and differentiating the effects of head injury on male vs female subjects.

Sci., Bethesda, MD

Abstract: Mild traumatic brain injury (TBI), frequently caused by low-intensity blast (LIB) exposure, has the highest reported TBI incidence in all military branches. Of significant concerns are the neurocognitive consequences commonly found in LIB-exposed service members and Veterans that require elucidation of their neurobiological mechanisms. Our previous studies have shown that open-field LIB exposure results in nanoscale ultrastructural abnormalities in the absence of macroscopic injury or apparent cellular damage in mice. In this study, we identified an increase in frequencies of miniature excitatory postsynaptic currents (mEPSCs) and a burst pattern of mEPSCs recorded in hippocampal CA3 neurons, a region involving synaptic plasticity, cognitive function, and memory processes in LIB-exposed mice at day-1 and -7 post-injury.

Blocking NMDA receptors with a specific antagonist significantly reduced LIB-induced mEPSC increases. Additionally, LIB increased the numerical density of asymmetric excitatory synapses in the hippocampus. Long-term cognitive function was assessed 90 days post-LIB exposure using an automated home-cage monitoring system with minimal human interference. By monitoring mouse behavior for 96 consecutive hours, we identified dynamic patterns of discrimination learning and cognitive flexibility deficits in LIB-exposed mice compared with sham controls. Bioinformatic analysis of quantitative global-proteomes of hippocampi showed alterations of synaptic proteins associated with learning deficits in LIB-exposed mice in the chronic phase. Our findings suggest that hyperexcitability caused by excessive glutamatergic synaptic inputs in the hippocampus is involved in long-term cognitive dysfunction following LIB. This study provides a platform to examine therapeutic strategies to prevent or mitigate long-term cognitive disorders caused by LIB.

Title: Traumatic brain injury leads to disrupted REM sleep in juvenile rats

Authors: *J. B. ORTIZ[1,2], K. R. GIORDANO[1,2], T. R. F. GREEN[1,3], R. K. ROWE[3,1,2]; [1]Dept. of Child Hlth., Univ. of Arizona, Col. of Med. - Phoenix, Phoenix, AZ; [2]Phoenix Veteran Affairs Hlth. Care Syst., Phoenix, AZ; [3]Dept. of Integrative Physiol., Univ. of Colorado - Boulder, Boulder, CO

Abstract: Traumatic brain injury (TBI) disrupts sleep, which impairs recovery and increases risk for long-term morbidities. In the clinic and in our laboratory, TBI evokes sleep-wake disorders in adults, but few studies have focused on sleep in pediatric TBI survivors. Sleep and wakefulness require a fine interplay between homeostatic and circadian drive, and in juveniles, sleep plays a critical role in development. Moreover, endocrine disruptions, or changes to hormone production and release, occur after TBI in adults and children. However, little is known about the interplay between TBI-induced endocrine disruptions and sleep-wake disorders in pediatrics. Here, we

implanted telemetry devices to obtain EEG and EMG signals in freely moving juvenile rats (post-natal day 35) subjected to a diffuse TBI (midline fluid percussion injury) or control sham surgery. Recordings were obtained and sleep-wake behaviors (active wake, quiet wake, non-rapid eye movement (NREM), rapid eye movement (REM)) were determined for 48hrs post-injury. In a separate cohort of rats, we utilized non-invasive piezoelectric sleep cages to measure long-term (i.e., 28 days post-injury) sleep-wake disturbances and TBI-induced changes to hormone profiles at various time points post-injury. We hypothesized that brain-injured rats would display altered NREM and REM sleep post-injury compared to uninjured sham rats, and that these sleep disturbances would be mediated by changes in specific hormones. Juvenile rats subjected to diffuse TBI had enhanced quiet wakefulness ($p < 0.05$) with no change to active wakefulness during the first 48hrs post-injury compared to shams. Interestingly, juveniles subjected to TBI displayed a significant decrease in REM sleep ($p < 0.05$) compared to controls but had comparable levels of NREM sleep. REM sleep is involved in the regulation of emotions and memory consolidation; thus, disrupted REM sleep may lead to the affective and cognitive symptoms experienced by pediatric TBI survivors. Currently, we are investigating growth hormone (GH) as one potential hormonal mechanism behind the observed changes in sleep. GH levels in juveniles are high as a result of development and GH also contributes to sleep regulation. Our previous work has shown that TBI leads to GH deficiency in the pediatric population, while others have shown that GH and sleep are interrelated. As such, our ongoing studies investigate TBI-induced changes in GH as a mechanism underlying post-TBI sleep disorders in juveniles. A comprehensive understanding of these underlying mechanisms will facilitate the development of effective pharmacotherapies and improve quality of life in survivors of pediatric TBI.

Title: Measured intrinsic cellular properties and afferent synaptic activity are not the cause of reduced orexin neuron firing at baseline activity levels following mild traumatic brain injury

Authors: *R. T. SOMACH[1,2], I. JEAN[2], A. S. COHEN[3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA;

[3]Anesthesiol. and Critical Care Med., Children's Hosp Philadelphia Univ. of Pennsylvania, Philadelphia, PA

Abstract: Sleep disorders are a common symptom following Traumatic Brain Injury (TBI), with 30-70% of patients experiencing some type of disrupted sleep after TBI. Patients that suffer a TBI have a higher rate of sleep disorders than occur by chance in the general population, which suggests that TBI may contribute to sleep disorders. Surprisingly, alterations in sleep circuitry caused by TBI are understudied. One of the critical regulators of sleep circuitry is the neuropeptide orexin, which promotes wakefulness. It is known that the production of orexin is reduced after TBI, but the mechanism underlying this reduction remains unknown. Our lab previously published evidence that mild TBI (mTBI) does not destroy orexin neurons, but can still cause sleep disruptions in mice. After mTBI, mice displayed an inability to maintain wakefulness for long periods of time. These injured mice also showed reduced orexin activity as measured with staining for the immediate early gene cFos. cFos staining indicates that orexin neurons fire fewer action potentials after injury but cannot explain if this reduced activity is due to changes in orexin neurons themselves or alterations to afferent signaling. To specifically elucidate the source of reduced orexin activity after injury, we recorded from orexin neurons using whole cell patch clamp electrophysiology. We used the Lateral Fluid Percussion Injury method on 6-8 week old mice to induce a mild TBI. Sham animals were used as controls and had the same procedures and anesthesia except for the final concussive injury. 1 week after injury, the animals were sacrificed and acute brain slices were cut that contained orexin neurons. Using current clamp recordings, we found that the action potential threshold was reduced in orexin neurons following injury, which would cause increased excitability. Using voltage clamp recordings, we found no differences in the afferent excitatory currents or the afferent inhibitory currents on orexin neurons after mild TBI. These results demonstrate that altered intrinsic excitability or afferent excitatory neurotransmission do not underlie the reduction in orexin activity induced by mTBI. Further exploration of these neural circuits is needed to determine the underlying mechanism(s).

Title: Mild traumatic brain injury cerebrovascular function and exacerbates stroke outcomes in mice

Authors: *B. WHITEHEAD, R. VELAZQUEZ-CRUZ, *K. KARELINA, Z. WEIL;
West Virginia Univ., Morgantown, WV

Abstract: Traumatic brain injuries (TBI) can produce long term disability and also impair cerebrovascular health. Importantly, TBI is also associated epidemiologically with increased incidence of ischemic stroke and our lab has demonstrated that mild TBI one week prior to an ischemic stroke leads to worsened functional and pathophysiological stroke outcomes in mice. Due to the links among TBI, stroke, and cerebral vascular function, we hypothesized that TBI-induced cerebrovascular impairments mediate this phenomenon of enhanced vulnerability to stroke. To test this hypothesis, we performed mild closed-head TBI, or an equivalent control procedure and collected tissue seven days later. In separate cohorts of mice, we assessed cerebrovascular function via pressure myography on isolated middle cerebral arteries, collected brains for immunohistochemical (IHC) analysis of pericyte and endothelial cell interactions, or performed a middle cerebral artery occlusion (MCAO). Cerebrovascular blood flow was assessed via laser speckle flowmetry 1 hour prior to and 3 hours post MCAO. Five days after MCAO, mice were assessed for functional recovery and infarct volume via 2,3,5-Triphenyltetrazolium chloride (TTC) staining. Results from the pressure myography revealed a decrease in middle cerebral artery dilation when exposed to acetylcholine in TBI mice compared to controls ($p<0.001$). IHC analysis revealed a decrease in pericyte coverage of vasculature in TBI mice compared to control animals ($p<0.05$). Laser speckle flowmetry results show a post-stroke decrease in blood flow in TBI mice compared to controls ($p<0.05$). Additionally, motor impairments were seen post-stroke in TBI mice compared to shams ($p=0.033$) and had significantly larger infarcts following TTC staining ($p<0.001$). Pressure myography results and IHC analysis suggest a role for dysfunction of pericyte-endothelial cell interactions in regards to cerebrovascular function, while the laser speckle flowmetry data show deficiencies in post-stroke reperfusion after TBI. Taken together, our data suggest that TBI impairs the function of cerebral vessels and results in poor blood flow during reperfusion, implicating TBI-induced impairments in the cerebral vasculature in post-injury vulnerability to subsequent ischemia.

Title: Posthemorrhagic hydrocephalus causes deficits in gait and cognition and loss of the essential motile cilia transcription factor YAP

Authors: *S. ROBINSON, **Y. KITASE**, M. FOUDA, S. HAMIMI, L. JANTZIE;
Johns Hopkins Univ., Baltimore, MD

Abstract: Young adults who suffer intraventricular hemorrhage from vascular lesions are prone to develop hydrocephalus. Hydrocephalus contributes to chronic neurological deficits beyond the need for cerebrospinal fluid (CSF) diversion. Hydrocephalus is more likely to develop in the setting of systemic inflammation. We hypothesized that intraventricular hemorrhage (IVH) and hydrocephalus would lead to deficits in gait and cognition in a preclinical model of posthemorrhagic acquired symptomatic hydrocephalus (ASH). We also predicted that this would occur with loss of the transcription factor YAP (yes-associated protein), which is modulated by inflammation and essential for ependymal motile cilia maturation. On postnatal days 21 (P21) and P23 rats received 3mg/kg lipopolysaccharide (LPS) or sterile saline i.p. On P25, under anesthesia, rats received bilateral intraventricular injection of lysed littermate red blood cells (IVH) or sterile saline. Both sexes were used. On P42, rats underwent computerized gait analysis, and began cognitive testing with a touchscreen platform. qPCR on ependyma was performed for YAP. Group differences were compared Mann Whitney test, with $p<0.05$ considered significant. Results indicate that compared to controls, rats with ASH spent less time in propel, stance and stride stages of gait. They also had shorter stride length, and increased stride frequency (n=5, all $p<0.05$). Passing rates were similar for ASH rats (n=26) and control rats (n=14) for visual discrimination. They made a similar number of errors, and required a similar number of correction trials, showing that ASH rats could complete touchscreen testing. During a Reversal learning paradigm, ASH rats committed more errors ($p=0.0007$) and required more correction trials ($p=0.03$) compared to controls, consistent with poor cognitive flexibility. YAP mRNA levels were reduced in ASH ependyma (n=7, $p<0.01$). Acquired posthemorrhagic hydrocephalus causes deficits in gait and cognition. CSF dynamics are complex and reflect changes in choroid plexus secretion, ependymal motile cilia propulsion and glymphatic reabsorption. Clarifying functional outcomes and molecular mechanisms will lead to effective treatments that are not dependent on surgery.

Title: A novel in vivo mouse mild repeated blast injury model with unrestrained head and its application in an Aldh2*2 disease model.

Authors: *Z. ZHANG[1], S. HERR[1], T. BEAUCLAIR[1], S. SUN[1], N. RACE[1], R. SHI[2];
[2]Depat. Basic Med. Sci., [1]Purdue Univ., West Lafayette, IN

Abstract: Blast-induced traumatic brain injury (bTBI) is characterized by an explosive overpressure wave traveling across the brain, resulting in acceleration-deceleration shearing forces that lead to tissue destruction. Due to the complex and heterogeneous nature of bTBI and the limitations of human studies, a reliable and clinically relevant animal model is needed to deepen our understanding of its underlying mechanism. The shock tube pneumatic blast model has the practical advantage to be performed in a confined laboratory space, with less variability compared to open-field chemical explosions. Damage to the rest of the animal's organs can be minimized using a sealed body shield, isolating blast injury in the brain. While our current model has predominantly been used for rats, we have recently modified and adapted it for investigating mbTBI in mice. Multiple parameters including the thickness of polyester membrane, the distance between animal's head and the shock tube ending, and the restraint status of the head (flexible vs fixed), were adjusted to accommodate mice based on the mortality, morbidity, and various pathological markers in the brain. The pressure wave profile was recorded using a piezoelectric transducer and analyzed by a custom-made LabVIEW program, which demonstrated a characteristic Friedlander waveform. Using such model, we have shown a significant increase of reactive aldehyde acrolein adducts, an established biomarker of oxidative stress and inflammation, 2 days post repeated mbTBI in mice carrying the aldehyde dehydrogenase 2 mutation (*Aldh2*2*), an enzyme known to detoxify acrolein. Consistent with our hypothesis, acrolein adducts elevation was less prominent in wildtype mice. Further, the elevation of acrolein was observed in mice with unrestrained flexible heads, but significantly less than in mice with restrained fixed heads during the blast, implying that allowing head movement during injury could result in more severe brain injury when compared to restrained or fixed head positions. Taken together, this data suggests that, similar to our rat mbTBI model, the newly established mouse mbTBI model can also elicit secondary injury indicated by the elevation of lipid peroxidation product acrolein, demonstrating that it is a suitable rodent bTBI model for studying post-mbTBI primary and secondary injuries. In addition, our study also indicates the critical role of ALDH2 in suppressing acrolein following mbTBI. This mouse mbTBI model will enable us to further elucidate the molecular mechanism of brain damage, particularly those related to the secondary injury mechanisms, by taking advantage of various available transgenic mouse model.

Title: The absence of NEP-like amyloid-beta degrading enzymes improves motor/memory performance post brain injury in mice

Authors: *R. A. MARR[1], K. C. MAIGLER[1], T. J. BUHR[1], C. S. PARK[1], S. A. MILLER[2], D. A. KOZLOWSKI[3];
[1]Ctr. for Neurodegenerative Dis. and Therapeut., [2]Dept. of Psychology, Rosalind Franklin Univ., North Chicago, IL; [3]Biol. Sci. and Neurosci. Program, DePaul Univ., Chicago, IL

Abstract: Traumatic brain injury (TBI) increases the risk for neurodegenerative diseases including Alzheimer's disease (AD). Furthermore, both human and animal model data indicate that the amyloid-beta (Aβ) peptide and its production machinery are upregulated by TBI. Considering the clear link between chronic Aβ elevations and AD, Aβ may have a role in the processes following brain injury. Proteases, including the neprilysin (NEP)-like enzymes, are key mediators of Aβ clearance and so may influence the susceptibility to pathology post-brain injury. We used a mouse model expressing normal human Aβ-precursor protein (APP) under its natural transcriptional regulation. These transgenic mice were also crossed with mice deficient in the NEP or NEP2 Aβ degrading enzymes and these lines were exposed to repeated closed-head TBI. Our results show that the presence of the human form of Aβ (not overexpressed or carrying familial-AD mutations) did not affect motor (Rotarod) and spatial learning/memory deficits (Morris water maze) post-injuries. However, NEP and NEP2 deficiency was associated with protection from motor (NEP or NEP2 deficient) and spatial learning/memory deficits (NEP deficient only) at acute time points post injury (*J Neurotrauma* 38(5):665-676). These data suggest that NEP and NEP2 peptide substrates are protective at acute time points post injury and a potential beneficial role for Aβ during the early response to brain injury.

Title: Actigraphic evidence of persistent sleep disruption following repetitive mild traumatic brain injury in a gyrencephalic animal model

Authors: S. C. SCHWERIN[1], A. OBASA[1], T. HAIGHT[2], M. RAY[3], *S. L. JULIANO[1]; [1]APG, Uniformed Services Univ. of Hlth. Grad. Program In Neurosci., Bethesda, MD; [2]Ctr. for Neurosci. and Regenerative Med., Bethesda, MD; [3]APG, USUHS, Bethesda, MD

Abstract: Disrupted sleep is prevalent after traumatic brain injury (TBI) and characterized by insomnia, increased awakenings, reduced sleep efficiency, and daytime somnolence. Sleep disruption frequently exacerbates other issues, such as depression, anxiety, stress, and pain. An animal model exhibiting disturbed sleep/activity patterns after brain injury will be useful to study neuropathological mechanisms of sleep disruption and to test therapeutics. We assessed sleep/activity patterns in adult male ferrets at baseline and following TBI. Ferrets wore an ActiGraph, which we evaluated at baseline, 4-5 weeks post injury, and 4 and 6 months post injury. The injured animals received repeated blast exposure and a rotational brain injury over a period of 2 weeks; a subset of animals also received stress prior to and concurrent with the brain injuries. At baseline, actigraphy patterns in ferrets show distinct clusters of active and inactive periods; the inactive periods correspond to sleep. At 4 weeks and 4 months post injury the ferrets in both the Injury Alone (I) and Injury + Stress (I+S) groups showed fractured and dispersed sleep/activity patterns. We calculated the frequency of high activity bout lengths and found that after injury, short bout lengths (1-5 minutes) were much more frequent than at baseline, while many fewer long high activity bout lengths (16-60 minutes) occurred. The percent of time spent inactive (asleep) decreased during the night for the injured group at 4 and 6 months post injury, while the percent of time spent in high and low activity bouts increased, reflecting reduced nighttime sleep efficiency. During the daytime, the percent time spent highly active decreased in the I+S animals, which may reflect increased daytime sleepiness. We further investigated changes in high activity using Loess analyses. Both the I and I+S groups spent significantly less time in high activity compared to the Sham group at 4 weeks and 4 months post injury. Overall our analysis shows that fragmented sleep persists until at least 6 months post repetitive mild TBI with and without stress.

Title: Retinal thickness changes may be detectable as objective biomarkers in the acute phase of concussions

Authors: L. WILKINS[1], T. R. ZUIDEMA[2], L. M. FERRIS[3], B. J. KING[2], ***N. L. PORT**[2]; [1]Dept. Psychological and Brain Sci., [2]Sch. of Optometry, Indiana Univ., Bloomington, IN; [3]Dept. of the Air Force, San Antonio, TX

Abstract: Purpose: Concussions are a growing public health concern. Photophobia and blur are two common symptoms of concussion, yet no objective visual biomarkers of concussion currently exist in practice. Optical coherence tomography (OCT), a microscopic tool for imaging in vivo human retina, is commonly used to detect neurodegenerative conditions and may serve as an objective biomarker for acute concussions. In this matched cohort pilot study, we analyzed visual symptoms and investigated whether retinal changes are detectable in the acute and/or recovery phase of concussion.
Methods: Acute concussion (≤ 72 hours) and recovery (2 weeks, 8 weeks, 6-18 months) data were collected on a total of n = 39 NCAA Division I collegiate athletes; n = 19 concussed and n = 20 age, sex, and sport-matched controls. At each visit, retinal OCT and a visual function survey were conducted. An ANOVA was conducted to analyze significance and descriptive statistics, including mean, variance, and effect size between injury groups measured with Cohen's d, to evaluate the behavioral and OCT data.
Results: Only one question on the visual function questionnaire (To what extent does sunlight currently bother you when you are not wearing sunglasses?) at 24-72 hours significantly differentiated concussed from non-concussed ($p < 0.05$). Retinal OCT data of the macula showed small, yet significant differences between concussed and control athletes in the outer superior macular nerve fiber layer (NFL) ($d = 0.05$, $p = 0.0456$), outer temporal macular NFL ($d = 0.58$, $p = 0.0226$), and the outer inferior macular ganglion cell layer ($d = 0.22$, $p = 0.0490$) between initial acute and 8-week recovery time points. No other macula or optic nerve head sectors were significant ($p > 0.05$).
Conclusion: Retinal OCT measurements may show promise as objective biomarkers for assessing acute concussion and recovery in collegiate athletes. Consistent with existing literature, photosensitivity is commonly reported and graded more severe in athletes suffering from acute concussion. These findings highlight a possible pathophysiological relationship between vision

and concussion. Further study is warranted, investigating the potential use of commercially available OCT devices for concussion assessment and management.

Title: Exploring associations between resting-state functional connectivity and concussion history in relatively young former collegiate football players

Authors: *S. R. WALTON[1], J. R. POWELL[1], W. YIN[1], B. L. BRETT[2], W. LIN[1], A. S. NENCKA[2], M. LIU[1], H. GUAN[1], M. A. MCCREA[2], K. M. GUSKIEWICZ[1], K. S. GIOVANELLO[1];
[1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: *PURPOSE*: Sport-related concussions (SRCs) and cumulative head impact exposure via contact sport participation may be risk factors for later-life neurodegenerative changes in former football players. Studies in typical aging, neurodegenerative disease, and acute SRC have reported similar patterns of altered resting state functional connectivity (rsFC) between large-scale brain networks (e.g., neural signatures of dysfunction). The purpose of this study was to investigate whether history of SRC was associated with similar neural signatures in rsFC among relatively young former football players removed from sport for at least 15-years.
METHODS: Former collegiate football players (*n*=54; aged 37.9±1.5 [range 35-41] years; body mass index [BMI]=30.8±4.2 $kg \cdot m^{-1}$) enrolled in this study reported 0 or 1 ("Low"; *n*=24) or 3+ ("High"; *n*=30; median[IQR]=6.5[4-10]) lifetime SRCs. Multisite resting-state fMRI and 3D T1-weighted images were acquired via Siemens Prisma 3T (*n*=38) or GE Signa Premier 3T scanners (*n*=16). T1-weighted images were pre-processed using the standard Freesurfer pipeline; fMRI images were pre-processed using FSL. Next, rsFC was calculated via custom Matlab code utilizing the Yeo et al. (2011) 7-network functional atlas. Based on prior research, between-network rsFC (average ROI-ROI correlation values) were calculated for the whole brain (i.e., average of all between-network rsFC values) and specifically between each of the Default Mode (DMN), Dorsal Attention (DAN), and Frontoparietal Control (FPCN) networks. All rsFC metrics were compared between Low and High SRC history groups using ANCOVA models accounting

for participant age, BMI, and acquisition site with *a-priori* α=0.05.
RESULTS: There were no differences between the High and Low SRC history groups for any of the between-network rsFC measures: whole-brain F=0.666, p=0.42, η^2_p=0.013; DAN-FPCN F=0.185, p=0.67, η^2_p=0.004; DAN-DMN F=0.065, p=0.80, η^2_p=0.001; DMN-FPCN F=0.011, p=0.92, η^2_p=0.000.
CONCLUSIONS: Neural signatures of altered between-network rsFC differences that have been observed in studies of typical and pathological aging, as well as acute SRC, were not observed in the High SRC history group when compared to the Low group in this study. Although SRC history has been associated with early and chronic changes in brain function in former football players, these preliminary data suggest that such an association, if it exists, may not be detectable in relatively young individuals.

Title: High-frequency specific spreading depression in EEG of traumatic brain injury patients

Authors: *A. L. SCHWAMB[1], M. E. LOE[1], J. H. WAGNER[1], S. KHANMOHAMMADI[1], L. N. EISENMAN[2], O. J. LAURIDO-SOTO[2], T. T. KUMMER[2], S. CHING[1];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Dept Neurol., Washington Univ. Sch. Med., Saint Louis, MO

Abstract: In spectral analysis of continuous EEG recordings from 32 patients with traumatic brain injury (TBI), we observed a novel form of electrophysiological depression. This depression was characterized by a gradual loss of power above the spectral edge, while the below-edge power remained constant (High-frequency specific spreading depolarization, HFSSD). The time-frequency spectrograms of the TBI patients we studied are generally characterized by dominant and stereotypical low frequency power below 10Hz, with diffuse and unstructured power at higher frequencies. In HFSSD, this higher frequency activity becomes significantly and repetitively attenuated (-20dB) over a time-scale of 10-15 minutes. The lower frequency activity, however, remains unchanged both in power and in any banded frequency structure that exists. To quantify and automatically detect HFSSD, we developed a novel EEG signal processing pipeline consisting of a combination of K-means clustering and Kalman smoothing. First, we used K means clustering and Kalman filter smoothing to define a set of discrete spectra that constitute

the overall spectrogram. From moment to moment, the spectrogram is defined as belonging to one of these discrete members. Sixteen canonical exemplars of HFSSD from nine patients were identified based on the aforementioned characteristics. We then used a supervised learning approach to match comparable time epochs from all 32 patients, defining these epochs as HFSSD.For the automatically detected HFSSD, post-hoc analysis of the spectrograms confirmed the same above spectral-edge loss of power as the exemplars. In 26 out of the 32 patients studied, this phenomenon localized to the area of injury (81.25%). Moreover, in these 26 patients, this phenomenon exhibited diffusive spatial spread to surrounding EEG channels, suggesting underlying cortical propagation. The timescale and the spreading nature of this phenomenon suggest that HFSSD could be associated with Cortical Spreading Depression (CSD). CSDs are known to localize to the area of injury and slowly spread out to other areas of the brain. In patients with TBI, CSDs are highly correlated with negative outcomes, but require invasive electrocorticography approaches to detect. An indication of CSD in EEG data could provide earlier and less invasive detection, which would improve understanding of their relationship to neurological outcomes and enable testing of treatment strategies.

Title: Mild TBI-induced changes in peripheral innate immune cell populations across time

Authors: *J. SMITH[1], T. NGUYEN[2], M. JUBOORI[2], K. NAUGLE[3], F. A. WHITE[4]; [1]Med. Scientist Training Program, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Anesthesia, [3]Kinesiology, Indiana Univ., Indianapolis, IN; [4]Anesthesia, Indiana Univ. Sch. Med., Indianapolis, IN

Abstract: Mild TBI-induced changes in peripheral innate immune cell populations across time Jared Smith[1,2,3], Tyler Nguyen[2,3], Mohammed Juboori[2], Kelly Naugle[4], Fletcher A. `White[2,3]· [1]Medical Scientist Training Program, School of Medicine, Indiana University Indianapolis, Indianapolis, Indiana.· [2]Department of Anesthesia, School of Medicine, Indiana University Indianapolis, Indianapolis, Indiana. · [3]Stark Neurosciences Research Institute, Indiana University School of Medicine, Indianapolis, Indiana, USA.· [4]Department of Kinesiology, School of Health and Human Sciences, Indiana University/Purdue University, Indianapolis, Indiana.

Post-traumatic headache (PTH) is one of the most common and persistent symptoms following mild traumatic brain injury (mTBI), often disrupting recovery in civilian and military populations. Despite the high prevalence of PTH following mTBI, the pathological mechanisms underlying the development of chronic PTH's remain poorly understood. Recent publications suggest that monocytic cell subpopulations have a much larger role in the initial evolution of TBI than previously appreciated and this inflammatory response after mTBI may ultimately contribute to subacute or chronic PTH sequelae. For our study, adult mTBI patients were recruited from Level I Emergency Department Trauma Centers completed study sessions at 1-week, 1-month (sub-acute), and 4-6-months (chronic) post mTBI (n=31) including a headache survey which included a 0-10 numeric pain rating scale (NRS) to measure average intensity of headache pain. Additionally, we isolated the PBMCs for flow cytometric analysis with CD45, CD14, CD16, CD56, CX3CR1, CCR2, and TLR4. Monocytes were subdivided by CD14 and CD16 expression with high CD14 expression denoting inflammatory monocytes while high CD16 suggests anti-inflammatory (nonclassical) monocytes. Our data suggest substantial dynamic changes in monocyte subsets and natural killer cell distributions over the 4-month time period which could contribute to the clinical outcomes of PTH pain which may serve as biomarkers or as potential therapeutic targets.

Title: Differential association between grey matter volume and S100B levels in mTBI

Authors: *S. CLIMIE[1], A. ANDRADE[2], T. ZUIDEMA[5], M. T. MOORE[3], J. M. CARLSON[4]; [1]Northern Michigan Univ. Departments of Biol. and Psychology, Marquette, MI; [3]Sch. of Hlth. and Human Performance, [4]Psychology, [2]Northern Michigan Univ., Marquette, MI; [5]Indiana Univ., Bloomington, IN

Abstract: Over the past decade, blood serum-based protein biomarkers have been explored as an objective measure of the neurobiological mechanisms of mild traumatic brain injury (mTBI), also known as concussion. One of the most utilized and researched biomarkers is a calcium binding protein known as S100B. The majority of S100B research has focused on its efficacy as a biomarker of concussion, with the findings regarding its efficacy varying. There is insufficient literature regarding the association between S100B and structural alterations in the brain following mTBI. Thus, the aim of this study was to (1) further explore the efficacy of S100B as a

biomarker of concussion as well as (2) evaluate the association between S100B and grey matter volume (GMV) alterations in concussed college athletes. Structural magnetic resonance images (sMRI) as well as blood serum samples were collected from 26 collegiate athletes. The experimental group included 13 athletes who were both diagnosed with a mTBI and recently cleared to return to play. A group of 13 athletes matched on age, sex, and sport were used as a control. Overall, there was not a significant difference in S100B levels between the concussed and control groups (t = -.29, p = .77). A voxel-based morphometry (VBM) regression analysis was performed to test for differential associations between S100B levels and regional gray matter volume in concussed and non-concussed athletes. Using a whole-brain cluster-level family-wise error (FWE) correction, the results showed a positive relationship between S100B and GMV in the insula in the mTBI experimental group. This suggests a positive relationship between the insula GMV and S100B levels following concussion. Lastly, the results showed that decreased GMV in the paracentral lobule, postcentral gyrus, and the superior parietal gyrus was negatively associated with S100B levels following concussion. Although more research is needed, this study provides initial insight into the relationship between serum S100B levels and GMV alterations in college athletes who experienced mTBI.

Title: Examining the relationship between perceived distress and salivary cortisol among Veteran participants with mild traumatic brain injury in a yoga trial

Authors: *M. DONOVAN[1,2], J. E. FORSTER[1,2], L. M. BETTHAUSER[1,2], C. STAMPER[1,2], M. PENZENIK[1], T. D. HERNANDEZ[1,2,5], N. BAHRAINI[1,2,3], L. A. BRENNER[1,2,3,4];

Abstract: Mild traumatic brain injury (mTBI) was one of the leading injuries sustained by Veterans during recent conflicts, with many Service Members suffering from post-concussive symptoms long after the initial injury. Post-concussive headaches (PCH), one of the most widely

reported symptoms, can be both distressing and debilitating. Thus, there is an increased need to understand relationships between PCH, perceived distress, and underlying physiological mechanisms in this population. Recent work has supported the use of yoga-based interventions for treating stress dysregulation in a variety of populations, thus making yoga trials a setting within which to compare subjective and objective measures of distress in Veterans with PCH. Here, within the context of 75-minute yoga sessions across 8 weeks, we explored the relationship between perceived distress and cortisol in 16 Veterans (12 male, 4 female) with mTBI and long-term PCH. The Visual Analogue Scale (VAS), a validated tool for measuring subjective distress, was administered to participants immediately before and after yoga sessions over the course of the intervention. To allow for a comparison with VAS, participants also provided salivary cortisol (pre- and post-yoga) at 8 of the sessions. Mean age was 38.3 (standard deviation=7.6). Repeated measures ANOVAs were used to model VAS and cortisol change (post- minus pre-class scores) over time. There was a significant reduction in VAS scores for 5 of the 8 assessed yoga classes, with the estimated mean change ranging from -1.3 to -2.0 for these 5 classes (all $p<0.01$). Interestingly, there were no significant changes in cortisol levels during any of the assessed yoga sessions. Moreover, no significant correlations were found between VAS scores and salivary cortisol levels. When looking at how cortisol levels changed over time (i.e. over the series of 8 classes), there was a significant downward trajectory in post-yoga cortisol (β=-0.005 ug/dL, p=0.03); however, this result was no longer observed when taking pre-class cortisol into account (i.e., within yoga session cortisol change over time). Taken together, we found that subjective distress, but not cortisol was reduced during yoga classes, thus highlighting the ongoing challenges of bridging the gap between subjective and objective measures. Future research should explore additional biomarkers alongside subjective measures to better understand the mechanisms underlying perceived distress in those with mTBI and PCH.

Title: Relationship between structural magnetic resonance imaging and the development of psychological distress in mild traumatic brain injury patients

Authors: *F. SIBILIA[1], R. M. CUSTER[1], A. IRIMIA[2,3], F. SEPEHRBAND[1], A. W. TOGA[1], R. P. CABEEN[1];

[1]USC Stevens Neuroimaging and Informatics Institute, Keck Sch. of Med., [2]Ethel Percy Andrus Gerontology Center, Leonard Davis Sch. of Gerontology, [3]Dept. of Biomed. Engineering, Viterbi Sch. of Engin., USC, Los Angeles, CA

Abstract: Traumatic brain injury is defined mild (mTBI) when patients have loss of consciousness less than 30 minutes, Glasgow Coma Scale score of 13-15 and post-traumatic amnesia less than 24 hours. Traumatic brain damages can alter different structural compartments and lead to the development of neuropsychological symptoms, that can persist overtime. This study aims to investigate the relationship between structural brain damages and psychological distress in a mTBI population, using multiple MRI-based modalities. Eighty-nine mTBI patients from the TRACK-TBI (Transforming Research and Clinical Knowledge in Traumatic Brain Injury) pilot study were considered for the analysis. Three subscales of the Brief Symptoms Inventory 18 (BSI18), namely Depression, Anxiety and Somatization, were used as outcome measures of psychological distress 6 months after the traumatic event. Glasgow Coma Scale scores were used to calculate improvement level. MRI was performed within 2 weeks post-injury. Perivascular spaces (PVS) number and volume were obtained by using an enhanced PVS contrast mask, both at a whole-brain and region-specific levels. Cortical thickness and grey matter structures volumes were calculated in Freesurfer, diffusion imaging indexes and multi-fiber tracts were extracted using the Quantitative Imaging Toolkit. The analysis was performed considering age, sex, education and post-injury improvement level as covariates. Perivascular spaces were found to be associated to somatization symptoms in the posterior cingulate, fusiform and postcentral areas. The three BSI subscales were associated to the cortical thickness of frontal-opercularis and occipital pole, putamen and amygdala volume, and corticospinal tract and superior thalamic radiation ($p < 0.05$, FDR corrected). Other significant associations were also found when the two hemispheres were analyzed separately. This study shows how perivascular, cortical and microstructural damages contribute to the onset of depression, anxiety and somatization symptoms in mTBI patients. The combination of different MRI modalities can reveal more on the brain areas that predict neuropsychological disorders. Future work will look at gender-based differences, and if such psychological symptoms persist after 6 months, considering BSI scores at more timepoints. Data and research tools used in the preparation of this article reside in and were analyzed using the Department of Defense (DOD) and National Institutes of Health (NIH)-supported Federal Interagency Traumatic Brain Injury Research Informatics System (FITBIR). Dataset identifier: [doi:10.23718/FITBIR/1419836].

Title: The pain facilitatory role of Oprm1-expressing brainstem to spinal cord-projecting neurons

Authors: *Q. WANG, G. NACHTRAB, M. MOHR, J. XIONG, L. YUAN, X. CHOU, J. V. L. KING, M. A. HOROWITZ, X. CHEN;
Stanford Univ., Stanford, CA

Abstract: Persistent mechanical pain caused by inflammation or nerve injury is a debilitating clinical problem. The spinal cord-projecting neurons in the rostral ventromedial medulla (RVM^{SC} neurons) play active roles in pain facilitation. However, the underlying circuitry and molecular mechanisms remain largely unknown. Using fiber photometry, we recorded robust calcium signals from $OPRM1^{+}$ RVM^{SC} neurons when animal respond to noxious stimuli. We then genetically ablated $OPRM1^{+}$ RVM^{SC} neurons or chemogenetically inhibited these neurons in behaving mice and demonstrated their essential role in both initiation and maintenance of chronic mechanical pain caused by nerve injury and inflammation. Using retrograde transneuronal tracing, we identified presynaptic neurons that provide the excitatory input onto the $OPRM1^{+}$ RVM^{SC} neurons and examined their role in the onset and maintenance of mechanical hypersensitivity. Together, our results revealed that the activity of $OPRM1^{+}$ RVM^{SC} is required for both initiation and maintenance of mechanical hypersensitivity in mouse models of inflammatory and neuropathic pain.

Title: Lidocaine and ketamine transiently revert the capsaicin-induced increase in functional coupling between the ongoing dorsal horn and brainstem neuronal activity

Authors: N. PLAMENOV[1], L. MORENO[1], D. CHÁVEZ[1], E. HERNÁNDEZ[1], B. ALVAREZ[1], P. REYES[1], S. GLUSMAN[1,2], ***P. RUDOMIN**[1,3];
[1]Cinvestav IPN Depto. Fisiologia, Mexico City, Mexico; [2]Stroger Cook County Hosp., Chicago, IL; [3]El Colegio Nacional, Mexico City, Mexico

Abstract: We have shown in the anesthetized cat that during the state of central sensitization induced by the intradermal injection of capsaicin there is a non-random (structured) increase in the functional connectivity between the ongoing activity generated by dorsal horn (DH) neuronal populations distributed along the L4-L7 spinal segments. These changes are supraspinally modulated and transiently reverted by the systemic injection of sub-anesthetic amounts of lidocaine (Contreras-Hernández et al., J. Physiol 2018). Ketamine, a non-competitive antagonist of the N-methyl-d-aspartate (NMDA) receptors, is now being used to induce a quick and enduring relieve of depression. Since activation of NMDA receptors plays a significant role in the reconfiguration of neuronal connectivity during nociception, we wondered on the extent to which ketamine also modified the capsaicin-induced functional coupling between supraspinal and DH neuronal populations. To this end we recorded the ongoing field potentials generated in the bulbar reticular formation and midline raphe nuclei (RVM), in the DH and in the L4-L7 Cord Dorsum spinal segments. We used standard computational methods to estimate the changes produced by capsaicin, lidocaine and ketamine on the correlation as well as on the power spectra and coherence between the field potentials recorded at these sites. We found that both lidocaine and ketamine transiently changed the frequency spectra of the field potentials generated by the RVM and spinal cord neuronal populations recorded during the action of capsaicin and reduced the coherence between them. Quite interestingly, during the decoupling induced by lidocaine and ketamine the patterns of functional connectivity in the examined spinal and supraspinal neuronal populations resembled their pre-capsaicin configurations. We are now in the process of testing several de-correlating procedures to induce a functional decoupling between the spinal and supraspinal increased correlation induced by nociception.

Title: Elucidating the role of testosterone in the descending pain pathway after activity-induced pain

Authors: *A. PLUMB[1], J. LESNAK[1], L. RASMUSSEN[1], K. A. SLUKA[2];
[2]Physical Therapy & Rehab Sci., [1]Univ. of Iowa, Iowa City, IA

Abstract: Females experience higher prevalence of chronic pain which emerges around the time of puberty suggesting that sex hormones play a role. We developed an activity-induced musculoskeletal pain model that produces behavioral sex differences in which females develop widespread hyperalgesia of longer duration, while males develop localized pain for shorter durations. Previously, we determined that testosterone mediates the behavior phenotype in male and female mice, and there are sex-dependent differences in expression of SERT in the RVM with females showing increased expression. The current study examined the role of RVM in mediating the testosterone-dependent behavior phenotype and SERT expression. The pain model was induced by two injections (pH 5.0 saline) into one gastrocnemius muscle combined with 6 minutes of fatiguing muscle contractions in C57/Black6 mice. Hyperalgesia was tested with withdrawal threshold of the gastrocnemius muscle using force sensitive tweezers. To determine if testosterone mediates antinociception centrally, we implanted a guide cannula in the RVM and microinjected drugs to modulate sex hormones in male and female mice. Since testosterone is converted to estrogen through the enzyme aromatase, we microinjected either an estrogen receptor antagonist (ICI182,780; 2-20uM) or an aromatase inhibitor (letrozole; 350uM-3.5mM) into the RVM. Blockade of either estrogen receptors ($p=.001$) or aromatase ($p=.046$) in the RVM resulted in contralateral hyperalgesia in male mice but had no effect in female mice ($p=.457$). To test the impact of testosterone on SERT expression, male mice were gonadectomized whereas female mice were implanted subcutaneously with testosterone pellets, and the RVM was immunohistochemically stained with a SERT antibody. Testosterone reduced SERT density in female mice ($p=.009$); however, gonadectomy in males has no effect on SERT levels ($p=.915$). Microinjection of a SERT inhibitor into the RVM reversed ipsilateral hyperalgesia in both male ($p=.022$) and female ($p=.041$) mice but required a higher dose to produce the same degree of analgesia in females. Our data suggests that males convert testosterone in the RVM to estradiol through aromatase to protect from development of widespread hyperalgesia. On the other hand, estrogen receptors in the RVM do not play a role in development of widespread hyperalgesia in female mice. The increased SERT expression in females is reduced by treatment with testosterone; however modulation of testosterone in males does not affect SERT expression. Understanding the sexual dimorphism in pain will lead to an optimization of individualized pain treatment.

Title: Cholinergic modulation of the descending pain circuitry

Authors: *S. SULLERE, A. KUNCZT, D. S. MCGEHEE;
Univ. of Chicago, Chicago, IL

Abstract: Acetylcholine and its receptors modulate neuronal activity to enable organisms adapt to various evolutionarily conserved and ethologically relevant stimuli. Although pharmacological agents targeting various cholinergic receptors modulate pain signaling, the impact of endogenous cholinergic circuits in acute and chronic pain conditions has not been investigated. We examined acute pain relief by cholinergic inputs to the descending pain pathway at the level of the ventrolateral periaqueductal gray (vlPAG) in adult male and female mice, and have identified pedunculopontine tegmental nucleus (PPTg) as a key mediator of cholinergic analgesia. Under chronic pain conditions, selectively stimulating cholinergic projections from PPTg to vlPAG relieved somatic and affective pain symptoms. Interestingly, chronic pain conditions are associated with decreased cholinergic tone in vlPAG, as assayed with the fluorescent ACh sensor - ACh3.0. By combining optical stimulation and pharmacology, we identified α7 nAChRs as the key cholinergic receptor mediating these analgesic effects. Finally, in-vivo calcium imaging using GCaMP6 revealed maladaptive hyper-excitability of α7 nAChR-expressing vlPAG neurons under chronic painful conditions, which is reversed by systemic treatment of α7 nAChRs agonists. These results implicate cholinergic mechanisms in acute and chronic pain-induced alterations in neuronal excitability, and will help identify novel targets for analgesia.

Title: Insights into supraspinal mechanisms of green light-induced antinociception.

Authors: *K. CHENG[1], L. F. MARTIN[2], M. S. DENTON[2], S. M. WASHINGTON[2], T. KRANZ[2], A. M. PATWARDHAN[2], M. M. IBRAHIM[2];

Abstract: The pain-relieving effects of green light therapy (GLED) have been characterized in animal and clinical studies, and its efficacy has been confirmed by independent groups for the treatment of a variety of pain conditions, including fibromyalgia and migraine. However, the exact underlying mechanisms utilized by GLED remain to be uncovered. Initial animal studies identified the visual system as the point of entry for GLED, though the specific photosensitive cells responsible have not yet been identified. Accordingly, hypotheses identifying either retinal cones or non-image-forming photosensitive cells as the photoreceptors responsible have arisen. Recently, a patient with protanomaly was recruited into the clinical GLED study for migraine pain. After undergoing 2 hours of GLED exposure per day for 10-weeks, the patient reported significant improvements in headache pain intensity, quality of life, and perceived headache frequency, measured by validated pain surveys. The fact that GLED was efficacious in a patient with a retinal cone pathology provides substrate for the hypothesis that intrinsically photosensitive retinal ganglion cells (ipRGCs) are key for players in GLED photoreception for pain modulation. Furthermore, previous studies suggest that GLED photoreception by the visual system ultimately acts on central pain modulation areas and the endogenous opioid system to elicit antinociception. Using pharmacological, behavioral, and in situ hybridization approaches in rodent studies, we identified that opioid receptor agonism by endogenous opioids in the rostral ventromedial medulla (RVM) was required for GLED-induced antinociception. Specifically, stereotaxic injection of naltrexone into the RVM of male rats exposed to GLED for 6 days, 8 hours/day reversed the effect of GLED in the HIV-gp120 model of neuropathic pain. Importantly, naltrexone injections only blocked mechanical, but not thermal, antinociception. In conjunction with our previous studies, these results suggest that GLED reduces descending RVM GABAergic inputs on spinal enkephalinergic interneurons to cause mechanical antinociception. Altogether, these recent findings further contribute to our understanding of supraspinal mechanisms of GLED-induced antinociception and provide the framework for future studies unveiling the exact pathway from photoreception to pain relief. An improved understanding of the mechanism of GLED antinociception will offer insights into additional clinical utility of this novel, efficacious, and non-pharmacologic pain therapy.

Title: The neurochemical basis of the "anti-diffuse noxious inhibitory control" phenomenon

Authors: *W. NEMOTO[1], S. N. TANSLEY[1], J. S. MOGIL[1,2];
[1]Dept. of Psychology, [2]Alan Edwards Ctr. for Res. on Pain, McGill Univ., Montreal, QC, Canada

Abstract: Diffuse noxious inhibitory control (DNIC), alternatively known as conditioned pain modulation (CPM) or descending control of nociception, is a "counterirritation"-like phenomenon whereby pain in one location inhibits pain in another location. CPM in humans is now widely investigated as a proxy measure of endogenous pain inhibitory capacity. We recently showed that noxious conditioning stimuli can produce hyperalgesia instead of hypoalgesia depending on the intensity of the noxious test stimulus (Tansley et al., *Pain*, 2019), but the mechanism underlying our "anti-DNIC" observation is unknown. DNIC has been reported to reduce firing rates of wide dynamic range neurons, which are modulated by brainstem noradrenergic and serotonergic projection neurons, in electrophysiological studies. In this study we examined the potential involvement of serotonergic and noradrenergic neurons in the anti-DNIC phenomenon. To produce anti-DNIC, following baseline thermal pain testing using the radiant heat paw-withdrawal test (20% maximum intensity), 0.9% acetic acid was injected intraperitoneally to CD-1 mice and subsequent thermal hyperalgesia at the hind paw was measured for 30 min. Citalopram and fluoxetine, selective serotonin reuptake inhibitors, or reboxetine, a norepinephrine reuptake inhibitor, was injected s.c. or i.t. before the injection of acetic acid. The systemic administration of citalopram (30 mg/kg, s.c.) and reboxetine (30 mg/kg, s.c.) did not affect the hyperalgesia. On the other hand, this hyperalgesia was significantly attenuated by an intrathecal (i.t.) administration of reboxetine (25 µg) and fluoxetine (25 µg) 10 min before the injection of acetic acid, but it was not affected by citalopram (25 µg). These results suggest that noradrenergic and serotonergic signals in the spinal cord are involved in the anti-DNIC phenomenon. Ongoing experiments with subtype-selective antagonists will clarify the neurochemical mediation of both anti-DNIC and DNIC in awake, behaving mice.

Title: Role of Medial Prefrontal Cortex Endocannabinoids Signaling in Descending Control of Neuropathic Pain

Authors: *C. M. MECCA, Y. FENG, M. PLASKI, Q. H. HOGAN, B. PAN;
Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Medial prefrontal cortex (mPFC) is involved in pain processing, especially in engagement of descending control of pain state. In our previous study, we found that there is dynamic change of neuronal activity of mPFC after painful peripheral nerve injury (spared nerve injury, SNI), which is correlated to the dynamic change of endocannabinoid (eCB) signaling. As descending inhibitory control of pain is directly relevant to mPFC neuronal activity, we hypothesize that eCB-dependent regulation of mPFC activity after injury contributes to the descending inhibitory control of neuropathic pain. AM4113, neutral antagonist of cannabinoid receptor type 1, was microinjected into mPFC on the day of SNI and continued for 21 days to counteract the activated eCB signaling in the early phase of SNI. Sensory tests were performed to assess pain-like responses over time (before injury, 7, 14, 21, 28, 35, and 43 days after injury). SNI reliably induced hyperalgesia and allodynia, which was reversed by mPFC injection of AM4113 starting from 14 days after SNI. To understand whether analgesic effect of mPFC administration of AM4113 is by regulating descending pain modulation system, recordings from dorsal horn wide dynamic range (WDR) neuron were performed. SNI reduced mechanical threshold to induce action potential firing of WDR neurons, which was reversed in rats with mPFC injection of AM4113. These results suggested that eCB-dependent mPFC activity contributes to the pain chronification and manipulation of eCB signaling in mPFC after painful nerve injury can reverse the pain-like behaviors by regulating descending pain control system.

Title: A new tool in PAR research: the PAR2-tdTomato tagged mouse

Authors: *M. KUME[1], S. BOITANO[3], J. VAGNER[4], G. DUSSOR[2], T. J. PRICE[2];
[1]UT Dallas Cognition and Neurosci. Grad. Program, [2]Sch. of Behavioral and Brain Sci., The Univ. of Texas at Dallas, Richardson, TX; [3]Arizona Resp. Ctr. and Dept. of Physiol., [4]The BIO5 Collaborative Res. Inst., Univ. of Arizona, Tucson, AZ

Abstract: Protease-activated receptor 2 (PAR2) is a G-protein coupled receptor linked to numerous pathologies, including acute and chronic pain. Its irreversible activation by endogenous or exogenous serine-proteases is known to cause neuronal plasticity and chronic pain via the MAPK/ERK pathways. Our previous work has shown that the neurons responsible for the mechanical hypersensitivity and spontaneous pain caused by PAR2-activating proteases is a very small subpopulation of dorsal root ganglion (DRG) neurons. Despite the known therapeutic potential of targeting PAR2, progress towards a PAR2 blocking drug has been slow, partly due to the lack of PAR2-specific pharmacological tools and nonspecific antibodies. In order to address these issues, we are actively developing potent and specific PAR2 agonists and antagonists, and we have now developed a PAR2-reporter mouse where PAR2 is tagged with tdTomato on the intracellular C-terminal. This tool will potentially allow us to analyze native PAR2 expression in nociceptors and the tissues they innervate without the use of PAR2 antibodies. In preliminary experiments, we have validated PAR2-tdTomato expression in colon goblet cells and in airway epithelial cells. We have also detected PAR2-tdTomato expression in cultured trigeminal ganglion and dorsal root ganglion neurons. The PAR2-tdTomato mouse will allow us to endogenously study changes in real-time subcellular distribution of PAR2 expression, trafficking, and recycling in response to proteases, guiding the future development of PAR2 therapeutics.

Title: Knee joint pathology and pain in mid-stage and advanced OA

Authors: T. VESEY[1], C. WILLIAMS[1], V. E. EATON[2], ***T. KING**[1];
[2]Biomed. Sci., [1]Univ. of New England, Biddeford, ME

Abstract: Osteoarthritis (OA) is characterized by progressive articular cartilage loss, new bone formation, and synovial proliferation resulting in pain, knee joint damage, and a lower quality of life. Patients with osteoarthritis can develop different pain phenotypes. Many patients report pain during joint use that abates during rest and that can be managed with non-steroidal anti-inflammatory agents (NSAIDs), described as mid-stage osteoarthritis. Some patients report development of persistent ongoing pain that is resistant to NSAIDs, termed advanced OA. We examined potential changes in the OA joint that may contribute to differences in these pain states in a mouse model of osteoarthritis. We tested the hypotheses that mid-stage and advanced OA pain have different levels of joint pathology and pathological sprouting of sensory fibers. Notably, females develop advanced OA pain at lower MIA concentrations compared to males. We examined the hypothesis that the sex differences in pain phenotype is independent of joint pathology suggesting central mechanisms mediating these sex differences. Mice were injected with different doses of monosodium iodoacetate (MIA) that produce different pain phenotypes corresponding to mid-stage and advanced OA pain. When looking at innervation within the knee joint, there is a noticeable difference in intensities between the control, mid stage, and advanced osteoarthritis animals. Further imaging shows that in cases of advanced osteoarthritis, nerves appear to sprout into the tibialis anterior muscle. Title: Changes in $GABA_A$ receptor function is dependent on osteoarthritis pain state

Authors: *V. EATON[1], K. TOWNSEND[1], T. E. KING[2];
[2]Biomed. Sci., [1]Univ. of New England, Biddeford, ME

Abstract: GABA signaling within the spinal cord is normally associated with pain inhibition. However, changes in GABA receptor function resulting in spinal disinhibition is proposed to be integral to the maintenance of chronic pain. A murine model of monosodium iodoacetate (MIA)-induced knee joint osteoarthritis (OA) was used to investigate the hypothesis that changes in spinal GABA signaling is dependent on the characteristics of the chronic pain state. We

compared the effects of $GABA_A$ receptor activation and blockade across different OA pain phenotypes. Mid-stage OA is associated with weight asymmetry without a persistent ongoing pain state. Advanced OA is characterized by both weight asymmetry and persistent ongoing pain. Spinal administration of the $GABA_A$ agonist (muscimol) and antagonist (bicuculline) were used to investigate alterations in $GABA_A$ receptor signaling across mid-stage and advanced-stage OA pain states. Our experiments demonstrate that spinal bicuculline did not alter weight asymmetry in mice with mid-stage OA whereas it normalized weight bearing in mice with advanced OA. Spinal muscimol normalized weight asymmetry in mice with mid-stage OA. Conversely, advanced OA mice showed no change in weight bearing. In mice with advanced OA, muscimol induced conditioned place aversion, indicated worsening of joint pain, whereas bicuculline induced conditioned place preference, indicating that bicuculline produced pain relief. Additionally, optogenetic activation of GABAergic interneurons showed normalization of weight bearing in mid-stage but not advanced OA mice, further indicating a paradoxical switch in spinal GABA function is only observed in a chronic OA pain state associated with persistent ongoing pain. Potassium chloride channel 2 (KCC2) has been implicated as a key mechanism driving altered $GABA_A$ receptor function in chronic pain. Restoring KCC2 function through spinal administration of CLP290 reversed weight asymmetry in mice with advanced but not mid-stage OA. These data indicate that $GABA_A$ receptors induce net inhibition in mid-stage OA, a chronic pain state characterized by intermittent joint pain. In contrast, $GABA_A$ receptors induce net excitation in advanced OA, a chronic pain state characterized by persistent ongoing joint pain. Supported by an Institutional Development Award (IDeA) from the National Institute of General Medical Sciences (NIGMS) of the National Institutes of Health (NIH, P20GM103643).

Title: Analgesic Dorsal Root Ganglionic Field Stimulation Blocks Conduction of Afferent Impulses in Rats with Monoiodoacetate-induced Osteoarthritis

Authors: D. CHAO, Q. HOGAN, *B. PAN;
Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Chronic joint pain is common in patients with osteoarthritis (OA). Non-steroidal anti-inflammatory drugs and opioids were used to relieve OA pain and their effects are not satisfied.

Dorsal root ganglion field stimulation (GFS) is an analgesic neuromodulation approach in use clinically. Even though it is not currently used in patients with OA pain, GFS is effective in a preclinical rat OA pain model. Here, we evaluated the cellular mechanism of analgesic effects of GFS on OA pain with electrophysiological teased fiber recordings in a monosodium iodoacetate (MIA)-induced OA (MIA-OA) rat model. Two weeks after intra-articular injection of MIA, those rats developed hypersensitivity to knee press stimulation, spontaneous pain with incapacitance test, and hypersensitivity to punctate mechanical stimulation to plantar skin of hind paw. In rats with MIA-OA, *in vivo* single unit recordings from nerve bundles teased from the saphenous nerve and third lumbar (L3) dorsal root showed higher incidence of spontaneous activities (SA) than those from control rats. GFS at L3 level blocked this SA. After MIA-OA, the threshold to induce action potential (AP) firing by punctate mechanical stimulation (von Frey) was reduced when recorded from bundles teased from the L4 dorsal root, which was reversed to normal after GFS. These results indicate that GFS takes analgesic effects in MIA-OA rat model by producing use-dependent blockade of SA and afferent AP trains induced by either knee moving or punctate mechanical stimulation to paw.

Title: Evidence of autonomic dysfunction in the male rat after surgical induction of osteoarthritis

Authors: *T. YEATER[1], J. ZUBCEVIC[2], J. GRIFFITH[1], K. ALLEN[1,3];
[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Dept. of Physiological Sci., [3]Dept. of Orthopedic Surgery and Sports Med., Univ. of Florida, Gainesville, FL

Abstract: *Objective:* Functional changes in the autonomic nervous system may help explain variability in the progression of knee osteoarthritis (OA). Indeed, autonomic dysregulation is implicated in rheumatoid arthritis, another chronic inflammatory joint disease. In this study,

autonomic nervous system shifts, as measured via heart rate response variables, were evaluated in rat knee OA models. *Methods:* Radiotelemetry probes were implanted to collect blood pressure measurements from which the heart rate was derived from the peaks in pulse pressure. Heart rate was evaluated as an indirect assessment of vagal nerve function, a key part of the autonomic nervous system. Recordings occurred at baseline and every other week for 8 weeks after induction of OA via medial collateral ligament transection plus medial meniscus transection (MCLT+MMT; n=7-10) or MCLT alone (n=4-5), with skin incision (n=7-9) used as a control. Cardiovascular responses were assessed in response to 1-phenylbiguanide, which has reported vagal activation properties (n=5-6/group). Cardiovascular responses to mechanical stimuli applied at the knee were used to indirectly assess cardiac vagal responses. Finally, changes in cartilage and bone architecture were quantified using custom artificial intelligence driven histological analysis pipeline. Experiments were done in accordance with ARRIVE guidelines. *Results:* Cardiac vagal tone decreased in MCLT+MMT animals during high activity periods, but not low activity. However, during low activity, MCLT and MCLT+MMT animals exhibited a slower heart rate than controls ($p<0.05$, week main effect). Mechanical stimuli at the knee resulted in a sudden drop in heart rate and blood pressure, with no differences seen between groups. Additionally, MCLT and MCLT+MMT animals tended to have a larger drop in heart rate following administration of 1-phenylbiguanide ($p=0.06$, surgery*dose interaction). Histological analysis revealed cartilage loss and subchondral bone thickening in MCLT+MMT animals compared to control and MCLT animals ($p's<0.05$). *Conclusions:* Acute mechanical stimulation of the knee produced an immediate reduction in heart rate, suggesting a direct neural joint-brain connection that may modulate autonomic responses in OA. Measurement of cardiovascular responses to pharmacological stimulation of the vagus nerve via 1-phenylbiguanide, which is reportedly able to induce acute cardiac vagal responses, demonstrate for the first time a shift in autonomic function in rodent knee injury models of OA. This, combined with the more prominent chronic reduction in heart rate in OA groups, suggests sensitization of cardiac vagal activation with OA.

Title: Neuropod-based modulation of DRG neuron excitability may underlie the pathophysiology of visceral abdominal pain

Authors: *T. D. ALEXANDER[1], J. BARTON[2], S. WALDMAN[2], M. COVARRUBIAS[1]; [1]Dept. of Neurosci. and Vickie and Jack Farber Inst. for Neurosci., [2]Dept. of Pharmacol. and Exptl. Therapeut., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Visceral abdominal pain affects around 10% of the US population and is a major burden on the healthcare system – accounting for over $40 billion in medical costs. The mechanisms underlying visceral abdominal pain are complex and involve spinal cord afferent neurons, including dorsal root ganglia (DRG) neurons, which signal to higher order pain centers. It has been recently shown that a new type of intestinal epithelial cells known as neuropods exhibit neuron-like properties and may synapse on spinal cord afferents. These neuropods are receptive to nociceptive cues and may communicate with visceral afferents through specialized chemical synapses. However, the underlying electrical properties of the neuropod and the spinal cord afferents with which they communicate have yet to be understood. Exploring this unique epithelial-neural signaling axis provides insight into the pathophysiology of visceral pain and reveals neuropod cells as a potential therapeutic target. To examine the underlying electrical properties of this system, we performed patch-clamp recordings on both DRG neurons and neuropods in coculture. Mouse neuropods expressing a fluorescent reporter and the surrounding crypt cells from small intestine were cocultured with mouse spinal cord embryonic DRG neurons, and various recording protocols were used to examine underlying electrical properties. Neuropods exhibited voltage-dependent inward and outward currents and a resting membrane potential (RMP) of -62 mV (range -27 to -95 mV, n=2); however, upon sustained current injection up to 180 pA for 1 s, neuropods did not fire action potentials (APs). Insufficient Na conductance under our experimental conditions may underlie this property. The RMP of DRG neurons with processes extending towards neuropods was comparable to that of DRG neurons not extending towards the neuropods (-60±11 mV, n=8, and -67±19 mV, n = 4, respectively, P=0.29). Remarkably, upon sustained current injection of 60 pA for 1 s, DRG neurons extending towards neuropods fired a median of 10 APs while DRG neurons not extending towards neuropods fired a median of 1 AP (P=0.01). DRG neurons which interact with neuropods may be hypersensitive, potentially as a result of signaling between these two cells. An increase in this signaling may manifest as increased visceral abdominal pain. We are currently examining the neuropod-specific effects of these changes, further effects on AP dynamics of both the neuropod and DRG neurons, and the implications in visceral abdominal pain.

Title: Acid-sensing ion channels modulate bladder nociception

Authors: N. MONTALBETTI, ***M. D. CARATTINO**;
Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Acid-sensing ion channels (ASICs) are cation permeable channels expressed in neurons that respond to extracellular acidification. In this report, we investigated the contribution of ASICs to bladder nociception in a model of chemical-induced cystitis. Female and male mice were injected intraperitoneally with a cyclophosphamide (CYP) solution (80 mg/kg) every other day for up to a week. We found that the administration of CYP to both female and male mice lacking ASIC3, a subunit primarily expressed in sensory neurons, generates pelvic allodynia at a time point at which only modest changes in pelvic sensitivity are apparent in wild type (WT) mice. To assess whether the referred pelvic allodynia seen in *Asic3* KO mice treated with CYP is caused by sensitized primary afferents, we examined the firing evoked by sustained electrical stimulation of acutely isolated bladder sensory neurons from WT and *Asic3* KO mice. Sensory neurons were classified based of the sensitivity of the action potential to tetrodotoxin (TTX), as TTX-resistant (TTX-R) or TTX-sensitive (TTX-S). As expected, sensory neurons from both WT and *Asic3* KO mice treated with saline display a phasic pattern of action potential firing in response to suprathreshold stimulation. In contrast, and consistent with sensitization, we noticed that sensory neurons with TTX-S action potentials from both groups of mice treated with CYP exhibited tonic firing. But strikingly, CYP treatment only sensitized neurons with TTX-R action potentials in *Asic3* KO mice. These findings indicate that the differences in mechanical pelvic sensitivity observed between WT and *Asic3* KO mice treated with CYP are mediated by sensitized bladder nociceptors with TTX-R action potentials. Lastly, our studies showed that the loss of ASIC3 from sensory neurons abolished their ability to discharge action potentials in response to extracellular acidification. Collectively, our studies support the notion that protons and their cognate ASIC receptors are part of a mechanism that operates at the nerve terminals to modulate nociceptor excitability and sensitization.

Title: TGF-β/P2X4 signaling pathway in sympathetic-mediated inflammatory low back pain

Authors: D. D. LÜCKEMEYER[1], W. XIE[1], R. TONELLO[2], T. BERTA[1], *J. A. STRONG[1], J.-M. ZHANG[1];
[1]Anesthesiol., Univ. of Cincinnati Col. of Med., Cincinnati, OH; [2]Mol. Pathobiology, NYU, New York, NY

Abstract: Although the sympathetic nervous system drives several pain conditions and local sympathetic blockade or lesion is clinically used to treat pain, the underlying mechanisms are remain poorly understood. To better understand these mechanisms, we developed in rats and mice a localized microsympathectomy (mSYMPX), which consists of cutting the grey rami containing postganglionic sympathetic fibers as they enter the spinal nerves near the lumbar dorsal root ganglia (DRG). We reported that this mSYMPX attenuated pain behaviors in several preclinical pain models including a mouse model of chemotherapy-induced peripheral neuropathy (CIPN model). Attenuation of pain behavior by mSYMPX in the CIPN model involved macrophages and anti-inflammatory actions of transforming growth factor-β (TGF-β) and its receptor TGF-βR1 at the level of the DRGs. In this study we asked whether the macrophage-enriched purinergic receptor P2RX4 and anti-inflammatory cytokine TGF-β are involved in sympathetic-mediated inflammatory low back pain/radiculopathy produced by intravertebral injection of the immune stimulator zymosan, causing mechanical hypersensitivity (LID model). Our previous microarray study in rats showed regulation of the macrophage cell marker ionized calcium binding adapter molecule 1 (*Iba1*), *P2rx4*, *Tgfb1* and its receptor *Tgfbr1* after LID. As previously reported in rats, we report that mice showed mechanical hypersensitivity assessed by calibrated von Frey filaments and transcriptional upregulation of *Iba1*, *Tgfb1* and *Tgfbr1* three days after LID. Interestingly, mSYMPX prevents mechanical hypersensitivity and it is associated with significant transcriptional upregulation of *Iba1*, *Tgfb1* and *Tgfbr1* and potential downregulation of P2rx4 (p=0.1) three days after LID. These findings suggest TGF-β signaling as a general underlying mechanism of local sympathetic blockade or lesion in several pain conditions, and indicate TGF-β and potentially P2RX4 as therapeutic targets to treat inflammatory low back pain/radiculopathy.

Title: Human TrkA^{R649W} and human NGF^{R100W} mutations impair nociception but differentially affect sweating and cognitive abilities: two mouse models of HSAN IV and V diseases

Authors: *P. PACIFICO[1], G. TESTA[1], R. AMODEO[2,1], L. MARCHETTI[3,4], J. ARÉVALO[5], S. CAPSONI[1,6], A. CATTANEO[1,7];

Abstract: In adulthood, the neurotrophin Nerve Growth Factor (NGF) produces a long-lasting thermal and mechanical hyperalgesia after tissue damage by activating its receptors TrkA and P75^{NTR}. The necessity for a functioning NGF-TrkA system is evident in individuals affected by Hereditary Sensory and Autonomic Neuropathies type IV and V (HSAN IV and V), caused by mutations in TrkA or NGF, respectively. Both diseases are characterized by loss of response to noxious stimuli while anhidrosis and variable mental retardation are found exclusively in HSAN IV patients. However, how mutations in TrkA or in NGF can lead to different clinical phenotypes remains to be discovered. To this aim, our laboratory previously generated a knock-in mouse line harboring the HSAN V R100W mutation in the human NGF gene (NGF^{R100W}). In agreement with HSAN V patients, NGF$^{R100W/m}$ mice lack to respond to noxious stimuli preserving cognitive abilities (Testa et al., 2019). Here, we show that the R649W mutation in TrkA tyrosine kinase domain affects phosphorylation in response to the binding of NGF without modifying the total amount of the protein. We found that R649W mutation decreased the ubiquitination and the membrane mobility, leading to an increase of the density of TrkA^{R649W} at the cell membrane surface. To verify whether TrkA^{R649W} influences *in vivo* the physiology of dorsal root ganglia (DRG) sensory neurons and pain sensitivity, we generated a knock-in mouse carrying the mutation R649W in the human TrkA. In the homozygous condition, the TrkA^{R649W} mutation is lethal, as observed in NGF$^{R100W/R100W}$ mice (Testa et al, 2019). We also demonstrated that, in both male and female heterozygous TrkA^{R649W} mice, nociception is specifically impaired, with a reduction of the response to thermal- and chemical- noxious stimuli. Moreover, we found that TrkA^{R649W} affects the expression of nociceptive markers in DRG and the skin innervation. Using a sweat assay, we observed that anhidrosis is strictly related to TrkA^{R649W} while no sweating deficits are detected in NGF$^{R100W/m}$. Finally, we showed that cognitive abilities linked to spatial-working memory, anxiety and sociability are impaired only in TrkA$^{R649W/m}$ mice. We conclude that not only TrkA$^{R649W/m}$ and NGF$^{R100W/m}$ mice accurately reproduce the clinical manifestations of the respective pathologies but suggest unexplored novel roles of TrkA in

thermoregulation and in sociability. The comparison between these transgenic mice could provide new knowledge about the role of NGF-TrkA signaling in nociception and pain perception, possibly leading to the isolation of new candidates for the development of innovative therapeutic strategies to alleviate chronic pain.

Title: Dynamics of spike time encoding in the olfactory bulb

Authors: *J. C. WERTH, T. A. CLELAND;
Psychology, Cornell Univ., Ithaca, NY

Abstract: Synchronized oscillatory activity at gamma frequencies (30-100 Hz) occurs in a variety of brain circuits which process sensory and perceptual information. In the olfactory bulb, the odor-evoked activity of principal neurons (mitral and tufted cells; MTCs) shows striking periodicity and synchronization, which is known to be necessary for fine odor discrimination in the analogous insect antennal lobe. While the relevance of spike timing on fast gamma timescales is clear, we lack a full understanding of how sensory information is embedded in this temporal framework - in part due to a limited capacity to control the receptor activation pattern, intensity profile, and timecourse of odor delivery on fine spatial and temporal scales.
We investigated the spike-timing properties of MTCs using an in vitro bulbar slice preparation mounted on a 120-channel planar multielectrode array, while delivering “artificial odor” stimuli using spatiotemporally patterned optogenetic stimulation. These “artificial odor” stimuli evoked persistent gamma oscillations in the local field potential, and generated gamma-synchronized spiking (lag $\leq$ 5 ms) among recorded MTCs. This synchrony occurred in an “odor”-specific manner, such that the MTCs with synchronized spikes depended on which “artificial odor” was presented, and were largely conserved across multiple presentations of the same “artificial odor”. These results suggest that MTC spike timing properties are conserved in OB stimulus representations.

Title: Active olfactory sensing and state-dependent regulation of olfactory processing by the basal forebrain

Authors: *E. HANSON MOSS[1], C. SMITH[2], P. J. PFAFFINGER[3], J. REIMER[3], B. R. ARENKIEL[4];

Abstract: Top-down regulation allows flexible modulation of sensory processing in response to behavioral states like attention and arousal.Understanding the impact of state-dependent modulation on olfactory processing has been limited by the spatial scale and temporal resolution of in vivo imaging platforms. Leveraging high-speed, meso-scale two-photon imaging in mice, we examine how spontaneous shifts in attention and arousal modulate spatiotemporal properties of odor responses across the olfactory bulb. Here, we describe an approach combining mesoscopic imaging of the olfactory bulb with temporally precise odor delivery and detailed behavioral state monitoring in awake mice. Using this approach, we visualize olfactory bulb odor response dynamics across spontaneous changes in behavioral state and with manipulations of state-dependent basal forebrain neuronal activity. To quantify active olfactory sensing, we apply a novel method using video-based tracking of nostril motion and temperature-based respiration recording. Additionally, we relate active olfactory sensing states to measures of arousal including wheel running and eye area to create a more comprehensive measure of behavioral state changes over time and across odor presentations. Then, using simultaneous, meso-scale two-photon recordings of olfactory bulb mitral cell somas and glomeruli, we relate glomerular and mitral cell body activity to active sensing and arousal states during passive odor exposures. Finally, using chemogenetic inhibition, we demonstrate how cholinergic input from the basal forebrain impacts state-dependent and odor-evoked olfactory bulb activity. Ultimately, our approach for combined behavioral state monitoring and mesoscopic two-photon imaging allows us to investigate how spontaneous behavioral state changes in awake mice modulate odor responses and

spatiotemporal patterns of activity across the glomerular and mitral cell layers of the olfactory bulb.

Title: The impact of odor stimulation on the responsiveness of mitral/tufted cell glomeruli.

Authors: N. SUBRAMANIAN, ***D. A. STORACE**;
Biol. Sci., Florida State Univ., Tallahassee, FL

Abstract: Localizing an odor requires that an organism carry out several perceptual computations in parallel. An odor percept of interest must be recognized at some distance from the source despite the presence of other background stimuli and approaching (or avoiding) the stimulus requires maintaining both sensitivity to concentration changes and a concentration-invariant representation of the odor. Here we examined whether mitral/tufted cells in the olfactory bulb could be involved in these perceptual functions. Odor-evoked activity was measured from mitral/tufted cell apical dendrites in the olfactory bulb glomerular layer using 2-photon calcium imaging in awake mice in response to a large range of concentrations presented with varying interstimulus intervals. Different mitral/tufted cell glomeruli exhibited a range of concentration sensitivities including those that changed monotonically over the tested concentration range, and others that were relatively concentration invariant. Subsets of MTC glomeruli also exhibited significant adaptation when odors were delivered repeatedly. The results suggest that different subsets of MTC glomeruli may be involved in coding for concentration changes, odor identity, and background segmentation.

Title: Main olfactory bulb reconfiguration by prolonged passive experience correlates with increased BDNF and improved innate olfaction.

Authors: *R. HERNÁNDEZ-SOTO[1], A. PIMENTEL-FARFAN[2], E. ADAN-CASTRO[2], C. CLAPP[2], F. PEÑA ORTEGA[2];

Abstract: The main olfactory bulb (MOB) can reconfigure its function and structure in response to acute and chronic environmental changes. Despite the extensive evidence of anatomical, functional, and behavioral changes in the olfactory system induced by a wealth of olfactory exposure protocols, it is still unknown whether prolonged passive odor experience could reconfigure the MOB at its input and network activity levels and whether these changes impact innate olfaction. To test these possibilities, we passively exposed adult CD-1 mice to 21 different odors for 21 days to later record their MOB glomeruli activation, with intrinsic optical signals, and their MOB local field potential in the anesthetized condition. Furthermore, we analyzed their olfactory innate detection and discrimination with the habituation/dishabituation test and characterized their preference/avoidance to attractive and aversive odors, respectively. Our results showed that mice chronically exposed to odors exhibit a reconfiguration in their glomerular maps that includes a reduction in the number of activated glomeruli, an increase in their activated area, and an enhancement in their intrinsic signals. We also observed a reconfiguration in the MOB population activity characterized by a decrease in slow oscillations (<12 Hz) and an increase in fast oscillations (>12 Hz), both in the absence and the presence of odors. Mice chronically exposed to odors also increased their sensibility to olfactory stimuli during the habituation/dishabituation test and improved their innate odor preference/avoidance. These changes in olfaction and the reconfiguration of the MOB function correlated with an increase in local BDNF (brain-derived neurotrophic factor) levels. Our results showed that prolonged olfactory experience reconfigures the MOB in adults, probably through BDNF-dependent mechanisms, and improves innate olfaction.

Title: Birthdate-dependent differences in the functional connectivity of postnatal-born olfactory granule cells

Authors: *J. S. HUANG[1], T. R. BRECHBILL[1], A. LAUER[1], N. G. GLASGOW[1], C. E. J. CHEETHAM[1], N. N. URBAN[2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Lehigh Univ., Bethlehem, PA

Abstract: Throughout life, the rodent olfactory bulb (OB) is continually supplied with new postnatal-born neurons originating as neural stem cells from the subventricular zone. About 90% of these postnatal-born neurons differentiate into olfactory bulb granule cells (GCs). GCs mediate lateral inhibition via synapses with mitral cells (MCs) and tufted cells (TCs), the primary output neurons of the olfactory bulb (OB). Anatomical evidence indicates that early postnatal-born GCs (P3-P7) occupy the superficial GCL, whereas late postnatal-born GCs (P14-60) are located in the deeper GCL (Lemasson et al. 2005). Like the dendrites of MCs and TCs, the superficial and deep subpopulations of GCs also extend their dendrites to distinct depths of the external plexiform layer (EPL) (Mori et al. 1983, Orona et al. 1983). It is thus plausible that GCs make preferential connections with MCs and TCs depending on their postnatal birthdate. In this study, we aimed to determine whether anatomical differences in OB circuitry translate to functional differences in connectivity. We used timed viral injections, optogenetics, and slice electrophysiology to test whether early postnatal-born GCs are preferentially connected with TCs, and whether late postnatal-born GCs are functionally connected with both MCs and TCs. We injected AAV2 Syn1:ChR2-YFP virus into the RMS of P2 and P14 C57BL/6NCrl mice to express YFP-tagged ChR2 in either early (P2) or late (P14) postnatal-born GCs. We sacrificed both cohorts for experiments at 4 wpi and recorded IPSCs in MCs and TCs following optogenetic stimulation of virally transduced postnatal-born GCs. Optogenetic activation of P2-transduced GCs resulted in IPSCs in 47% of MCs (n = 15 cells) and 42% of TCs (n = 12 cells). In contrast, optogenetic activation of P14-transduced IPSCs resulted in IPSCs in 81% of MCs (n = 21 cells) and 40% of TCs (n = 15 cells). At both timepoints, MCs showed larger light-evoked IPSC amplitudes than TCs (-22.7 pA vs. -7.7 pA for P2, and -185.0 pA vs. -36.2 pA for P14; unpaired t-tests, $p < 0.05$ and $p < 0.02$). These findings suggest that both early and late postnatal-born GCs provide stronger inhibition onto MCs than onto TCs. Activation of early postnatal-born GCs evoked IPSCs in a similar proportion of MCs and TCs, suggesting a similar level of connectivity between MCs and TCs and early postnatal-born GCs. Late postnatal-born GCs, however, seem to preferentially connect with MCs over TCs. These results provide evidence for

differences in functional connectivity between subpopulations of postnatal-born GCs and olfactory bulb output neurons.

Title: Odor information processing by glomerular interneurons of the olfactory bulb : a structural/functional in vivo imaging study

Authors: *M. LOIZEAU[1], A. ANGELOVA[2], B. DETAILLEUR[1], H. CREMER[1], H. ROUAULT[2], J.-C. PLATEL[2];

Abstract: Olfaction is a crucial sense in animals allowing them to survive and reproduce. The first step of olfactory processing takes place in olfactory bulb (OB), in specialized structures called glomeruli that receive axons from olfactory sensory neurons. In glomeruli, the olfactory signal is processed by a variety of interneurons while being transferred to OB output neurons, the mitral and tufted cells. Yet, due to the high density and diversity of interneurons, the role of each population of interneurons in the OB circuit is still fragmentary. We aim to understand how interneurons that project on the same glomerulus are activated, how they participate in the odor processing and in particular how they code odor concentration.We chose to focus on a specific population of interneurons of the glomerular layer, the external tufted cells (ETCs). ETCs, which are the only excitatory interneurons in the OB, represent an entry door to study population coding inside the glomeruli. We crossed the ND6 transgenic mouse line with a fluorescent reporter and a calcium genetic sensor line. We designed a new experimental approach by combining high resolution two-photon structural imaging to reconstruct the morphology of ETCs and assign them to a specific glomerulus, with calcium imaging to record their response to odors *in vivo*. By using this approach, we observed that upon olfactory stimulation, ETCs can be activated and surprisingly, they can also be inhibited or generate complex responses *in vivo*.

These response profiles are similar to the one reported for OB output neurons, which could suggest that ETCs drive their activity *in vivo*. We showed that the ETCs display an odor-dependent response profile: the same ETC can be activated by one odor and inhibited by another. However, ETCs attached to the same glomerulus respond with the same response profiles, reinforcing the idea that glomeruli behave as specific functional units in the OB. Then, we characterized how interneurons connected to a single glomerulus respond to increasing odor concentrations. We showed that ETCs are progressively responding in a concentration dependent manner, representing a cellular recruitment map for each glomerulus. We aim to observe if these cellular recruitment maps change or remain stable over time varying from days to months. Our work describes both the properties of ETCs in the OB circuit and a new cellular mechanism for odor concentration coding in glomeruli.

Title: Bilateral sensory signals for odor source localization in freely-moving mice

Authors: *K. A. BOLDING[1], J. TAI[1], D. P. LEMAN[2], I. G. DAVISON[1];
[1]Biol., Boston Univ., Boston, MA; [2]Biol., Brandeis Univ., Waltham, MA

Abstract: During sensory-guided navigation, animals constantly refine their ongoing movement through a series of dynamic, iterative sensory-motor algorithms. In natural contexts, odors form key navigational cues that signal food sources and social partners, offering an ethologically relevant window on motivated sensory search. While odor-evoked activity has been studied intensively in head-fixed animals and decision-making tasks, little is known about the nature of the dynamic sensory signals that guide freely moving animals during active sampling of their environment. Such data is critical to resolve the sensory-motor strategies available to the animal at each stage of their sensory search. Animals may navigate using comparison of signals across successive discrete 'sniff' samples, using instantaneous 'stereo' comparison across hemispheres, or employ both under different conditions. To overcome the challenges of measuring bilateral odor responses in unrestrained animals, we developed new miniaturized microscopy tools for large-scale visualization of neural activity, and used them to image both hemispheres of the main olfactory bulb in mice exploring odor sources in an open arena. Sensory-evoked activity was

detectable only within a restricted area of ~10 cm surrounding the odor source and occurred in discrete sensory bursts, consistent with intermittent odor encounters and active sampling. Increasing proximity to the source activated additional glomeruli, revealing that spatial information is encoded by progressive recruitment of receptor pathways of varying affinity. A bias in directional preference for stimuli nearest the corresponding naris emerged in a subset of glomeruli at close proximity. Bilateral imaging enabled the identification of homologous pairs of glomeruli with correlated signals in either hemisphere. The difference between these left and right signals produced strongly biased directional tuning and predicted a bias in turning direction in a motivated foraging task. These data suggest that animals may employ multiple strategies to localize odor sources during free exploration, initially comparing the degree of glomerular recruitment across time during early approach phases, and ultimately reading out a bilateral direction code at close proximity.

Title: Neuronal classes in primate auditory cortex have different temporal response dynamics

Authors: *X.-P. LIU[1], X. WANG[2];
[1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Neurons in auditory cortex show a diversity of response properties in their spiking activity, but it is unclear to what extent this diversity results from neuronal type diversity. We collected single-unit recordings from auditory cortex of awake marmosets, and classified these units into three dominant classes based on extracellular waveform, spike timing, and spontaneous rate criteria. Most units were classified as regular spiking while a substantial minority were classified as fast spiking or bursting. A second method using unsupervised clustering on a set of informative features identified the same dominant classes with high agreement. Based on this classification, we find that the temporal dynamics of responses to synthetic and natural stimuli are strongly influenced by unit type. Among other differences, fast spiking units exhibited the weakest adaptation, while bursting units exhibited the strongest adaptation, preferentially responding at the onsets of sounds. Correspondingly, in response to sinusoidally amplitude modulated stimuli, bursting units had high vector strengths, could phase-lock to high

modulations rates, and peaked early in the rising phase of each cycle. These differences were also present in responses to conspecific vocalizations, with bursting units firing transiently at particular moments, reflected in higher values of the correlation index metric (Joris et al., 2006). Bursting units showed indication of finer spike timing information in their vocalization responses as assessed by a decoding metric spanning from rate to temporal coding (Victor and Purpura, 1996). We hypothesize that bursting units may implement a transformation accentuating acoustic edge landmarks and form the basis for parallel temporal and rate codes in auditory processing.

Title: Network localized Granger causality reveals cortical network changes under difficult listening conditions

Authors: B. SOLEIMANI[1], I. M. D. KARUNATHILAKE[1], P. DAS[4], S. E. KUCHINSKY[2], B. BABADI[1], *J. Z. SIMON[3];
[1]Electrical & Computer Engin., [2]Dept. of Hearing and Speech Sci., [3]Univ. of Maryland, College Park, MD; [4]Dept. of Anesthesia, Critical Care, and Pain Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: Growing evidence from neuroimaging suggests that networked activity of different cortical areas may facilitate speech comprehension under difficult listening conditions. Inferring the underlying causal relationships is critical for understanding the neural mechanisms behind successful speech comprehension. Granger causality (GC) has been widely used for this purpose in functional magnetic resonance imaging analysis, however, due to the low temporal resolution there, it is not possible to capture millisecond-scale interactions. Magnetoencephalography (MEG) provides millisecond resolution, but only gives low-dimensional, noisy, and linearly mixed surrogates of cortical activity, thus making GC inference a challenging task.
Existing methods for cortical network inference typically proceed in two stages by first performing MEG source localization, followed by GC inference. As such, the spatiotemporal biases induced by source localization in the first stage may propagate to the second stage and result in false alarms and missing the true GC links. To address this challenge, we introduce the

network localized Granger causality (NLGC) inference paradigm, in which cortical source dynamics are modeled as latent sparse multivariate autoregressive processes whose parameters are directly estimated from the MEG measurements, without the need for intermediate source localization.
We demonstrate the utility of NLGC inference using experimentally recorded MEG data from younger and older participants performing an auditory task: sustained listening to speech under different noise conditions. In analyzing the networked activity of frontal, temporal, and parietal areas, NLGC reveals novel hemispheric and lobe-specific dependence of network connectivity patterns in younger vs. older adults and across task difficulty. The age effects are more prominent in the most difficult listening conditions. Interestingly, the network connectivity patterns dissociate from the time-locked activity levels. Our results suggest that NLGC inference can be used as a robust alternative to existing methods for network-level analysis of MEG data that underlie auditory processing.

Engin., [10]Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Numerous studies have reported a link between musical training and enhanced neural processing and perception of sound, including speech in “noise”. However, the generalizability

of these effects remains unclear for several reasons, including small samples, small and inconsistent effect sizes, and varying methodological and analytical techniques. To address these issues, we are conducting a large-scale, multi-site study involving six universities, aiming to examine the robustness of the purported musician advantage across the adult lifespan by replicating and extending eight key experiments involving the perception and neural coding of speech and non-speech sounds across a large sample of listeners spanning a wide range of musical experience. All six sites collected data for all eight experiments. Preliminary data have been collected from n=173 subjects (n=104 female; n=67 male; n=2 other; ages 18-83 years old), with a final sample size goal of $n \geq 300$. Behavioral measures include melody perception, pitch discrimination, speech-in-noise perception, speech and non-speech informational masking, frequency selectivity, and extended high frequency thresholds. Neural measures include scalp-recorded EEG responses to passively attended phonemes (/da/ in multi-talker babble and the Mandarin tone /mi3/ in quiet). Behavioral trends suggest the musician advantage is most robust for tasks directly relevant to musical training (e.g., melody perception and pitch discrimination). So far, no evidence has emerged for enhanced neural encoding of sound in musicians relative to non-musicians (quantified as spectral encoding for the F0 or upper harmonics at electrode Cz). Formal statistical analyses are preregistered on the Open Science Framework (https://osf.io/duq34/) and will be conducted once full data collection is complete.

Abstract: The entrainment of neural oscillations in the auditory system to acoustic inputs has been proposed as a mechanism aiding processing of simple sounds and speech. However, evoked potentials to prominent acoustic events complicate the measurement of neural oscillations. One potential way to establish the presence of entrained oscillations is to measure if they outlast acoustic stimulation. While there are multiple non-human and human studies using this approach, some show positive and others negative results potentially due to methodological differences. Here, we used both simple sounds and speech stimuli in two tasks while recording EEG invasively in epilepsy patients to elucidate if the neural entrainment outlasts the stimulus duration. We leveraged the high spatial and temporal resolution of invasive electroencephalography recordings in a total of 17 epilepsy patients (9 females). In the first experiment, 12 participants listened to 4 simple sounds presented at a rate of 2.8 Hz or 3.7 Hz and were instructed to detect a specific sound in noise presented at various offsets to the entrainment sounds. We analyzed 43 contacts in Heschl's gyrus (HG) and 24 in the superior temporal gyrus (STG) from the 2.8 Hz condition, and 56 in HG and 27 in STG contacts from the 3.7 Hz condition. We found no evidence of ongoing oscillations at stimulation frequencies outlasting entrainment stimulus presentation for more than one cycle in either locations ($F(3,438)=3.86$ and $F(3,438)=1.38$, $p>0.01$). In the second experiment, 12 participants listened to speech from which we extracted 346 acoustic edge events that were shown in previous studies to drive the coherence between brain and speech. We analyzed 105 contacts in HG and 59 contacts in STG. We found that these acoustic edges did indeed drive theta-alpha band entrainment that outlasted acoustic stimulation for two cycles in both HG and STG ($F(3,1956)=14.25$ and $F(9,1956)=41.23$, $p<0.01$). Thus, we provide incremental evidence supporting the presence of neural entrainment of oscillations to speech but not to the rhythmic simple sounds in the human HG and STG. Furthermore, these results point out the importance of careful consideration of the task and stimulus design in studies examining the presence of neural oscillations outlasting acoustic stimulation.

Title: Nonlinear cortical representation of natural sounds

Authors: *G. R. HAMERSKY, L. A. SHAHEEN, S. V. DAVID;
OHSU, Portland, OR

Abstract: In everyday hearing, listeners often encounter auditory scenes containing a complex, spectrally overlapping combination of sound sources. Successful perception of a single source, an ability called auditory streaming, requires grouping cues, statistical regularities of natural sounds in the time and frequency domains. Though a substantial number of psychoacoustic studies have described auditory streaming as a perceptual phenomenon, there has been little description of its underlying neural basis, particularly using ethologically-relevant sounds. This study recorded single unit activity in the auditory cortex (AC) of awake marmosets to compare neural responses to natural sounds presented concurrently versus in isolation. Passively listening marmosets were presented with pairs of overlapping natural sound excerpts chosen from ethologically relevant categories of sound textures (backgrounds, BGs) and transients (foregrounds, FGs). Neural responses to overlapping sound pairs (BG+FG) were modeled as linear weighted combinations to the BG and FG sounds in isolation. The model weights showed that responses to the combined sounds were frequently suppressed relative to the individual sound responses. Effects varied across neurons and stimuli, though neural identity, rather than stimulus identity, more strongly predicted the extent of suppression. The linear model also showed that FG responses were more suppressed than BG responses in primary (A1) AC, an effect not observed in non-primary (belt) AC. In addition, responses were often strongly nonlinear and could not be predicted fully from the linear model. Taken together, these results suggest that neural tuning, as well as spectrotemporal cues that distinguish BG and FG categories, contribute to the nonlinearities observed during the presentation of overlapping sounds, an effect that can be explored in more detail by fitting spectrotemporal encoding models and relating spectrotemporal feature selectivity to nonlinear responses to individual natural sounds.

Title: Auditory corticocollicular neurons display weak and widespread clusters during complex sound processing

Authors: *T. T. X. SCHMITT, S. L. WADLE, K. M. A. ANDREA, J. J. HIRTZ;
Biol., Univ. of Kaiserslautern, Kaiserslautern, Germany

Abstract: The auditory cortex (AC) modulates the activity of upstream pathways in the auditory brainstem via descending (corticofugal) projections. This feedback system plays an important role in the plasticity of the auditory system by shaping response properties of neurons in many subcortical nuclei. Around half of layer 5 (L5) neurons are corticofugal, of which the majority projects to the inferior colliculus (IC). This pathway is involved in processing of complex sounds, auditory-related learning and defense behavior. Partly due to their location in deep cortical layers (500 - 800 µm), population activity patterns of corticofugal neurons within neuronal ensembles of the AC remain poorly understood. We employed two-photon imaging to record the activity of hundreds of L5 neurons simultaneously in anesthetized and awake mice (male and female, postnatal day 45-70). To focus on corticocollicular (CC) neurons, we injected rAAV2-retro (Tervo et al. 2016. A Designer AAV Variant Permits Efficient Retrograde Access to Projection Neurons. Neuron. 92: 372-382) into the mouse IC. Using this approach, we expressed GCaMP7f exclusively in CC neurons and presented animal vocalizations of different species to investigate neuronal ensemble activity. In addition, we mapped the AC using widefield imaging to distinguish between different subfields containing CC neurons. In a further set of experiments, we expressed GCaMP7f in AC, either exclusively in pyramidal neurons or indiscriminately of neuron subtype in awake or anesthetized mice, respectively. By additionally injecting rAAV2-retro-tdTomato into the IC we could image activity of L5 neurons in general, but were also able to identify the subpopulation of CC neurons and analyze their specific network properties.
During complex sound processing, CC neurons intermingle with other L5 neurons and form on average 6 sound-specific clusters. Correlating the activity exclusively of CC neurons revealed that more CC neurons per field of view formed clusters, compared to all L5 neurons. However, CC clusters featured weaker correlations between sound-evoked responses. This finding supports the idea of the “broadcast” function of L5 CC neurons (see for example: Williamson and Polley. 2019. Parallel pathways for sound processing and functional connectivity among layer 5 and 6 auditory corticofugal neurons. eLife. 8:1-21). Furthermore, we found differences in the physical extent of CC clusters between the subfields, implying the existence of subfield-specific tasks for CC neurons during complex sound processing.

Title: Poisson-wiener prediction of auditory temporal processing in response to artificial and natural sounds

Authors: *C. SABOURIN, X. BAO, S. TAVUKÇU, S. G. LOMBER;
McGill Univ., Montreal, QC, Canada

Abstract: Compromised auditory temporal processing is predictive of impaired speech and language comprehension in patients with auditory neuropathy, cochlear implants, age-related speech deficits, and dyslexia. Temporal modulation transfer functions (tMTFs), descriptions of the sensitivity of auditory neurons to fluctuations in amplitude over time, can be used for the diagnosis and prognosis of auditory neuropathologies. Despite their clinical relevance, the time-consuming and labor-intensive nature of psychophysical measurements of tMTFs, limits their use in routine clinical practice. Recent studies suggest that a system identification method, the Poisson-Wiener theory, can be applied to biologically relevant sounds which often differ based on their temporal patterns, such as speech and other conspecific communication. To assess the predictability of the model in the awake auditory cortex, extracellular recordings of primary auditory cortex neurons were obtained from chronically implanted domestic cats (*Felis catus*, n=2, female) in response to acoustic stimuli: (1) periodic clicks trains to construct tMTFs, (2) Poisson-distributed impulse trains to compute the kernels, and (3) cat vocalizations (purring). For each neuron, Poisson-Wiener kernels were derived and used to estimate prestimulus time histograms, rate modulation transfer functions, and tMTFs specific to that unit. Trends observed in the recordings were consistent with previous findings including observations of monotonic decay and post-activation suppression in first-order kernels. The model was able to accurately capture the tuning properties specific to its unit. Bandpass tuning was the most frequently observed tuning shape for both measured and predicted transfer functions. Presently, greater accuracy is observed for periodic click trains than for purring vocalizations. Our preliminary results suggest the model has the potential to accurately estimate the auditory temporal processing of both natural and artificial sounds. Following successful application to the prediction of conspecific communication, extension of the model to humans has the potential to provide a more efficient and accurate assessment of temporal processing than currently used clinical measures.

Title: Dioptic stimulation transiently facilitates V1 spiking responses

Authors: *B. MITCHELL[1], K. DOUGHERTY[2], J. A. WESTERBERG[1], B. M. CARLSON[1], L. DAUMAIL[1], A. V. MAIER[1], M. A. COX[3];

Abstract: Neurons in primate primary visual cortex (V1) play a key role in combining monocular inputs to form a binocular response. Research over the past decades has made great inroads into delineating V1 responses to discrepant (dichoptic) images in the two eyes. Also critical, however, is to decipher how V1 neurons respond to concordance between the two eyes. This question is important since dioptic stimuli occur during many natural viewing conditions. Here, we investigated the extent to which balanced binocular stimulation at (or near) zero disparity modifies V1 contrast responses in awake macaque monkeys. To do this, we presented static gratings to either eye or both at corresponding retinal points while animals passively fixated a central cue. Gratings appeared on screen parafoveally for 250ms and varied in Michelson contrast [0, 0.225, 0.45, 0.9] between trials. We recorded neurophysiological responses to these stimuli using linear multielectrode arrays placed in the parafoveal region of V1. For each V1 unit, contrast response functions were measured to compare between stimulation of one or both eyes. On average, binocular stimuli evoked significantly stronger V1 activity than their monocular counterparts. This binocular facilitation was most prominent during the transient peak (50-100ms) of V1 spiking responses. Notably, higher contrast stimuli attenuated binocular facilitation. This contrast-dependency suggests that response amplification under binocular viewing predominately occurs for low to medium contrast stimuli, reminiscent of the perceptual contrast gain that characterizes binocular vision. Taken together, our results reveal contrast-dependent, transient facilitation in V1 for dioptic stimulation. We will discuss these results in context of down-stream visual processes involved in binocular integration.

Title: V1 shows facilitation rather than suppression during onset of binocular rivalry flash suppression.

Authors: *B. M. CARLSON[1], M. A. COX[2,1], K. DOUGHERTY[3,1], B. MITCHELL[1], J. A. WESTERBERG[1], A. MAIER[1];

Abstract: When the two eyes are presented with different stimuli that cannot be perceptually fused, neurons in primate primary visual cortex (V1) tend to fire less than during regular binocular vision (dichoptic cross orientation suppression, or dichoptic suppression). It has been suggested that this broadly suppressed response to interocular conflict destabilizes neuronal population activity in V1. The resulting destabilization might initiate a sequence of perceptual alternations between each eye's view in response to the interocular conflict (binocular rivalry). Here we test this hypothesis by examining neural activity during binocular rivalry flash suppression (BRFS). Binocular rivalry and BRFS are similar paradigms, except that the latter incorporates a period of monocular adaptation before the onset of interocular conflict. Our rationale was that if interocular suppression is required for igniting perceptual alternations more generally, it should be of similar magnitude at the onset of both binocular rivalry and BRFS. To test this prediction, we recorded laminar V1 spiking responses in two awake behaving macaques who passively observed BRFS. As expected, we observed interocular suppression in the spiking responses for simultaneously presented incongruent stimuli. To our surprise, we found facilitation rather than suppression of spiking responses at the onset of BRFS. This finding suggests that dichoptic suppression in V1 does not serve as a general prerequisite for perceptual alternations.

Title: Stimulus dependence of theta rhythmic activity in primate V1 and its potential relevance for visual perception

Authors: *P. FANYIWI[1], B. AGAYBY[1], R. KIENITZ[2,3], M. HAAG[4], M. SCHMID[1,4];
[1]Biosci. Inst., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Ernst Struengmann Inst. (ESI) For Neurosci., Frankfurt, Germany; [3]Epilepsy Ctr., Goethe Univ., Frankfurt, Germany; [4]Fac. of Sci. and Med., Fribourg Univ., Fribourg, Switzerland

Abstract: A growing body of psychophysical research reports theta (3-8 Hz) rhythmic fluctuations in behavioural performance that are often attributed to an attentional sampling mechanism in the brain. Recent studies showed correlates of this sampling in higher-level brain areas[1]. However, it remains unclear whether theta oscillations can be found already in early sensory areas, such as the primary visual cortex (V1). Earlier research suggests that many V1 neurons are tuned to visual stimulus temporal frequencies in the theta range[2]. V1 neurons could therefore act as a filter to generate theta rhythmic spiking activity. To address this question, we recorded multi-unit activity (MUA) from two macaque monkeys passively viewing a static visual stimulus with variable sizes and contrasts. We found that among the visually responsive electrode sites, more than 50 % showed a spectral peak at theta frequencies. Theta power varied with size and contrast of the stimulus. Within each of these stimulus property domains (e.g., size), there was usually a single stimulus value that induced the strongest theta. In addition to these variations in theta power, the peak frequency of theta oscillations increased with increasing stimulus size. Control analysis confirmed that this neural theta rhythm was indeed stimulus induced and did not arise from small fixational eye movements (microsaccades). When the monkeys performed a detection task of a target embedded in a theta-generating visual stimulus, reaction times (RT) also tended to fluctuate at the same theta frequency as the one observed in the neural activity. The present study shows that a highly stimulus dependent neuronal theta oscillation can be elicited in V1 that appears to influence the temporal dynamics of visual perception.

Title: Unexpected behavioral synergy from a multidimensionally tuned sensory population

Authors: B. LIU, J. BECK, **L. C. OSBORNE**;
Neurobio., Duke Univ., Durham, NC

Abstract: Sensory signals are multiplexed throughout the brain such that spike trains encode information about more than one stimulus feature: sound frequency and intensity, color and orientation, odor identity and concentration, etc. Sensory multiplexing might arise naturally from correlations in the environment, yet even nominally independent stimulus features are jointly represented by sensory neurons. Do multidimensional representations arise solely from anatomic

or metabolic necessity, or is there a computational advantage? Multidimensional tuning functions create ambiguity at the unit level, but also enhance information coding - what we term “stimulus synergy”. When uncorrelated, information about a vector of stimulus features must equal or exceed the summed information about individual features, even when tuning functions for each feature are separable. But the scale of the information boost and its implications for population coding and behavior have not been understood. We analyzed synergy in a sensory population and in a closely coupled motor behavior to understand how multidimensional tuning impacts downstream decoders.
Cortical area MT units are tuned for multiple motion features, e.g. motion direction and speed. We found that MT units encode 30-40% more information about the motion vector than the summed information about direction and speed, a large level of stimulus synergy. Does the brain recover that extra information and, if so, what does that reveal about the nature of visual population decoding? MT provides the visual drive for smooth pursuit, an oculomotor behavior tightly coupled to visual motion. For the eye to track a target, downstream circuits must estimate both its speed and direction. For stimulus synergy to benefit pursuit, MT population response must be synergistic and the brain’s decoders must recover the additional information. Standard population models with homogenous tuning functions do not predict synergistic behavior, yet we observed 20% synergy in smooth pursuit. We investigated populations that produce synergy, and the decoding model that matched both the precision and synergy observed in pursuit. We simulated heterogeneous populations of correlated MT units, varying population size, level of differential correlations, and tuning function diversity. We found that even small deviations from pure homogeneity result in synergistic population coding. To match the level of precision and synergy observed in pursuit, a decoder needs to estimate direction and speed jointly weights derived from the Fisher information matrix and full knowledge of the stimulus dependence of the population noise covariance matrix.

Title: Linear alignment of neural modes compensates for drift across trials in early visual cortex population activity

Authors: *C. GODIN[1], J.-P. THIVIÈRGE[2];
[1]Univ. de Moncton, Moncton, NB, Canada; [2]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: In recent years, advances in neural recordings have provided the ability to record from thousands of neurons simultaneously across many areas of the cortex. It is well established that neural activity across large populations of cortical neurons is characterized by low dimensionality. In other words, much of the variance in neural activity can be captured with only a few dimensions, termed *neural modes*, that are extracted by dimensionality reduction techniques. Whereas neural modes have been extensively studied in the motor cortex, less is known about their characteristics in primary visual areas. Here, we extracted neural modes from areas V1 and V2 of three macaque monkeys using a recently developed technique termed frequency-dependent principal components analysis. This technique yields a decomposition of activity into modes that are each delimited to a given frequency range. Animals were shown sets of 8 different orientation gratings across 400 trials per stimulus in the span of 5 different sessions. A Fisher linear decoder was applied to read out stimulus orientation from neural modes of population activity. This decoder attained high accuracy with less than 10 dimensions of neural modes, suggesting that a linear readout can rely on low-dimensional information to extract sensory information. Furthermore, population activity from V2 required fewer dimensions than V1. However, across both V1 and V2 activity, we found a rapid drift in representation among consecutive trials: a decoder trained on a given trial generalized poorly to subsequent ones. This drift could be compensated by a linear alignment of neural modes across trials, effectively "registering" neural modes on a given trial to a reference trial that served as baseline. These findings provide a solution to the stability of a population code for visual processing that rectifies rapid trial-to-trial fluctuations by a fixed linear projection of low-dimensional activity.

Title: Representational drift in the mouse visual cortex

Authors: D. DEITCH, A. RUBIN, *Y. ZIV;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Recent studies have shown that neuronal representations gradually change over time despite no changes in the stimulus, environment or behavior. However, such representational drift has been assumed to be a property of high-level brain structures, whereas earlier circuits,

such as sensory cortices, have been assumed to stably encode information over time. Here, we analyzed large-scale optical and electrophysiological recordings from six visual cortical areas in behaving mice that were repeatedly presented with the same natural movies. Contrary to the prevailing notion, we found representational drift over timescales spanning minutes to days across multiple visual areas, cortical layers, and cell types. This drift had different properties from those of habituation or adaptation. Notably, neural-code stability did not reflect the hierarchy of information flow across areas. Although individual neurons showed time-dependent changes in their coding properties, the structure of the relationships between population activity patterns remained stable and stereotypic. Such population-level organization may underlie stable visual perception despite continuous changes in neuronal responses.

Title: Linking microscale neural computations to global brain dynamics using deep learning

Authors: *B. SAHOO, A. C. SNYDER;
Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Brain mechanisms span a wide range of temporal and spatial scales. Large-scale brain activity is captured by EEG with a coarse spatial resolution on the cortical surface and millisecond precision. Whereas, micro-scale neural computations can be accessed using single-neuron recording and local field potentials that have a much finer spatial scale. Even though both these techniques are widespread in cognitive neuroscience research, the inter-relationship between the mechanisms they measure is poorly understood to date. Cognitive processes such as attention, decision making, etc. likely involve an interplay between network-level global coordination among cortical areas and local neural processes. For this reason, an empirical evaluation of the inter-relationship between EEG and spiking activity or LFP would advance our insights into the mechanisms underlying cognition. We recorded spiking activity from area V4 and PFC in the adult monkey brain, simultaneously with scalp-wide EEG activity, while the animal was performing a selective attention task. The change detection task consisted of two

distinct perceptual features i.e. color and motion. The features in the stimulus were tagged with distinct flicker frequencies to evoke distinct neural oscillations encoding individual features. Using novel data analysis tools, we delineated signatures of local neural processing in each area i.e. V4 and PFC, and the inter-areal coordination of information. We used a latent generative model to describe the EEG signals' temporal dynamics and estimated a low-dimensional representation of the high-dimensional EEG signals. Further, we asked how such low-dimensional representations of EEG explain the local vs inter-areal processes. Our results show that within area V4, EEG signals are more aligned with the activity that is targeted to a downstream area i.e. PFC rather than the activity that is primarily local. Additionally, the association between EEG and LFP was enhanced specifically for the feature information that was relevant to the task. Although EEG signals can capture information at a global level due to volume conduction, our work provides a first-in-line insight into the nature of this information. In the future, we will quantify the association between this interplay of EEG and LFP with the animal's behavior.

Title: Modulation of orientation selectivity by orientation precision

Authors: *H. J. LADRET[1], N. CORTES[1], L. IKAN[1], F. Y. CHAVANE[2], C. F. CASANOVA[1], L. PERRINET[2];
[1]Univ. of Montreal, Montreal, QC, Canada; [2]CNRS & Aix-Marseille Univ., Marseille, France

Abstract: The primary visual cortex (V1) processes complex mixtures of orientations to build neural representations of our everyday visual environment. It remains unclear how V1 adapts to the highly volatile distributions of orientations found in natural images. We used naturalistic stimuli and measured the response of V1 neurons to orientation distributions of varying bandwidth. Although broad distributions decreased single neuron tuning, a neurally plausible decoder could robustly retrieve the orientations of stimuli from the population activity at all bandwidths. This decoder demonstrates that V1 population co-encodes orientation and its precision, enhancing population decoding performances compared to sole orientation decoding.

This internal representation is mediated by temporally distinct neural dynamics and supports a precision-weighted description of neuronal message passing in the visual cortex, in line with predictive processing theories.

Supplementary Figure 1. Motion Clouds capture the variety of orientation distributions found in natural images. (**a**) Distribution of orientations found in a natural image (São Miguel Island, Azores, Portugal, picture taken by H.J.L.), retrieved with a Histogram of Oriented Gradients (16x16 cell size, 200^2 pixel subset of the image). (**b**) Two Motion Clouds, oriented at 90° relative to the horizontal axis, with orientation bandwidths of respectively $B_\theta = 15.4°$ and $B_\theta = 36.0°$.

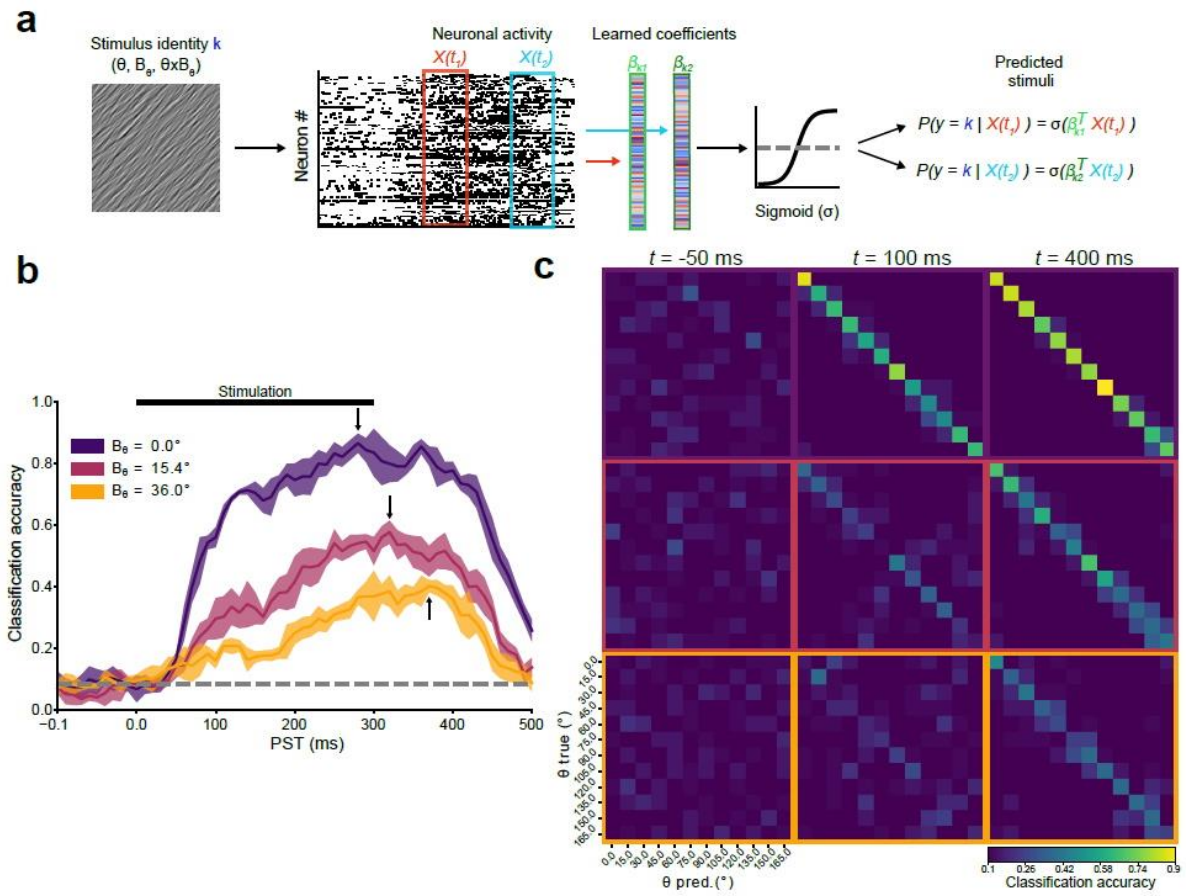

Figure 2. Decoding orientation from population activity. (**a**) Illustration of the decoding model. For each trial, spikes from all single units in a given time window were pooled in a single neural activity vector $X(t)$. A multinomial logistic classifier predicts the identity k of the stimulus in this trial by estimating the probability for different hypothesis y. This is achieved by learning a weight vector β_k which maximizes the accuracy of the prediction $P(y = k|X(t)) \approx \sigma(\beta_k^T X(t))$, where σ is the sigmoid function. The resulting accuracy of this classifier serves as a proxy for the discriminability of the population's neural activity within feature space. (**b**) Time course around the peri-stimulus time (PST) of the accuracy of three independent decoders trained to predict the orientation θ of Motion Clouds for a given orientation bandwidth B_θ. Solid dark line represent the mean accuracy of a 5-fold cross validation and filled contour the SD. Decoding at chance level (here, $\frac{1}{12}$) is represented by a gray dashed line. Arrows indicate the time at which maximum average accuracy was reached. (**c**) Confusion matrices of the decoders at three time points around stimulation time. Values inside the diagonals of each matrix represent the instances of correct decoding, that is, where $\theta(t)_{\text{pred}} = \theta_{\text{true}}$. Each row of matrices is framed with the color code of the corresponding decoder in (b).

Title: Coarse-to-fine processing drives the efficient coding of natural images in mouse primary visual cortex

Authors: *R. SKYBERG[1], S. TANABE[2], H. CHEN[1], J. CANG[1,2];
[1]Biol., [2]Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: The sequential analysis of information in a coarse-to-fine (CtF) manner is a fundamental processing strategy of the visual system. Previous studies have shown that neurons in the primary visual cortex (V1) of anesthetized animals can process spatial information in a CtF fashion, shifting their spatial frequency (SF) preference from low (coarse) to high (fine) during their response to simple grating stimuli. However, many central questions regarding CtF processing, such as whether it occurs in awake behaving mice and potential computational advantages it may provide animals, remain unexplored. Here, we performed large-scale single unit recordings to characterize CtF processing in both anesthetized and awake mice, determine its developmental profile, and study its role in encoding ethologically relevant natural images. Using high-density multielectrode silicon probes and subspace mapping of receptive fields, we found that the vast majority of V1 neurons from awake adult mice (P40-80) displayed two temporally discrete peaks in their spatiotemporal receptive field, each with distinct SF preferences (which we refer to as “2 peak cells”, 75.3%, n = 195/259, 15 mice). The SF shift between these 2 peaks was large (mean: 2.19 octaves) and nearly always from low to high. Interestingly, anesthesia attenuated the percentage of 2 peak cells (51.2%, n = 99/191, 8 mice) and the average magnitude of their SF shift (0.9 octaves). Additionally, we discovered CtF processing develops postnatally and requires visual experience. The percentage of 2 peak cells was reduced in P17 (57.9%, n = 44/76, 10 mice) and dark reared mice (DR; 58.7%, n = 145/247, 12 mice). The remaining 2 peak cells in P17 and DR mice showed substantially lower average SF shift than that of adult control mice (1.43 octaves for both). Next, we revealed that CtF processing acts to dynamically adjust the SF tuning of V1 as a whole from low-pass to one that represents SFs more uniformly. Finally, we studied how this temporally dynamic cortical SF tuning might affect the processing of natural images with complex SF statistics. Excitingly, we demonstrated that CtF processing reduces redundancy in the neural representation of natural images by shifting the population response away from the high-power, low-SF components of these stimuli. This redundancy reduction led to an increase in the representational efficiency of natural images that did not occur in anesthetized mice with attenuated CtF processing. Collectively, these findings establish a novel, state-dependent, computation of cortical circuitry that develops after vision onset to allow the animal to efficiently encode the spatial statistics of natural images.

Title: The operating regime of sensory cortex

Authors: *J. J. PATTADKAL[1], B. V. ZEMELMAN[1], I. R. FIETE[2], N. J. PRIEBE[1]; [1]Dept. of Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Dept. of Brain and Cognitive Sci. and McGovern Inst., MIT, Cambridge, MA

Abstract: Cortical activity results from a combination of external input and internal circuitry. Using calcium imaging in awake marmosets we assay the contributions of the input and internal circuitry in generating cortical dynamics in sensory area MT, known for motion processing. We first uncovered the functional organization in area MT: nearby cells shared their direction preference and the preference varied smoothly along the cortical surface, repeating every 400 microns. We compared the population activity patterns in area MT to three circuit models which show amplification of motion signals, but which differ in the stability of the selective network states. The first model, the homogeneous model (Goldberg et al, 2004), is largely feed-forward input driven and when the external input is unstructured, the network displays only baseline non-selective activity. The second model, the continuous attractor model (Goldberg et al, 2004), uses recurrence to keep generating direction selective output, even in the absence of structured external input. The third model, the transient amplification model (Murphy and Miller, 2009), also uses recurrent excitation to generate strong amplification, but this is rapidly quenched by the dominant inhibition in the network. If internal circuitry is biased towards enhancing direction-specific activity, then we would expect activity patterns in the absence of visual stimuli to resemble those evoked by direction stimuli. We observed such direction selective spontaneous activity patterns in area MT and their occurrence is directly linked to increases in overall network activity. These results are not consistent with the homogenous model, but could emerge from an attractor or transient amplification model. To distinguish which of those frameworks are present in area MT we measured the network dynamics and found that they are rapid, consistent with the transient amplification model. Finally, we performed two additional tests of the attractor model (shifting stimulus direction and coherence) which, like the dynamics measurements, demonstrate that the operating regime is consistent with a transient amplification model. Using both spontaneous and stimulus-evoked conditions, we demonstrate that the internal circuits in sensory areas are geared towards isolating and enhancing feature selective activity using fast non-normal amplification by E and I cells, consistent with the transient amplification model. This network mode allows the circuits to remain sensitive to changes in external environment while amplifying weak signals with internal circuitry.

Title: Origin and functional consequences of noise correlations in mouse V1

Authors: *R. O'SHEA[1], X.-X. WEI[1,2], I. M. NAUHAUS[1,2];
[1]Dept. of Psychology, Univ. of Texas At Austin, Austin, TX; [2]Dept. of Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Sensory neurons show considerable variability in their response to repeated presentations of a stimulus. In primary visual cortex (V1), this "noise" is correlated between nearby cells, potentially limiting the stimulus information present in the V1 population code. To date, it has been challenging to delineate the sources of these noise correlations in V1 due to the combination of feedforward and recurrent inputs that drive V1 neurons. Recent work in rodent retina has shown that the spatial extent of pairwise noise correlations in retinal ganglion cells differs between scotopic and photopic levels of light adaptation (Ruda et al., Nat. Comm. 2020), though the implications of this finding for downstream processing in V1 remain unclear. By integrating experiment and modeling, we seek to understand the origin and functional consequences of V1 noise correlations by varying the spatial distribution of noise correlations in the retinal input. We employ two-photon fluorescent calcium imaging to measure noise correlations in mouse V1 during repeated presentations of sine wave gratings under scotopic and photopic conditions. Our preliminary analysis shows that the pattern of noise correlations over cortical space in V1 is very similar between the two light levels and can be well described by an exponential decay function over distance. For both light levels, pairwise Pearson correlation values range from 0.15-0.25 for neighboring cells less than 100μm apart, decaying to near zero for cells separated by 500μm or more. To understand these experimental observations, we have constructed a two-layer neural network model in which noise correlations between V1 units are inherited from correlated noise in the inputs from the retina. By varying the spatial extent of noise correlations in the input layer, we find that a substantial component of the spatial pattern of noise correlations in V1 under scotopic and photopic regimes can be explained by a purely feedforward model. However, the spatial extent of non-zero noise correlations in our data is larger than would be possible in the purely feedforward framework. We are adding physiologically constrained recurrent connections between V1 units in the model to explore whether this improves the correspondence between the model prediction and our data from mouse V1. We are also employing this network model to understand how the spatial distribution of noise correlations may limit the fidelity of visual coding of large neuronal populations in V1.

Title: Adaptation restructures V1 and V4 representations of crowded displays

Authors: *C. A. HENRY[1], A. KOHN[2];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Albert Einstein Coll Med., Bronx, NY

Abstract: Adaptation adjusts cortical responses to visual stimuli based on what has been shown in the recent past. This adjustment is thought to tailor the cortical representation to the current environment, but it has been difficult to establish a clear functional improvement of adaptation-induced changes in neuronal responses. We wondered whether this difficulty arose because previous work has focused on stimuli presented in isolation. If adaptation adjusts representations to favor some stimuli in the environment over others, its functional benefit might only be evident when multiple stimuli compete for perceptual awareness. We tested this possibility using visual crowding, whereby stimulus discriminability is impaired by the presence of adjacent distractor stimuli.

We recorded neuronal population responses in anesthetized (V1) and awake, fixating (V1 and V4) macaque monkeys. On some trials, we presented small gratings (targets) in isolation, centered over the population aggregate receptive field. Targets varied in orientation by small (4 degree) steps. On other trials—crowded trials—targets were surrounded by 4-8 distractor gratings of similar orientation. We quantified how well target orientation could be discriminated using the measured activity. The presence of distractors reduced the discriminability of target orientation in single neurons and neuronal populations, with moderate effects in V1 and more pronounced deficits in V4. We then asked how adaptation affected the cortical representation of target orientation in crowded displays. Adapters were high contrast distractor stimuli, either matched or orthogonal in orientation to the distractors of the subsequent test stimuli. Adaptation with matched distractors improved target orientation discriminability in both V1 and V4. Adaptation with mismatched distractors, in contrast, reduced the discriminability of crowded targets. Altered performance arose from an adaptation-induced change in how distractors modulate neuronal responsivity and tuning.

Our results show that adaptation alters neuronal population information for the features of a

target stimulus when it is embedded in an environment with competing stimuli. Thus, the perceptual benefit of adaptation may be most evident in visual environments with multiple, competing stimuli.

Title: Coordination of sparse neural traveling waves (nTWs) in large-scale, multi-region networks of spiking neurons through feedforward and feedback connectivity

Authors: Z. W. DAVIS[1], R. C. BUDZINSKI[2], G. BENIGNO[2], C. C. STEWARD[2], J. H. REYNOLDS[1], ***L. MULLER**[2];
[1]SNL-R, Salk Inst., La Jolla, CA; [2]Western Univ., London, ON, Canada

Abstract: The cortex is never silent: ongoing, spontaneous activity occurs continuously, providing cortical neurons with constantly fluctuating synaptic input (Arieli et al., *Science* 273, 1996). In recent work, we found spontaneous fluctuations in awake cortex are organized into neural traveling waves (nTWs) propagating across single cortical areas (Davis*, Muller*, et al., *Nature* 587, 2020). Spontaneous nTWs modulate excitability as they propagate across the retinotopic map, affecting perceptual sensitivity in a visual detection task. Based on the speed of nTW propagation, we hypothesized the underlying mechanism for these waves is the axonal time delays from unmyelinated horizontal fibers in cortex (0.1-0.6 m/s; Girard et al., *J Neurophys* 85, 2001), which range up to tens of milliseconds on the scale of a 4x4 mm Utah array. We have recently found that the addition of these axonal time delays in a spiking network model shapes asynchronous-irregular (AI) activity into sparse nTWs, where only a small fraction of the local population spikes as a wave passes (Davis*, Benigno*, Fletterman*, et al., *in review*). We call this unique operating mode, where the benefits of the asynchronous-irregular state can coexist with sparse nTWs across the cortex, the “sparse wave regime”. To understand the organization of

multiple spontaneous nTWs generated by the dense horizontal connectivity in each visual area, we now extend this spiking model to include multiple regions. We find that diffuse feedforward and feedback projections can transiently coordinate spatiotemporal activity patterns in multiple regions. These results have several important implications for the structure of ongoing activity in the visual system. Specifically, retinotopic coordination of spontaneous nTWs can boost the response to weak inputs across multiple areas in the visual system. Importantly, because we have previously shown spontaneous nTWs occur during the complex, non-narrowband fluctuations of ongoing activity, the coordination observed in our models provides a novel potential mechanism of inter-area information transfer in the absence of narrowband oscillations.

Title: Spontaneous traveling waves in V1 and V4 are retinotopically coordinated

Authors: *Z. W. DAVIS[1], M. H. MOFRAD[2], A. JASPER[3], J. SMITH[4,5], A. KOHN[3], A. J. PARKER[4,6], L. MULLER[2], J. REYNOLDS[1];

Abstract: Understanding the spatio-temporal structure of cortical activity is a fundamental question in neuroscience. Some fluctuations of cortical activity travel as waves across the cortical surface. These neural traveling waves (nTWs) are predictive of local fluctuations in excitability, which have recently been shown to modulate the magnitude of sensory evoked responses to visual motion in area MT of common marmosets (Callithrix jacchus) and impact the perceptual sensitivity of these monkeys as they perform a detection task. It is unknown whether spontaneous nTWs occur independently across cortical areas or are coordinated in their occurrence. We examined simultaneous recordings of chronically implanted multielectrode

arrays in areas V1 and V4 of behaving rhesus and cynomolgus macaques. Spontaneous activity in both V1 and V4 contains nTWs, which are more likely to co-occur than expected by chance. This may imply that nTWs are coordinated to align local excitability topographically across these cortical areas. Owing to differences in the visual representations in V1 and V4, such retinotopic alignment would require an appropriate scaling of wave properties to keep waves in retinotopic register. We found the properties of nTWs in V1 and V4 do indeed differ between the cortical areas according to their relative size in a way that would favor translation of waves in retinotopic coordination. Consistent with such a coordination, we found significant phase similarity during spontaneous nTWs between the two cortical areas as a function of the relative proximity of receptive fields. Our results confirm spontaneous nTWs are observable in visual cortex during active perception and appear to be coordinated across cortical areas with regard to retinotopic representations of visual space.

Title: Long-term stability of neuronal ensembles

Authors: *J. PÉREZ-ORTEGA, T. ALEJANDRE-GARCÍA, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Neuronal ensembles are causally related to behaviors, perceptions, and memories, but it is still unknown how stable or flexible they are over time. Here, we used two-photon multiplane calcium imaging to track over weeks the activity of the same pyramidal neurons in layer 2/3 of visual cortex from awake mice (Vglut1::TIGRE2.0 GCaMP6s/f, n = 6) and recorded their spontaneous and visually-evoked responses. Fewer than 50 % of the neurons were commonly active between two sessions. These “common neurons” formed ensembles, most of which lasted for weeks. Stable ensembles preserved ~68 % of their neurons for up to 46 days, and these core neurons had stronger functional connectivity. Stable ensembles were also stably tuned to visual stimulation or modulated by locomotion. Our results demonstrate that neuronal

ensembles can last for weeks and could serve as a substrate for a long-lasting representation of behaviors, perceptions, and memories.

Title: Cell-type specific connectivity of sensory and motor cortical input to dorsal striatum

Authors: *B. D. SANABRIA, S. BASKAR, C. R. LEE, D. J. MARGOLIS;
Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: The striatum, a key input structure of the basal ganglia, facilitates sensorimotor integration by sorting information about our environment, decisions, and reward due to its extensive innervation by the cortex and thalamus. A large part of the computational complexity of the striatum derives from the functional organization of its microcircuitry. Excitatory projections from the primary sensory (S1) and motor (M1) cortex overlap in the dorsal striatum (DS). Our lab previously revealed that optogenetic stimulation of S1 corticostriatal synapses preferentially excites striatal parvalbumin-expressing fast-spiking interneurons (FSIs) and reduces behavioral responding during a texture-discrimination task in mice (Lee et al. 2019). In contrast, M1 corticostriatal optogenetic stimulation excites striatal spiny projection neurons (SPNs) and FSIs equally, and promotes behavioral responding in the task. How striatal SPNs and FSIs integrate excitatory signals from S1 and M1 remains unclear. We investigated the hypothesis that there are distinct differences in the anatomical connectivity of S1 and M1 projections onto SPNs and FSIs. We injected AAVs expressing Ruby2 or GFP spaghetti monster fluorescent proteins (sm.FPs) into both S1 and M1 to label corticostriatal inputs. This was followed by ex vivo whole cell current clamp recordings of striatal neurons with biocytin to label single neurons. Slices were processed with immunohistochemistry for the two sm.FPs as well as biocytin. Confocal z-stacks were acquired and 3D reconstructed using Imaris software. Corticostriatal projections from S1 and M1 were observed to course through the striatum and terminate in puncta. Puncta making close approximations to filled neurons were quantified and the corresponding distance from the soma calculated. Preliminary results indicate an increased density of inputs originating from M1 than from S1 on striatal MSNs. These results suggest that

one mechanism underlying the stronger functional innervation of MSNs by M1 than S1 is the increased density of synaptic inputs from M1. Our findings will have fundamental implications for how sensorimotor integration is performed in the striatum.

Title: Striatal phase locking to the gait cycle during walking

Authors: *L. YANG, S. C. MASMANIDIS;
Neurobio., UCLA, Los Angeles, CA

Abstract: The striatum plays an important role in regulating voluntary movements, including walking. Previous work shows that striatal neurons encode the start and stop of body movement, as well as body speed. However, since whole-body speed is the result of multiple coordinated limb movements, there is still an incomplete picture of how striatal neurons encode single-limb kinematics during walking (i.e., gait). Here, using high resolution, high-speed video tracking (80 fps), we recorded mice freely walking in a large open arena (60 cm x 60 cm). Simultaneous electrophysiological recordings were performed in the dorsal striatum. The large open field enabled mice to walk at a wide range of speeds. Using open-source machine-learning based behavioral tracking techniques, we successfully extracted the trajectory of each limb's position, which allowed us to examine how neural activity is related to body kinematics at the single-limb level. Drawing on the concept of spike-LFP phase locking from the literature, we used circular analysis methods to test whether individual neurons are locked to specific phases of gait. Indeed, the majority of striatal neurons (~60 %) we recorded were significantly phase locked to gait. While the preferred phase varied across the population, the majority of phase-locked cells showed peak firing around the start of the stride phase. Taken together, these findings show that striatal neurons continuously represent the phase of individual limb movements, suggesting a more nuanced coding scheme than whole-body speed. This work also opens new avenues for exploring how brain activity during walking is disrupted in movement disorder models.

Autonoma De SLP, San Luis Potosi, Mexico

Abstract: Recent studies suggest that the basal ganglia and specifically, the striatum nucleus (NSt) play an important role in autistic spectrum disorder (ASD), characterized by deficits in social communication and interaction, repetitive behavior, and cognitive rigidity. One of the components of the NSt that participates in cognitive processes is the cholinergic interneurons (ChIns). These ChIns are the principal source of acetylcholine (ACh) into the NSt and participate in different processes, such as cognitive behavior, choice of actions, and decision-making. In this sense, diverse studies show that the ACh level decreased in animal models of ASD, at least in the prefrontal cortex (PFC) and the NSt. The decrease of ACh in the PFC was due to an increase in the level of the acetylcholinesterase (AChE, enzyme that degrades ACh) and the low level of choline acetyltransferase (ChAT, the enzyme that synthesizes ACh). Whereas in the NSt, the data suggest that the decrease of the ACh levels was due to an increase in the enzyme AChE, but this is not still clear, whether is due to an increase of AChE activity or exist another possibility, for example, that the ChIns may be affected in the ASD model. This imbalance of ACh levels in the NSt could be lead to alterations in the behavior and changes in the activity of the striatal circuit. Because of this, we study the cholinergic system in the NSt of rats exposed to valproic acid (VPA, as an autism model) for that aim we employed behavior tests and immunohistochemical assay for the enzyme ChAT. So far, the present study shows that the striatal cholinergic system is affected in the rats exposed to VPA. The VPA-exposed animals, exhibited a significant reduction in the number of cells immunoreactive to the enzyme ChAT

(ChAT+), compared with control animals. This decreased was the most important at the dorsolateral striatum. Likewise, we did extracellular recordings of these animals and observed changes in the global activity of NSt, since by giving trains of somatosensory stimulation on a forelimb, we found an exacerbated and non-attenuated response like in control animals. These results could explain part of the hyper response to a sensorial stimulus of patients with ASD.

Title: Environment-selective choice of gradient-valued objects is represented in the globus pallidus external segment (GPe) and subthalamic nucleus (STN)

Authors: *A. YOSHIDA, O. HIKOSAKA;
Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: The basal ganglia choose objects whichever their values are flexible or stable (Kim & Hikosaka, 2013). This is controlled by the direct pathway (choose good objects) and the indirect pathway (reject bad objects) (Amita & Hikosaka,2019). However, in real life, there are many objects which may have multiple gradient values (e.g., 5 (best)> 4>3>2>1 (worst)). Moreover, only some of them may be present in a particular environment. For example, objects with the value of 5 and 3 are in environment A, and objects with value 3 and 1 are in environment B. We used many scenes (similar to “Google Map”) as environments and many fractals for objects (target). We first found that the monkey subjects learned many scenes with many objects very quickly (i.e., chose the better object in each scene: rejected value-3 object in scene A, but chose value-3 object in scene B). Can the basal ganglia still control such scene-based object choice? We found task-related neurons in the dorsal part of the caudal GPe (cdGPe). About half of them were excited (excited-type) by the better object (e.g., value-5 in scene A, value-3 in scene B), but not the worse object (e.g., value-3 in scene A, value-1 in scene B). Notably, the excitation to the scene A which implied value-5 object would appear was greater than to the scene B. These results suggest that cdGPe encode two types of information: 1) which object to choose in an environment and 2) how much value will be acquired. Here, a new question arises. How is the activity of the excited-type cdGPe neurons modulated? This may not be caused by the indirect pathway from the striatum because the striatal input to cdGPe is inhibitory. Instead, we

hypothesized that excitatory inputs from subthalamic nucleus (STN) modulate the activity of excited-type cdGPe neuron. Therefore, we recorded from STN. Similar to cdGPe neurons, most STN neurons were excited by the better object, but not the worse object, and the excitation to the scene A was greater than to the scene B (e.g., value-5 in scene A = value-3 in scene B).These results suggest that the STN-cdGPe pathway may be involved in the choice of the better object in any environment and that there is the possibility this STN-cdGPe pathway works in choosing objects, besides the direct, indirect, and hyperdirect pathways.

Abstract: Motor control dysfunction is associated with numerous neuropsychiatric and neurodevelopmental disorders, including autism spectrum disorder, schizophrenia, attention-deficit/hyperactivity disorder and Tourette syndrome. Copy number variation of genes encoding for synaptic adhesion molecules, such as Neurexin1 (Nrxn1), have been shown to confer a significantly increased risk for these disorders, however, the underlying neural etiopathology is currently unknown. Recent findings have revealed that loss of Nrxn1α function results in decreased synaptic strength of dorsal prefrontal cortical inputs to the indirect pathway of the dorsal striatum, providing a potential neural mechanism for related motor dysfunction. However, it is unclear how these synaptic deficits neural dynamics in intact in vivo systems. We hypothesize that corticostriatal synaptic deficits from loss of Nrxn1α contribute to neural alterations associated with motor deficits. We employed a novel treadmill based operant task that allows for the comprehensive study of various motor control features including initiation, suppression, task-relevant sensory integration, timing, and action invigoration. Using dual-site in vivo electrophysiological recordings, we were able to obtain local field potential and single unit activity from cortical areas concurrently with their downstream dorsal striatal targets.

Preliminary results suggest genotypic differences in behavioral performance that may correlate with neural changes in corticostriatal circuitry. These findings will provide valuable insight into the neural mechanisms associated with Nrxn1a related motor deficiencies, as well as further elucidating corticostriatal dynamics involved in motor regulation.

Title: Anatomical and functional connectivity of POm-striatal projections

Authors: *A. J. YONK, D. J. MARGOLIS;
Dept. of Cell Biol. and Neurosci., Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: The integration of sensory and motor signals is an essential role of the dorsal component of the striatum, the main input nucleus of the basal ganglia. Despite the widespread excitatory afferents from neocortex and thalamus, the roles of specific cortical and thalamic inputs to this region, such as posteromedial thalamic nucleus (POm), remain poorly elucidated. Thus, it is critical to understand (1) how these POm-striatal inputs influence striatal microcircuitry and (2) where these inputs contact striatal projection neurons (SPNs) and interneurons. Here, we interrogated the anatomical and functional connectivity of thalamic input from POm onto identified striatal cells in the dorsolateral striatum. Channelrhodopsin-2 (pAAV-hSyn-hChR2(H134R)-EYFP) was expressed unilaterally in POm of male and female mice. Ex vivo whole-cell current clamp recordings were carried out on genetically identified dopamine receptor expressing-1 SPNs (D1-SPNs), D2-SPNs, and parvalbumin-expressing interneurons (PV-INs) in the ipsilateral anterior dorsolateral striatum. Identified cells were confirmed via responses to hyperpolarizing and depolarizing current injections including resting membrane potential, half-height width, and other qualitative characteristics (ramp depolarization, spike adaptation frequency, etc.). Our initial results indicate that optogenetic activation (through the 40X objective; ~3.5mW intensity) of POm-striatal terminals readily elicits moderate subthreshold postsynaptic potentials (PSPs) in putative SPNs and suprathreshold responses in

PV-INs. For the single pulse (one 2.5ms pulse, 460nm) protocol at reduced light intensity (~0.3mW; avoid suprathreshold responses), PV-INs exhibited robust subthreshold PSPs (9.12 ± 0.258mV). For the paired pulse (five 2.5ms pulses, 50ms IPI), putative SPNs exhibited moderate PSPs (5.65 ± 0.06mV; ~3.5mW), while PV-INs exhibited robust PSPs (8.89 ± 0.298 mV; ~0.3mW). For the train (25 2.5ms pulses, 97.5ms IPI, 10Hz) protocol, PV-INs also exhibited robust PSPs (8.05 ± 0.413mV; ~0.3mW) with little short-term amplitude changes. Overall, our results appear to show that POm-striatal projections more robustly activate PV-INs (potentially more so than S1/M1 corticostriatal projections) compared to putative SPNs. Also, PV-INs exhibited little short-term amplitude changes to POm-striatal projection activation, which contrasts other striatal-projecting thalamic nuclei.

Title: Role of Layer 1 inhibition and apical tuft activity in motor cortex in a decision making task

Authors: *E. MARISTANY[1], J. LEDDEROSE[2], S. SHARMA[2], C. EBNER[1], R. N. SACHDEV[2], D. JAEGER[3], M. E. LARKUM[1];

Abstract: Anterolateral motor cortex (ALM) is involved in action selection and motor initiation. ALM is linked to basal ganglia, cerebellum and superior colliculus via the motor thalamus input (VM /VA), which has a prominent input to layer 1 (L1) of ALM. The VM input targets interneurons and apical tuft dendrites of pyramidal neurons in L1. Our earlier work showed that activity in VM axons is related to action initiation (Takahashi et al., 2021). Here, we examined whether apical tuft dendrites of pyramidal neurons in were active in a decision-making task, and whether L1 interneurons can influence the behavioral outcome. Mice were trained to attend to air puffs presented to their right or left whiskers, and after a delay, to respond with a lick to the right or left. Additionally, once trained, mice had to relearn a contextual change within a session. More concretely, right puffs were not anymore associated with right licks but as left puffs, with left licks. First, we characterized the animal's behavior by tracking different body parts (nose,

paws, tongue) during the task. We found several movement patterns during the preparatory period, which differed from each other based on trial type and outcome. We imaged Ca^{2+} activity of pyramidal cell apical dendrites in L1 and show that a proportion of dendritic activity is selective for trial type -- right or left lick -- and epoch, i.e., lick delay or response window. Next, we used optogenetics to examine whether activating L1 interneurons biased performance. To our surprise, in the control behaviour paradigm, there was no effect of activating L1 interneurons on the performance of the learned task. However, in the contextual relearning paradigm we found that L1 inactivation played an important role for the mice's capacity to adapt to the new task. To further understand how apical dendrites compute task relevant information, we are currently combining Ca^{2+} imaging with glutamate release imaging (iGluSNFRs) and are directly targeting apical dendrites during the task to test their influence on action selection.

Title: Input specificity and mechanisms underlying junk-food induced increases in calcium permeable AMPARs, and roles in food motivation

Authors: *T. L. FETTERLY[1], C. R. FERRARIO[1,2];
[1]Dept. of Pharmacol., [2]Psychology Dept., Univ. of Michigan, Ann Arbor, MI

Abstract: Alterations in brain reward centers, including the Nucleus Accumbens (NAc), contribute to over-eating and craving that drives the development and persistence of obesity in humans. In rats, cue-triggered food-seeking is enhanced in obesity-prone males and this behavior is mediated by calcium-permeable AMPA receptors (CP-AMPARs) in the NAc. After consuming sugary, fatty junk-food, a rapid and persistent increase in both NAc CP-AMPAR synaptic transmission and surface expression is observed in male obesity-prone, but not obesity-resistant rats. Interestingly, the synaptic incorporation of CP-AMPARs requires a brief 24 hr junk-food deprivation period in which rats are returned to ad lib standard chow. However, it's unclear in which inputs to the NAc this increase in CP-AMPARs is occurring, and what mechanism may be driving insertion of these receptors during the junk-food and subsequent deprivation period. The NAc receives glutamatergic input from a wide variety of brain regions,

including direct connections from the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA). To differentiate these inputs, we used whole-cell patch clamp recordings in combination with a viral optogenetic strategy to selectively record glutamatergic transmission from either the mPFC or BLA inputs to NAc neurons. Following stereotaxic injection of pAAV-CamKII-Chronos-GFP into either input, we prepared ex vivo brain slices containing the NAc and then recorded optically-evoked AMPAR currents in medium spiny neurons. The contribution of CP-AMPARs to AMPAR transmission was determined using naspm (200 µM), a CP-AMPAR selective antagonist. Initial data show that eating junk-food (10 days, 24 hr deprivation) enhanced CP-AMPAR transmission in mPFC-to-NAc inputs but did not alter transmission in BLA-to-NAc inputs. Thus, results suggest that junk-food induced enhancements in CP-AMPARs occur preferentially at mPFC inputs. We hypothesized that the increase in CP-AMPARs following junk-food/deprivation may be due to decreased mPFC activity. In ongoing experiments, we are assessing whether decreasing activity in mPFC inputs is sufficient to cause increases in synaptic CP-AMPARs. Finally, given the role of NAc CP-AMPARs in cue-triggered motivation, we are also determining how junk-food alters cue-potentiated feeding and cue-triggered food-seeking. In the future we hope to understand the specific role of CP-AMPARs in the mPFC-to-NAc inputs in regulating these behaviors.

Title: Investigating accumbal firing during hedonic food seeking in obesity

Authors: B. A. MATIKAINEN-ANKNEY[1], A. V. KRAVITZ[2];
[1]Washington Univ. in St. Louis, Saint Louis, MO; [2]NIDDK, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Obesity is a leading cause of preventable death in the United States and prevalence of obesity is growing worldwide. Despite widespread knowledge of the health risks associated with obesity, successful treatments remain elusive. One reason may be because we do not understand how obesity changes the brain. Though work over the past several decades has advanced our understanding of how obesity alters brain activity in areas linked to homeostatic feeding, less is known about how motivational components of feeding are altered in obese states. Here, we

investigated how obesity altered neural firing in a brain region linked to motivation and palatable food seeking - the nucleus accumbens. Using chronic in vivo electrophysiological recordings on a novel behavioral platform, we asked how neural activity was affected by obesity as mice seek food and exert effort to acquire food rewards. Obese mice exhibited increased effort output during food seeking relative to lean mice. Accumbal firing was significantly higher during approach and lower during lever press in obese mice relative to lean, suggesting that accumbal encoding of food seeking is dysregulated in obesity. Furthermore, analysis of spontaneous and evoked units suggests that this may be due to aberrant burst firing in the accumbens of obese mice relative to lean. These findings implicate the nucleus accumbens as an in vivo target of persistent synaptic modifications during obesity.

Title: Brain-wide cellular ensembles of persistent to incubated relapse to food craving

Authors: *E. R. SZELENYI[1,2], R. MADANGOPAL[3], B. T. HOPE[3], Y. SHAHAM[3], S. A. GOLDEN[1,2];
[1]Biol. Structure, [2]Ctr. of Excellence in Neurobio. of Addiction, Pain, and Emotion (NAPE), Univ. of Washington, Seattle, WA; [3]Behavioral Neurosci. Res. Br., IRP/NIDA/NIH, Baltimore, MD

Abstract: Background: Obesity is a costly and unyielding public health issue faced by modern society. Currently, successful treatments for obesity focus on behavioral modifications where individuals abstain from highly palatable foods, but often result in relapse due primarily to food craving. This is analogous to the well-studied phenomenon of incubation of drug craving, where abstinence duration sensitizes drug relapse vulnerability. Yet, the brain-wide neural mechanisms underlying this process are poorly understood. Here, we establish a novel operant conditioning procedure for the study of palatable food seeking and incubation of craving. We combine this approach with a cellular resolution whole-brain imaging pipeline to survey the brain-wide neural ensembles engaged by persistent and incubated behavioral relapse. **Methods:** Male outbred CD-1 mice were trained to lever press for highly palatable food pellets (68% carbohydrates) using a

fixed-interval 20-second reinforcement schedule over 7 daily, 60-minute sessions. Following 1, 15, or 60 days of abstinence, mice underwent a 60-minute non-reinforced test trial in the training context using a between-subjects design. Whole-brain activation maps of each group of animals, including controls, were generated using iDISCO+ Fos whole-mount staining and light sheet fluorescent microscopy image acquisition. Volumetric registration, regional annotation, and cell segmentation were performed with ClearMap open-source software and custom python scripts. **Results:** Subjects reliably acquired palatable food self-administration and were tested on days 1, 15 and 60 for relapse. Persistent relapse was seen on days 1 and 15, and incubation was observed on day 60. Brain-wide Fos+ activation maps revealed a progression of regions recruited by food craving in an abstinence duration-dependent fashion, that originated and persisted at early time points (e.g. infralimbic cortex, claustrum, endopiriform cortex, basomedial amygdala, dlPAG) and expanded to nearby (e.g. sensory cortices, basolateral amygdala,) and adjacent (e.g. lateral hypothalamus, olfactory tubercle, entorhinal cortex, pontine reticular nucleus) regions at 60-day, concomitant with behavioral incubation. **Conclusion:** Incubation of food craving ensembles are generated through a "conserved recruitment" effect, whereby persistent relapse brain areas sensitize in activation over time - with a recruitment of neighboring structures observed during behavioral incubation. These results provide critical insight into the neural mechanisms driving relapse to palatable food and offer novel therapeutic entry points in the treatment of obesity.

Title: Macronutrient control of food reward

Authors: A. HARTLE[1], J. SISCO[1], K. RUNYON[1], K. MARSCHALKO[1], A. DIFELICEANTONIO[2], ***W. HOWE**[1];
[1]Virginia Tech. Neurosci. PhD Program, Blacksburg, VA; [2]FBRI at Virginia Tech., Roanoke, VA

Abstract: Neural representations of the sensory/hedonic qualities of a food, as well as caloric density are known to be key determinants of food attractiveness. Recent studies have also shown that when controlling for caloric density and hedonic impact, food items made of combinations of fats and carbohydrates ("combo") are associated with greater monetary value and evoke

unique patterns of activity in striatal reward circuits compared to foods made either macronutrient alone. Given previous data demonstrating that post-ingestive signals of both fat and carbohydrate intake can modify activity in midbrain dopamine (DA) populations, we hypothesized that previous exposure to combo foods amplifies future consumption-evoked striatal DA release, and this enhances the attractiveness of these foods. Here, we examined the impact of single and combo macronutrient foods on reward seeking and DA release in mice. We found that when given free access to familiar food stimuli made of carbohydrate, fat, or combo (equal parts fat and carbohydrate), mice consumed nearly 4 times as much combo compared to either macronutrient alone (n=16). This preference was observed in both sexes and was independent of satiety. Measurements of DA release using DLight and fiber photometry revealed a near doubling of phasic DA release events in the nucleus accumbens during consumption of the combo compared to isocaloric amounts of the fat or carbohydrate stimuli (n=7, $p<0.001$). Together, these results suggest that the macronutrients in a food modify its effect on the DA release, and this contributes to its attractiveness. Future experiments will assess the ability of these different foods to modulate DA in the dorsal striatum, activity in the broader hindbrain-to-midbrain circuitry they recruit, as well as their ability to modulate motivated food seeking.

Title: Investigating the role of the dorsal hippocampus in driving reinforcing behaviors.

Authors: *K. IBRAHIM[1], N. MASSALY[1], H. E. FRYE[1], H.-J. YOON[1], R. SANDOVAL[1], A. ZEC[1], S. PATHIRANAGE[1], O. IDOWU[1], S. WILLIAMS[1], T. KASH[2], A. V. KRAVITZ[1], J. MORON-CONCEPCION[1];
[1]Washington Univ. St. Louis, St. Louis, MO; [2]UNC- Chapel Hill, Chapel Hill, NC

Abstract: The dorsal hippocampus (dHPC) has been repeatedly shown to play an important role in the formation, maintenance, and retrieval of contextual, spatial, and drug-induced memories. Interestingly, pharmacologically inhibition of the nucleus accumbens (NAc) also disrupted contextual and spatial memories, suggesting the presence of functional coordination between the

dHPC and NAc in maintaining memory formation (Xia et al. 2017, Ito et al., 2008). Recently, Trouche (2019) has highlighted the critical role of the dCA1 CaMKII+ projecting neurons to the fast-spiking interneurons in the NAc shell in retrieving reward-induced memories. While silencing this projection may impair memory retrieval, the sufficiency of the dCA1 activation in driving reinforcing behaviors has yet to be determined. To investigate the role of dHPC activation in reinforcement, we used both un-cued real-time place test (RTPT) and self-stimulation (SS) paradigm to determine the active seeking of operant dHPC photo-stimulation in a more translational model. Channelrhodopsin (ChR2) or control virus was expressed in dHPC CaMKII+ neurons of C57/BL6 male mice before implantation of optic fibers. In both experiments, we observed that the mice that expressed ChR2 not only prefer stimulation of dHPC neurons but also actively seeking for stimulation. To investigate the effect of neuronal activity in the NAc with the activation of dHPC excitatory neurons, we expressed GcAMP (or control virus) in the NAc together with ChR2 (or control virus) in the dHPC before the implantations of fibers. We observed that stimulation of dHPC CaMKII+ neurons in the home cage induced an increase in calcium transient, a marker for cellular activity, in the NAc. Pairing this with the SS paradigm, we determined that the increase in neuronal activity of the NAc is due to the activation of dHPC and not the cue. Lastly, we narrowed down our focus in the NAc and investigate the effect of dHPC activation on dynorphin- and enkephalin-containing neurons. Currently, our data shows that the dHPC excitatory neurons are not only necessary for the retrieval of contextual memories but also encode reinforcing values that may trigger reward-seeking via the activation of the Nac shell.

Title: Delays to reward delivery enhance the preference for an initially less desirable option: role for the basolateral amygdala and retrosplenial cortex

Authors: *M. J. LEFNER[1], A. P. MAGNON[1], J. M. GUTIERREZ[1], M. R. LOPEZ[3], M. J. WANAT[2];

[2]Neurosciences Inst., [1]Univ. of Texas at San Antonio, San Antonio, TX; [3]Biol., Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Reward-based decisions are driven by cost-benefit analyses. A purely economic decision should be influenced solely by the *future* costs associated with earning a reward. However, evidence across species demonstrate that *past* costs (i.e. sunk costs) influence decision-making policies. Sunk costs can result in subjects persisting in the current reward-seeking action despite better options, which suggests that sunk costs increase a reward's value. The effect of sunk costs on behavior has been primarily studied in tasks in which choosing one course of action comes at the expense of an alternative outcome. However, this approach cannot determine if sunk costs increase the value of the chosen outcome and/or decrease the value of the alternative outcome.

To address this, we developed a rodent task to determine how sunk temporal costs prior to a reward delivery subsequently alters reward consumption and preference. We first identified the relative preference between different flavored food rewards in a free-feeding test. Rats then underwent training sessions in which the initial less preferred reward was delivered after long delays (high temporal cost), while the initial preferred reward was delivered after short delays (low temporal cost). The impact of these training sessions on reward value (consumption) and preference was then assessed in a second free-feeding test performed after training. We found that high temporal costs imposed during training sessions subsequently increases the value and relative preference for the initial less desirable reward.

We probed whether this change in reward preference involved neural systems that contribute to timing, reward valuation, and learning. Pharmacological manipulations and site-specific lesions were performed to examine the potential involvement of the dopamine system, the orbitofrontal cortex (OFC), the basolateral amygdala (BLA), and the retrosplenial cortex (RSC). The change in reward preference was unaffected by systemic dopamine receptor antagonism or OFC lesions. In contrast, lesions of the BLA or the RSC prevented the enhanced consumption and preference for the initial less desirable reward. These findings demonstrate that both the BLA and RSC participate in how sunk temporal costs alter reward value and preference. Preliminary photometry recordings were performed to determine when these regions are responsible for updating preference. Taken together, our data highlights a previously unappreciated role for the BLA and RSC in mediating enhanced preference for a less desirable reward that follows a long temporal delay.

Title: Medial prefrontal cortex neural encoding in an Alzheimer's disease rat model during an outcome devaluation task

Authors: *T. J. SLOAND[1,2], M. NIEDRINGHAUS[1], E. A. WEST[1,2];
[1]Cell Biol. and Neurosci., Rowan Univ. SOM, Stratford, NJ; [2]Rowan Univ. GSBS, Stratford, NJ

Abstract: Alzheimer's disease (AD) is characterized by the accumulation of neuropathological markers (Aβ plaques, tau pathology, and neuronal loss) and profound memory loss. However, additional learning and cognitive deficits may also contribute to changes in quality of life in AD patients. AD rats (TgF344-AD) expressing mutant amyloid precursor protein and presenilin-1 exhibit age-dependent (18-24 months) AD pathology (i.e., plaques, tau pathology, oligomeric Aβ and neuronal loss), but show hypofunction within the rodent medial prefrontal cortex (mPFC) at an earlier timepoint (6 months). We have shown that neural activity during learning in the mPFC predicts and is necessary for the ability of rats to suppress behavior following outcome devaluation. Thus, we aimed to determine if AD rats would show aberrant neural activity and/or behavioral responding to reward predictive cues following outcome devaluation. Here, we recorded mPFC (prelimbic and infralimbic) *in vivo* electrophysiological activity during an outcome devaluation task in rats. AD rats (n=3) and wild-type litter mate controls (n=4) were presented with two distinct cues as conditioned stimuli (CS+; predicting a sugar or food pellet) and two cues that did not predict a reward (CS-); 10 trials each. After 10 sessions, rats underwent a devaluation procedure to induce a conditioned taste aversion (LiCl, i.p., 0.3 M; 10 ml/kg) to the sugar pellets. Rats were then tested on the same Pavlovian task (under extinction) to evaluate their ability to avoid CS+ associated with the devalued outcome. Control rats spent less time in the food cup during the CS+ associated with the devalued outcome (12.6%) compared to the CS+ that predicted the non-devalued outcome (18.5%). AD rats did not differ in the time spent in the food cup during the devalued CS+ compared to the non-devalued CS+ (13.0% vs. 12.3%, respectively). Electrophysiological recordings in the mPFC revealed distinct neuronal populations that were excited or inhibited during the cues (classified as "phasic"). Interestingly, phasic neurons in AD rats were exclusively excited to the cues, where the phasic neurons in control animals consisted of both excited and inhibited neurons. There was no difference in % of neurons excited (EXC), inhibited (INH), or nonphasic (NP) to the non-devalued CS+ (27.1% INH, 18.8% EXC, 54.2% NP) compared to the devalued CS+ in control rats (27.1% INH, 12.5% EXC, 60.4% NP; n=48) and no difference between the non-devalued CS+ (0.0% INH, 34.4% EXC, 65.6% NP) or the devalued CS+ (0.0% INH, 34.4% EXC, 65.6% NP; n=32) in AD rats. In the future, we will correlate these neurophysiological characterizations with the behavioral deficits in AD rats.

Title: Rats self-administer right, but not left, cervical vagus nerve stimulation

Authors: J. BROUGHER[1], U. AZIZ[1], M. CHATURVEDI[1], A. JULES[1], I. SHAH[1], ***C. THORN**[2];
[1]Univ. of Texas At Dallas, Richardson, TX; [2]Univ. of Texas at Dallas, Richardson, TX

Abstract: The vagus nerve is an important carrier of sensory information from the gut and other visceral organs to the central nervous system. Emerging evidence suggests that activation of ascending projections through the right, but not the left, nodose ganglion strongly modulates reward-related behavioral responses and striatal dopamine release (Han et al., 2018). Building on these recent findings, we hypothesized that, if right vagal activation conveys visceral information to the mesolimbic DA system more effectively than left vagal activation, then standard electrical stimulation of the right vagus nerve (r-VNS) may drive self-administration (SA) more readily than VNS that is traditionally delivered on the left side (l-VNS). Here, 14 adult male Long-Evans rats were randomly assigned to r-VNS (n = 7) or l-VNS (n = 7) treatment groups and implanted with cervical VNS electrodes around the targeted nerve prior to undergoing a VNS SA assay. After recovery, rats were habituated to press a lever to receive food reward. After these initial sessions, food was removed and 5 VNS SA sessions were given, in which lever pressing resulted in the immediate presentation of a visual cue paired with delivery of VNS. We found that rats in the r-VNS group quickly learned to self-administer r-VNS, but that l-VNS was not sufficient to sustain lever pressing behavior. After 5 days of SA, rats were given 5 extinction (EXT) sessions, during which VNS and visual cue were no longer delivered. During EXT, r-VNS treated rats stopped engaging in the lever press task. Following EXT, rats were given an initial session of reinstatement (R1) in which the visual cue (but no VNS) was delivered following each lever press. Rats in the r-VNS treatment group exhibited significant cue-induced reinstatement of lever pressing during R1, suggesting strong reinforcement of reward-predictive stimuli via engagement of mesolimbic dopaminergic nuclei. After cue-only reinstatement, rats received an additional reinstatement session (R2) in which VNS was again paired with lever pressing. To ensure that both r-VNS and l-VNS groups received equal amounts of stimulation during R2, each rat in the l-VNS group was yoked to a rat in the r-VNS group and VNS was simultaneously delivered to both rats contingent on the behavior of the r-VNS rat. Ninety minutes after R2, rats were sacrificed and c-Fos expression was subsequently examined in the VTA and SNc. c-Fos expression in both TH+ and TH- cell populations in both regions was significantly elevated

following r-VNS treatment compared to l-VNS. Taken together, our behavioral and histological results suggest that r-VNS activates mesolimbic reward circuits more effectively than l-VNS.

Title: Dissociable activity dynamics in projection-specific midbrain dopamine subpopulations contribute to reward association and motivation

Authors: *J. ELUM[1], B. JUAREZ[2], S. NG-EVANS[3], L. S. ZWEIFEL[2];
[1]Grad. Program in Neurosci., [2]Pharmacol., [3]Univ. of Washington, Seattle, WA

Abstract: The midbrain dopamine (DA) system regulates reinforcement learning and motivation. Anatomical and functional heterogeneity among ventral tegmental area (VTA) DA neurons with defined projection patterns to the nucleus accumbens (NAc) are proposed to distinctly contribute to these processes. Cell-type specific targeting of genetically isolated VTA DA populations with optogenetic manipulations during classical and instrumental conditioning showed that DA neurons with distinct projections to NAc core and shell subregions differentially regulate reward association and reward motivation. While these studies established the necessity and sufficiency of NAc core and shell-projecting DA subpopulations for learning and motivation, how the activity of these neurons might contribute to the distinct phases of acquisition, extinction, and reinstatement of an appetitive behavior remains unresolved. Here, we selectively expressed GCaMP6m in genetically isolated VTA DA populations with divergent projection patterns to subregions of the NAc and utilized fiber photometry to record intracellular calcium dynamics across these different phases of behavior. We observed that both populations are activated by cues, actions, and rewards during instrumental behavior. However, shell-projecting VTA DA neurons display prominent ramping of calcium signals leading up to the lever press (action) that develops rapidly during the acquisition of the action- and cue-reward association. These ramps are absent in NAc core-projecting VTA DA neurons. Further, the NAc shell-projecting DA population maintains an increase in the calcium signal between the action and presentation of the reward-predictive cue, and between the cue and the reward delivery. In

contrast, these signals in the core-projecting population return to baseline between the discrete events. During unexpected reward omission, the NAc core-projecting population displays temporally discrete decreases in calcium signals that is not observed in the NAc shell-projecting cells. Our data demonstrate that calcium signals at the level of the cell bodies of NAc core- and NAc shell-projecting VTA DA neurons are distinct and suggest that NAc core-projecting dopamine neurons provide temporally discrete information about actions, cues, and outcomes to facilitate reward association while NAc shell-projecting VTA neurons provide sustained signals through these events to promote motivated behavioral responses. These results provide further evidence that the midbrain DA system contains functionally distinct subpopulations for the regulation of learning and motivation.

Title: Cue-reactivity, reappraisal and savoring in human heroin addiction- an fMRI study

Authors: *Y. HUANG[1], A. O. CECELI[1], S. KING[1], G. KRONBERG[1], P. MALAKER[1], E. GARLAND[2], N. ALIA-KLEIN[1], R. Z. GOLDSTEIN[1];
[1]Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Ctr. on Mindfulness and Integrative Hlth. Intervention Develop., The Univ. of Utah, Salt Lake City, UT

Abstract: Drug addiction is characterized by impaired Response Inhibition and Salience Attribution (iRISA), including enhanced neurophysiological/corticostriatal reactivity to drug vs. nondrug cues and reinforcers. Cognitive strategies to reinterpret drug cues and competing nondrug reinforcers (reappraisal of drug, savoring of food) have been employed to modulate emotional reactivity and normalize incentive salience. However, drug cue reactivity has been less extensively studied in opioid addiction, and whether reappraisal and savoring may normalize cue reactivity-related brain function remains unresolved. To this end, 32 participants (age = 40.24 ± 8.82; 25M) with heroin use disorder (HUD) underwent a novel cue reactivity fMRI task with instructions to passively view heroin, food, and neutral cues, reappraise heroin cues and savor food cues. Results were analyzed by FSL and cluster-corrected to $p<.05$. We hypothesized that heroin vs. food/neutral cues would upregulate corticostratal reward networks, while reappraisal and savor conditions would enhance prefrontal function related to cognitive control [e.g., dorsolateral prefrontal cortex (dlPFC) and inferior frontal gyrus (IFG)]. Although subjective

ratings revealed significantly higher craving of food vs. heroin [$F(1,31)=23.09$, $p<.01$], passive drug vs. neutral/food cue viewing was associated with increased activations in the reward network [midbrain, striatum and ventromedial PFC (vmPFC)] and cognitive control network (bilateral IFG/dlPFC), among other regions [e.g., posterior cingulate cortex (PCC), amygdala, hippocampus] (drug>neutral at $Z>3.1$; drug>food at $Z>2.3$). Compared to their respective passive viewing conditions, both reappraising heroin and savoring food cues showed increased activation in the left IFG, along with left dlPFC activation during savoring ($Z>3.1$), and higher activation in the bilateral IFG and PCC during reappraisal compared to savoring ($Z>3.1$). Additionally, the vmPFC showed higher activations during passive drug cue viewing than reappraising ($Z>2.3$). Our novel task support the iRISA model, revealing pronounced corticostriatal activity to drug vs. nondrug cues in HUD. Additionally, increased IFG activity during drug reappraisal and both IFG and dlPFC during food savoring alludes to the suppression of drug cue reactivity via top-down cognitive control processes; the vmPFC may facilitate this process by decreasing the value assigned to the drug cues during reappraisal. The neural mechanisms of drug cue reactivity and its suppression via reappraisal and savoring in HUD may highlight target brain areas for cognitive and neuromodulatory interventions.

Title: Amygdalae off the leash ! : Cocaine patients carrying a genetic variant linked to over-response of the stress (cortisol) system show heightened resting connectivity between the left amygdala and the ventromedial prefrontal cortex (vmPFC).

Abstract: AIM: Our amygdalae are critical first responders in the brain, leaping into action at the first whiff of danger -- or reward. In the healthy brain, these important functions are 'on a leash', tightly regulated by other (inhibitory) brain regions, so that we are not in a chronic state of fear or reward motivation. As stress can undermine the 'leash', we recently tested and confirmed that cocaine patients carrying a genetic variant linked to over- response of the cortisol *stress* system (i.e., the minor G allele of rs3800373, for the FKBP5 gene) have heightened ('unleashed') responding to drug cues in motivational circuits (SfN 2019). Here, we tested whether the vulnerability allele might be linked to heightened functional connectivity between the amygdala and motivational circuitry nodes, *even when the brain is at rest*. **METHODS:** Using BOLD fMRI (3T), we collected six-minute, eyes-open, resting scans in detoxified, treatment-seeking male cocaine inpatients. Resting data were analyzed within the SPM8 connectivity toolbox, generating voxel-wise functional connectivity maps for (R; L) amygdalae in carriers of the minor G (vulnerability) allele (TG, GG; n=15) for rs3800373 of FKBP5, and in TT homozygotes (n=12). The resulting correlation maps (r to Z transformed) were examined for each group, and then formally compared across the two genetic subgroups (group difference t maps thresholded 2-5 for display; FWE- corrected). **RESULTS:** For both cocaine subgroups, there was robust positive "intra-limbic" connectivity between the amygdala (R; L) and multiple motivational nodes (e.g., the ventral tegmental area, ventral pallidum, ventral striatum/putamen, and insula) - and both groups lacked inverse ('leashing') connectivity with the dorsomedial prefrontal cortex (PFC). In addition, carriers of the minor (vulnerability) allele for FKBP5 showed *heightened* resting connectivity between the left amygdala and two motivational nodes, the ventromedial PFC and the insula, as compared to the TT homozygotes. **CONCLUSION**: These new data highlight the 'unleashed' motivational circuitry in cocaine patients, and suggest that carriers of the minor G (vulnerability) allele of rs3800373 for the FKBP5 gene may be at additional risk for psychopathologies related to amygdala over-activity, whether in the domain of aversive (e.g., pain/anxiety/stress/PTSD) or appetitive (e.g., drug reward/relapse) motivation. These genetic findings encourage novel (behavioral, pharmacologic, or neuromodulatory) interventions to boost or to restore regulation of the amygdala, especially for carriers of the vulnerability allele.

Title: Cortico-striatal volume changes in human cocaine and heroin addiction

Authors: *A. O. CECELI, G. KRONBERG, Y. HUANG, P. MALAKER, P. MILLER, N. ALIA-KLEIN, R. Z. GOLDSTEIN;
Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: While all drugs of abuse share dopaminergic targets, differences in neural morphology between psychostimulant and opiate addiction remain largely unresolved. Compared to opiates, psychostimulant use accompanies increased impulsivity (via inferior frontal gyrus [IFG] and dorsolateral prefrontal cortex [dlPFC]) in humans, and enhanced cue-extinction (via ventromedial PFC [vmPFC]) and neuroplasticity (via nucleus accumbens [NAcc]) in preclinical models. We hypothesized parallel neuroanatomical changes in individuals with cocaine or heroin use disorder (CUD/HUD): specifically, increased NAcc/vmPFC but decreased IFG/dlPFC volumes in CUD vs. HUD. Voxel-based morphometry quantified gray matter volume differences via T1-weighted MRI in demographic/IQ-matched individuals with CUD (n=20; mean age: 42.8 ± 7.3; 5 females), HUD (n=20; mean age: 40.9 ± 10.0; 6 females), and healthy controls (HC; n=20; mean age: 41.4 ± 8.8; 5 females). In line with prior literature, addicted individuals displayed smaller vmPFC volumes than HC ($p<0.05$-corrected)—an effect driven by HUD ($p<0.05$-corrected; similar NAcc compression). Importantly, as hypothesized, there were significant right IFG reductions in CUD vs. HUD ($p<0.05$-corrected); trends for midbrain/NAcc and vmPFC volume increases were further revealed in CUD vs. HUD (uncorrected). Craving was significantly correlated with posterior putamen volume in CUD compared to HUD (the higher the craving, the higher the posterior putamen volume; $p<0.05$ corrected). Consistent with the literature, compared to HC, addicted individuals exhibited mesolimbic cortical/sub-cortical compression. IFG compression and NAcc/vmPFC expansion in CUD vs. HUD extend clinical/preclinical findings, offering for the first time a direct contrast between human CUD and HUD neuroanatomy. The increased posterior putamen volume as a function of craving may be a neural signature of enhanced cue sensitivity in severe CUD. Overall, results suggest neurobiological conservation across species and mechanistic bases for substance-specific neuropsychological differences in humans, with implications for fine-tuning addiction treatment by primary drug of abuse.

Title: Inter-subject correlations of fMRI responses to cinematic heroin use in individuals with heroin use disorder

Authors: *G. KRONBERG, A. O. CECELI, N. MCCLAIN, D. VASA, P. MALAKER, N. ALIA-KLEIN, R. Z. GOLDSTEIN;
Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Neurophysiological responses to drug cues remain poorly understood in heroin use disorder (HUD). While naturalistic dynamic stimuli (e.g. movies) provide several advantages over traditional fMRI tasks, neural responses to heroin-related naturalistic stimuli have not been studied in HUD. We recorded BOLD activity in 30 treatment-seeking HUD (40.51±9.06 years, 23 M) participants and 16 age, sex, race, and education-matched healthy controls (HC; 43.79±10.33 years, 10 M), while watching the first 17 minutes of the movie "Trainspotting", which contains scenes of explicit heroin use, as well as scenes that are highly salient but not directly related to heroin use. Importantly, the overarching narrative structure of the clip is centered around drug-addiction, including complex contextual elements relevant to HUD (e.g. social, emotional, and economic challenges of addiction). For our analyses, the movie clip was divided into distinct scenes, which were then classified as drug or non-drug, based on whether drugs or speech about drugs appeared in the scene. After watching the movie, participants freely recalled movie details along with relevant personal reflections and rated individual scenes based on their emotional response and heroin craving. To assess neurophysiological responses, we computed whole-brain inter-subject correlation/functional connectivity (ISC/ISFC) of the BOLD signal during the movie, and compared between HUD and HC groups for drug and non-drug scenes. Per the impaired Response Inhibition and Salience Attribution (iRISA) model of drug addiction, whereby excessive incentive salience is ascribed to drug at the expense of non-drug cues/reinforcers, we hypothesize increased ISC during drug-related scenes in the HUD group in reward, salience, habit, executive, self-directed, and memory networks. We also expect ISCs in reward/salience, habit and self-directed networks during drug-related scenes to correlate with craving for those scenes. Similarly, we expect scene-resolved ISCs in the salience and memory networks to correlate with scene recall. Since the movie content should preferentially evoke self-referential thought in the HUD group, we expect these subjects to show elevated ISFC in the default mode network that is time-locked to the explicit drug scenes. This elevated ISFC should predict the duration of self-referential speech when subjects freely recall the movie. Insights

from naturalistic drug cue exposure may better characterize the neural mechanisms of drug cue reactivity in heroin addiction.

Title: Mindfulness, Future Valuation, and Active Engagement with Integrative Health Practices Support Recovery from Substance Use Disorders

Authors: *S. LYNN[1], J. C. BASSO[3], M. K. SATYAL[2], L. N. ATHAMNEH[4], W. K. BICKEL[5]; [1]Virginia Tech., Roanoke, VA; [2]Virginia Tech., Blacksburg, VA; [3]Human Nutrition, Foods & Exercise, Virginia Tech. Univ., Roanoke, VA; [4]Ctr. for Transformative Res. on Hlth. Behaviors, Fralin Biomed. Res. Inst. at VTC, Roanoke, VA; [5]Advanced Recovery Res. Ctr., Roanoke, VA

Abstract: Substance Use Disorders (SUDs) are chronic, remitting, relapsing disorders that are a global public health concern, causing both financial and health burdens for up to 20% of the world population, and requiring long-term treatment. An individual's quality of SUD recovery is multifaceted, including aspects of physical, mental, and social health. However, it is unknown what behavioral determinants underlie success in recovery. We hypothesized that cultivating intentional states of mind, for example through engagement in Integrative Health Practices (IHPs), may be integral in promoting successful recovery. Participants were recruited from the International Quit and Recovery Registry (IQRR), an online research, education, and support platform for individuals who self-report substance misuse. For this study, N=242 individuals meeting the DSM-5 criteria of a lifetime SUD were recruited. Engagement in IHPs was assessed using the International Complementary and Alternative Medicine Questionnaire (I-CAM-Q), whereas state of mind was captured using the Five Facet Mindfulness Questionnaire (FFMQ), Mindful Attention Awareness Scale (MAAS), and the Minute Delay Discounting Task. Quality of recovery was assessed using days in recovery, quality of life, craving, and remission status. We utilized linear and logistic regression modeling to assess whether mindfulness, future valuation, and engagement in IHPs predicted any of our recovery outcomes of interest. Our predictors statistically significantly predicted 1) days in recovery ($F(11, 230)=22.638$, $p<0.001$), accounting for 56% of the variance; 2) quality of life ($F(11, 230)= 26.468$ $p<0.001$), accounting

for 55.9% of the variance; and 3) craving ($F(11, 230)=8.192$, $p<0.001$), accounting for 28.1% of the variance. Additionally, our predictors statistically significantly predicted regression status ($x^2(11)=77.206$, $p<0.001$). Individuals in remission experienced improved quality of life, enhanced future valuation, increased mindfulness, decreased craving, and greater engagement with IHPs. Our results suggest that engaging in IHPs such as meditation, yoga, or tai chi may cultivate states of mind (i.e., mindfulness; future valuation) that promote success in recovery.

Title: Prefrontal-habenular tract abnormalities associated with recent cocaine use in human drug addiction

Authors: *S. KING[1], P.-O. GAUDREAULT[2], J. XU[3], P. MALAKER[4], N. ALIA-KLEIN[5], R. Z. GOLDSTEIN[6];
[1]Icahn Sch. of Med. At Mount Sinai Grad. Training Program In Neurosci., New York, NY; [2]Psychiatry Dept., Icahn Sch. of Med. At Mount Sinai, New York City, NY; [3]Radiology, [4]Icahn Sch. of Med. At Mount Sinai, New York, NY; [5]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [6]Dept. of Psychiatry, Mount Sinai Sch. of Med., New York, NY

Abstract: Drug addiction encompasses neuroadaptations in mesocorticolimbic networks that regulate reward valuation and inhibitory control. The habenula (Hb), an epithalamic hub for communication across cognitive and emotion processing regions, including the prefrontal cortex (PFC), is central to adaptive behaviors that are driven by rewarding or aversive stimuli. Functional impairments in the lateral Hb predict relapse-like behaviors in preclinical models of addiction. However, the Hb's anatomical connections with the PFC, as well as their role in drug addiction, have not been comprehensively studied in humans. Using high-resolution diffusion MRI tractography and diffusion tensor imaging (DTI), we mapped PFC-Hb anatomical connections and examined their white matter microstructure in individuals with cocaine use disorder (CUD; n = 8 female/23 male, mean age = 46 years) and healthy controls (CTL; n = 11 female/17 male, mean age = 42 years). All subjects provided a urine toxicology test for cocaine on the day of scanning, which was used to classify the CUD group into short-term abstinent (CUD-, n = 15) and currently using (CUD+, n = 16) individuals. Tracts were segmented into

component subcortical fiber bundles, the anterior limb of the internal capsule (ALIC) and stria medullaris (SM), and mean DTI metrics were extracted. Analyses of variance (ANOVAs) were performed using a Group × Fiber Bundle × Side design. Two other prefrontal-subcortical white matter projections with trajectories in the ALIC, connecting to the thalamus and midbrain, were similarly examined as a control. The mean fractional anisotropy, a surrogate measure of the coherence of diffusion, showed a significant interaction effect for Group × Fiber Bundle ($F = 6.95$, $p = .001$), with reductions in CUD- vs. CTL along the ALIC ($p = .001$) and in CUD+ vs. CTL along the SM ($p = .018$). There was an additional main effect of Group for the mean diffusivity, which was elevated in CUD- vs. CTL along the entire PFC-Hb tracts ($F = 6.68$, $p = .002$). In the SM, these abnormalities in fractional anisotropy were also significantly correlated with measures of individuals' recency, but not chronicity, of cocaine use ($r = -0.46$, $p = .009$). These effects were specific to the Hb and did not generalize to the adjacent control regions. These results are suggestive of both acute (in the SM) and longer duration (in the ALIC) impairments and support further research into the recovery trajectories of white matter tracts. Importantly, these findings contextualize existing preclinical evidence for PFC-Hb circuit abnormalities in addiction, supporting further investigation into the human Hb and its potential neurodegeneration in addiction.

Abstract: To flexibly respond to changes in the environment is essential for adaptive behavior in daily life. Flexible decision-making can be modelled using laboratory tests of cognitive flexibility such as probabilistic reversal learning (PRL). Indeed, impairments in cognitive flexibility have been reported in both cocaine and gambling addictions. The mechanistic microstructure of these deficits, however, remains incompletely understood. Reinforcement learning (RL) is the process by which feedback from the environment, such as reward or punishment, is used to adjust behaviour with the aim of maximizing reward and minimizing punishment. RL models have helped gain a more detailed, mechanistic explanation of the latent behavioral processes involved in reversal learning tasks, and how these are altered in various psychiatric disorders. For example, it has been shown that there are decreased learning rates and reinforcement sensitivity (‘value-based’ learning parameters) in depression (Mukherjee et al, 2020), decreased stimulus-bound perseveration (also known as ‘stickiness’, a ‘value-free’ parameter) in obsessive-compulsive disorder, and increased ‘stickiness’ in stimulant use disorder (Kanen et al, 2019). It remains unknown how parameters such as the reward rate, reinforcement sensitivity, location stickiness (motor perseveration) and stimulus stickiness (stimulus-bound perseveration) are differentially affected in cocaine use disorder (CUD) versus gambling addiction and could further fractionate disorders of compulsivity. In the present study, we performed a Bayesian hierarchical reinforcement learning analysis on data from a PRL task conducted on fifty-six participants, which consisted of control subjects (n=18), participants diagnosed with CUD (n=20) or gambling disorder (GD) (n=18). Results demonstrate a reduced reward learning rate in the CUD group and an increase in location stickiness. Strikingly, location stickiness was enhanced in GD, however stimulus stickiness was abnormally low in individuals with GD. Low stimulus stickiness in GD may reflect increased exploratory behavior that is insensitive to outcomes and has been observed in OCD. Alongside the behavioral data, we analyzed task-based fMRI data to relate the observed behavioral findings to their underlying neural mechanisms. Overall, our analysis identified differences between the behavioral processes involved in reversal learning in patients with CUD and GD and brain regions that may be

mediating them. Moreover, we deepen support for RL models providing enhanced specificity for distinguishing perseverative deficits present in different addictive disorders.

Title: Functional connectivity alterations in patients with opioid abuse at high suicide risk

Authors: *H. OH[1,2], M. PATRIQUIN[2,1], R. SALAS[1];
[1]Psychiatry and Behavioral Sci., Baylor Col. of Med., Houston, TX; [2]The Menninger Clin., Houston, TX

Abstract: INTRODUCTION: Suicide is a major mental health problem commonly characterized by self-harm and persistent thoughts of wanting to die. Death by suicide is a tragic event that occurs at higher rates in those with psychiatric disorders, including opioid abuse. It remains

unknown whether suicide risk is associated with functional brain connectivity in opioid users. We studied the resting state functional connectivity (RSFC) between the orbitofrontal cortex (OFC) and dorsal striatum (putamen and caudate) in patients at high risk for suicide with and without opioid use. METHODS: Psychiatric patients (N = 75) were recruited from abstinent adult inpatients at The Menninger Clinic (Houston, TX) and divided into groups of opioid-using suicidal patients (OS, N = 35) versus non-opioid-using non-suicidal patients (psychiatric controls: PC, N = 40) based on the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) for the opioid category and the Columbia-Suicide Severity Rating Scale (C-SSRS) guidelines. OS and PC groups were matched for gender and age. Patients were scanned in a 3T Siemens Trio MR scanner in the Center for Advanced MR Imaging at Baylor College of Medicine. A 4.5 min MPRAGE (1mm isotropic voxels, TE = 2.66ms, TR = 1200ms) was collected, followed by 5 min resting state scan (3.4x3.4x4 mm voxels, TE = 40ms, TR = 2s). RSFC data were preprocessed using the CONN Functional Connectivity Toolbox. The preprocessing pipeline included realignment, slice-timing correction, structural and functional normalization, ART-based outlier detection and smoothing with an 8 mm full width at half maximum Gaussian smoothing kernel. RESULTS: Preliminary data revealed that OS showed significantly higher RSFC between the left medial OFC and left putamen (0.082) than PC (-0.022) ($p < 0.05$). OS also showed higher RSFC between the left medial OFC and right putamen (0.068) than PC (-0.006), but we did not find a significant difference between two groups ($p = 0.1$). RSFC between the left medial OFC and bilateral striatum did not show a significant difference between two groups ($p = 0.9$). CONCLUSIONS: Findings revealed that OS group showed higher functional connectivity between the left medial OFC and left putamen than the PC group. Our data demonstrate that the left medial OFC may be a promising brain target area for brain stimulation techniques for psychiatric patients with high risk of suicide and opioid use. Additional research investigating the potential therapeutic efficacy of brain stimulation (e.g., transcranial magnetic stimulation) to the OFC will be required to provide an effective brain stimulation treatment for patients with suicidality and opioid use.

Title: Whole-brain white matter microstructure abnormalities in human cocaine and opiate use disorder

Authors: *P.-O. GAUDREAULT, S. KING, P. MALAKER, N. ALIA-KLEIN, R. Z. GOLDSTEIN;
Mount Sinai Sch. of Med., New York, NY

Abstract: Functional MRI studies in individuals with substance use disorder commonly show functional connectivity impairments across cortico-striatal circuits that underlie executive control, reward processing and salience attribution. However, substantially few studies have assessed structural connectivity, especially of white matter (WM) tracts, in drug addiction. Our study aimed at using state-of-the-art diffusion MRI analyses to assess whole-brain WM integrity in individuals with cocaine (CUD) or opiate (OUD) use disorder as compared to healthy controls (HC). Diffusion MRI using a 3T scanner was acquired in 58 HC (39.3±8.6yo, 21F), 60 individuals with CUD (current users/CUD+, N=28, 47.7±6.5yo, 6F; and abstinent users/CUD-, N=32, 47.3±7.9yo, 4F) and 30 individuals with OUD (40.3±9.0yo, 6F) on medication-assisted treatment. Diffusion tensors were computed and Tract-Based Spatial Statistics was used for whole-brain/voxel-wise analyses of metrics assessing the coherence of water diffusion along specific orientations [FA-fractional anisotropy, MD-mean diffusivity, AD-axial diffusivity, and RD-radial diffusivity] corrected for age and total intracranial volume. Permutation statistics (p-corrected) were used for group comparisons. Compared to HC, individuals with substance use disorder showed decreased FA and increased AD, MD, and RD ($p<.05$) in all major WM tracts - these effects being primarily driven by CUD+ and OUD. Nevertheless, compared to HC, the CUD- had reduced FA in the left anterior thalamic radiation ($p<.05$). Finally, there was a trend for an increased FA in CUD+ compared to OUD in the forceps major, a posterior WM fiber bundle connecting both occipital lobes through the splenium of the corpus callosum ($p=.05$). Together, these results suggest that individuals with substance use disorder show whole-brain WM impairments defined by less diffusion coherence and directionality as well as increased diffusivity, which are thought to reflect axonal packing attenuation and demyelination. The between-group analyses showing specific whole-brain WM impairments in both groups with positive urine for either cocaine (CUD+) or opiates (OUD) suggest that recency of use might be associated with more severe impact on anatomical connectivity. However, results in the abstinent group (CUD-) also suggest that some WM impairments may persist for longer periods. Further analyses are needed to explore the associations between WM impairments and drug-specific use patterns.

Title: Chronic Opioid Administration Potentiates Striatopallidal and Striatonigral GABAergic Transmission

Authors: *W. WANG[1], X. XIE[1], X. ZHUANG[1], T. TAN[1], Z. HUANG[1], H. GANGAL[1], Y. HUANG[1], W. PURVINE[1], X. WANG[1], M. HOOK[1], Y. HUANG[2], J. WANG[1,2];

Abstract: Opioids such as morphine and fentanyl induce addiction presumably by activating mu-opioid receptors (MORs) in the midbrain and consequently increasing dopamine release in the striatum. The striatum also contains high levels of MORs in spiny projection neurons (SPNs) within the patch compartments. These MOR-positive (MOR+) SPNs project to the internal globus pallidus (GPi) and the substantia nigra pars reticulata (SNr), giving rise to the direct pathway (dSPNs). However, whether chronic opioid exposure alters the activity of MOR+ dSPNs and their outputs remains unclear. Here, we show that MOR activation acutely suppressed inhibitory postsynaptic currents (IPSCs) from dSPNs to habenula-projecting GPi (GPh) neurons through a presynaptic mechanism. Notably, repeated morphine injections potentiated this IPSC or IPSCs from MOR+ SPNs to the GPh. We also discovered that intravenous self-administration (IVSA) of fentanyl enhanced IPSCs from dSPNs to dopamine neurons in the substantia nigra pars compacta (SNc), suppressing dopaminergic activity. Together, these data suggest that chronic opioid use strengthes GABAergic projections from MOR+ dSPNs to both GPh neurons and SNc dopamine neurons, suppressing their activity; such suppression may contribute to the negative emotional states in opioid use disorder.

Title: Sex differences in the effect of chronic delivery of the buprenorphine analog BU08028 on heroin relapse and choice in a rat model of opioid maintenance

Authors: *L. ALTIDOR[1], A. E. TOWNSEND[2], I. FREDRIKSSON[1], A. SHEKARA[1], S. HUSBANDS[3], A. SULIMA[1], K. C. RICE[1], M. I. BANKS[2], Y. SHAHAM[1], J. M. BOSSERT[1]; [1]IRP/NIDA/NIH, Baltimore, MD; [2]Virginia Commonwealth Univ., Richmond, VA; [3]Univ. of Bath, Bath, United Kingdom

Abstract: Background: Maintenance treatment with opioid agonists (buprenorphine, methadone) decreases opioid use and relapse. We recently modeled maintenance treatment in rats and found that chronic delivery of buprenorphine or the mu opioid receptor (MOR) partial agonist TRV130 decreases relapse to oxycodone seeking and taking. Here, we tested the effect of the buprenorphine analog BU08028 on different heroin relapse-related measures and heroin vs. food choice. **Methods**: For relapse assessment, we trained male and female rats to self-administer heroin (6-h/d, 14-d) in context A and then implanted osmotic minipumps containing BU08028 (0, 0.03, or 0.1 mg/kg/d). We then tested the effect of chronic BU08028 delivery on (1) incubation of heroin seeking in a non-drug context B, (2) extinction responding reinforced by heroin-associated discrete cues in context B, (3) reinstatement of heroin seeking induced by reexposure to context A, and (4) reacquisition of heroin self-administration in context A. For choice assessment, we tested the effect of chronic BU08028 delivery on heroin vs. food choice. **Results:** Chronic BU08028 delivery decreased incubation of heroin seeking in both sexes and extinction responding in males only. Unexpectedly, BU08028 *increased* reacquisition of heroin self-administration selectively in females. Chronic BU08028 had minimal effects on context-induced reinstatement and heroin vs. food choice in both sexes. **Conclusions:** Chronic BU08028 delivery had both beneficial and detrimental sex-dependent effects on different triggers of heroin relapse and had minimal effects on heroin choice in both sexes. Results suggest that BU08028 will not be an effective opioid maintenance treatment in humans.

Abstract: Rats are widely used in animal addiction and pain models. To manipulate μ-opioid receptor-expressing neurons critical to opioid reward and anticonception, we developed a transgenic rat that expresses Cre recombinase under the μ-opioid receptor 1 (*Oprm1*) gene promoter.
We used CRISPR/Cas9 to place T2A self-cleaving peptide and iCre recombinase coding sequences before the termination codon of rat *Oprm1* gene. A long single-stranded DNA donor with short homology arms (98 and 101 nt) flanking the T2a-iCre sequence was synthesized. The donor was mixed with a high specificity sgRNA (5' ACTGCTCCATTGCCCTAACT 3' (PAM = GGG)) and enhanced specificity Cas9 protein prior to Sprague-Dawley (Crl:CD(SD)) rat zygote microinjection. Two founders carrying intact DNA donor in the desired location were identified by DNA sequencing. G0 founders transmitted the correct target T2A-iCre coding sequence to their offspring. For Cre-dependent recombination, we injected a Cre-dependent viral vector into different brain areas to express green fluorescent protein (GFP) in μ-opioid receptor-expressing neurons, identified by *Oprm1* mRNA expression. In initial behavioral characterization, we trained *Oprm1* rats and wild-type littermates to self-administer palatable food. We tested other rats for morphine-induced analgesia and morphine tolerance.
Founder Oprm1-iCre rats selectively expressed P2A-iCre DNA sequence before the stop codon Oprm1 gene. GFP expression was selective to Oprm1-expressing regions: layers 5-6 of mPFC and striatal patches. Dual FISH co-localization studies of iCRE and Oprm1 transcripts in several regions showed that the transgene was exclusively expressed in Oprm1-expressing cells. Food self-administration, morphine-induced analgesia, and morphine tolerance were similar in the transgenic rats and their wild-type littermates.
Oprm1-iCre rats showed selective Cre recombination in brain regions critical to opioid self-administration and relapse. Insertion of Cre under the *Oprm1* gene promoter did not alter palatable food self-administration, morphine-induced analgesia, or morphine tolerance. We introduce a transgenic rat that can be used to gain new insight on the role of μ-opioid receptors-expressing neurons in opioid reward, analgesia, and other behaviors.

Title: Role of ventral subiculum neuronal ensembles in incubation of oxycodone craving after electric barrier-induced voluntary abstinence

Authors: *I. FREDRIKSSON[1], A. BATISTA[1], A. SHEKARA[1], S. V. APPLEBEY[1], A. MINIER-TORIBIO[1], L. ALTIDOR[1], C. CIFANI[2], B. T. HOPE[1], J. M. BOSSERT[1], Y. SHAHAM[1];
[1]NIH, NIDA, IRP, Baltimore, MD; [2]Univ. of Camerino, Sch. of Pharm., Camerino, Italy

Abstract: Background: We recently developed a rat model of incubation of oxycodone craving after voluntary suppression of drug self-administration by adverse consequences of drug seeking. Here, we studied the role of ventral subiculum (vSub) neuronal ensembles in this incubation, using the activity marker Fos, muscimol-baclofen (GABAergic agonists) inactivation, and Daun02 chemogenetic inactivation. **Methods:** We trained Sprague-Dawley or *Fos-lacZ* transgenic male and female rats to self-administer oxycodone (0.1 mg/kg/infusion, 6-h/d) for 14 days. The rats were then exposed for 14 days to an electric barrier of increasing intensity (0.1 to 0.4 mA) near the drug-paired lever that caused voluntary abstinence or were exposed to 14 days of forced abstinence. We tested Sprague-Dawley rats for relapse to oxycodone seeking without shock and drug on abstinence day 15 and extracted their brains for Fos-immunohistochemistry, or tested them after vSub vehicle or muscimol-baclofen injections on abstinence days 1 and 15. We performed Daun02 inactivation of relapse-activated vSub Fos neurons in Fos-lacZ transgenic rats on abstinence day 15 and then tested them for relapse on abstinence day 18. **Results:** Relapse after electric barrier-induced abstinence increased Fos expression in vSub. Muscimol-baclofen inactivation or Daun02 selective inactivation of vSub Fos-expressing neuronal ensembles decreased “incubated” oxycodone seeking after voluntary abstinence. Muscimol-baclofen vSub inactivation had no effect on non-incubated opioid seeking on abstinence day 1 or incubation after forced abstinence. **Conclusions:** Results demonstrate a selective role of vSub neuronal ensembles in incubation of opioid craving after cessation of drug self-administration by adverse consequences of drug seeking.

Title: Choice between social interaction and remifentanil in rats

Authors: *J. J. CHOW[1], J. M. CHABOT[1], M. VENNIRO[2], Y. SHAHAM[1];
[1]IRP/NIDA/NIH, Baltimore, MD; [2]Univ. of Maryland, Baltimore, MD

Abstract: Background: Clinical and preclinical studies have demonstrated that the availability of non-drug rewards can decrease choice for opioids. In humans, non-drug alternatives are primarily social in nature. Addressing this preclinical-clinical gap, we developed a rat model of operant social self-administration and choice between social interaction and drugs. Here we examined how access duration to social interaction and remifentanil dose affects choice. **Methods:** We trained rats (n=16; 8 females) to lever-press for social interaction and tested different durations of access (3.75s to 240s). We then assessed if these different durations influenced the rewarding aspect of social interaction, using progressive ratio and choice procedures. Next, we trained another cohort of rats (n=16; 7 females) to lever-press for 15s social interaction. Following IV-catheterization, we trained the rats to self-administer 10 µg/kg/infusion remifentanil. We trained the rats on a controlled reinforcer frequency choice procedure and conducted discrete-trials probe-tests, comparing choice between 15s of social interaction and remifentanil (0, 1.0, and 10 µg/kg/infusion). **Results:** We observed a decrease in social rewards earned as access duration increased. However, progressive ratio and choice measures revealed that rats were not sensitive to access duration. Rats trained for social interaction and remifentanil choice demonstrated preference for remifentanil at 10 µg/kg/infusion, indifference at 1.0 µg/kg/infusion, and preference for social interaction at 0 µg/kg/infusion. **Conclusions:** Rats' insensitivity to access duration allows the use of shorter durations of social interaction, optimal for time-sensitive in vivo recording measures. Choice between remifentanil and social interaction was dose-dependent, proving useful for the development of our choice model and investigation into neurobiological mechanisms of preference for social interaction vs. opioid drugs.

Title: Role of piriform cortex afferent projections in relapse to fentanyl seeking after food choice-induced voluntary abstinence

Authors: *D. J. REINER[1], S. M. CLAYPOOL[1], S. BEHDIN[1], J. ORIHUEL[1], Y. SHAHAM[2]; [1]IRP-NIDA, NIH, Baltimore, MD; [2]IRP/NIDA/NIH, Baltimore, MD

Abstract: Background: We previously showed a role of piriform cortex (Pir) in relapse to fentanyl seeking after food choice-induced voluntary abstinence, a procedure that mimics abstinence due to availability of alternative non-drug rewards. Here, we used retrograde tracing to determine projection-specific activation of Pir afferent projections during fentanyl relapse by using Fos plus the retrograde tracer cholera toxin B (injected into Pir). **Methods:** We trained male and female rats to self-administer palatable food pellets for 6 days (6-h/day) and fentanyl (2.5 microgram/kg/infusion, i.v.) for 12 days (6-h/day). We assessed relapse to fentanyl seeking after 14 voluntary abstinence days, achieved through a discrete choice procedure between fentanyl and palatable food (20 trials/day). **Results:** Relapse to fentanyl seeking was associated with increased Fos expression in neurons in anterior insular (AI) and prelimbic (PL) cortex that project to Pir but not Pir-projecting cortical neurons in adjacent areas or Pir-projecting thalamic neurons. Preliminary anterograde tracing in AI or PL confirmed these AI-to-Pir and PL-to-Pir projections. **Conclusions:** Results demonstrate a correlational role of AI-to-Pir and PL-to-Pir projections in relapse to fentanyl seeking after food choice-induced abstinence. In future experiments, we will determine the causal role of these projections in relapse to fentanyl seeking after food choice-induced abstinence.

Title: Lack of effect of different pain-related manipulations on opioid self-administration, reinstatement of opioid seeking, and opioid choice in rats

Authors: *S. CLAYPOOL[1], E. TOWNSEND[2], J. ORIHUEL[1], S. V. APPLEBEY[1], M. BANKS[2], Y. SHAHAM[1], S. NEGUS[2], D. J. REINER[1];
[1]Natl. Inst. on Drug Abuse, Baltimore, MD; [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: Rationale and Objective: Pain-related factors increase risk for opioid addiction, and pain may function as a negative reinforcer to increase opioid taking and seeking. However, experimental pain-related manipulations generally do not increase opioid self-administration in rodents. This discrepancy may reflect insufficient learning of pain-relief contingencies or confounding effects of pain-related behavioral impairments. Here we determined if pairing noxious stimuli with opioid self-administration would promote pain-related reinstatement of opioid seeking or increase opioid choice over food.
Methods: In Experiment 1, rats self-administered fentanyl in the presence or absence of repeated intraplantar capsaicin injections in distinct contexts to model context-specific exposure to cutaneous nociception. After capsaicin-free extinction in both contexts, we tested if capsaicin would reinstate fentanyl seeking. In Experiment 2, rats self-administered heroin after intraperitoneal (i.p.) lactic acid injections to model acute visceral inflammatory pain. After lactic acid-free extinction, we tested if lactic acid would reinstate heroin seeking. In Experiment 3, we tested if repeated i.p. lactic acid or intraplantar Complete Freund's Adjuvant (CFA; to model sustained inflammatory pain) would increase fentanyl choice over food.
Results: In Experiments 1-2, neither capsaicin nor lactic acid reinstated opioid seeking after extinction, and lactic acid did not increase heroin-induced reinstatement. In Experiment 3, lactic acid and CFA decreased reinforcement rate without affecting fentanyl choice.
Conclusions: Results extend the range of conditions across which pain-related manipulations fail to increase opioid seeking in rats and suggest that enhanced opioid-addiction risk in humans with chronic pain involves factors other than enhanced opioid reinforcement and relapse.

Title: Circuit-level mechanism for adjustments of learning to uncertainty in reward environment

Authors: *S. FARASHAHI[1], A. SOLTANI[2];
[1]Ctr. for Computat. Neurosci., Flatiron Inst., New York, NY; [2]Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Successful learning involves integration of reward outcomes over time. However, determining the time constant of this integration is non-trivial when reward is probabilistic and reward contingencies can unpredictably change over time, as in naturalistic settings. Fitting of choice behavior using reinforcement learning or more mechanistic models of synaptic plasticity suggests that the learning rates, which determine the time constant of reward integration, are adjusted according to uncertainty and volatility of the reward environment. However, it is currently unknown how such adjustments can be instantiated by circuit-level interactions.To answer this question, we constructed biologically-inspired recurrent networks of excitatory and inhibitory point neurons endowed with plausible reward-dependent Hebbian learning rules. We trained these recurrent neural networks (RNNs) to perform a probabilistic reversal learning (PRL) task with different reward probabilities (controlling uncertainty) and reversal length (controlling volatility or frequency of changes in reward contingencies).We found that the trained RNNs can robustly perform the PRL task by dynamically adjusting their learning according to uncertainty and volatility. Analyses of neural response and connectivity in RNNs revealed that adjustments of learning to uncertainty and volatility relied on distinct synaptic currents in the circuit. More specifically, the adjustment of learning rate to uncertainty was accompanied by modulations in the strength of synaptic currents from inhibitory to excitatory units. In contrast, the adjustment of learning rate to volatility was accompanied by modulations of synaptic currents between excitatory units. Analysis of lesioned neural networks confirmed the causal role of these currents in adjustments of the learning rate and were compatible with our correlation analysis. Together, our results provide a plausible circuit-level mechanism for adjustments of learning to different types of uncertainty, and moreover, provide testable predications about distinct roles of inhibitory and excitatory connections in adaptive behavior.

Title: History integration across diverse temporal horizons in retrosplenial cortex may give rise to hyperbolic-like behavior

Authors: *B. P. DANSKIN, Y. E. ZHANG, R. HATTORI, M. C. AOI, T. KOMIYAMA; Univ. of California San Diego, La Jolla, CA

Abstract: Animals integrate history information to guide future decisions, particularly in a dynamic environment. Reinforcement learning (RL) theory provides a model to estimate integrated action values for decision making. However, this estimation is insufficient to capture certain aspects of decision-making. Specifically, standard RL models (e.g. Rescorla-Wagner model) fail to capture heavy-tailed integration—the temporal decay of near and distant past experience at different rates—that is common feature of decision-making in dynamic environments. Here we explore an alternative model where decision is reached by multiple independent integrators that update their expected value across a spectrum of learning rates. We trained mice to perform a foraging task in which the reward probability changes dynamically and unpredictably. The mice integrate information about past choice and reward to estimate the difference in value of the two options to guide their decision. The pattern of history weighting by mice showed a heavy-tail that was better approximated by hyperbolic than exponential integration. To explore the neural basis of such behavioral integration, we analyzed neural population activity recorded from six cortical areas during this behavioral task. Individual history-encoding neurons integrate reward-choice history with a variety of temporal horizons, and the discounting patterns were closer to exponential than hyperbolic, in contrast to behavior. In the retrosplenial cortex (RSC), the distribution of time constants of history integration across neurons was particularly skewed to longer time constants compared to the other five areas. The summation of these diverse integration patterns across RSC neurons reproduced the hyperbolic-like behavioral integration in mice. Our results suggest that value maintained separately across neurons yields the heavy-tailed integration observed in the behavior, and identify RSC as a repository of this diverse temporal information.

Title: Resonance-based flexible selection of cognitive tasks and memory suppression in a hippocampus-prefrontal cortex network regulated by the nucleus reuniens

Authors: *R. F. O. PENA, H. G. ROTSTEIN;
NJIT, Newark, NJ

Abstract: Our ability to switch and perform an action in response to attended information is known as cognitive flexibility. The prefrontal cortex (PFC) is responsible for selecting and flexible routing oscillatory items from the hippocampus (HPC) to target areas. These may receive commands from PFC to suppress items in HPC. Recently, a PFC modeling study showed that multiple stored items could be selected by making use of firing rate resonance (f_r) and lateral inhibition (Sherfey et al., 2020). However, there is evidence that PFC and HPC transient coupling via oscillatory-synchrony is favored and switches due to the nucleus reuniens (Re). The mechanisms governing how these structures cooperatively operate are not well understood. We develop a PFC-HPC-Re model having principal cells (PCs) and interneurons (INs). For the PFC, two PC populations connected through a lateral IN population represent gates to downstream activity; For the HPC, local INs are connected preferentially to closer PCs which receive square-wave Poisson modulated spikes with different frequencies generating oscillatory activity; the Re provides excitatory input to both HPC and PFC with variable degree of excitation. This extends previous models by using (i) simpler neurons, facilitating the mechanistic understanding of the routing, (ii) a HPC network where memory is stored prior to PFC activation, and (iii) the effect of Re, which provides additional network flexibility. Gate PCs receiving an input frequency from HPC closer to f_r will fire more and engage with the IN population suppressing other PCs. Only firing rate resonance and inhibition suffice for this PFC effect as showed before. We show that the PFC chosen inputs (given its proximity with the gate's internal f_r,) can be switched by the Re activity, which alters the selected item periodicity. In addition, Re input into PFC can awaken an otherwise suppressed gate and engage with HPC reversing the direction flow. Thus Re provides a wider range of network flexibility influencing the cognitive selection and memory suppression. A reduced rate model reproduces the same pattern of choices and suppression when Re input is provided. Our results demonstrate the importance of Re in routing oscillatory-synchrony HPC-PFC in both directions confirming previous experimental observations. HPC local inhibition maintains many stored items in the same network agreeing with recent observations, which suggest that INs allow memory separation by their connectivity pattern. Re allows flexible

control of the HPC-PFC creating competition between PFC resonant networks in cognitive selection and HPC memory storage through activation of local inhibition.

Title: The geometry of neural representations can predict significant but unexpected behavioral differences in two monkeys

Authors: *V. FASCIANELLI[1,2], F. STEFANINI[1,2,3], S. TSUJIMOTO[4], A. GENOVESIO[5], S. FUSI[1,2,6,7];
[1]Ctr. for Theoretical Neuroscience, Columbia Univ., New York, NY, NY; [2]Mortimer B. Zuckerman Mind Brain Behavior Institute, Columbia Univ., New York, NY; [3]Currently at Facebook Reality Labs, Menlo Park, CA; [4]The Nielsen Co., Singapore, Malaysia; [5]Dept. of Physiol. and Pharmacology, Sapienza Univ., Rome, Italy; [6]Dept. of Neuroscience, Columbia Univ., New York, NY; [7]Kavli Inst. for Brain Sciences, Columbia Univ., New York, NY

Abstract: Our ability to perform cognitive tasks depends on the geometry of neural representations. High dimensional representations allow a downstream linear readout, like a neuron, to implement a large number of I/O functions. In contrast, low dimensional representations, which typically require a process of abstraction, allow for better generalization, but they restrict the I/O functions implementable by a linear readout. An interesting compromise is to dynamically adjust the geometry depending on task demands. Using analytical tools developed to study abstraction, we observed that the geometry of the neural representations can change rapidly during the trial and, importantly, it can explain different behaviors.
We studied the activity of dorsolateral prefrontal cortex in two monkeys performing a visually cued strategy task. Two visual stimuli of different shapes and colors cued the repetition of the previous response (stay strategy), whereas other two visual stimuli cued to shift to the alternative response (shift strategy). Most relevant task variables are decoded with high accuracy in both monkeys, including the visual cue and the strategy. However, only a few were in an abstract format. In particular, during the cue presentation, the first monkey represents the visual cue in an abstract format, while the second represents the strategy in an abstract format, as indicated by the Cross Condition Generalization Performance (the performance of a linear decoder able to generalize to task conditions not used for training). The first monkey shows a reaction time (RT) that depends on the cue's shape, regardless of the strategy. While the second, shows a RT depending on the strategy, regardless of the shape. To address this difference, we trained a

feedforward neural network per monkey to perform the task. The main difference in the two models is the presence of an autoencoder in the output layer forcing one network to reproduce the visual cue, and the other to reproduce the previous response. We succeeded in reproducing the neuronal representations of task variables along with different dynamics, mimicking the RTs of both monkeys.
Our analysis reveals interesting differences in neuronal representations in two monkeys performing the same task with high performance. This difference is mirrored by the different geometry of the neural representation of two task variables: the visual cue and strategy. Interestingly, the geometry can predict a difference in RT that we were not aware of, which we discovered by reanalyzing the details of monkeys' behavior. This relation between geometry and behavior is explained by a simple model.

Title: Effects of volatility on prefrontal neural dynamics and possible underlying neural mechanisms

Authors: *M. MORADI SPITMAAN[1], C. H. DONAHUE[3], D. LEE[4], A. SOLTANI[2]; [2]Psychological & Brain Sci., [1]Dartmouth Col., Hanover, NH; [3]Neurosci., The Gladstone Inst., San Francisco, CA; [4]Neurosci., Yale Sch. of Med., New Haven, CT

Abstract: Activity of cortical neurons exhibits multiple dynamics related to the integration of task-relevant signals such as choice and reward outcomes. In addition, the time constant of reward integration is correlated with the time constant of behavioral adjustments to reward, often measured by the learning rate in reinforcement learning (RL) models. Although there is growing behavioral evidence for adjustments of learning to volatility in the reward environment, it is currently unknown if different dynamics of neural response are modulated by volatility and if so, how such modulations are instantiated in the brain. To address these questions, we analyzed single-cell recordings in three cortical areas (dlPFC, OFC, and ACC) during a probabilistic reversal learning task involving reward probability and magnitude, and under two levels of volatility. Reward magnitudes on two alternative options were presented on each trial while

reward probabilities, which must be learned through reward feedback, remained unchanged or underwent reversals in the stable and volatile conditions, respectively. Moreover, we used two different learning models based on plastic and metaplastic synapses to study the encoding and decoding of reward information in an ensemble of estimators with different levels of plasticity. We found evidence for the effects of volatility on the integration of reward outcome (reward memory) and identity of the chosen stimulus (stimulus memory). Specifically, reward-memory timescales were larger in the volatile than the stable condition in both OFC and ACC. In contrast, stimulus-memory timescales were smaller in the stable condition but only for dlPFC neurons. Moreover, the variance of both reward- and stimulus-memory amplitudes were significantly larger in the volatile condition in all cortical areas. These suggest that volatility could expand the heterogeneity in the integration of task-relevant signals by modulating memory timescales and diversifying memory amplitudes to allow better estimation of task-relevant signals in volatile environments.We next used the two computational models to explain the link between such modulatory processes and the involvement of neurons in integrating reward information. We found that the metaplastic model showed higher performance in estimating reward probability by creating more heterogenous estimates across the ensemble. Together, our results suggest that metaplasticity can create a heterogeneous ensemble of reward estimators similar to a diverse ensemble of reward-integrating neurons, and this allows for better decoding of reward in volatile environments.

Title: Discovering flexible models of neural population dynamics underlying decision-making

Authors: *M. GENKIN[1], C. CHANDRASEKARAN[2], K. V. SHENOY[3], T. A. ENGEL[1]; [1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Psychological & Brain Sci, Anat. & Neurobiology, Ctr. for Systems Neuroscience, Biomed. Eng, Boston Univ., Boston, MA; [3]EE, BioE, Neurobiology, Wu Tsai Neurosci. Inst. & Bio-X, Stanford Univ. & Howard Hughes Med. Inst., Stanford, CA

Abstract: Behaviorally relevant signals are often represented in neural population dynamics, which evolve on a low-dimensional manifold embedded into a high-dimensional space of neural responses. Revealing population dynamics from spikes is challenging because the dynamics and embedding are nonlinear and obscured by diverse responses of individual neurons and spiking noise. For example, the decision-related activity of single neurons was hypothesized to arise from either gradual ramping or abrupt stepping dynamics on single trials, but selection between these alternatives is brittle due to the diversity of neural responses. Moreover, ramping and stepping are impoverished hypotheses for heterogeneous decision-related neural populations. We need frameworks that can flexibly identify neural population dynamics from data.
We developed a flexible framework for inferring neural population dynamics from spikes. In our framework, population dynamics are modeled by a latent nonlinear dynamical system defined by a potential function. The framework covers a continuous space of hypotheses represented by different potential shapes. The activity of individual neurons is related to the population dynamics through unique firing-rate functions, which account for the heterogeneity of neural responses. We incorporate the distribution of the population state at the trial start and boundary conditions modeling trial termination, such as commitment to a choice when reaching a decision boundary. The potential, firing-rate functions, and initial state distribution are continuous functions that are inferred from data using gradient-descent optimization.
On simulated neurons, our framework correctly recovered the ramping and stepping models, which correspond to linear and three-well potentials, respectively. We applied the framework to neural activity recorded from the macaque dorsal premotor cortex (PMd) during a decision-making task. The inferred potential revealed dynamics that evolve gradually towards the correct choice but have to overcome a potential barrier towards the incorrect choice. We obtained the same results by fitting multiple neurons simultaneously or each neuron separately, and the results were robust across neurons. Our results are consistent with the dynamics generated by attractor models of decision-making (e.g., Wang 2002) and differ from ramping and stepping hypotheses proposed previously. Our study demonstrates that a flexible approach can discover new hypotheses about decision-related population dynamics from spiking activity.

Abstract: Decisions often involved accumulating evidence over time, and this process has commonly been characterized using diffusion decision models (DDMs). In this class of models, subjects accumulate decision evidence up to a certain fixed bound, at which time they make a choice. We tested how DDMs are supported by neural data recorded in human subjects. We recorded cortical/subcortical neural signals in 8 humans engaged in decisions that required integration of individual quanta of evidence. The subjects communicated their choice using eye or hand movements. We recorded data in two versions of the task. In the fixed duration (FD) task, the time to make a choice was cued; in the reaction time (RT) task, subjects could indicate their choice at any time. We first inferred a decision variable (DV) for this task according to the Signal Detection Theory. The DV faithfully captured the subjects' choices and reaction times. We then identified the neural signals that encode the DV. In particular, we regressed signal features in specific frequency bands, using signals from all channels, on the DV. This provided us with the neural signal (NS) representing the diffusion process in this task. In line with the DDMs, the NS represented the accumulated evidence. The drift rate was proportional to the DV. As expected, this ramping activity was weak in the error trials. Single-trial analysis revealed that the ramps were real, not a consequence of averaging discrete jumps. Moreover, in accordance with the DDMs, the NS reached a fixed bound in the FD task. Intriguingly, the neural signal did not reach a fixed bound in the RT task. In this task, the NS remained strongly graded by the DV at the time of the subjects' choice (examples of this phenomenon are shown for two subjects in the figure). This prominent finding is in odds with the common formulations of the DDM and also in odds with the signals reported in monkey area LIP, which show a fixed bound in RT tasks. Our results suggest that classic formulations of the DDMs may need to be expanded to accommodate bounds of varying levels, flexible bounds, or revisit the concept of a bound entirely.

Title: Choice-selective sequences dominate in cortical relative to thalamic inputs to nucleus accumbens, providing a potential substrate for credit assignment.

Authors: *A. BAIDYA[1], N. F. PARKER[2], J. M. COX[3], M. S. GOLDMAN[1], I. B. WITTEN[4];
[1]Univ. of California Davis, Davis, CA; [2]The Rockefeller Univ., New York City, NY;

Abstract: A central question in reinforcement learning is how actions and outcomes separated in time become associated with each other. Multiple lines of evidence have implicated the nucleus accumbens, a part of the ventral striatum that receives cortical and thalamic inputs as well as dopaminergic signals associated with reward prediction errors, in learning action-outcome associations. Here we image the activity of cortical and thalamic neurons projecting directly to the nucleus accumbens during a two-armed bandit task in which an animal must determine the

lever corresponding to the higher probability of reward. Prelimbic cortical inputs preferentially encoded animals' recent actions (choices) on a given trial, whereas thalamic neurons preferentially encoded external cues (stimuli). The cortical input population exhibited choice-selective sequences of neural firing that bridged a delay period between action (choice) and outcome (reward). Through computational modeling, we demonstrate how such choice-selective sequences can create the precisely timed reward prediction error seen in dopamine neurons which, in turn, can support the neural implementation of reinforcement learning algorithms for associating actions and outcomes separated in time, both in a circuit model based on dopamine-dependent changes in synaptic plasticity and one based on dopamine-dependent changes in neural dynamics. By optogenetically manipulating both the cortical and thalamic input neurons we tested and confirmed core predictions of both the circuit models. Thus, by recording and manipulating glutamatergic inputs to the NAc and integrating these data with computational modeling, we provide specific proposals for how reinforcement learning could be implemented by neural circuitry and suggest a computational role for choice-selective sequences of neural activity.

Title: Neurocomputational markers of cue-specific exploration in alcohol use disorder

Authors: *E. M. CAMPBELL[1], G. SINGH[1], E. D. CLAUS[2], K. A. WITKIEWITZ[1], V. D. COSTA[3], J. HOGEVEEN[1], J. F. CAVANAGH[1];

Abstract: Humans often face the difficult decision between exploring novel options with uncertain outcomes, versus exploiting familiar options with a known reward value. Prior work has linked hypersensitivity to familiar rewards to alcohol use disorder (AUD), but the neural computations mediating the drive to explore novel alcohol cues in individuals with AUD remain unclear. We merged EEG and computational modelling of a probabilistic reinforcement learning task to assay the neurocomputational bases of novelty-driven exploration in AUD. Individuals with AUD (n = 28) and matched controls (n = 27) completed a three-armed bandit task with

images of alcoholic beverages and non-alcoholic beverages, which were periodically replaced by novel stimuli with unknown reward values. Behavior and computational modelling results converged to demonstrate heightened cue-specific exploration of alcohol stimuli in individuals with AUD. This finding was associated with aberrant P3a responses in AUD, which scaled with enhanced cue-specific exploratory behavior suggesting that changes in functional cortical dynamics characterize stimulus-dependent exploration in AUD.

Title: A neural representation of probabilistic belief in human posterior parietal cortex

Authors: *N. M. SINGLETARY[1], J. GOTTLIEB[1], G. HORGA[2];
[1]Mortimer B. Zuckerman Mind Brain Behavior Inst., [2]Psychiatry, Columbia Univ., New York, NY

Abstract: Bayesian theory states that optimal probabilistic beliefs require the integration of new evidence with prior beliefs in proportion to the reliability of each factor. However, human neuroimaging studies have incompletely dissociated neural responses to posterior probability, prior probability, and likelihood (the reliability of new information), making it difficult to elucidate the neural mechanisms by which humans update their beliefs. In addition, the studies have not controlled for expected value (EV), which is correlated with posterior probability when participants make instrumental decisions. To examine these questions, we developed a probabilistic inference task in which human participants (N = 23, 9 female, age: 19-64 years) estimated the posterior probability of being in one of two hidden states: a "portrait gallery" containing more pictures of faces than scenes or a "landscape gallery" containing more pictures of scenes than faces. We independently manipulated the prior probability of being in each type of gallery (7-93%), the type of new information (a face or landscape picture randomly drawn from the true gallery), and the diagnosticity of the information (an indicator of the likelihood) to identify the neural correlates of each factor. Moreover, we used an incentive-compatible procedure to elicit posterior estimates and varied the penalty for an incorrect estimate ($10 or $20 subtracted from a $30 endowment) to control for EV. Analysis of behavior showed that

participants incorporated prior probability and likelihood into their posterior probability estimates but were not influenced by the size of the penalty. Analysis of fMRI blood oxygen level-dependent (BOLD) activation identified two regions of the left superior parietal lobule (SPL) and intraparietal sulcus (IPS) that showed significant correlation with posterior probability estimates and were also positively correlated with both prior probability and likelihood. Activation in these regions could not be explained by eye or hand movements or, crucially, by EV. Thus, we propose that human SPL and IPS represent probabilistic posterior beliefs and may be neural substrates for approximating Bayesian inference.

Title: Hippocampal sharp-wave ripples and cortico-hippocampal interactions during goal-directed navigation

Authors: *K. KIM[1], C. RANGANATH, Ph.D.[1], J. A. OVERTON[1], R. S. DHANAK[1], F. GIRGIS[2], K. SHAHLAIE[1], J. LIN[3], R. C. O'REILLY[1], I. SAEZ[1];
[1]UC Davis, Davis, CA; [2]Univ. of Calgary, Calgary, AB, Canada; [3]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA

Abstract: Hippocampal sharp-wave ripples (SWRs) reflect synchronized bouts of neuronal firing. Research in rodents suggests that SWRs are associated with rapid memory replays (Jadhav et al., 2012; Roumis & Frank, 2015; Roux et al., 2017) and interactions with the prefrontal cortex (Tang & Jadhav, 2019) during memory-guided decision making and spatial learning. Much less is understood about SWRs in humans, but recent work suggests that awake hippocampal SWRs in the human brain may also play an essential role in online cognitive behaviors such as memory retrieval (Norman et al., 2019). In the present study, we investigated the role of the awake hippocampal SWRs during goal-directed spatial navigation and learning, as well as cortico-hippocampal interactions during SWR events. Specifically, we hypothesized that hippocampal SWRs would increase as a function of learning, especially prior to events that involve rapid retrieval and evaluation of prior experiences - such as decision responses and goal expectations. To test this, we recorded intracranial electroencephalography (iEEG) from human patients (N = 6) while they were engaged in a navigation task that has a learning component.

Patients controlled an agent to navigate through 2D mazes and reach a hidden goal (i.e., exit) position as efficiently - with fewest number of moves - as possible. Importantly, paths in the mazes were only partially visible and were revealed along the routes the agent took, and thereby the goal location was not visible until the agent reached a near-goal location. The task included 30 unique mazes, which were repeated across 2 blocks. We analyzed iEEG data from hippocampal and orbitofrontal cortex (OFC) electrodes. We found that SWR rates were greater in the second block compared to the first block at the critical events of interest: prior to decision responses and prior to goal revelation. Strong broad-band oscillatory activity emerged in the OFC during hippocampal SWRs. The present results suggest that hippocampal SWRs may drive memory replay during memory-guided, goal-directed behaviors in the human brain.

Title: A neurobiological model of entorhinal cortex and hippocampus to explain forgetting and spacing effects

Authors: *J. ANTONY[1], X. LIU[2], C. RANGANATH, Ph.D.[3], R. O'REILLY[1];
[1]Univ. of California, Davis, Davis, CA; [2]Ctr. for Neurosci., [3]UC Davis, Davis, CA

Abstract: Episodic memory involves binding various pieces of information to a particular context and relies on the hippocampus (HC). Recent work suggests that the entorhinal cortex (EC), one major input to the HC, may play a crucial role in representing information about temporal context. Specifically, EC neurons “drift”, or change slowly across a spectrum of time scales, from seconds to hours. Intriguingly, this drifting temporal representation may constitute an episodic memory cue itself, becoming weaker over time and explaining phenomena such as forgetting curves. It could also help explain the robust, time-varying phenomenon known as the spacing effect, i.e. how re-learning after longer (versus shorter) delays improves long-term memory. Here, we advanced a neurobiologically realistic model of the EC and HC with time-drifting properties that accounts for forgetting and the spacing effect. Learning in our model is driven by error, or differences between stored and current patterns, which also drives learning in the brain (O’Reilly et al., 2021). We predicted that spacing effects arise because longer delays produce larger differences between the stored and current temporal contexts in EC, which results

in greater error and stronger HC learning. We tested memory performance in the model on a paired associate task, whereby the model learned to relate two random input vectors along with the concurrent temporal context. We simulated temporal drift as input vectors into EC that gradually changed across a spectrum of timescales. We then tested the ability of the model to reproduce the target associate while varying temporal delays (drift) between successive learning episodes and/or for the final test. First, we found that greater delays after learning in the model reproduced forgetting curves. Next, we tested model performance after different delays between learning episodes. We found that increasing delays produced both greater error in HC area CA3 and better subsequent long-term memory performance. We also tested learning across logarithmically expanding intervals - a commonly studied learning technique - against contracting intervals. In accord with prior behavioral work, expanding drift helped memory after long delays while contracting drift helped after short delays. Additionally, representational activation patterns in CA3 across rounds of learning showed that, with greater drift, the model learned by reducing its reliance on short time scale patterns, effectively generalizing over time. Altogether, these results could provide a mechanistic formalization for established learning concepts such the importance of varying contexts and errors during learning.

Title: Representations of predictive relations in entorhinal cortex and middle temporal gyrus as a function of exposure and time

Authors: *A. LESHINSKAYA, M. A. NGUYEN, C. RANGANATH, Ph.D.;
Univ. of California, Davis, Davis, CA

Abstract: The ability to learn predictive relations among events (such as thunder preceding rain) is an essential aspect of adaptive behavior. Anterior-lateral entorhinal cortex (alERC) is critical for the acquisition and initial recall of predictive relations from experience, but there is reason to believe that neural representations of such relations might change or become reorganized over time. To investigate such changes, we used fMRI to measure neural representations of predictive relations between events both immediately after learning (Session 1) and after a one week delay

and additional exposure (Session 2). Twenty-four human participants were scanned as they watched 6 movies, each depicting a distinct object embedded in a sequence of animated visual events. In each sequence, one event A strongly predicted another event B, while events C - F were unpredictable. Among Consistent sequences, the same event served as predictable event B, whereas among Inconsistent sequences, the predictable event B was swapped with an event that was unpredictable in the other sequences. After each movie, participants saw a Probe phase, in which they saw the same events in discontinuous, randomized order. To identify neural representations of predictive relations, we subtracted voxel pattern similarity between predictive events pairs A & B vs that between unpredictive event pairs such as A & C ("Associative Coding"). The same protocol was repeated a week later. We used pre-registered regions of interest in alERC and right middle temporal gyrus (rMTG), a candidate area for long term semantic memory. We hypothesized that Associative Coding would be stronger in Consistent than Inconsistent sequences and would shift from alERC to rMTG with time. We found that in Session 1, alERC showed Associative Coding in Consistent sequences, more so than Inconsistent ones, whereas rMTG showed no effects. In Session 2, this pattern flipped, and rMTG showed Associative coding in Consistent objects, more so than Inconsistent ones; alERC showed no effects. These findings demonstrate that both alERC and rMTG represent predictive relations and integrate information across learning experiences, but do so at different times, and suggest one way in which semantic memory sites may update with experience.

Title: Integrating region- and network-level contributions to episodic memory with multilevel structural equation modeling

Authors: *K. KURKELA, R. COOPER, E. RYU, M. RITCHEY;
Dept. of Psychology and Neurosci., Boston Col., Chestnut Hill, MA

Abstract: An important challenge for cognitive neuroscience is understanding how individual brain regions function within the context of larger networks. In the context of episodic memory, activation in a posterior medial (PM) network has been consistently associated with successful recollection. Existing approaches have either considered how the network as a whole supports recollection or how the individual regions support recollection, but less is known about how

individual regions contribute to the network effect on memory. The goal of the present report was to bridge region- and network- focused approaches by using multilevel structural equation modeling (SEM) to simultaneously model the contributions of individual regions and the combined network to episodic remembering. Using data from a previously published fMRI study of 28 healthy young adults (Cooper & Ritchey, 2019), we first mapped trial-specific measures of regional activation onto a single latent variable representing network wide coactivation. We then mapped trial specific measures of memory for three distinct episodic features onto another latent variable, representing overall memory for each episode. Using these latent variables, we then simultaneously modeled the statistical dependency between each region and the overall memory latent variable, as well as the network latent variable and the overall memory latent variable. This approach allowed us to estimate a unique effect for each region in the network while also accounting for its membership within the larger network (Bolt et al. 2018). The results showed that the contributions of the PM network regions to memory were largely explained by the joint engagement of the network. However, two regions displayed extra-network contributions to memory, with the PHC positively predicting and the MPFC negatively predicting memory when controlling for their membership within the PM network. In a separate analysis, we additionally addressed whether the PM network may be composed of two related subnetworks, as has been recently suggested in the literature (Cooper et al., 2021; Barnett et al., 2021; Buckner & DiNicola, 2019). A bifactor model of PM subnetworks revealed that both the ventral and dorsal subnetworks supported high quality remembering, and the ventral did so uniquely when controlling for the contributions of the dorsal subnetwork, but not vice versa. Moreover, the bifactor model appeared to fit our data better than a single factor model. Overall, our approach provides for a more integrated understanding of the PM network, combining regional and network levels of analysis.

Title: Parallel memory systems for efficient recognition

Authors: *A. JAFARPOUR[1], J. LIN[3], R. T. KNIGHT[4], E. A. BUFFALO[2];
[1]Univ. of Washington, White/Caucasian, WA; [2]Physiol. and Biophysics, Univ. of Washington,

Abstract: Remembering the order of event occurrence is fundamental to episodic memory. Converging evidence suggests that at least two copies of events are encoded in parallel in distinct brain regions during memory formation. One system retains events with high fidelity and is hippocampal-dependent. The other system encodes the gist of events and has schematic information, monitored by the prefrontal cortex. How the two copies of memories are employed at recall is currently unknown. In this study, we investigated the neural dynamics within the hippocampus and the prefrontal cortex that support recognition of the temporal order of events from long-term memory. Epilepsy patients undergoing seizure monitoring with stereoencephalographic electrodes (sEEG; n=8) watched a movie and, after a 3-5 minutes delay, determined the order of movie frames that were presented in pairs. In half of the trials, the movie frames were from visually distinct scenes that occurred less than 11 seconds apart in the movie (i.e., close events); the remaining probes pairs occurred at longer intervals in the movie (i.e., far events). The far events were more likely to have distinct contexts, unlike the close events that shared a context, according to the annotation of event boundaries of the movie by an independent group of participants (n = 80). Recalling the order of close events had a longer response time (2 sec, SD = 0.79) than recalling far events (1.7 sec, SD = 0.73; paired-wise comparison $t(7) = 2.6$, $p = 0.03$). Using sEEG, we observed that theta power in the left anterior hippocampus was higher for correct recognition of the order of close events than for far events (peak at 6.5 Hz, FDR corrected $p<0.001$). In contrast, the beta power in the left medial orbitofrontal cortex (OFC) was higher for far compared to close events (peak at 22 Hz, FDR corrected $p = 0.019$). Previous studies have demonstrated impaired temporal order recognition in patients with damage to either the hippocampus or the OFC. The data presented here demonstrating the dynamics of the hippocampus and OFC activity at recognition support distinct contributions of these two regions at retrieval. Recalling memories with high temporal precision requires the hippocampus and longer intervals between events rely on the OFC and the overall movie schema to enhance recall. The benefits of multiple memory traces have been shown to contribute to long-term consolidation. We suggest that in the short-term multiple memory traces enhance the recognition of the order of events.

Title: Hippocampal and entorhinal contributions to naturalistic event context reinstatement

Authors: *A. I. DELARAZAN[1], A. B. KARAGOZ[1], M. E. MONTCHAL[2], M. A. YASSA[2], C. RANGANATH[3], Z. M. REAGH[1];

Abstract: Remembering the temporal context of a past event is a defining feature of episodic memory. Medial temporal lobe (MTL) structures such the dentate gyrus and CA3 (DG/CA3) hippocampal subfield and the anterolateral entorhinal cortex (alERC) have previously been linked temporal memory precision. Hippocampal activity has furthermore been implicated in segmenting and representing naturalistic experiences as events. However, little is known about the way retrieved representations are shaped by the narrative structure of encoded events. In this study, participants viewed a 28-minute television episode and were later tasked with identifying, on a continuous timeline, when events occurred during high-resolution fMRI scanning. In line with prior results, we found increased activity in the hippocampus at transitions between events (event boundaries). Interestingly, this activation was significant at corrected thresholds only in the DG/CA3 hippocampal subfield. We next conducted representational similarity analyses to investigate whether activity patterns at retrieval were more similar for trials with images from the same encoding events versus different encoding events. Surprisingly, trials with images from the same encoding events were not more similar than the average inter-trial comparison. In contrast, pattern similarity throughout the MTL was greater for trials where temporal judgments subjectively grouped them into the same encoding event, regardless of the objective structure of the episode, suggesting construction of a subjective event context. We next examined encoding-retrieval similarity as a function of encoding event. Given that the precision of participants' temporal judgements determined event pattern reinstatement at retrieval, we incorporated a contrast of behavioral sensitivity into these analyses via a median split on test trials, resulting in retrieval patterns corresponding to precise and imprecise timeline judgments. DG/CA3 showed increased pattern similarity between encoding and retrieval for objective (but not subjective) event information for precise compared to imprecise trials. Conversely, alERC showed increased pattern similarity for subjective (but not objective) event context information for precise compared to imprecise trials. Finally, posteromedial entorhinal cortex (pmERC) showed a precise versus imprecise difference for both objective and subjective event contexts. These results provide evidence for representations of both objective and subjective event contexts in the MTL. Ongoing analyses investigate data-driven measures of event structure among different regions of interest.

Title: Correcting the hebbian mistake: toward a fully error-driven hippocampus

Authors: *Y. ZHENG, X. L. LIU, S. NISHIYAM, C. RANGANATH, R. C. O'REILLY; Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: The hippocampus plays a critical role in the rapid learning of new episodic memories. Many computational models propose that the hippocampus is an autoassociator that relies on Hebbian learning (i.e., “cells that fire together, wire together”). However, Hebbian learning is computationally suboptimal as it modifies weights unnecessarily beyond what is actually needed to achieve effective retrieval (“pattern completion”), causing more interference and resulting in a lower learning capacity. Our previous computational models have utilized a powerful, biologically plausible form of error-driven learning by contrasting local activity states at different points in time to create error signals in hippocampal CA1 (Ketz et al., 2013). New evidence regarding neurophysiological properties of the hippocampal subfield CA3 suggests that the hippocampus might be even more reliant on error-driven learning. Based on these findings, we propose a new model called Theremin (Total Hippocampal ERror MINimization) that incorporates biologically-based principles of error-driven learning in CA3 as well as CA1. In the model, CA3 pyramidal cells respond to the entorhinal cortex (EC) monosynaptic input (EC-CA3) prior to the EC disynaptic input through dentate gyrus (DG) (EC-DG-CA3). This signal delay gives rise to the temporal difference between the earlier EC-driven CA3 patterns and the later ones when DG inputs start to dominate, creating error signals to train the EC-CA3 connection and CA3-CA3 recurrent connection. In other words, DG serves as a teacher to CA3, correcting its patterns into more pattern-separated ones, thereby reducing interference. Results showed that Theremin, compared with our original model, has increasing model capacity and learning speed. Besides, we showed actication dynamics in hippocampal subregions over the course of a learning trial, and over multiple interations of learning. We will also present novel predictions from the model that can be tested in future studies.

Title: C57 and CD-1 mice strains differ in behavioral and pharmacological responses after maternal immune activation as a preclinical model of schizophrenia/autism

Authors: *D. A. GONZÁLEZ-FRANCO[1], P. C. BELLO-MEDINA[2], M. PÉREZ-MORALES[1], J. GARCÍA-MENA[3], S. DIAZ-CINTRA[2], G. PACHECO-LÓPEZ[1];

Abstract: Autism spectrum disorder and schizophrenia (ASD/SCZ) are neuropsychiatric diseases closely related to neurodevelopmental alterations. It has been shown that maternal immune activation (MIA) during gestation primes the central nervous system development inducing cognitive-emotional impairments in the offspring. One of the most popular and widely used approaches to study the effects on MIA is the maternal administration of the RNA viral mimic poly-inosinic/cytidylic acid [Poly(I:C)], which triggers the production and release of pro-inflammatory cytokines; IL-1β, IL-6, and TNF-α. Poly(I:C) treatment in MIA models results in numerous neurochemical and brain morphological abnormalities in the adult offspring. To date, most published preclinical research has been carried out in the mouse C57 inbred strain, therefore very little is known about the behavioral characteristics in other mice strains or outbreed mice models. In the present study, we administered poly(I:C) at gestational day 12 to induce MIA in pregnant C57 (inbred) and CD-1 (outbred) mice strains, followed by behavioral phenotyping as well as neuropharmacological sensitivity test of male and female offspring from both strains. Our results show an increase in the marble burying test in C57 males (repetitive and persevering behavior related to obsessive compulsive disorder), but unexpectedly, a decrease

was observed in CD-1 males in the same test. Data analyses also show decreased social interaction test, anhedonia, and sensitivity to the psychotomimetic drug amphetamine in males of both strains. Remarkably, MIA treatment did not induce any observable effect in the female offspring of both strains. Our results suggest that mouse strain and sex must be considered to analyze the effects of MIA in preclinical models of ASD/SCZ. However, despite the differences observed between the strains, it is possible to find consistent and robust effects of MIA treatment that allow identifying the symptoms of these disorders in the outbred strain for preclinical models. Our data also show that males of both C57 and CD1 strains are particularly more susceptible than females to display symptoms of these disorders after MIA, which agrees with epidemiological human evidence. Additional neurophysiological and neuromorphological studies are necessary for a better interpretation of the between-strains differences observed in this study.

Title: Developmental Pyrethroid Exposure and Autism-related Behaviors in Prairie Voles

Authors: K. K. ZADE[1], J. A. CARLSON[1], B. P. KISTLER[2], C. NAWOR[2], M. A. CURTIS[1], F. NAGHAVI[1], K. L. NEIFER[1], *J. P. BURKETT[1];

Abstract: Autism Spectrum Disorder is a cluster of incurable neurodevelopmental disorders with a prevalence of 1 in 54 people. Although autism is commonly thought of as a genetic disorder, up to 50% of autism risk derives from environmental sources. Exposure to pyrethroid pesticides during pregnancy has recently been linked to autism risk by epidemiology studies. Our previous experiments in mouse suggest that developmental exposure to pyrethroid pesticides causes an autism-related phenotype, including decreased vocalizations, repetitive behaviors, learning deficits, and hyperactivity. In this study, we exposed female prairie voles to the EPA reference pyrethroid, deltamethrin, throughout pregnancy and lactation, and tested the resulting

offspring for autism-related phenotype. Route of administration mimicked human exposure by being consumed in food at a concentration below the EPA benchmark dose (3 mg/kg every 3 days in peanut butter). One pup per litter was used for each test in a behavioral battery that included ultrasonic vocalizations, marble burying, repetitive behaviors, 24-hour mobility, operant conditioning, partner preference, consoling behavior, and fear conditioning. Biological samples were collected for FOS immunochemistry and omics applications. Results will be discussed in the context of relevance to autism and other developmental disorders.

Title: An in vitro model to study the association of genetic diversity and neurological conditions reveals novel genes in Dyrk1a-related disorders and axonal injury linked to susceptibility and resilience

Authors: *D. CORTES[1], M. PERA[2];
[2]Res., [1]The Jackson Lab., Bar Harbor, ME

Abstract: Genetic differences play an important role in how individuals cope with the environment, making some individuals more resilient and others more susceptible to insults. Here we developed a model to study in a rapid and reliable fashion how genetic differences modify the outcome of neurological conditions. As a proof of concept for our model, we decided to study axonal injury/recovery and inhibition of Dyrk1a which is associated with autism, microcephaly, and mental disabilities. Our approach was to use the eight CC founder mouse-derived embryonic stem cells (mESCs) and differentiate them into neurons. Current protocols can only differentiate mESCs from the 129 strain or substrains but not others. For that reason, we developed a novel protocol to differentiate diverse strains with high efficiency and that works in humans stem cells as well. Minor modifications of the protocol create cerebral organoids or generate different neuronal subtypes. Upon neural differentiation, we found that DYRK1a inhibition differentially affects the eight CC founder mESC-derived neurons due to their genetic diversity. B6 strain lies on the susceptible end of the spectrum whereas WSB strain lies on the resilient end. Bulk RNA-seq analysis showed only 13 genes affected by the inhibition of Dyrk1a during neural precursor differentiation on WSB whereas more than 700 were affected on B6. A group of genes that has been independently associated with microcephaly, mental retardation, and Down syndrome was affected when Dyrk1a was inhibited. We also found that neurogenesis

and axonal growth differentially affected both strains. Regulatory network analysis showed Foxb1, Hoxa4, and Hoxd3 to be part of the transcriptional factors found in response to Dyrk1a inhibition and a possible cause for microcephaly. During maturation, cerebral organoids showed that DYRK1a inhibition affected gliogenesis in most strains and gene sets associated with the deposition of extracellular matrix. Electrical activity was more impaired on B6 compared to WSB which correlated with a downregulation of Scn5a on B6 compared to WSB. We conducted an in vitro axotomy model which showed that B6 could not grow axons back whereas WSB did. CCN family and hypoxia response genes were differentially expressed, and Ascl1, Olig2, and Creb5 were found to regulate the differential response. Overall, our model proved to be a reliable tool that confirmed previous results in other animal models and humans and discovered novel mechanisms and genes associated with Dyrk1a inhibition and axonal regeneration. This model can be used or adapted to other neurodevelopmental or neuronal disease-related questions.

Title: Elucidating the effects of developmental pyrethroid pesticide exposure in mouse brain using a multiomics approach

Authors: *M. CURTIS, K. ALGANEM, A. IMAMI, K. L. NEIFER, R. SHUKLA, R. E. MCCULLUMSMITH, J. P. BURKETT;
Neurosciences, Univ. of Toledo Col. of Med. and Life Sci., Toledo, OH

Abstract: Autism Spectrum Disorder (ASD) is a cluster of incurable neurodevelopmental disorders with a prevalence of 1 in 54 people. Despite its high incidence and a rise in prevalence each year, less than 10% of autism cases have an identifiable cause. The recent CHARGE study has suggested that developmental exposure to pyrethroids, a common pesticide widely used due to its supposed safety, may increase autism risk. To evaluate the effects of developmental pyrethroid exposure, mouse dams were administered deltamethrin (or vehicle) during pregnancy and lactation. The offspring were raised to adulthood and euthanized for tissue collection. Split-sample transcriptomic, kinomic, and metabolomic analyses were performed on whole brain tissue, to provide a comprehensive understanding of the multi-modal biophenotype induced by

pyrethroid exposure. Results from the transcriptomics analysis revealed decreased expression of two genes, *per2* and *ciart*, which function to regulate circadian rhythm. Other transcriptional pathways were also significantly impacted by developmental exposure, including signal transduction pathways, interferon associated pathways, apoptosis, and cell cycle regulation. Results from kinomics analysis showed overactivity of casein kinase 1 (CK1), which plays a key role in circadian clock control by phosphorylating *per2*. Other kinases involved in neuronal development, axon specification, and neurotransmitter release were differentially active between the groups. The metabolomics results predicted a set of metabolites that were significantly different between the groups. Pathway analysis using these metabolites resulted in significantly enriched pathways for folate biosynthesis, tryptophan metabolism, xenobiotic metabolism by cytochrome P450s, and steroid hormone biosynthesis. The impacted pathways observed in our metabolomics results also significantly overlap with the metabolome signature of autism from human prefrontal cortex. Using a multiomics approach, we have elucidated and identified biological entities and pathways in the brain which are dysregulated by developmental pyrethroid exposure in the mouse. These findings have important implications for the ongoing widespread use of this pesticide in the human environment.

Title: Ghrelin Mitigates Acetaminophen (APAP)-Induced Developmental Abnormalities in Rats.

Authors: *J. GUSS DARWICH[1], J. A. HERRINGTON[1,2], *C. HARSHAW[3], A. M. BRIGANDE[1], E. B. LEIF[1], P. J. CURRIE[1];
[1]Psychology, Reed Col., Portland, OR; [2]Mt. Hood Community Col., Gresham, OR; [3]Univ. of New Orleans, New Orleans, LA

Abstract: Previous research suggests that early-life exposure to the analgesic acetaminophen (APAP) results in oxidative stress that increases the risk of developing autism spectrum disorder and attention-deficit hyperactivity disorder in adulthood. The neuropeptide ghrelin (GHR) has antioxidant properties and neuroprotectant therapeutic potential as shown in rodent models for Parkinson's Disease. We therefore tested whether GHR administration reduces behavioral abnormalities induced by early-life exposure to APAP. Seven-day old rat pups (N=36) each received subcutaneous injections of either APAP (51.97 mg/kg), GRH (1 mg/kg), GRH + APAP (at the aforementioned doses), or saline vehicle. In Open Field (OF) testing in adulthood, rats

that had been treated with APAP alone showed reliably less thigmotaxis (center:edge ratio as a measure of anxiety) than vehicle-treated rats. Rats treated with GRH in addition to APAP showed levels of thigmotaxis similar to vehicle-treated controls. Rats treated with APAP alone made significantly fewer rotations during OF testing than rats given both GRH + APAP. These findings suggest that (A) APAP-induced developmental changes can be induced following a single, early-life, allometrically-scaled dose, and (B) GHR may provide some neuroprotection against APAP-induced developmental damage.

Title: A novel mouse model of autism spectrum disorder (ASD)-related MYT1L Syndrome displays autistic-like behaviors and altered brain development

Authors: *J. CHEN[1], X. GE[2], K. B. MCCULLOUGH[1], K. K. NOGUCHI[3], J. R. GARBOW[2], J. N. CONSTANTINO[3], H. W. GABEL[4], S. E. MALONEY[3], J. D. DOUGHERTY[1];

Abstract: Human studies have identified heterozygous mutations on MYT1L, a transcriptional factor, as the cause for ASD-related MYT1L Syndrome. However, MYT1L's role in brain development and function remains unknown. Here, we established the first mouse model of germline MYT1L mutation to investigate its loss of function *in vivo*. First, we showed that $MYT1L^{+/-}$ mice exhibited various phenotypes reminiscent to those found in MYT1L Syndrome patients, including hyperactivity, social deficits, obesity, and microcephaly. Next, by performing ATAC-seq and RNA-seq at different developmental time points, we found MYT1L loss results in genomic structure and transcriptional changes across pathways for neurogenesis and neuronal maturation. At last, we validated decreased neuronal proliferation during mouse embryonic brain development upon MYT1L loss. Those findings suggest MYT1L loss impairs brain development

and function, providing molecular and cellular mechanisms underlying the MYT1L Syndrome pathogenesis.

Title: The Effect of Propionic Acid on Habituation to Social Odours by Adult Male Rats

Authors: *C.-D. TYSON, *M. KAVALIERS, K.-P. OSSENKOPP;
Univ. Western Ontario, London, ON, Canada

Abstract: Accumulating evidence suggests that disturbances of the gastrointestinal tract involving metabolites of the gut microbiome play a role in the etiology of autism spectrum disorder (ASD). Specifically, the short-chain fatty acid, propionic acid (PPA), is of interest as it can cross both the gut-blood and blood-brain barriers, and induce central effects. One way ASD may contribute to social deficits, is through impaired habituation to sensory and social stimuli. To date, there has been no consideration of the effects of PPA on the habituation to sensory social cues. The present study examined effects of systemic administration of PPA in male adult Long Evans rats, and their ability to habituate to and discriminate between unfamiliar social and non-social odour cues. To ensure sufficient PPA was in the central nervous system to promote behavioural effects, prior to test days, rats were given intraperitoneal (i.p.) injections of 500 mg/kg PPA or phosphate buffered saline (PBS) for 4 successive days. On each of the baseline and 4 test days, rats received 500 mg/kg i.p. injections of PPA or PBS. On the baseline day, rats were exposed to clean bedding. To examine habituation, the next 3 test days, rats were either exposed to a repeated social odour cue from one stranger rat's bedding, or a non-social odour cue of diluted vanilla extract. On the last test day, a novel odour from a new stranger rat's bedding was introduced for social groups, and diluted almond extract was introduced for non-social groups. Behaviour was video recorded for 10 minutes while rats were in a 2-chambered open-field, with the odour in a petri dish on one chamber, and the other chamber empty. The open-field apparatus detected all vertical and horizontal activity via infrared beams, and total self-grooming, approach toward the odour cue and sniffing of the odour cue were manually scored from videotapes. Across baseline and test days, PPA treated rats showed significantly more self-

grooming than PBS rats in both social and non-social groups. Across the first 3 test days, the PPA-social group showed trends of reduced habituation compared to the PPA non-social group concerning duration near the odour cue, number of entries into the odour exposure area, and total horizontal activity. Total rest time was also significantly higher for PPA groups compared PBS groups during baseline and habituation days. PBS rats also showed a higher increase in sniffing than PPA rats when the novel odour was introduced on the last test day, compared to the previous day with the familiar odour. These results suggest that one means whereby PPA may contribute to social deficits in ASD is by impairing habituation to sensory social cues.

Title: Characterizing autism-like social behaviors in Drosophila melanogaster.

Authors: *E. ALMS[1], D. LENT[2];
[2]Dept. of Biol., [1]California State University, Fresno, Fresno, CA

Abstract: Studies have shown individuals diagnosed with autism can present with impairments and changes in socialization behaviors. These behavioral differences can include, among other things, increased aggression, impaired communication, and, interestingly in some individuals, better socialization between autistic peers. Autism, like many other neurological conditions, is diagnosed most often using behavioral surveys rather than medical confirmation testing. However, Fragile X Syndrome (FXS) is the most prevalent monogenic cause of hereditary autism currently known and it is one of the most commonly studied biological underpinnings in the D. melanogaster models of autism. In humans, FXS is the result of a mutation of the fragile X mental retardation 1 (FMR1) gene which has homolog in the D. melanogaster (dFMR1). The purpose of this study was to characterize the effect of selective dFMR1 knockdown in different neural circuitry on courtship social behaviors. Specifically, we looked at the effects of discriminatory mating patterns between flies with and without dFMR1 knockdown and within flies with or without dFMR1 knockdown. There were significant differences in the socialization behaviors of dFMR1/wildtype pairings compared to dFMR1/dFMR1 and wildtype/wildtype pairings. The observed differences in socialization in our fruit fly model have helped us better understand the autism-like socialization impairments and the improved within-group

socialization that has been observed in some individuals with autism. The latter is of particular interest as it has been suggested that the autistic individuals that socialize better with their autistic peers rather than with neurotypicals is related to a phenomenon called the double empathy problem. If the results are supported this may provide evidence that in D. melanogaster, there may be a neurobiological foundation for this phenomenon.

Title: Impairments in behavioral flexibility in the BTBR mouse model of autism spectrum disorder.

Authors: *B. ALVAREZ, C. MORALES, C. CAVAZOS, L. AMODEO, D. AMODEO; Psychology, California State University, San Bernardino, San Bernardino, CA

Abstract: Individuals diagnosed with autism spectrum disorder (ASD) display impairments in behavioral flexibility, as evidenced by deficits in probabilistic reversal learning. Similarly, the BTBR T+Itpr3tf/J (BTBR) mouse model of ASD shows a similar deficit in probabilistic reversal learning, when compared to C57BL/6J control mice when utilizing a spatial maze learning paradigm. In addition, many of these studies have failed to include female subjects. The first goal of these experiments was to examine the reproducibility of these findings using mouse operant chambers. We predicted that the impairments found with the spatial T-maze would parallel results using operant chambers. Secondly, we hypothesized that female BTBR mice would express similar impairments to male BTBR mice. Mice were tested in operant discrimination task using an 80/20 probabilistic reinforcement procedure. Mice were tested on a two-choice operant task, each mouse was tested on acquisition and then reversal learning across several days. Mice learned to obtain a sucrose pellet reinforcement from the magazine once a “correct” nose poke was made (reinforced on 80% of trials) compared with the “incorrect” nose poke (reinforced on 20% of trials). The learning criterion in both phases was choosing the ‘correct’ location on 80% of trials. For the initial operant discrimination, female mice regardless of strain required less days to reach learning criterion than male mice. For both days needed to reach criterion and total trials needed to reach criterion, both female and male BTBR mice were impaired. This impairment parallels findings utilizing a spatial learning task. Further error analysis shows that the impaired behavioral flexibility was due to an inability to maintain a new choice pattern once the reversal was made, rather than an initial inability to inhibit the initial learned choice behavior. These findings demonstrate that the behavioral inflexibility found in

BTBR mice is persistent and resistant to changes in behavioral paradigms. Together these findings further support the testing of this strain in the hopes of discovering of new treatments aimed a reducing behavioral inflexibility.

Title: Autism-associated mutations in kv7 channels induce gating pore current

Authors: *T. M. GAMAL EL-DIN[1], T. LANTIN[2], C. TSCHUMI[2], B. JUAREZ[2], M. QUINIAN[2], J. LI[2], L. S. ZWEIFEL[1], W. A. CATTERALL[2];
[1]Pharmacol., [2]Univ. of Washington, Seattle, WA

Abstract: Autism spectrum disorder (ASD) adversely impacts >1% of children in the U. S., causing social interaction deficits, repetitive behaviors, and communication disorders. Genetic analysis of ASD has advanced dramatically through genome sequencing, which has identified >500 genes with mutations in ASD. The voltage-gated potassium (K_V) channel K_V7 (KCNQ) ranked high among the ion channel genes having mutations in individuals with neurodevelopmental disorders. The K_V7 channel in brain is typically a heterotetramer of $K_V7.2$ and $K_V7.3$ subunits. These channels are tonically active at the resting membrane potential to regulate voltage sensitivity, frequency, and pattern of action potential firing in brain neurons. Like other K_V channels, K_V7 is composed of four subunits having six transmembrane segments (S1-S6). The S1-S4 segments form the voltage sensor, whereas the S5 and S6 segments form the pore. Mutations that alter arginine gating charges in the voltage sensor of the voltage-gated potassium channel K_V7 (KCNQ) are among those frequently associated with ASD. We hypothesized that these gating charge mutations would induce gating pore current (also termed ω-current) by causing an ionic leak through the mutant voltage sensor. Unexpectedly, we found that wildtype K_V7 conducts outward gating pore current through its native voltage sensor at positive membrane potentials, owing to a glutamine in the third gating charge position. In bacterial and human K_V7 channels, gating charge mutations at the R1 and R2 positions cause inward gating pore current through the resting voltage sensor at negative membrane potentials,

whereas mutation at R4 causes outward gating pore current through the activated voltage sensor at positive potentials. Remarkably, CRISPR/Cas expression of the K_V7/R2C ASD-associated mutation *in vivo* in dopamine neurons of mice disrupts action potential generation and repetitive firing. Overall, our results reveal native and mutant gating pore current in K_V7 channels and implicate altered control of action potential generation by gating pore current through mutant K_V7 channels as a potential pathogenic mechanism in autism.

Title: The DYT6 dystonia transcription factor THAP1 regulates myelination and ECM homeostasis

Authors: *D. YELLAJOSHYULA[1], A. E. ROGERS[2], S. S. PAPPAS[3], W. T. DAUER[3]; [1]Neurol., Univ. of Michigan, Ann Arbor, Ann Arbor, MI; [2]Mol. Cell. and Developmental Biol., Univ. of Michigan, Ann Arbor, MI; [3]Peter O'Donnell Jr. Brain Inst., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The development and function of the nervous system is profoundly influenced by interactions of neurons with glial cells and the extracellular matrix (ECM). Mechanisms regulating the maturation of oligodendroglial progenitor cells (OPCs) into myelinating cells to facilitate CNS myelination play an essential role in circuit plasticity, including motor learning. Prior studies have established that OPC maturation into myelinating cells is acutely sensitive to ECM content and composition. Yet we understand little about the cellular mechanisms regulating the synthesis and composition of the brain ECM. Our work has identified that THAP1, a transcription factor whose loss of function leads to the neurodevelopmental movement disorder DYT6 dystonia, drives OPC development by regulating the breakdown of glycosaminoglycans (GAGs), which are major ECM components. Conditional deletion of *Thap1* from the oligodendrocyte (OL) lineage significantly impairs CNS myelination by restraining the maturation of OPCs to myelin producing cells. Our studies show that THAP1 modulates the ECM content produced by the OPCs by binding to and regulating the *Gusb* gene, which encodes for β-glucuronidase, a GAG-catabolic lysosomal enzyme. Our studies of the transcription factor THAP1 in the OL lineage have identified that GAGs produced and secreted by OPCs act in an

autocrine fashion to inhibit their lineage progression, highlighting a unique mechanism regulating the pool of mature oligodendrocytes.

Title: Oligodendrocyte-mediated myelin plasticity

Authors: *S. PAJEVIC[1], D. PLENZ[1], P. J. BASSER[2], R. D. FIELDS[2];
[1]Natl. Inst. of Mental Hlth., [2]NICHD, NIH, Bethesda, MD

Abstract: The most efficient mechanism for adjusting the timing of signals among different neurons in vertebrate brains is by altering conduction velocity through the dynamic and adaptive remodeling of myelin, i.e., myelin plasticity (MP). Oligodendrocytes (OL) play an important role in MP, but the precise feedback mechanisms for adjusting the degree of axonal myelination and timing are currently not known. The models that we propose here address this problem and are motivated by the fact that a single OL cell preferentially extends its processes to multiple axons rather than myelinating the same axon multiple times. We propose two mathematical but biologically plausible models of oligodendrocyte-mediated myelin plasticity (OMMP), in which we explore the role OLs can play in mediating synchronization of signals traveling via different axonal pathways they myelinate: 1) a *passive model* (PM), in which the relative timings of axonal spikes at different processes of oligodendrocytes are driving/influencing myelination; and 2) an *active model* (AM) in which the recently observed ability of some OL cells to produce their own spikes is used as a reference signal for synchronization. The essential features of these models are relative timings and temporal profiles of the release of various “factors” within the OL cells in response to axonal spikes. The passive model allows oligodendrocytes to effectively mediate synchronization of signals, while requiring only two factors, one that promotes the myelination (local, having different concentration on each of the OL processes), and another that catalyzes the release of the myelinating factor (global/somatic, having the same concentration for a given OL cell). Assuming that the demyelination rate is constant, in its simplest form the PM has only $3+n_a$ dynamical variables per OL cell, where n_a is the number of axons the OL myelinates, whereas the AM model required $6 + 2\ n_a$ variables to have stable dynamics. The full

model consists of a sequential "chain" of n_o OL cells in which the myelination pattern across all OLs is prescribed by the myelination matrix (n_o x n_a). In this work we present results of simulations in which we test the ability of OL chains to recover from structural perturbations in conduction delays and re-synchronize the signals with consistent timing differences. The initial spread of arrival times (varied between 5 and 20 ms) can be reduced to only a few milliseconds (1-4 ms), yielding better results for low spiking rates (<20 Hz). We also show that both OMMP models leave the arrival time spread unchanged when independent and random (Poisson) spike trains are transmitted through the chain.

Abstract: Aging results in gray and white matter degeneration, but the specific microglial responses are unknown. Using single-cell RNA sequencing from white and gray matter separately, we identified white matter-associated microglia (WAMs), which share parts of the disease-associated microglia (DAM) gene signature and are characterized by activation of genes implicated in phagocytic activity and lipid metabolism. WAMs depend on triggering receptor expressed on myeloid cells 2 (TREM2) signaling and are aging dependent. In the aged brain, WAMs form independent of apolipoprotein E (APOE), in contrast to mouse models of Alzheimer's disease, in which microglia with theWAMgene signature are generated prematurely and in an APOE-dependent pathway similar to DAMs. Within the white matter, microglia frequently cluster in nodules, where they are engaged in clearing degenerated myelin. Thus, WAMs may represent a potentially protective response required to clear degenerated myelin accumulating during white matter aging and disease.

Title: Role of Tim-2 in central nervous system myelination

Authors: *Q. W. WADE, E. B. NEELY, J. R. CONNOR;
Penn State Col. of Med., Hershey, PA

Abstract: Myelin, which is formed by oligodendrocytes (OLs) in the central nervous system (CNS), is crucial for efficient signal transduction and neuronal function. Iron is a critical micronutrient for OLs due to its role as a cofactor for myelin synthesis, and it is well-known that OLs are the highest iron staining cells in the brain. Inadequate iron delivery to OLs frequently results in severe and long-lasting neurological deficits that are attributed to hypomyelination. Our laboratory and others have identified H-ferritin (Fth), traditionally considered solely an iron storage protein, as the primary iron delivery protein to OLs. We have also found that H-ferritin utilizes a novel receptor on rodent OLs, T-cell immunoglobulin and mucin domain-containing protein-2 (Tim-2). To determine the importance of H-ferritin-mediated iron delivery through Tim-2 on OLs for myelination, we have generated *Timd2$^{fl/fl}$ Plp1-Cre/ERT* conditional knockout mice to eliminate Tim-2 expression specifically from OLs following consecutive tamoxifen injections. We hypothesize that removal of Tim-2 from OLs will lead to decreased H-ferritin uptake, which will in turn lead to insufficient myelination. In this study, we observed that *Timd2$^{fl/fl}$ Plp1-Cre/ERT* mice injected with 75 mg/kg tamoxifen on post-natal days 7-9 to induce the knockout displayed a trend towards poorer motor performance on the rotarod as measured by increased number of falls and decreased latency to fall. Moreover, there was a statistically significant reduction in myelin basic protein (MBP) and proteolipid protein (PLP) in addition to a decrease in myelin staining in the corpus callosum of Tim-2 knockout animals compared to controls. Essentially, the data from this study indicates that myelin is negatively affected following Tim-2 knockout from OLs during development.

Abstract: Oligodendrocyte precursor cells (OPCs) play a crucial role in the CNS by serving as progenitors for oligodendrocytes, which are mobilized to ensure proper developmental myelination, adaptive myelination in response to learning, and myelin repair following injury and disease. However, the early emergence of these OPCs during development, their highly dynamic nature and their persistence within gray matter throughout life has raised the possibility that these cells perform other functions in neural circuits. Assessing their possible non-progenitor roles has been difficult, as there is limited information about the structure of OPCs in the intact brain.

To help define the function of OPCs in the developing CNS, we used high throughput serial section EM and computational segmentation to examine the detailed ultrastructure of OPCs in mouse visual cortex (aged P36 and P49), providing the first complete 3D reconstructions of these cells. Unexpectedly, we discovered that the fine processes of OPCs frequently surrounded terminal axon branches and included numerous lysosomes and phagolysosomes (PLs) containing fragments of axons and presynaptic terminals, containing 40 nm vesicles within their chambers. Single- nucleus RNA sequencing and DNA-methylation analyses indicated that cortical OPCs express key phagocytic genes, as well as methylated neuronal transcripts, consistent with active axonal engulfment.

To compare their phagocytic activity to microglia, long considered the primary phagocytes in the brain, we counted PLs in 18 microglial cells from both datasets and compared the numbers and density of PLs to those in 18 OPCs. This analysis showed PLs were ~10x more abundant in OPCs at these ages than other glia. Immunostaining using anti-LAMP-2 antibody revealed that OPCs acutely isolated from developing visual cortex contained numerous lysosomes, further indicating that these cells are highly phagocytic at this age. PLs in OPCs declined with age and lineage progression, suggesting that OPCs contribute to the refinement of neuronal circuits during later phases of cortical development by pruning synapses and terminal axonal branches.

Title: The Effect of Jedi-1, an engulfment receptor on Oligodendrocyte Lineage cell Development and Proliferation

Authors: *J. TEPAN[1], B. D. CARTER[2], V. MORRISON[3];
[1]CUNY Hunter Col., New York, NY; [2]Dept. of Biochem. Vanderbilt Brain Inst., Vanderbilt Univ. Med. Sch., Nashville, TN; [3]Biol., Georgetown Univ., Washington, TN

Abstract: Jedi-1 is an engulfment receptor that aids in phagocytosis and clearance of apoptotic debris in the peripheral nervous system. In the central nervous system of Jedi-1 knockout (KO) mice, phagocytic clearance is disrupted and proliferation decreases in the subventricular zone (SVZ), a neurogenic region known for high levels of proliferation and apoptosis Here, we ask whether Jedi-1, through its effects on the SVZ, influences oligodendrocyte lineage cell (OLC) development. OLCs arise from the SVZ and colonize the corpus callosum, where they ensheath

and insulate axons, thereby increasing action potential velocity. We previously found that despite a decreased number of neural precursors in the KO SVZ, more became OLCs than in wild types (WT) at postnatal day 7 (P7). Thus, we hypothesized that adult KO mice would have a larger pool of OLCs relative to WT. Immunofluorescent labeling of the oligodendrocyte (OL) lineage marker, OLIG2+ in brain sections showed no significant difference between genotypes in total OLCs in the corpus callosum at P28. Given this finding, the increase in OLIG2+ cells at P7 could represent a transient compensatory increase in oligodendrogenesis, perhaps to compensate for reduced neural precursors. There might also be increased proliferation within the OLC population that could explain comparable numbers of OLC in the adults. To address this, we stained for EdU, a fluorescent nucleotide analog incorporated into cells dividing at the time of EdU administration,and quantified the proportion of proliferating OLCs. Increasing OL production postnatally can provide insight on treating demyelinating diseases such as multiple sclerosis.

Title: Aging-dependent transcriptomic changes in oligodendrocyte precursor cells

Authors: *D. HEO[1], V. N. DOZE[3], L. A. GOFF[1,2,4], D. E. BERGLES[1,4];
[1]Neurosci., [2]Genet. Med., Johns Hopkins Sch. of Med., Baltimore, MD; [3]Col. of St. Benedict/St. John's Univ., St. Joseph, MN; [4]Kavli Neurosci. Discovery Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: OPCs represent an abundant, highly dynamic, widely distributed population of glial cells in the CNS that are responsible for generating myelinating oligodendrocytes during development. These cells are also mobilized to form new myelin in the adult CNS in response to environmental and behavioral changes, and play a crucial role in regenerating myelin in multiple sclerosis (MS). However, the rates of OPC proliferation and differentiation decline dramatically with aging, impairing homeostasis, myelin repair, and potentially adaptive myelination during learning. The mechanisms that cause this shift in behavior are not yet known. In Alzheimer's disease (AD), there is evidence that OPCs can become senescent, characterized by increased

immunoreactivity of p21 and p16, key proteins involved in inhibiting cyclin-dependent kinases during cellular division. In MS, similar patterns of OPC and OL senescence have been identified, suggesting that aging-related changes in OPCs may contribute to these neurodegenerative diseases. To determine how OPCs change with age, we isolated these cells using FACS from the cerebral cortex of a novel transgenic mouse line that expresses EGFP under the endogenous promoter of matrilin-4 (*Matn4*-mEGFP), allowing us to enrich for these cells with high purity. We then performed single-cell RNA sequencing from more than 30,000 OPCs from mice aged P30, P180, P360, and P720. Gene expression clustering analysis revealed three major subtypes of cortical OPCs: cycling, quiescent, and differentiating. Cycling OPCs were further subclassified into three different populations based on their position in the cell cycle, the proportion of which declined with aging. We then performed aging-dependent differential gene expression analysis on different subsets of OPCs (cycling, quiescent and differentiating) and identified co-regulated gene patterns. Unexpectedly, quiescent OPCs were transcriptionally stable over the course of aging, suggesting that these cells have an intrinsic potential to self-renew and rarely become senescent in the naïve brain. We then performed single-cell ATAC-seq to determine aging-dependent changes in chromatin accessibility that may ultimately contribute to the decreased potential for differentiation and proliferation with aging. These datasets provide a valuable reference of OPC gene expression patterns to help define their behavior in various physiological and pathological contexts. Further, they will provide a deeper understanding of the homeostatic roles performed by these cells, and reveal new approaches for restoring their regenerative potential in aging-associated diseases and injury.

Title: Sex differences in visual cortex development: is there a role for myelin?

Authors: *L. MONTEIRO, D. SINGH, K. M. MURPHY;
McMaster Univ., Hamilton, ON, Canada

Abstract: There are well-known sex differences in visual perception, and the visual cortex (V1C) is >20% larger in males than females. Nevertheless, the issue of sex differences in V1C development has not been well-studied. For example, sex hormones such as estradiol enhance

oligodendrogenesis which promotes myelin production. Also, various disorders that affect cortical myelin such as multiple sclerosis, and bipolar disorder are more prevalent in females than males, suggesting sex-specific disparities. Myelin is a complex multiprotein that has been shown to serve more than one role in V1C development and plasticity. In the critical period, an increase in myelin-derived signaling puts the 'brakes' on developmental plasticity. Paradoxically, in the adult V1C, myelin increases in response to enriched sensory experience suggesting that it facilitates plasticity. Together, these raise the question of whether the molecular composition of myelin differs by age and sex? To address this, we analyzed the development of a network of myelin-associated genes (n=58, e.g., MBP, PLP1, MAG, MOG) using a developmental transcriptomic database from post-mortem tissue samples of the human primary V1C (n=48, samples, F=21, M=27, age range: 4 months -80 years). First, we characterized the lifespan changes for the network of genes by fitting locally estimated scatterplot smoothing (LOESS) curves with 95% confidence intervals for each gene and sex pair (n=116). We noticed that some genes showed monotonic increases or decreases across the lifespan. In contrast, others had an undulating pattern unique to adolescence coinciding with the end of the sensitive period in the human V1C. Second, we conducted unsupervised hierarchical clustering of the myelin gene development and found 8 distinct trajectories that describe the developmental profile of myelin in human V1C. We listed the genes in each trajectory cluster and found minimal overlap between the sexes. For example, the major components of myelin, MBP and PLP1, had different developmental trajectories for females and males. This trajectory analysis identified robust age- and sex-related differences in the development of myelin genes in human V1C. These novel findings suggest that myelin may play different roles in transitioning from juvenile to adult plasticity in V1C of females and males.

Abstract: In multiple sclerosis (MS), destruction of myelin sheaths and insufficient repair contributes to axonal degeneration and neurological dysfunction. Endogenous remyelination requires the differentiation of adult oligodendrocyte progenitor cells (OPCs). As such, pharmacologic interventions for MS requires an understanding of molecular regulators of human OPC (hOPC) maturation. We have previously shown that the $G\alpha_q$ muscarinic M_3 receptor (M_3R) inhibits hOPC differentiation, and conditional deletion of M_3R in OPCs promotes remyelination. We hypothesized that Ca^{2+} signals downstream $G\alpha_q$-coupled-receptor (G_qR) signaling regulates hOPC cell fate. We exposed hOPCs to a panel of selective ligands that target G_qRs identified by RNA-seq. Only muscarinic agonist oxotremorine (Oxo-M) and the metabotropic glutamate receptor 5 ($mGluR_5$) agonist CHPG induced prolonged oscillatory $[Ca^{2+}]_i$ in hOPCs and blocked hOPC differentiation while another G_qR agonist had no effect. Oscillatory $G\alpha_q$-$[Ca^{2+}]_i$ was also dependent on store operated calcium entry (SOCE) and was reduced following treatment with SOCE antagonists and siRNA-mediated knockdown (KD) of either STIM1 or STIM2. Interestingly, STIM2 KD reduced $[Ca^{2+}]_i$ oscillatory frequency and abolished effects of muscarinic agonist on differentiation. To further examine the role of oscillatory SOCE, we used optogenetic STIM lentivirus to directly induce SOCE by blue light stimulation at various frequencies. Following long-term live cell imaging, we observed a frequency-dependent effect of SOCE activation resulting in blockade of hOPC differentiation and stimulation of proliferation. Lastly, in our preliminary *in vivo* studies using conditional deletion of SOCE components *Stim1/2* in $NG2^+$ OPCs, we found *Stim1/2* ablation increases oligodendrocyte (OL) generation following demyelination. These findings afford insights into mechanisms that regulate hOPC proliferation and differentiation, suggesting a key role for SOCE in the regulation of OL cell fate.

Title: Role of PARG in oligodendrocyte differentiation during CNS development

Authors: *Y. WANG[1,2], S. ZHANG[1,2], B. KIM[1,2], F. GUO[1,2];
[1]Univ. of California, Davis, Sacramento, CA; [2]Shriners Hosp. for Children - Northern California, Sacramento, CA

Abstract: Oligodendrocyte differentiation and myelination are essential for the normal function of the central nervous system (CNS). Defects of these two events result in saltatory nerve conduction disruption, axonal degeneration and neurological disabilities such as periventricular leukomalacia and multiple sclerosis. Hence, understanding the mechanisms and identification of critical regulators underlying OL development and myelination facilitates the development of therapeutic targets for CNS demyelinating diseases. We have previously reported that Poly(ADP-ribose) polymerase 1 (PARP1) plays an essential role in oligodendroglial lineage progression through its enzymatic activity mediated PARylation, a process of covalently attaching poly (ADP-ribose) unites to target proteins. However, the rapid PAR turnover is catalyzed by the PAR degrading enzyme Poly(ADP-ribose) glycohydrolase (PARG). Our *in vivo* study showed that stabilizing PARylation by PARG inhibitor (PDD 00017273) treatment augmented PARylation through dampening PAR degradation. The number and differentiation of oligodendrocyte were significantly increased in the corpus callosum of PDD treated mice compared with that of control mice. For *in vitro* study, both PDD treatment and siRNA-mediated PARG knockdown in primary cultured rat OPCs significantly increased the expression of myelin genes and pro-differentiation factor suggesting that PARG regulates OPC differentiation in a cell-autonomous manner. Therefore, our studies demonstrate that inhibiting PARG activity or decreasing PARG expression is sufficient to promote OPC differentiation and suggest that PARG-mediated pathway may be a potential therapeutic target for myelin repair in demyelinating disorders.

Title: White matter integrity of Alzheimer's disease characterized by diffusion tensor imaging

Authors: *D. XIAO[1], K. WANG[3], L. THERIAULT[2], C. ELHELOU[2];
[1]STEM, [2]Regis Col., Weston, MA; [3]Dept. of Family and Community Health, Sch. of Nursing, Hlth. Sci. Center, West Virginia University, WV 26506,, Morgantown,, WV

Abstract: The white matter degeneration is suggested to predict the early sign of Alzheimer disease (AD). Changes in AD are reflected on the microstructure of white matter tract, for example the degree of myelination. The purpose of this research is to study the changes of white matter tract integrity, the specific Diffusion Tensor Imaging (DTI) measures, in AD patients in

comparison to control brains.We have studied 4 DTI measures, Mean Diffusivity (MD), Fractional Anisotrophy (FA), Radial Diffusivity (RD) and Axial Diffusivity (AxD) in 42 AD patients and 42 controls in 12 main brain white fiber tract regions on both hemispheres, corpus callosum, fornix, cingulum hippocampus, uncinate, internal and external capsule, corona radiata, cerebellar peduncle, longitudinal fasciculus, fronto-occipital fasciculus, striatum, thalamus radiation and corticospinal tract. The following brain regions show a bilateral significant increase in MD, RD, AxD and decreased FA among AD patients: fornix, corpus callosum, anterior corona radiata and cingulum hippocampus. Adjusted for other covariates, education is not associated with DTI measurers ($p > 0.05$). Females had lower MD values, in certain brain regions such as cerebral peduncle, fornix and superior longitudinal fasciculus. Elder people had higher MD values in most DTI measures. Finally, we saw differences in left *vs* right side in certain regions. Left side, not the right side, shows significant MD changes in anterior limb of internal capsule and external capsule, FA changes in posterior corona radiata, RD changes in external capsule. On the other hand, right side shows significant FA changes in uncinate, RD changes in posterior limb of internal capsule. Overall, we has studied DTI changes in all the major white matter tracts in the central nervous system. It shows limbic structures related to memory and emotions have significant changes in AD in comparison to control, consistent with some other studies, but not corticospinal tract that is involved in primary motor functions. Left and right sides of these structures of the brain are affected with differences in certain tracts. There might be gender differences in terms of the severity of these DTI changes, indicated by MD.

Title: White matter hyper-intensities and cognitive decline in APOE4 carriers

Authors: *A. CHAKHOYAN[1], G. BARISANO[1], A. MONTAGNE[1], T. L. S. BENZINGER[2], J. C. MORRIS[3], B. V. ZLOKOVIC[1];

[1]Keck Sch. of Med. - Zilkha Neurogenetic Inst., USC, Los Angeles, CA; [2]Dept. of Radiology, [3]Dept. of Neurol., Washington Univ. Sch. of Med., St Louis, MO

Abstract: Purpose: Subcortical white matter sessions, assumed to be on ischemic bases, are common in older subjects and correlate with cognitive decline in aging and during AD progression. Less pronounced than in the hippocampus, our team observed a trend of early blood-brain barrier (BBB) breakdown in the white matter of patients with mild cognitive decline (MCI), raising the possibility that BBB breakdown and not ischemia is an early determinant of white matter hyper-intensity. Indeed, ApoE4 gene is a major genetic risk factor for Alzheimer's disease. Here, we investigated the white matter hyper-intensities (WMH) burden in addition to ApoE4 gene and cognitive performances. 135 patients were included in this study with available high-resolution T2w-FLAIR MRI. **Methods**: Out of 135 subjects, 64 were ApoE4 non-carriers (3/3) and 71 ApoE4 carriers (3/4+4/4). In ApoE4 non-carriers, 54 were cognitively normal and 10 were showing Clinical Dementia Rating (CDR®) score of 0.5. In ApoE4 carriers, 60 were cognitively normal and 11 were CDR 0.5. WMH burden (reported in mL) was estimated on a T2w FLAIR-MRI high-resolution images (1x1x1.2mm^3). **Results**: Results suggest that ApoE4 carriers demonstrates larger WMH burden with age in cognitively normal patients. Moreover, study findings suggest that WMH burden is not significantly different in ApoE4 non-carrier and carriers. As supported by the results, patients who manifest cognitive decline, their WMH burden is larger compared to cognitively normal patients. **Conclusions**: High-resolution MRI is a powerful tool to assess white matter hyper-intensities and its relationship to BBB integrity. To understand BBB permeability contribution in WMH progression, we will next analyze DCE-MRI extracted Ktrans values within WMH burden as well as in normal-appearing white matter.

Abstract: Hydroxyoctadecadienoic acid metabolites (9-HODE and 13-HODE) have anti-inflammatory properties but their clinical associations with Alzheimer's disease (AD) and subcortical ischemic vascular disease (SIVD) have not been established. We aim to examine these metabolites with respect to cognition and microstructural white matter integrity.
Patients from memory and stroke prevention clinics (n=69) were stratified based on SIVD (minimal vs. abundant white matter hyperintensities [WMH] based on 3.0T structural MRI), and AD (clinical diagnosis). Oxylipins were extracted from serum using solid phase extraction and their concentrations measured by ultra high-performance liquid chromatography mass spectrometry. Microstructural tissue integrity was examined as fractional anisotropy (FA) and mean diffusivity (MD) using diffusion tensor imaging. Executive function was measured by the Trail Making Test B (TMT B).
Using a linear regression model controlling for age, sex, AD, and SIVD, both 9-HODE and 13-HODE were associated with better performance on the TMT B (β=0.279 p=0.008 and β=0.276 p=0.010) but had no significant associations with verbal memory measured by long delay free and cued recall in the California Verbal Learning Test. 9-HODE was associated with higher FA in normal appearing white matter in the left superior frontal (β=0.284 p=0.023), right middle frontal (β=0.243 p=0.044), and 9-HODE and 13-HODE in the left inferior frontal region (β=0.274 p=0.026 and β=0.283 p=0.022). In these same regions, normal appearing white matter FA was associated with better performance on the TMT B (β=0.255 p=0.027, β=0.277 p=0.020, and β=0.322 p=0.005). 13-HODE was associated with higher FA in deep WMH in the left superior frontal (β=0.465 p=0.004) and 9-HODE and 13-HODE in right middle inferior frontal regions (β=0.744 p=0.002 and β=0.570 p=0.021). 9-HODE was associated with lower MD in deep WMH in the left middle medial frontal (β=-0.506 p=0.040) region. 9-HODE and 13-HODE were associated with less atrophy in the left temporal (β=-0.207 p=0.024 and β=-0.240 p=0.009) and right temporal (β=-0.255 p=0.016 and β=-0.239 p=0.011) regions. In patients with only SIVD, 9-HODE and 13-HODE were associated with smaller periventricular WMH volume (β=-0.524 p=0.043 and β=-0.594 p=0.013).
Anti-inflammatory oxylipins were associated with better performance on the TMT B, smaller vascular brain lesion volumes and lesion microstructural characteristics, less atrophy, and preserved white matter microstructural integrity in frontal regions. Together, these associations suggest a neuroprotective role of 9-HODE and 13-HODE on the small vessels and executive function.

Title: Postmortem neocortical ^{3}H-PiB binding and levels of unmodified and pyroglutamate Aβ in Down syndrome and sporadic Alzheimer’s disease

Authors: *V. PIVTORAIKO[1], T. RACIC[1], E. E. ABRAHAMSON[1,3], V. L. VILLEMAGNE[2], B. L. HANDEN[2], I. T. LOTT[4], E. HEAD[5], M. D. IKONOMOVIC[1,3];

Abstract: Individuals with Down syndrome (DS) have a genetic predisposition for amyloid-β (Aβ) overproduction and earlier onset of Aβ deposits compared to sporadic late-onset Alzheimer’s disease (AD). Positron emission tomography (PET) with Pittsburgh Compound-B (PiB) detects fibrillar Aβ pathology in living people with DS and AD, but its relationship with heterogeneous Aβ forms aggregated within amyloid deposits is not well understood. We performed quantitative in-vitro ^{3}H-PiB binding assays and enzyme-linked immunosorbent assays of fibrillar (insoluble) unmodified Aβ40 and Aβ42 forms and N-terminus truncated and pyroglutamate-modified AβNpE3-40 and AβNpE3-42 forms in postmortem frontal cortex and precuneus samples from 18 DS cases aged 43-63 years and 17 late-onset AD cases aged 62-99 years. Both diagnostic groups had advanced stages of amyloid plaque pathology, and DS cases had, on average, more severe vascular amyloid pathology (cerebral amyloid angiopathy, CAA). Compared to the AD group, the DS group had higher levels of Aβ40 and AβNpE3-40, while the two groups did not differ by Aβ42 and AβNpE3-42 levels, in both the frontal cortex and precuneus. This resulted in lower ratios of Aβ42/Aβ40 and AβNpE3-42/AβNpE3-40 in the DS

group compared to the AD group, in both cortical regions. Correlations of Aβ42/Aβ40 and AβNpE3-42/AβNpE3-40 ratios with CAA severity were strong in DS cases, and weak in AD cases. The two diagnostic groups did not differ significantly by ^{3}H-PiB binding levels in the frontal cortex or in the precuneus. These results demonstrate that compared to late-onset AD cases, adult DS individuals with similar burden of cortical Aβ plaques have a preponderance of both pyroglutamate-modified AβNpE3-40 and unmodified Aβ40 forms which are associated with greater CAA pathology. Despite the distinct molecular profile of Aβ forms and greater vascular amyloidosis in DS cases, cortical ^{3}H-PiB binding does not distinguish between diagnostic groups that are at an advanced level of amyloid plaque pathology. These results underscore the need for development of CAA-selective PET radiopharmaceuticals in order to detect and track the progression of cerebral vascular amyloid deposits in relation to Aβ plaques at the earliest pathology stages in individuals with DS.

Title: Markers of brain aging in cognitively characterized marmosets (Callithrix jaccus)

Authors: *C. FREIRE-COBO[1,2], M. VARGHESE[1,2], E. ROTHWELL[3], M. EDWARDS[3], W. G. M. JANSSEN[1], A. LACREUSE[3], P. R. HOF[1,2,4];

Abstract: The common marmoset (*Callithrix jacchus*), a small nonhuman primate with highly developed social and cognitive abilities that lives for about 10 years and shows AD-like neuropathology in old age, constitutes an important primate model for longitudinal studies of neurocognitive aging. Some of the hallmarks of AD pathology, including amyloid beta and tau deposition, astrocytic proliferation and microglial atrophy, have been described in the brains of old marmosets. However, the relationships between these pathological hallmarks and cognitive function have not been established in this species. In addition, the loss of dendritic spines or

changes to their morphology, which have been proposed to mediate age-related cognitive decline in macaques has not been assessed in marmosets. We analyzed brain tissues from 16 male and female marmosets (7-9 years old) that had been behaviorally characterized in a 4-year longitudinal study as they transitioned to old age (Rothwell et al., in revision). Analysis of cognitive trajectories, focused on reversal learning, indicated that some monkeys maintained or even improved cognitive performance across aging, while others showed a decline starting around age 8. The analysis of brain tissues was focused on the dorsolateral prefrontal cortex (dlPFC, layer III of area 8b/9) and the CA1 field of the hippocampus, for their relevance reported in cognitive studies in NHP. We targeted several neural and glial markers in a series of immunofluorescence assays including: glial fibrillary acidic protein (GFAP) and ionized calcium-binding adaptor molecule 1 (Iba1) in astrocytes and microglia cells respectively; cluster of Differentiation (CD68) for identifying lysosome activation; anti-beta amyloid antibody (MOAB-2) for analyzing soluble and insoluble forms of amyloid deposits; anti-Collagen IV for brain blood vessels and Neurotrace as a neuronal pan marker. For the morphological analysis of spines we performed iontophoretic dye-filling of pyramidal neurons, followed by confocal imaging of their dendritic segments and three-dimensional reconstruction of spines. The analysis revealed
highly variable degrees of amyloid beta neuropathology among individuals. Glial changes included changes on branching and soma size in astrocytes, increased microglia activation and cell atrophy. We also identified differences in spine vulnerability during aging in marmosets. Our preliminary analysis suggests that some marmosets show an accelerated or pathological aging profile characterized by a higher degree of amyloid beta deposition, astrogliosis, morphologic alterations in microglia and loss of dendritic spines.

Title: Total hippocampal and CA4-DG volumes are reduced in Alzheimer's Disease compared to Vascular Cognitive Impairment

Authors: *I. KWAK[1], D. HOBBS[2], C. A. RAJI[2];
[1]Washington Univ. in St. Louis Sch. of Med., St. Louis, MO; [2]Washington Univ. in St. Louis Sch. of Med., St.Louis, MO

Abstract: Total hippocampal and CA4-DG volumes are reduced in Alzheimer's Disease compared to Vascular Cognitive Impairment

Iris Kwak, BA; Diana Hobbs, PhD; Cyrus A. Raji, MD, PhD
(1)Washington University in St. Louis School of Medicine 660 S Euclid Ave, St. Louis, MO 63110

Background: Hippocampal volume abnormalities are detailed in multiple neurocognitive disorders. Hippocampal subfields may add value in clinically delineating these conditions. Manual segmentation remains the gold standard but is limited by time and inter-operator variability. We therefore utilized the automated segmentation tool, volBrain's HIPS pipeline, to analyze hippocampal subfield volumes in Alzheimer disease (AD) and diagnoses of mixed dementia.

Methods: A total of 134 participants (ages 56-94) were drawn from the Open Access Series of Imaging Studies 4 (OASIS-4) and classified into 5 diagnostic groups: AD/Dementia (AD/D, n = 50), AD/Vascular Dementia (AD/VD, n = 38), Frontotemporal Dementia (FTD, n = 20), Parkinson's Disease (PD, n = 10), and Vascular Cognitive Impairment (VCI, n = 16). T1- and T2-weighted brain MRI scans collected on a 3T scanner were processed through volBrain's HIPS pipeline, resulting in 5 subfield volumes: Cornu Ammonis (CA) 1, CA2-CA3, CA4-Dentate Gyrus (DG), Strata Radiatum/Lacunosum/Moleculare (SR-SL-SM), and Subiculum. Analysis of covariance (ANCOVA) were used to compare subfield volumes between diagnostic groups when controlling for age, sex, and intracranial volume (ICV). Results were corrected for multiple comparisons ($p < 0.005$).

Results: Subfield volumes varied by diagnosis with medium to large effect sizes. Total hippocampal volume is lower in AD/D ($p < 0.001$, $d = 1.37$) and AD/VD ($p < 0.005$, $d = 1.06$) when compared to VCI. CA4-DG volume is lower in AD/D ($p < 0.005$, $d = 1.05$) and AD/VD ($p < 0.005$, $d = 1.12$) when compared to VCI.

Conclusions: Decreased hippocampal volume is a core biomarker of AD and is used to stage progression of AD pathology. The subgranular zone of the dentate gyrus is a critical site of neurogenesis that is impaired in AD. We found that both total hippocampal and CA4-DG volumes were significantly lower in AD when compared to VCI. Further study will validate the use of volBrain and other automated segmentation protocols as a potential diagnostic tool for neurocognitive disorders.

Title: Modeling multimodal brain-predicted age in early symptomatic and preclinical Alzheimer disease

Authors: *P. MILLAR, P. LUCKETT, B. GORDON, T. BENZINGER, S. SCHINDLER, A. FAGAN, J. HASSENSTAB, J. MORRIS, B. ANCES;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Background: The “brain-predicted age” approach quantifies apparent brain age compared to normative trajectories of neuroimaging features. Elevated brain-predicted age has been observed in symptomatic Alzheimer disease (AD), but has not been evaluated in preclinical AD. Prior studies have typically modeled brain age differences with volumetric magnetic resonance imaging (MRI), but other modalities, including resting-state functional connectivity (FC) and multimodal models, have only been more recently explored. In the present study, we modeled brain age using unimodal FC and volumetric data, as well as multimodal models, to compare the models’ sensitivity to symptomatic and preclinical AD, and further, test relationships with cognitive performance.
Methods: We measured regional brain volumes and FC in 493 control participants (cognitively normal, amyloid-negative, 18-89 years old). We trained three Gaussian process regression models to predict age from (1) FC, (2) volumetric, and (3) multimodal features. We applied the trained models to separate sets of 153 older adult controls, 141 preclinical AD (cognitively normal, amyloid-positive), and 154 symptomatic AD participants to test for group differences. Preclinical AD pathology was assessed using PET (Centiloid) and CSF (amyloid β 42 [Aβ42], phosphorylated tau 181 [pTau], pTau/Aβ42 ratio). Cognition was assessed using a composite of neuropsychological tests across multiple domains.
Results: All models successfully predicted age in the control training set, with the multimodal model (mean absolute error [MAE] = 5.3 years) outperforming the FC (MAE = 8.3) and volumetric models (MAE = 6.0). In all three models, the brain age gap (BAG) was significantly elevated in symptomatic AD compared to cognitively normal controls (p’s < .003). In the FC and multimodal models, BAG was marginally reduced in preclinical AD participants with elevated pTau (p’s < .06). In symptomatic AD, lower global cognitive composite scores were associated with elevated volumetric and multimodal BAGs.
Discussion: Both FC and volumetric estimates of brain age are sensitive to symptomatic AD, consistent with previous reports. Additionally, FC-based brain age may exhibit a biphasic

response to preclinical AD pathology while volumetric brain age may be sensitive to cognitive decline in the symptomatic stage. Multimodal estimates of brain age capture each of these modality-specific relationships, and further, improve sensitivity to healthy age differences. Hence, multimodal neuroimaging models may be useful in staging early symptomatic and preclinical AD.

Abstract: Background: Cognitive-motor integration (CMI) is a type of visuomotor integration that involves concurrent thought and action and requires the interaction of large networks in the brain. Previous findings have shown that CMI performance is impaired in individuals with specific dementia risk factors (family history of dementia and presence of the APOE e4 allele) in advance of any cognitive impairments. These findings suggest that CMI impairments are associated with early dementia-related brain changes. The objectives of the current research study are to assess the relationship between grey and white matter changes and CMI performance, as well as the impacts of dementia family history, sex, and APOE status. Methods: Participants included right-handed older adults with a family history of dementia (n=25, 12 female) or no family history of dementia (n=24, 12 female). APOE genotyping was determined from salivary measures. Participants were tested on four visuomotor tasks where reach and gaze were increasingly spatially dissociated using two linked touchscreens. These included a standard condition requiring direct interaction with visual targets, and three dissociated non-standard conditions requiring CMI (visual feedback reversal, plane-change, and plane-change + feedback reversal). T1-weighted anatomical scans were used to quantify grey matter volume and thickness in brain regions important for CMI. Diffusion tensor imaging (DTI) measures of fractional anisotropy, mean diffusivity, radial diffusivity, and axial diffusivity were collected to look at white matter integrity. Results: Males had smaller left inferior parietal lobule thickness compared

to females ($F_{1,43} = 10.15$, $p < 0.01$). Our previous behavioural results demonstrated that males performed worse on the feedback reversal condition compared to females, and research has shown that the inferior parietal lobule is important for visually-guided reaching. Changes in DTI measures in several major white matter tracts were a significant predictor of poorer CMI performance only in APOE e4 carriers. The interaction effect between diffusion measures and APOE status on CMI performance were all significant at $p < 0.05$. These data support our hypothesis that disruptions in CMI performance are associated with identifiable brain alterations early in disease progression. Conclusion: The preliminary findings provide insight into the impact of AD pathology, genetics, and sex on neural networks underlying complex visuomotor transformations, and demonstrate that the CMI paradigm discussed in this study may be used as a non-invasive, easily accessible assessment tool for dementia risk.

Abstract: An ideal neuroimaging PET tracer should have high signal to noise ratio in pathologically relevant brain regions, be able to monitor progression or regression of disease in correlation with clinical findings, and have utility for guiding treatment and new drug development. Currently, no such PET imaging agent is available for neurodegenerative disorders. For Alzheimer’s disease, clinical diagnosis is frequently not well correlated to imaging findings with Amyloid beta and current tau tracers. Among the disease-specific abnormal proteins reported, abnormalities in the dynamics of microtubules have been identified as a validated biomarker for neurodegenerative disorders and its loss in Alzheimer’s disease and other neurodegenerative disorders are in correlation with neurodegeneration. At present, the blood brain barrier-penetrating PET tracer, [^{11}C]MPC-6827, which we have developed is the

only PET tracer available for in vivo imaging of microtubules in brain. The central hypothesize is that microtubule targeted PET tracer will provide a higher signal to noise ratio, compared with tau, and Amyloid beta tracers, since the presence of tau and amyloid beta proteins likely represents only a subset of microtubule associated abnormalities present in neurodegeneration. The hypothesis was tested via head-to-head comparison of [^{11}C]MPC-6827 with tau PET tracer, [^{18}F]MK-6240 in transgenic tau mouse models of hTau, PS19 and age matched controls (n=4 per group). Preclinical imaging was performed Siemens Focus 220 microPET scanner for 30-minute dynamic acquisitions with the above mentioned two PET tracers. PET image analyses showed reduced whole brain, hippocampus and prefrontal cortex uptake of [^{11}C]MPC-6827 in hTau and PS19 mouse groups, whereas, [^{18}F]MK-6240 exhibit a modest higher binding in corresponding mouse models than controls. [^{11}C]MPC-6827 has higher standardized uptake value and effect size compared to [^{18}F]MK-6240 binding in both transgenic mouse models. This pilot preclinical imaging studies show a trend of reduced binding of the microtubule targeted PET ligand, [^{11}C]MPC-6827 in whole brain and brain regions of hTau and PS19 transgenic mouse models compared to control group and is inversely correlated with [^{18}F]MK-6240 binding. This suggests a likelihood of a higher binding difference of [^{11}C]MPC-6827 than tau tracer in human Alzheimer's disease compared to control subjects. Therefore, [^{11}C]MPC-6827 can be used as a potential PET tracer for human brain imaging of Alzheimer's disease and other neurodegenerative diseases.

Title: Age-related changes in mice with a single copy insertion of human App with familial Alzheimer's disease mutations using diffusion tensor imaging

Authors: *Z. MORRISSEY[1], L. ZHAN[3], O. A. AJILORE[1], T. C. SAIDO[4], T. SAITO[5], A. LEOW[1], O. LAZAROV[2];

Computer Engin., Univ. of Pittsburgh, Pittsburgh, PA; [4]RIKEN Brain Sci. Inst., Saitama, Japan; [5]Neurocognitive Sci., Nagoya City Univ., Nagoya, Japan

Abstract: Alzheimer's disease is a progressive neurodegenerative disease. The familial form (FAD) is caused by mutations in amyloid precursor protein (APP) or presenilin-1,2. While many mouse models expressing FAD-linked mutant forms have been produced, transgenic overexpression of APP raised concerns of severe artifacts. The *App*$^{NL\text{-}G\text{-}F/NL\text{-}G\text{-}F}$ (APPKI) model has a single copy knock-in of human *App* with the Swedish, Arctic, and Beyreuther/Iberian mutations, which may offer improved clinical translation. In this study, we utilized diffusion tensor imaging in wild-type and APPKI mice in young, middle, and late age groups to observe how FAD-linked APP mutations alter white matter architecture to identify potential early biomarkers of AD. A 9.4 T Agilent MRI system was used to scan wild-type and APPKI female mice *in vivo*. A T2-weighted sequence followed by 12-direction diffusion-weighted sequence was then performed. The tensor model was fit to the diffusion-weighted data using FSL's dtifit. Atlas labels were registered to each individual's subject space. The mean fractional anisotropy (FA) was then measured in each region of interest (ROI) for each subject as a proxy of white matter integrity. A three-way mixed ANOVA was then used to model the data, using age group and genotype as between-subjects measures and brain ROIs as a repeated measure. We observed statistically significant main effect of genotype, as well as statistically significant interactions between age group and brain region and between genotype and brain region. The largest reductions in FA were observed in the hippocampus and cortex as well as the anterior commissure and the hypothalamus. Together, these results suggest that microstructural impairments take place in these specific regions in the APPKI mice. Furthermore, these changes occur between 10- and 17-months of age, which is approximately middle- to late-aged in humans, suggesting that this may represent a time window with early macroscale white matter changes that are potential targets for therapeutic investigation.

Title: Investigating temporal dynamics of vascular changes in Alzheimer's disease mouse model using optical coherence tomography

Authors: *J.-H. LEE[1], T. YANG[2], J. NIE[1], J. LEE[1];
[1]Brown Univ., Providence, RI; [2]Korea Univ., Seoul, Korea, Republic of

Abstract: Vascular dysfunction shows its high prevalence in Alzheimer's disease (AD), but much is still unknown for vascular alterations in relation to key AD pathological changes such as cognitive impairment, amyloid beta plaque accumulation, and neuronal loss. In this study, we demonstrated a label-free spectral-domain optical coherence tomography (SD-OCT) imaging to thoroughly observe temporal dynamics of vascular alterations *in vivo* using AD transgenic mouse model (3xTg-AD). We acquired OCT angiogram (OCTA) and Doppler OCT (DOCT) datasets to quantify relative changes in diameter and blood flows for pial vessels and penetrating arterioles and venules. The OCT imaging started at 11 weeks of age (WOA) then repeated every 4 weeks until the mice reach 57 WOA for mice groups. To confirm cognitive impairment, we conducted novel object location test as a behavioral test repeated every 4 weeks also. We performed Bielschowsky silver staining as post-mortem immunohistochemistry for validating amyloid burden in hippocampal and cortical region. As a result, we found the cognitive decline occurring at 40 WOA whereas the diameter change of pial vessels occurred much earlier at around 20 WOA for AD mice group. Similar to the tendency found in OCTA analysis, for DOCT, the diameter change for penetrating arterioles in AD group showed early change at around 13 WOA, whereas the change in penetrating venules seemed trivial. Interestingly, the change (from 11 to 57 WOA) in mean diameter for penetrating arterioles (3.6 μm) was about 9-fold compared to that of penetrating venules (0.4 μm) in AD group. For blood flow change, penetrating arterioles and venules both showed the decaying tendency with the rapid change occurred at early stage before 20 WOA for AD group. To determine whether vascular alteration affects cognitive function, we used 3 different drugs that are known to have vasodilating effect: one vasodilating drug, nicorandil, and one FDA-approved AD drug, memantine. These drugs were administered via drinking water starting after 15 WOA. We found no sign of cognitive decline and no significant diameter change in pial vessels from these two drug-administered mice groups, similar to that of wild-type (WT) group. For the change in diameter and blood flows for penetrating arterioles and venules, these two drug-administered groups again showed the similar tendency to that of WT group, implying that the vasodilating effect seems to be correlated with cognitive impairment. Overall, our finding supports that understanding the temporal dynamics of vascular alterations in relation to cognitive decline could serve as a basis for translational research aiming toward early diagnosis of AD.

Title: Predictive models of cognitive scores in aMCI using functional connectomics

Authors: *D. J. NOWLING, G. C. WARNER, N. BUSTOS, K. L. BARLIS, J. E. JOSEPH; Neurosci., Med. Univ. of South Carolina (MU Neurosci. Inst. - Graduate), Charleston, SC

Abstract: Alzheimer's Disease (AD) is a leading cause of cognitive decline and death. Mapping its prodromal stage amnestic Mild Cognitive Decline (aMCI) is critical to risk identification and intervention, and functional MRI (fMRI) connectomics can help identify networks important to specific cognitive domains in aMCI. Many network studies of aMCI only focus on a few or one cognitive domain at a time. To create a more complete picture of network profiles important in aMCI this exploratory study uses graph theory to build and compare predictive graph theory (GT) based models of 7 cognitive domains. 90 male and female human subject resting fMRI scans from the Alzheimer's Disease Neuroimaging Initiative with an average age of 68.18 years were used. Datasets were split into subgroups based on available cognitive score: Mini-Mental State Examination (MMSE) n = 90, Logical immediate (LIMM) and delayed (LDEL) n = 88, Trails A (TRAA) and B (TRAB) n = 72, Multilingual Naming Test (MINT) n = 52, and Rey Auditory Verbal Learning Test (RAVLT) immediate n = 51. GT measures of strength* (STR), eigenvector centrality (EVC), and clustering coefficient (CC) were calculated from time series of 276 a priori nodes. Dimension reduction involved using Principal Components Analysis (top 25 variance explaining components) or highest ranking 25 nodes for each GT measure, which were used as predictors of cognitive score in SPSS Automatic Linear Modeling (42 models were tested). The best model for each cognitive score was defined as the model that yielded at least 50% significant models across 20 cross-validations. The network profile for LIMM had auditory and post central gyrus nodes based on CC, RAVLT had postcentral sensory and posterior cingulate cortex nodes based on CC, TRAA had precuneus, middle frontal, fusiform, and paracingulate gyrus nodes based on EVC, and TRAB had posterior cingulate, entorhinal, superior parietal, frontal pole, and temporooccipital cortex nodes based on EVC. These results show that different cognitive domains in aMCI not only have different important anatomical features, but they also vary in terms of GT properties, indicating different aspects of functional organization and communication affect different cognitive domains in the same network. These preliminary findings warrant further work into developing a comprehensive map of aMCI network models to identify both interactions and differences in the network dynamics of cognitive processes disrupted during prodromal AD, as a first step toward creating clinically meaningful phenotypes.

Title: Bold fmri mean signal changes in healthy aging and dementia: a preliminary study

Authors: *M. P. MCAVOY, M. S. GOYAL, B. A. GORDON, B. M. ANCES, J. C. MORRIS, A. G. VLASSENKO, T. L. S. BENZINGER;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: BOLD resting state fMRI is enjoying great popularity with its inclusion in many large neuroimaging studies. Analyses have been largely confined to the temporal fluctuations of the BOLD time series, while the mean signal of these fluctuations has been virtually ignored. Here we show that changes in mean BOLD signal distinguished between groups of healthy aging adults, individuals with significant PET amyloid deposition and those with Alzheimer disease (AD). Cohorts included 117 cognitively normal, PET amyloid negative individuals (i.e. “normal”, age 49 - 91.3), 55 cognitively normal, PET amyloid positive individuals (i.e. “preclinical”, age 57 - 87.4) and 30 PET amyloid positive, AD symptomatic individuals (i.e. “symptomatic”, age 62 - 89). All data were collected on a 3T Siemens Biograph mMR PET-MR system and included two six minute eyes open resting state BOLD scans (TR = 2.2s). The subjects’ BOLD mean signals were input to a group ANOVA implemented via a general linear model that included age variables centered for each cohort. In an analysis of 84 Freesurfer gray matter regions, statistically significant differences between the three cohorts after Bonferroni correction ($p = 0.05/84 = 0.0006$) were found in the caudate bilaterally and right caudal anterior cingulate. These cohort effects were further decomposed with three post hoc paired comparisons: 1) normal vs preclinical, 2) normal vs symptomatic and 3) preclinical vs symptomatic, which were Bonferroni corrected ($p = 0.05/3 = 0.017$). Left caudate was found to be affected by cognitive decline and amyloid deposition, while right caudate was affected only by cognitive decline and the right caudal anterior cingulate was affected only by amyloid deposition. In an age analysis, all cohorts in all regions showed a trend for decreasing BOLD mean signal with age, however this only reached statistical significance for the normal cohort in the right caudate ($P < 0.05$). Our results suggest that the mean BOLD signal, whose source requires further

investigation though is likely in part related to oxygen metabolism, might be a valuable measure of resting physiologic changes of the brain in healthy aging and AD.

Title: Harmonizing MRI using Attention-Guided Generative Adversarial Networks improves Alzheimer's Disease Classification Performance

Authors: *S. SINHA[1], S. I. THOMOPOULOS[2], P. LAM[3], A. MUIR[3], P. M. THOMPSON[4]; [1]USC, San Jose, CA; [2]USC, Marina del Rey, CA; [3]USC, Los Angeles, CA; [4]Stevens Inst. for Neuroimaging & Informatics, Univ. of Southern California (USC), Marina Del Rey, CA

Abstract: Alzheimer's disease (AD) is characterized by irreversible memory loss and declining performance across multiple cognitive domains, and is the most common form of dementia accounting for over half of dementia cases worldwide. Magnetic resonance imaging (MRI) can be used to detect subtle and diffuse brain structural changes in AD, offering opportunities to develop deep learning methods to detect AD. However, scanners and imaging protocols differ widely, and image classification models need to be tolerant to shifts in image characteristics. Here we evaluated a new deep learning approach for domain adaptation of MRI scans from various sources to test whether this step assisted AD classification performance using a convolutional neural network model. To achieve MRI harmonization, we adapted an Attention Guided Generative Adversarial Network as defined in (Tang et al. 1) and tested it on 3 public MRI datasets: ADNI, AIBL and OASIS. The Attention-GAN architecture optimized an objective function including adversarial loss, cycle-consistency loss, pixel loss and attention loss. Following domain adaptation, we performed AD classification with a well-established 2D AlexNet CNN (Krizhevsky et al. 2) adapted to handle brain MRI. MRI harmonization improved AD classification accuracies by more than 9% (reaching 84 % accuracy) as compared to accuracies using non-harmonized images from the 3 datasets. As AIBL only included AD cases, we even tested our hypothesis using just ADNI and OASIS and observed a 2-3% increase in accuracy. The smaller increase in accuracy may reflect the lower number of OASIS subjects and a greater domain shift with ADNI dominating the dataset. To increase efficiency, we tested

optimizing the position of the axial, sagittal and coronal 2D slice subsets used for classification. MRI harmonization increased AD classification accuracy irrespective of slicing positions. Figure 1 shows an example of the MRI harmonization results.

Title: Ambulatory EEG sleep monitoring in Alzheimer disease A Pilot Study

Authors: *B. KENT[1], S. CARLUCCI[2], A. CASCIOLA[2], M. CHEN[2], P. SLACK[2], A. KAZEMI[4], M. MIRIAN[2], S. STAGER[5], J. VALERIO[2], M. MCKEOWN[2], H. FELDMAN[6], H. B. NYGAARD[3];
[1]Simon Fraser Univ., Burnaby, BC, Canada; [3]NEUROLOGY, [2]Univ. of British Columbia, Vancouver, BC, Canada; [4]Univ. of California, Davis, Davis, CA; [5]McMaster Univ., Hamilton, ON, Canada; [6]Univ. of Califrnia, San Diego, La Jolla, CA

Abstract: Sleep disturbances are common in Alzheimer’s disease (AD), with estimates of prevalence as high as 65% across AD and Mild Cognitive Impairment (MCI). A major limitation to a formal, qualitative assessment of sleep in these populations is the requirement for inpatient polysomnography (PSG), which is often not well tolerated in patients with dementia. We have recently developed a deep learning model to reliably analyze lower quality EEG data obtained from a simple, 2-lead EEG headband. This methodology allows for ambulatory assessment of sleep, with the potential for more widespread sleep staging particularly in vulnerable populations. Here we present a pilot study of ambulatory EEG sleep assessment in patients with

AD and non-demented control subjects. A total of 20 AD patient and 17 age-matched, non-demented control subjects underwent ambulatory EEG. Recording from 4 AD patients and 4 control subjects were discarded due to corrupt data. Each subject wore the headband for up to 3 nights. A deep learning model was previously developed by our group in healthy volunteers undergoing both PSG as well as headband EEG recordings. The training model contained three convolutional layers (8 filters) followed by two LSTM layers (64 units). EEG features in the following categories were extracted: a) frequency domain; b) time domain; c) higher-order statistical analysis (HOSA)-base, and (d) wavelet based. In order to increase the validity of the predictions, we generated 12 models based on a subset of the original PSG validation study. When a majority of models did not agree on a prediction, the data were discarded. AD patients exhbited less N3 sleep than control subjects. No differences were found in N2 or REM sleep stages. Actigraphy supplementing the EEG will be presented. We show that ambulatory EEG is feasible in patients with AD. Moreover, using a deep learning model, relatively low quality, 2-lead EEG headband data can stage sleep in an ambulatory setting. Similar to studies using PSG, we find that N3 sleep is reduced in patients with AD. Our findings suggest that ambulatory EEG is a promising approach for future studies addressing sleep quality in patients with dementia.

Title: Examining behavior of a double transgenic (APP/tau) mouse model of Alzheimer's disease on zinc and copper supplementation

Authors: *T. GERVASE, A. BOOTH, S. NEFF, R. HOYOS JUSTINIANO, M. S. LAMARCHE, L. E. ALLEN, J. M. FLINN;
George Mason Univ., Fairfax, VA

Abstract: Alzheimer’s Disease (AD) is an extremely prevalent neurocognitive disorder influencing both brain and behavior. AD is neurologically characterized by two major components; amyloid plaques and neurofibrillary tangles. Although many mouse models contain only one of these components, our lab recently developed a dual transgenic (Tg) mouse which contains both amyloid and tau via a J20 (hAPP) and P301L (Tau) cross. As this mouse model does not contain mutations on the Presenlin-1 (PS1), one of the most common causes of early-onset AD, this mouse models late-onset AD. Additionally, prior research in our lab indicated an

improper balance of biological metals such as Zinc (Zn) may exacerbate AD-pathology and behavioral deficits. However, as Zn has been shown to decrease Copper (Cu) levels it is unclear whether these deficits were due to an excess of Zn or an induced copper deficiency. To assess this WT (n=42) and Tg (n=40) mice were given either lab water (n=27), water supplemented with 10 ppm Zn (n=27), or water supplemented with 10 ppm Zn and 2.5 ppm Cu (n=28). Hippocampal damage is one of the first regions affected by AD and is known to play a large role in spatial memory. Previous research in our lab used the Barnes Maze to assess spatial memory deficits, however, in our current study we examined spatial memory via the Morris Water Maze (MWM) to further examine this mouse model. Mice were tested at 3.5 months of age with latency to find the platform being assessed. Using ANOVA our findings indicated that Tg mice showed significant spatial memory impairments compared to WT mice, ($p < .001$). Although there were no differences between groups based on metal supplementation this matches previous data in our lab which did not find differences at 4 months possible because the genotype effects were so strong. Results will be reanalyzed at 7-months of age including circadian activity, burrowing, and nesting. Additionally, brains will be analyzed using Western Blots for proteins of interest. Our findings provide additional evidence that this new Tg mouse is able to properly model the behavioral deficits seen in late-onset AD without PS1.

Title: Naturalistic risky decision-making in a mouse model of Alzheimer's disease

Authors: B. SCHUESSLER[1], N. KIM[2,3], J.-H. JANG[5], J. KIM[1,4], *E. KIM[1];
[1]Psychology, [2]Hlth. Systems and Population Hlth., Univ. of Washington, Seattle, WA; [3]Computing and Software Systems, Univ. of Washington, Bothell, WA; [4]Program in Neurosci., Univ. of Washington, Seattle, WA; [5]Pharmacology, Sch. of Med., Keimyung Univ., Daegu, Korea, Republic of

Abstract: While considerable Alzheimer’s disease (AD) research has focused on destructive loss of memory, much less is known about the impact of AD on other cognitive functions, such as

risky decision-making which plays pervasive roles in daily life. Here, we examined whether the ability to discern safety-danger boundaries and make optimal foraging decisions was altered in a mouse model of AD. Five familial AD (5XFAD) transgenic mice (4-8 mos old, both sexes) that overexpress amyloid precursor protein and presenilin 1 were tested in a naturalistic 'approach food-avoid predator' paradigm (Choi & Kim, 2010). Animals underwent nest habituation, baseline foraging, and predator testing. During the test trials, as the mouse approached a food pellet, placed 38.1, 25.4, and 12.7 cm from the nest, a taxidermied weasel on wheels was automatically activated to surge 30 cm distance (60 cm/s). Mice were given 3 min to procure the pellet (one trial each distance) per daily session. There were no reliable differences across sex and age groups, and thus mice were pooled in each genotype. In response to the surging weasel, both wildtype (WT) and 5XFAD mice promptly fled into the nest, and the latency to procure pellets located at 38.1 cm increased significantly. However, 5XFAD animals' latency to procure pellets placed at 25.4 cm did not differ from the baseline foraging latency, suggesting precarious decisions. Given that animals naturally switch their foraging strategies from high predator to low predator density area (Stephens et al., 2007), we then tested whether 5XFAD mice were able to adjust their foraging in 'conditional threat' situations. To do so, grain-based and chocolate-flavored pellets were placed in separate arms of a T-shaped maze. After mice have freely chosen their preferred and non-preferred pellets, on the test trials, every time the animal near the preferred pellet, the predator surged forward. While the WTs appropriately switched their choice from the preferred to non-preferred pellets, the 5XFADs continued to choose their preferred pellets, indicating impairment in adjusting their foraging behavior. Lastly, when animals were subjected to contextual fear conditioning to assess fear responses to physical pain, both WTs and 5XFADs exhibited comparable postshock freezing and contextual freezing the next day. In 5XFAD (but not WT) animals, high levels of amyloid β deposition were found in the prelimbic cortex, hippocampal CA1, and amygdala, regions implicated in risky decision-making in humans and rodents. These results suggest that risky decision-making is impaired in AD mice and may be a more sensitive behavioral phenotype of AD than conditioned fear responses.

Title: Impaired cognitive function and reduced nicotine intake in male TgF344-AD rats

Authors: *Z. DING[1], X. TAN[1], B. T. LAMB[2], A. OBLAK[3];
[1]Pennsylvania State Univ. Col. of Med., Hershey, PA; [2]Stark Neurosciences Res. Inst., Indianapolis, IN; [3]STARK Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Background: Alzheimer's disease (AD) is associated with various neuropsychiatric symptoms, including motor disturbance and cognitive dysfunction. Tobacco smoking is a risk factor to the development of AD. Nicotine is the major addictive component of tobacco and has been shown to improve cognitive function. We hypothesize that AD rats would consume more nicotine than control rats due to the cognition-enhancing effects of nicotine serving as a self-medication mechanism, which may exacerbate the negative impact of tobacco smoking on AD. **Method:** Male TgF344-AD rats and wild-type (WT) F344 rats (n=15-18/genotype, starting ~ 6 months) were assessed for basal locomotor activity (LMA) in an open field test followed by spatial learning and memory function in a radial arm maze (RAM) test reinforced by a piece of Froot Loops at the distal end of each arm. Three primary parameters were assayed: (1) entries-to-repeat (ETR) defined as the total number of arm entries before making an error by repeating an arm entry, (2) session time defined as either the maximum of 300 seconds or time during which rats finish entry to all arms, whichever comes first, and (3) Froot Loops consumed. Following the RAM test, rats were trained for operant intravenous self-administration (IVSA) of nicotine (0.03 mg base/kg/infusion). **Results:** AD and WT rats did not differ in ambulatory distance travelled across sessions (p = 0.28). Compared to AD rats, WT rats achieved significantly greater numbers of ETR (p = 0.000, 4.3 vs 2.1/session), completed sessions significantly faster (p = 0.000, 251 vs 290 s/session), and consumed significantly more Froot Loops (p = 0.001, 4.2 vs 1.6/session). Data from IVSA revealed significant effect of session x genotype interaction (p = 0.026), with significantly more infusions in WT rats than AD rats toward the last week of IVSA (p = 0.024, 8.5 vs 1.4 infusions/session). **Conclusions:** Our data indicate that TgF344-AD rats display normal basal LMA and impaired spatial learning and memory function, but didn't consume more nicotine than WT rats. These results suggest the hypothesized cognition-enhancing effects of nicotine may not serve as a self-medication mechanism to increase nicotine intake in AD rats.

Title: Oral senolytic treatment improves cognition and metabolism female APP $^{NL-F}$ knock-in Alzheimer's disease mice

Authors: *Y. FANG, D. MEDINA, R. STOCKWELL, S. MCFADDEN, K. QUINN, M. PECK, L. ALEWELT, A. BARTKE, K. HASCUP, E. HASCUP;
Southern Illinois Univ., springfield, IL

Abstract: Cellular senescence is characterized by an irreversible cell-cycle arrest accompanied by distinctive secretory phenotypes. Senescent cells accumulate in numerous tissues and organs, and contribute to functional alterations associated with aging and neurodegenerative diseases including Alzheimer's disease (AD). A causal link has been shown between the accumulation of senescent cells and cognition-associated neuronal loss. Deletion of senescent cells genetically or pharmacologically with senolytic drugs in the mouse brain led to functional improvements in AD models. However, it is unclear if the stage of disease progression at intervention or sex play a role in treatment response. Here, we examine the effects of early and prolonged senolytic drug treatments in the APP^{NL-F} knock-in mouse model of AD. Male and female APP^{NL-F} knock-in mice were orally administered Fisetin (100 mg/kg BW), Dasatinib (5 mg/kg BW) plus Quercetin (50 mg/kg BW; D+Q), or vehicle control starting at 4 months of age. The treatments were carried out once/month for 8 months. At the end of treatment, all mice underwent glucose tolerance test (GTT) and insulin tolerance test (ITT) to examine glucose metabolism, indirect calorimetry to determine energy metabolism, and the Morris water maze (MWM) to ascertain cognitive abilities. The results revealed that senolytic treatments did not alter glucose metabolism in APP^{NL-F} knock-in mice (GTT and ITT). Senolytic treatment altered the energy metabolism in a sexually dimorphic manner whereby D+Q treatment increased oxygen consumption (VO2) and energy expenditure (EE) in female APP^{NL-F} knock-in mice accompanied with significant reduction of abdominal adipose tissues, while Fisetin decreased respiratory quotient (RQ) in male APP^{NL-F} knock-in mice. Importantly, D+Q treatments in female APP^{NL-F} knock-in mice led to improved long-term memory retrieval (MWM). Together, these data support improved spatial learning and memory in D+Q treated female APP^{NL-F} knock-in mice accompanied with the enhanced peripheral energy metabolism and decreased abdominal adiposity.

Title: Females have it worse: In mouse models of Alzheimer's disease and mixed dementia females are more severely affected by a high fat diet than males

Authors: *O. J. GANNON[1], L. S. ROBISON[2], C. ABI-GHANEM[1], F. M. MANSOUR[1], A. E. SALINERO[1], R. BRAWLEY[3], A. TYAGI[1], K. L. ZULOAGA[1];

Abstract: Diabetes and prediabetes are major risk factors for all-cause dementia. 1 in 10 people in the United States currently have diabetes- a figure that is on the rise. Prediabetes is even more common, affecting roughly 1 in 3 in the U.S. who are frequently unaware of this diagnosis. There is much to learn about how prediabetes can contribute to dementia decades later and examining this relationship may unveil new targets or emphasize prediabetes as a risk factor. Here we examine the impact of prediabetes on two of the most common types of dementia: Alzheimer’s disease (AD) and mixed dementia (MxD) which is the overlap between AD and vascular pathology. Furthermore, given that there are sex differences in both the prevalence and presentation of dementia types, we ask if prediabetes influences males and females differently. There is evidence to suggest the heightened severity of diabetes as a dementia risk factor for women: women with diabetes have a 19% greater risk of vascular dementia than men with diabetes. We hypothesize that female mice will face a greater degree of pathology in response to prediabetes modeled by a high fat diet and that this will exacerbate AD and vascular pathology in mouse models of AD and MxD. Using male and female B6129SF2/J mice as wild type (WT) controls, we modeled AD using the 3xTg-AD mouse model of Alzheimer’s disease and MxD by performing a unilateral common carotid artery occlusion surgery to produce chronic cerebral hypoperfusion. To model prediabetes, we administered a high fat diet (60% fat). Control mice received a control diet (10% fat). We found that high fat diet led to greater metabolic effects in females (increased weight gain and glucose intolerance) and that this was exacerbated by 3xTg-AD genotype in females only. We measured classical features of AD pathology: astrogliosis and beta-amyloid burden using IHC and tau pathology using western blot. We have found that females had greater levels of hippocampal astrogliosis and cortical beta-amyloid positive cells than males with no effect of diet. However, MxD trended toward increasing amyloid pathology only in high fat fed females ($p=0.06$). In sum, our findings demonstrate increased sensitivity of females to the negative metabolic effects of high fat diet and the pathological effects of AD and MxD.

Title: Effects of unpredictable stress on cognitive function and amyloid-beta in C57BL6/J mice

Authors: *K. BRICE[1], P. BRADEN[2], M. J. CHUMLEY[3], G. W. BOEHM[4];
[1]Texas Christian Univ., Bossier City, LA; [2]Psychology, [3]Biol., [4]Texas Christian Univ., Fort Worth, TX

Abstract: Alzheimer's disease (AD) is a progressive form of dementia marked by severe cognitive decline and memory loss for which there is no cure. Around 6.2 million people in the U.S. suffer from this devastating neurodegenerative disease, and these numbers continue to increase. For most AD cases, the causes underlying the development of the disease are not well understood. Evidence suggests that lifestyle-related environmental factors may be partially to blame, including significant chronic stress. Unfortunately, over two-thirds of U.S. adults report regularly experiencing stress that negatively impacts their mental and physical health, with unusual increases in stress occurring during the year 2020. Previous research has shown that individuals with mild cognitive impairment (MCI) who underwent chronic stress were more likely to develop AD compared to those with MCI who did not experience chronic stress. Furthermore, amyloid-beta, a protein that aggregates abnormally to create plaques that disrupt neural communication in AD, is elevated following extended activation of the HPA axis. Moreover, inflammatory processes that have been implicated in the initiation and progression of AD, occur in response to increased glucocorticoids in the brain. To further explore these relationships, the present study investigated the interaction between unpredictable stress, inflammation, and AD-like pathology in non-transgenic C57BL/6 mice. Previous work in our lab has shown that mice administered seven consecutive days of LPS, a bacterial mimetic, exhibit cognitive impairment and increased proinflammatory cytokines and amyloid-beta in the brain. In Experiment 1, adult C57BL/6 mice underwent 7 days of unpredictable stress, after which contextual fear learning and extinction learning were assessed. In Experiment 2, adult C57BL/6 mice underwent 21 days of unpredictable stressors and received LPS injections during the final 7 days of the stress paradigm. Following the final day of stress and injections, mice underwent contextual fear conditioning to assess cognitive function, and hippocampal amyloid-beta was quantified. Although, in the current studies, LPS administration had no effect on amyloid-beta or cognition, both 7 days and 21 days of unpredictable stress were associated with learning impairments in contextual fear conditioning. Furthermore, 21 days of chronic unpredictable

stress led to a slight increase in hippocampal amyloid-beta. Given the large percentage of U.S. adults who report experiencing chronic stress and the continued increase in AD prevalence, understanding the link between significant psychological stress and AD is imperative.

Title: Quantifying effects of amyloid beta reduction with BACE inhibitors in Alzheimer’s mice

Authors: *A. SINGH[1], M. MAKER[1], C. S. MITCHELL[2];
[2]Biomed. Engin., [1]Georgia Inst. of Technol., Atlanta, GA

Abstract: Beta-secretase (BACE) is an enzyme that cleaves the amyloid precursor protein (APP). In recent years, BACE inhibiting drugs have become the focus of much research into the development of treatments for Alzheimer’s Disease (AD) with the intent that inhibiting the cleavage of APP will prevent the formation of amyloid-beta plaques and, consequently, cognitive decline. In the past, several BACE1 inhibitors have been developed; however, evidence for positive effects in both animals and humans has been minimal. This study focuses on quantifying the level of BACE and amyloid-beta level reductions necessary to significantly improve cognition in transgenic AD mice as measured via Morris Water Mouse (MWM). In order to observe the effects of BACE inhibitors on the production of amyloid-beta and the cognitive effects it had on mice, a meta-analysis was performed using a database of over 3,000 Alzheimer’s mouse model peer-reviewed articles. Using the keywords “Alzheimer’s disease, amyloid-beta, beta-secretase, and Morris Water Maze”, 23 acceptable peer-reviewed studies were found. Escape latency of Morris Water Maze, both the insoluble and soluble 40/42 amyloid-beta levels, and the BACE levels were extracted from each study and included for analysis. An unsupervised machine learning analysis was performed on the data using principal component analysis followed by k-means clustering method to identify separable clusters based primarily on amyloid-beta 40 and 42 levels. When comparing amyloid-beta 42 to escape latency, clustering showed a 25 percent decrease in amyloid-beta led to a 10 percent decrease in escape latency in AD mice, while a 40 percent decrease in amyloid-beta led to a 20 percent decrease in

escape latency. For reference, wild-type (WT) mice have an escape latency 25 percent less than the AD model. Chi-square statistical analysis confirmed a significant difference in cognition in transgenic AD mice groups based on three different levels of amyloid-beta reduction using BACE inhibitors. Results demonstrate that amyloid-beta needs to be greatly reduced, by about 40 percent, in order to achieve WT levels of cognition. These findings conclude BACE inhibitors could have a significant effect on the cognitive decline of patients with either familial or sporadic AD but require a tremendous amount of amyloid-beta reduction to achieve it. Thus, it is likely that BACE inhibitor treatment in humans would need to start pre-onset by identifying patients with predictive biomarkers well before there are functional symptoms of AD.

Title: Spatial memory deficits are observed across the lifespan of TgF344-AD rats, a transgenic rat model of Alzheimer’s disease

Authors: *M. M. OH[1], C. HICHERI[1], A. S. BUELL[1], C. LIN[1], C. SPAENI[1], N. VILCEK[1], D. NICHOLSON[2], C. GEULA[3], J. F. DISTERHOFT[1];
[1]Physiol., Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL; [2]Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL; [3]Mesulam Cogn Neurol & Alzhei Dis Cent, Northwestern Univ. Med. Sch., Chicago, IL

Abstract: TgF344-AD is a transgenic rat model of Alzheimer’s disease (AD) that has been designed to express the human amyloid precursor protein harboring the Swedish mutation (*APP_{SW}*) and human presenilin 1 with the αE9 mutation (*PS1αE9*) on the Fischer 344 rat background, which leads to aging-related AD pathology: e.g., increased amyloid plaques, hyperphosphorylated tau and cell loss at old age as compared to young adults (PMID:23575824). The initial study also showed that the middle-aged (15 month old: mo) TgF344-AD rats were impaired in spatial learning on the Barnes dry/land version of the water maze task, as compared to their wild-type littermates (WT). No difference in learning rate was reported between the young adult (6mo) TgF344-AD and WT rats, and only a deficit on the last day of training was reported in the aged (24mo) TgF344-AD rats as compared to the aged WT rats. A number of other reports has tested the learning ability of young adult and middle-aged TgF344-AD rats on

the spatial water maze task and have found altered search strategies without deficits on the location of the hidden-platform, but impairments on reversal learning. Given the potential impact of age-related AD pathology in TgF344-AD rats on learning, we examined their performance on the spatial water maze task in a cross-sectional study: in young adult (6-8mo), middle-aged (12-14mo) and aged (18-22mo) rats. We did not observe sex (male, M; female, F) differences on the water maze task, similar to previous reports using TgF344-AD rats. Compared to young adult WT rats (9F, 14M), we found that 13/28 (46%) young adult (11F, 17M), 10/33 (30%) middle-aged (11F, 22M) and 61/79 (77%) aged (45F, 34M) TgF344-AD rats were impaired on the water maze task, while 4/8 (50%) middle-aged (2F, 6M) and 45/77 (58%) aged (44F, 33M) WT rats were impaired. We have also trained a subset of aged TgF344-AD and WT rats on the trace eyeblink conditioning task and found that 12/40 (30%) WT and 49/76 (64%) TgF344-AD rats were unable to learn this task. Additional trace eyeblink conditioning will be conducted using young adult and middle-aged rats. These are the first comprehensive cross-sectional experiments that show increasing proportion of transgenic rat population that display learning deficits in young adult rats that increase as they age. We hypothesize that the aging-related learning deficits are correlated with increasing AD pathology in these TgF344-AD rats. Immunohistochemical experiments examining amyloid plaques, hyperphosphorylated tau, and cell loss are ongoing to test our hypothesis.

Title: Inflammatory Biomarkers in Progressive Alzheimer's Disease

Authors: *K. CALVIN[1], L. CREW[1], A. PLATT[1], E. FLORES[1], R. A. WIRT[2], J. M. HYMAN[3]; [1]Univ. of Nevada, Las Vegas, Las Vegas, NV; [3]Psychology, [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: One of the core features of Alzheimer’s disease (AD) is neuroinflammation, which is driven by the chronic activation of neuroimmune defense cells. Epidemiology and biological research have shown a strong link between neuroinflammation and cognitive decline. Currently there is little known about biological markers for cellular and molecular alterations of inflammation that occur in early disease stages of AD. The present study is a preliminary

glimpse into potential neuroinflammatory biomarkers for early detection that may lead to clinical intervention.
This data was collected from participants at the Center for Neurodegeneration and Translational Neuroscience (CNTN) who are enrolled in a longitudinal, natural history study of neurodegeneration and cognitive function. We reviewed correlations between blood levels of several biomarkers of neuroinflammation; including interleukin-4 (IL-4), interleukin-9 (IL-9), interleukin-15 (IL-15) lymphotoxin-alpha (LT-α), macrophage migration inhibitory factor (MIF), and Chemokine (C-C motif) ligands 4 (CCL4), with amyloid plaque positivity as determined by PET scan. Biomarker levels were assessed via Luminex multiplex assay in participants' first year of data collection. We also reviewed correlations between these biomarkers and a Polygenic Risk Score (PRS) derived from a number of AD risk alleles. Lastly, we determined if there was any variation between participants whose diagnosis remained stable and those whose diagnoses progressed. Participants in this analysis included cognitively normal controls (CNC) as well as those with diagnoses of Mild Cognitive Impairment (MCI), and both mild and moderate AD.Using a one-way ANOVA, we found a significant increase in biomarkers IL-4, IL-9, IL-15, LT-α, MIF, and CCL4 in participants with progressive cognitive impairment diagnoses. Interestingly, when correlated with PRS and amyloid plaque positivity as determined by PET scan, we found a positive correlation in biomarkers IL-9, LT-α, and CCL4.
More analysis is needed; however, given that neuroinflammation has been shown to indicate fast progression of cognitive impairments in AD patients, these preliminary results may be a glimpse into the early detection of AD and intervention. LT-α, IL-9 and CCL4 are important immune regulators, and we found correlations with each of these biomarkers and PRS and amyloid status, as well as an increase in levels in participants with progressive cognitive decline diagnoses. Biomarker levels were tested during participants' first year of study participation, indicating that these correlations could be potential early markers that appear prior to disease progression.

Title: Neuroimaging biomarkers in aging: testing the independence of white matter hyperintensity volume, dopamine synthesis, and Alzheimer's disease-related pathology

Authors: *J. EPSTEIN[1], C. J. CIAMPA[2], J. H. PARENT[2], V. R. TENANT[4], V. D. SHAH[4], T. M. HARRISON[4], W. J. JAGUST[5], A. S. BERRY[3];

[1]Brandeis Univ., Waltham, MA; [2]Brandeis, Waltham, MA; [3]Brandeis, Berkeley, MA; [5]Helen Wills Neurosci Inst., [4]UC Berkeley, Berkeley, CA

Abstract: Identifying neuroimaging biomarkers associated with cognitive decline, as well as identifying potential interactions between biomarkers, is critical for advancing treatment of the growing aging population. Previous research from Rieckmann and colleagues identified associations between white matter hyperintensity (WMH) volume and multiple dopamine PET measures (transporter availability, D1 receptor availability), but found no relationship between WMH volume and Alzheimer's disease (AD)-related β-amyloid pathology in cognitively normal older adults (Rieckmann et al., 2016). We replicated these analyses in a sample of cognitively normal older adults (n=47, average age=77) using the dopamine PET tracer 6-[^{18}F]fluoro-L-*m*-tyrosine ([^{18}F]FMT) to measure dopamine synthesis capacity, [^{11}C]Pittsburgh compound B ([^{11}C]PiB) to measure β-amyloid, and 3T fluid-attenuated recovery inversion (FLAIR) magnetic resonance imaging to measure WMH volume. Further, we probed relationships with AD-related tau pathology using [^{18}F]Flortaucipir PET, and cognition using a composite measure of processing speed (Trails A Test, Stroop neutral condition, and the Digit Symbol test). We did not find a relationship between WMH volume and the [^{18}F]FMT net tracer influx (Ki) measure of striatal dopamine synthesis capacity (beta = .063, p= .714). However, for a model including entorhinal cortex [^{18}F]Flortaucipir standardized uptake value ratio (SUVR), we observed a significant interaction between WMH volume and EC [^{18}F]Flortaucipir SUVR in predicting striatal [^{18}F]FMT Ki ($beta_{interaction\ term}$ = .517, p= .048). Greater WMH volume was associated with higher striatal [^{18}F]FMT Ki for those participants with greater tau burden. The positive association between [^{18}F]FMT Ki and WMH is consistent with our previous findings suggesting elevated dopamine synthesis is a compensatory mechanism in aging. We found no overall association between WMH and EC [^{18}F]Flortaucipir SUVR (r=-.047, p=.789) nor WMH and [^{11}C]PiB status (r=-.046, p=.789). Consistent with reports linking WMH and processing speed performance, we found greater WMH volume was associated with reduced processing speed (beta=-.421, p=.019). There was an additive effect of EC [^{18}F]Flortaucipir SUVR (WMH beta=-.436, p=.015; tau beta= -.343, p=.050) revealing white matter integrity and tau burden as critical measures of interest in understanding the neurobiological mechanisms underlying individual differences processing speed in cognitively normal older adults.

Title: Quantitation of neuronal proteins Nf-L, t-Tau, pTau181, and inflammatory cytokines IL-6, IL-10, TNFa in Alzheimer's disease plasma

Authors: *A. CHENNA, J. W. WINSLOW, C. J. PETROPOULOS;
Monogram Biosci. Inc/Labcorp, CA, CA

Abstract: There are more than 6 million Americans who have Alzheimer's disease (AD), currently ranked as the sixth leading cause of death in the U.S. Changes in blood levels of neuronal proteins (NF-L, t-Tau, p-Tau181) and inflammatory cytokines (IL-6, IL-10, TNFα) are associated with brain cellular damage, and are actively being explored as as possible prognostic/diagnostic biomarkers of AD. The low blood concentrations of several of these proteins require application of a sensitive and reproducible assay technology, therefore, single molecular array (Simoa) immunoassays were used to measure protein levels. In this study, we have characterized the protein markers NF-L, t-Tau, pTau181, IL-6, IL-10, and TNFα in human AD plasma (n=72) and healthy human control plasma (n=64). AD plasma sample groups consisted of mild (n=8, MMSE > 23-30), moderate (n=24, MMSE 16-22) and severe (n=40, MMSE <16) cognitively impaired AD. Concentrations (pg/mL) were determined with machine dilutions 4x for all plasma samples. Data analysis measuring differences of each of the plasma proteins within control and AD patient subgroups, was performed together (Krustal-Wallis) or pairwise (Mann-Whitney). For NF-L, t-Tau, p-Tau181, IL-6, IL-10, and TNFα, there is a significant increase in median levels of all proteins in the combined AD group (n= 72; $p < 0.0001$), relative to controls (n= 64). The levels of all biomarkers are elevated in the moderate and severe AD patient subgroups ($p < 0.0001$). Similar results were observed in a comparison of moderate AD samples (n=24; ave age = 75.6) with an age-matched subset of control samples (n= 30; ave age = 72.1) ($p \leq 0.0004$). There was no significant difference between all 6 protein levels in plasma samples from mild AD patients compared to control samples, however, the sample size is small (n= 8). The plasma neurodegenerative biomarkers NF-L, p-Tau181, and t-Tau were significantly correlated to each other in the AD group (Spearman $r = 0.5\text{-}0.7$, $p < 0.0001$) as were the three cytokines (IL-6, IL-10, TNFα: $r = 0.5\text{-}0.7$; $p<0.0001$). Cross-correlation between neurodegenerative proteins and cytokines indicated the strongest correlation between NF-L and t-Tau and the three cytokines ($r = 0.5\text{-}0.66$, $p<0.0001$), whereas correlations between p-Tau181 and cytokines were either weaker (IL-10, TNFa $r = 0.37\text{-}0.41$; $p = 0.0015$; 0.0004) or not significant (p-Tau181 vs IL-6; $r = 0.155$; $p = 0.197$). In summary, moderate and severe AD plasma samples were significantly elevated in levels of NF-L, t-Tau, p-Tau181, IL-6, IL-10, and TNFα. A combination of plasma neuronal neurodegenerative and inflammatory cytokine biomarkers may effectively identify AD patients.

Title: Perturbed cerebral glucose uptake and glymphatic system in a mouse model of Huntington's Disease

Authors: *H. LIU[1], L. CHEN[2], C. ZHANG[3], L. CHENG[4], J.-L. DONG[4], J. HUA[2], C. A. ROSS[6], P. ZIJL[2], J. XU[2], W. DUAN[5];

Institute, Baltimore, Baltimore, MD; [3]Johns Hopkins Univ. school of medicine, Baltimore, MD; [5]Dept Psychiatry, [4]Johns Hopkins Univ., Baltimore, MD; [6]Div. of Neurobio., Johns Hopkins Med. Sch., Baltimore, MD

Abstract: The clinical diagnosis of Huntington's disease (HD) is currently based on the presence of movement disorders. However, subtle-to-prominent brain functional changes can precede by many years the motor-based onset of HD. Given the availability of predictive genetic testing, it is possible to identify HD subjects before motor symptoms are present. This provides a unique opportunity to identify potential early biomarkers to be used for evaluating the disease-modifying therapies. Glucose Chemical Exchange Saturation Transfer (glucoCEST) MRI is a newly developed technique that can detect unlabeled glucose at physiologically relevant concentrations using proton-only MRI scanners. Our recently improved MRI sequence, on-resonance variable delay multiple pulse (onVDMP), allows the detection of low concentration glucose through the chemical exchange of protons between hydroxyl groups and has the capacity to measure glucose clearance from the cerebrospinal fluid (CSF). In this study, we applied onVDMP MRI to measure glucose uptake in the brain and its clearance from the CSF after intravenous injection of D-glucose in the zQ175 HD mouse model. By comparing the DGE curves and maps, the glucose uptake in the striatum of HD mice (4.4 ± 1.35 %) was significantly reduced comparede to the age and gender-matched control mice (7.16 ± 1.36 %, p =0.012), suggesting the presence of an impaired glucose transporter at the blood-brain and blood-CSF barriers of zQ175 mice. . Interestingly, a significantly slower glucose clearance from CSF was found in the CSF of zQ175 HD mice compared to the age and gender-matched controls by examining the CSF DGE signal at 30 min with respect to the signal at 10 min (DGE[30min - 10min]=2.96± 1.7% for HD vs -1.7± 1.7% for WT, $p<0.05$)., suggesting the presence of an impaired glucose transporter at the blood-brain and blood-CSF barriers of zQ175 mice. Further mechanistic molecular study confirmed indicated decreased levels of astrocyte water channel aquaporin-4 (AQP4, ~ 40% reduction in HD mice) in the striatum of zQ175 mice. These results suggest imply that a dysfunctional glymphatic system are evident in the zQ175 HD mouse

modelmice. and onVDMP MRI measures have the potential to be further developed as valuable biomarkers to monitor disease progressionfor HD and evaluate potential treatment for HD.

Title: Utilizing RabMAb®Tau antibodies for targeting different PTM sites aiding the identification of AD subjects

Authors: *M. DROESCHER[1], I. WOLLENBERG[2], J. BERNHARD[1], H. WIELAND[1], A. KARPATI[2], S. BARGHORN[1];
[1]AbbVie Deutschland GmbH & Co. KG, Ludwigshafen, Germany; [2]Abcam plc, Cambridge, United Kingdom

Abstract: Background The current clinical screening methodology for Alzheimer's disease is resource-intensive and results in a high screening failure rate identifying genuine AD-subjects. Although the acquisition is considered an invasive procedure, for cerebrospinal fluid several well validated technologies are available. However, the desired analysis of non-invasively acquired blood samples for informative biomarkers, still poses a great challenge. **Objectives**Cross-characterization of multiple pTau biomarker assays to identify potential to aid robust identification of patients with underlying AD pathology aiming not only for resolution of CSF but also of plasma matrices.**Methods**Novel assays were developed using rabbit monoclonal capture antibodies with high binding affinities. Next to a discovery cohort encompassing soluble brain extracts, CSF and plasma from different donors serving the direct comparison, a Phase 0 AD cohort with matching CSF and plasma samples was used to compare the performance of pTau181, pTau217 and pTau231.**Results**In the CSF matrix, the pTau assay data show a very strong positive correlation with each other (Spearman R's of >0.90). Interestingly, also the very C-terminal pTau396 data correlated well with the described modifications of pTau181 and pTau231. However, in the plasma matrix strong correlations were observed only for some distinct pTau pairings. Notably, the modifications in the MTBR and C-terminal region, pTau262/263 and pTau396, showed a
reduced correlation with other pTau assays. Overall, we describe 8 PTM site-specific assays resolving the CSF and plasma matrix. While in CSF all assays achieve the discrimination of AD to Control subjects, in plasma only 5 assays accomplished this. In a more powered cohort with matching CSF and plasma, pTau231 was identified as the most robust assay. pTau231 not only

achieved significant differentiation of the AD and Control groups (both $p<0.001$). A remarkable performance of AUC = 0.87 was also reached for predicting Amyloid-PET positivity and differentiating MCI-Aß$^{+}$ and MCI-Aß$^{-}$ groups ($p=0.002$).**Conclusion**Blood-based pTau biomarkers have great potential to aid the diagnosis of patients with underlying AD pathology, to simplify both clinical and pre-clinical study designs, reduce patient burden, as well as enabling the continuous monitoring of the effect of potential therapeutic drug candidates.**Disclosures**MD, JB, HW, and SB are employees of AbbVie. Title: Higher tau deposition in the dorsal attention network is associated with visual attention deficits in posterior cortical atrophy

Authors: *Y. KATSUMI, D. PUTCHA, R. ECKBO, B. WONG, M. QUIMBY, S. MCGINNIS, A. TOUROUTOGLOU, B. C. DICKERSON;
Harvard Med. Sch. and Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Localization of tau pathology, as measured with 18F-flortaucipir (FTP) PET imaging, is highly relevant for characterizing clinical phenotypes of Alzheimer's disease, including posterior cortical atrophy (PCA). The spatial topography of covariance in tau accumulation across Alzheimer's disease patients resembles the topography of intrinsic functional connectivity in healthy young adults, suggesting that tau pathology spreads though functional networks in the cerebral cortex. The present study investigated the degree to which the cortical distribution of elevated FTP uptake varies across individual patients with PCA, with the goal of identifying functional networks of heightened vulnerability to tau pathology in this population. Seventeen patients with PCA and 22 amyloid negative older healthy control subjects underwent MRI and FTP PET scans. Individual FTP standardized uptake value ratio maps were computed and projected to template cortical surface space, which were converted to W-score maps to identify cortical areas with elevated FTP uptake. Percent overlap maps were created based on the binarized individual W-score maps. A parcellation of the cerebral cortex into seven intrinsic functional networks was used to characterize the spatial topography of elevated FTP uptake. At the overall group level, PCA patients showed prominent FTP uptake in widespread areas of the cerebral cortex including bilateral frontal eye fields, superior parietal lobule, and area MT, which are key nodes of the dorsal attention network (DAN). An examination of the consistency of elevated FTP uptake across each individual PCA patient showed that the visual network and DAN were most consistently affected, with 100% of the patients showing elevated uptake in at least some parts of the two networks. Impaired visual attention was associated with elevated FTP uptake specifically in the anterior DAN (bilateral frontal eye fields). The ratio of elevated FTP uptake between the anterior vs. posterior DAN nodes was the strongest correlate of visual attentional impairment, suggesting that PCA patients who had more advanced tau spread from posterior to anterior nodes within the DAN showed greater impairment in visual cognition. These results support the hypothesis that tau pathology in PCA universally affects the key nodes of the DAN consistent with the visual attention deficits commonly observed in PCA, including oculomotor apraxia (impaired voluntary control of eye movements). Although cross-sectional, these data provide strong support for the hypothesis that tau deposition in PCA begins posteriorly and that visual cognition declines as it propagates within the DAN.

Title: Chronic circadian disruption in an AβPP/PS1 and $APP^{NL\text{-}F/NL\text{-}F}$ model of Alzheimer's disease

Authors: *J. BRITZ[1], E. R. HASCUP[2], K. N. HASCUP[2], E. OJO[2], S. TISCHKAU[2];
[1]SIU Med., Divernon, IL; [2]Neurology, Neurosci. Institute, Ctr. for Alzheimer's Dis., Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: The circadian system uses environmental cues to coordinate the plethora of physiological functions that occur with diurnal rhythmicity, with light being one of the strongest regulators of the circadian system. The suprachiasmatic nucleus (SCN) is positioned at the top of the circadian hierarchy, receiving photic input from the retina and using neuronal, humoral and endocrine signals to synchronize oscillatory patterns across virtually all organ systems. Though the circadian system is plastic to deviations from a normal light/dark (LD) cycle, there are biological limits as to the rate and degree to which the SCN can adapt to these deviations. Recent evidence suggests that circadian disruptions may precede noticeable cognitive deficits associated with AD. Our study aims to determine whether inducible circadian disruption via exposure to our social jetlag protocol, taking advantage of manipulating light exposure to disrupt the circadian system, can exacerbate the rate and severity of AD pathology in both the AβPP/PS1 and $APP^{NL\text{-}F/NL\text{-}F}$ mouse models of AD. WT; C57BL/6J controls, AβPP/PS1 and $APP^{NL\text{-}F/NL\text{-}F}$ AD models were entrained to a control light/dark cycle starting at 6 weeks of age. Following 2-weeks of entrainment, half of the animals were maintained on the control schedule, and half were exposed to our circadian disruption paradigm, involving an 8-hour phase advance on day 5 and an 8-hour phase delay on day 7 of repeated 7-day sessions up until 6 or 12-months. One month prior to the endpoint, activity measures and GTT were performed, following which the animals were all entrained to a normal 12:12 LD schedule for 3-5 weeks. Finally, animals underwent an 8-day Morris Water Maze (MWM) to assess effects of chronic disruption on AD-related cognitive decline. Animals were sacrificed and tissues collected at Zeitgeber time (ZT) 12. In all genotypes, female animals showed a higher degree of re-entrainment to the phase advancement of the lighting schedule going into the subjective weekend (day 6-7). Arginine vasopressin (AVP) and vasoactive intestinal peptide (VIP) expression in the SCN were significantly dampened as a result of chronic disruption in 12-month male AD mice. Amyloid plaque analysis indicated a severely worsened pathological phenotype in AβPP/PS1 mice as compared to age and sex-matched $APP^{NL\text{-}F/NL\text{-}F}$ mice. MWM data provides evidence for impaired spatial learning in both AD models that is significantly worsened by chronic jetlag exposure. Taken together, the data suggests that chronic exposure to the social jet lag schedule disrupts rhythmic behavior, and spatial learning significantly in both AD animal models.

Title: Disrupted projection signaling in sleep disorders and parkinsonism

Authors: *T. SANDERS;
Univ. of Colorado Boulder, Boulder, CO

Abstract: Healthy humans switch seamlessly between activity states, wake up and fall asleep with regularity, and cycle through sleep stages necessary for restored homeostasis and memory consolidation each night. This study examined whether such smooth behavioral transitions are accompanied by low noise transitions between stable neural states within the brain. We found that electrical brain activity measured in pathological conditions of 1) impaired human sleep and 2) non-human primate parkinsonism displays significantly increased phase disruption compared to healthy controls. Our analyses used a new set of measures we recently developed to detect and quantify disruptions in EEG signals across a broad range of frequencies [1], here referred to as “phase discontinuity” measures. In humans reporting impaired sleep, we found that phase discontinuity decreased with increasingly deep sleep, and that greater and more variable phase discontinuities were associated with increased drowsiness, impaired deep sleep, and shorter REM sleep. A 10 sec phase discontinuity summary measure (the *phase jump indicator*) closely tracked the annotated sleep stages and enabled discrimination between short (< 10 min) and longer REM periods. Increased phase discontinuity only occurred in sleep stages that showed impairment. A measure of total phase discontinuity correlated inversely with broadband EEG power, suggesting that reduced spurious signaling may facilitate increased synchronization. In older patients the power vs. phase discontinuity correlation shifted to positive during drowsiness, suggesting potential deficits in inhibition. These results provide evidence that phase discontinuity measures extend current capabilities for assessing sleep and may yield new insights into pathological brain states. In monkeys with Parkinsonism, we found that phase discontinuities are also increased in cortical and subthalamic LFPs. We show via modeling how circuit changes that occur during Parkinson’s disease may lead to increased disruptions in cortico-basal ganglia signaling that can be quantified with phase discontinuity measures.

Abstract: Rapid eye movement (REM) sleep behavior disorder (RBD) is often co-expressed with Parkinson's disease (PD) and in many cases occurs before the overt motor signs of PD. This has led to increased interest in the mechanisms underlying movements during REM sleep. In this study we sought to increase our understanding of basal ganglia involvement in REM sleep movements and whether it is engaged differently than wakeful movements. Local field potentials from directional deep brain stimulation (DBS) leads in the globus-pallidus internus (GPi) and scalp EEG polysomnography were recorded in four PD patients (one identified with RBD) and movement-related changes in oscillatory activity in wake and REM states were characterized. During wakeful movements, all patients showed desynchronization of beta (13-35Hz) and synchronization of high-frequency oscillations (150-350Hz). Conversely, during REM sleep movements, all patients exhibited beta synchronization in addition to synchronization of high-frequency oscillations. Our findings suggest that REM sleep movements irrespective of RBD are likely not mediated by the same motor circuit as during wakefulness.

Title: Non-motor symptoms and altered Dorsal Raphe oscillatory activity in a mice model of Parkinson´s Disease

Authors: S. VEGAS-SUAREZ[1], A. SANZ-MAGRO[1], N. GRANADO[1], L. UGEDO[2], *R. MORATALLA[3];
[1]Inst. Cajal, CSIC, Madrid, Spain; [2]Univ. of the Basque Country, Leioa, Spain; [3]Cajal Institute, CSIC, Madrid, Spain

Abstract: The dorsal raphe nucleus (DRN) is a brainstem nucleus that contains a heterogeneous population of neurons, among which serotonergic neurons predominate. The DRN is implicated in several cognitive, motor and affective functions and its alteration has been linked with the onset of non-motor symptoms of Parkinson's disease, like anxiety and depression. In this work, we used the aphakia mice, a genetic model that mimicked mild-mid stages of Parkinson's disease to link the non-motor symptoms with DRN functional alterations. To address this objective, we analyzed electrical properties through extracellular single-unit recordings in the DRN and oscillatory activity between DRN and motor cortex under urethane-anaesthesia, accompanied by complete behavioural and anatomical characterization. The results suggest that in the aphakia mice, the reduction of dopamine DRN neurons alters serotonin DRN neurons activity, which presented abnormal electrophysiological properties and diminished oscillatory activity together with an enhanced synchronization with the motor cortex. These alterations are concomitant with the presence of anxiety and depressive sings in the aphakia mice. Altogether, these findings suggest that in the aphakia mice, the DRN electrical properties are compromised by the dopaminergic decline and establish the aphakia mice as an appropriate model for the non-motor symptoms in moderate Parkinson's disease.

Title: Characterizing Cellular Activation following L-DOPA Treatment in a Hemiparkinsonian LacZ Rat Model

Authors: M. COYLE, A. CENTNER, N. LIPARI, S. COHEN, E. WHEELIS, T. TOWNER, C. BISHOP;
Binghamton Univ., Binghamton, NY

Abstract: Parkinson’s disease (PD) is the 2nd most prevalent neurodegenerative disorder in the world, characterized by dopamine (DA) depletion of the nigrostriatal pathway. Although bradykinesia, rigidity, and tremor are considered cardinal motor symptoms, numerous non-motor symptoms frequently precede PD diagnosis such as sleep disturbance, autonomic dysfunction, gastrointestinal issues, depression, and anxiety. While DA replacement therapy (DART) using l-3,4-dihydroxyphenylalanine (L-DOPA) ameliorates motor symptoms, chronic use induces neuroplastic changes affecting DA, serotonin, and glutamate neurotransmission. Consequentially, DART can exacerbate existing PD-associated psychosis (PDAP) symptoms including hallucination, delusion, and affective disorder while also precipitating the development of novel motor and non-motor side effects such as L-DOPA-induced dyskinesia (LID), impulse control disorders, orthostatic hypotension, and de novo psychosis. Understanding the neural underpinning of these changes remains a paramount goal for the field. For this investigation, adult male LacZ Sprague Dawley rats were rendered hemiparkinsonian with an infusion of 6-hydroxydopamine into the left medial forebrain bundle and vehicle infusion into the right. While all rats produce c-fos in active neurons, the LacZ rat genome features an insertion of β-galactosidase (LacZ) after c-fos, resulting in the production of LacZ in all active neurons. As this enzyme is present in all active neurons and cleaves X-gal into an insoluble blue product, neuronal activity can be characterized post-mortem. Following recovery, animals received 2 weeks of daily injections of either L-DOPA (6 mg/kg; s.c.) or vehicle during which all animals underwent the abnormal involuntary movements (AIMs) test. After a brief washout period, animals were administered either L-DOPA or vehicle to investigate the effects of lesion, and acute or chronic L-DOPA treatment. On the last day of the experiment, AIMs severity was monitored for 60 minutes prior to transcardial perfusion. Brains were prepared and X-Gal staining was performed on 40µm tissue slices to quantify active neurons at the time of perfusion

in a region- and sub-region-specific manner across motor and non-motor areas to identify areas demonstrating ectopic activity relative to the sham-lesioned hemisphere . Such findings will illuminate the influences of lesion and treatment and provide clues to the PD features that emerge throughout disease progression.

Title: Phosphodiesterase 10A regulation of dopamine signals in striatal neurons.

Authors: *B. KOCHOIAN[1], C. G. SINON[2], C. BURE[3], T. YABUMOTO[3], K. PENDERGRAST[3], R. HALVERSON[3], S. M. PAPA[4];
[1]Emory Univ., Decatur, GA; [2]Neurosci., [4]Neurol., [3]Emory Univ., Atlanta, GA

Abstract: BACKGROUND: L-Dopa-induced dyskinesias are abnormal involuntary movements that commonly occur with long-term L-Dopa therapy, the primary treatment for Parkinson’s disease (PD). Previous work has revealed decreased striatal expression levels of the cyclic nucleotides, cAMP and/or cGMP, second messengers involved in dopaminergic signaling cascades of striatal projection neurons (SPNs). Cyclic nucleotide levels are regulated by phosphodiesterases (PDEs), and inhibition of these PDEs may help regulate DA signaling in SPNs. PDE10A is highly expressed in the striatum and has substrate affinity for both cAMP and cGMP. To understand the impact of PDE10A function on striatal SPN responses to DA, we assessed the effect of PDE10A inhibition directly on the SPN activity in the non-human primate (NHP) model of PD, starting with the early phases of parkinsonism. METHODS: An MPTP-treated macaque with mild parkinsonism was used for striatal single-cell recordings with local microinjection of a selective PDE10A inhibitor (PDE10A-I). Our approach was to analyze firing changes of SPNs with continuous recordings from the OFF state, to 1 min and 5 min after local PDE-I injection, to 20 min following a systemic L-Dopa administration (ON state) and to the point of peak-dose dyskinesias (whether or not present). We also analyzed motor behavior using standard measures for NHP. RESULTS: In this mildly parkinsonian animal, the activity of SPNs consistently displayed low firing frequencies. In D1R-like SPNs, we observed an increase in firing rate following local injection of PDE10A-I and a synergistic effect of L-Dopa (ON state) sustaining the frequency increase. In D2R-like SPNs, we did not observe a significant change in

firing rate after local administration of PDE10A-I but did see a significant decrease in firing during the ON state compared to the OFF state. We also analyzed the impact of systemic coadministration of L-Dopa (2 doses: optimal and suboptimal) and an escalating dose of PDE10A-I (0-7.5 mg/kg s.c.) on motor outcomes. DISCUSSION: Our previous work has demonstrated that systemic administration of PDE10A-I decreases dyskinesias. Our current data showed coherent and discrete synergistic and antagonistic effects of the PDE10A-I on D1R-like and D2R-like SPNs, respectively, as predicted by the model. These results suggest that more advanced dopamine loss in animals with more severe parkinsonism could increase PDE10A-I effects, particularly antagonizing dopamine signals in indirect SPNs, and this mechanism may explain the antidyskinetic effects of PDE10A inhibitors that we have previously observed.

Abstract: The striatum is the largest nucleus of the basal ganglia. Dopamine depletion of the striatum is the crux pathophysiological feature of Parkinson’s disease (PD). The striatum is mainly composed of projection neurons, the medium spiny neurons, which are GABAergic and express the dopamine- and cyclic-AMP-regulated phosphoprotein DARPP-32. The striatum also contains interneurons which modulate and control the striatal output. Most interneurons are GABAergic; various types are identified on the basis of their protein phenotypes: parvalbumin

(Pv+), calretinin (Cr+), neuropeptide Y, somatostatin, nicotinamide adenine dinucleotide phosphate-diaphorase (NADPH+), and tyrosine hydroxylase (TH+). Another non-GABAergic type are the cholinergic interneurons which express the enzyme choline acetyltransferase (ChAT+). These are thought to play an important role in normal physiological responses (i.e. learning, reward, etc.) and basal ganglia disorders. We used unbiased stereological methods to estimate the volume density of every neuron population in the whole extension of the striatum of control monkeys and monkeys treated with MPTP to produce striatal dopamine depletion. The treated monkeys were classified in symptomatic and non-symptomatic groups. All the analyses on the various neuron populations were performed within the same subjects using similar processing conditions and analysis parameters, thus allowing for reliable data comparisons. The projection neurons (DARPP-32+) were the most abundant neuron type in the striatum: they account for ~86% of the total striatal population. The interneurons made the remaining 14%. Among the interneurons, Cr+ neurons were the most abundant type (57.09%; 7.9% of the total striatal neurons), followed by Pv+ neurons (18.24%; 2.6% of the total), NADPH+ interneurons (13.09%; 1.8% of the total), and ChAT+ interneurons (11.04%; 1.5% of the total). The least abundant interneuron type was that expressing TH (0.54%; 0.1% of the total). No significant changes in volume densities occur in any striatal population following DA depletion, except for the TH+ interneurons, which increased in the non-symptomatic subjects and even more in the symptomatic monkeys. The data obtained are relevant for translational studies targeting specific neuron populations of the striatum. Dopaminergic denervation, even when severe, does not cause neuronal loss in any type of striatal neuron. Such resilience has potential pathophysiological implications.

Title: Functional connectivity in a cortico-subthalamic network for a progressive Parkinsonian non-human primate model

Authors: *C. TOTH[1], J. C. BORE[1], B. CAMPBELL[1,4], H. CHO[1], F. PUCCI[2,3], O. HOGUE[2], R. GOPALAKRISHNAN[2], A. G. MACHADO[1,2,3], K. B. BAKER[1,2];

Abstract: Parkinson's Disease is a degenerative neurological disease that manifests with cardinal motor signs including bradykinesia and tremor. Although beta-band hypersynchrony in the cortico-basal ganglia network is thought to play a role in disease manifestation, resulting effects on network connectivity are unclear. We examined local field potentials from a non-human primate across the naïve, mild, and moderate disease states (model was asymmetric, left-hemispheric dominant) and probed cortico-cortical and cortico-subthalamic connectivity using Granger causality, a measure of directed effective connectivity, and a subsequent graph-theoretic analysis. Our network included the left subthalamic nucleus (L-STN), bilateral primary motor cortices (L-M1, R-M1) and bilateral premotor cortices (L-PMC, R-PMC). Results showed two distinct Granger causality peaks (Peak A at 5-20 Hz, Peak B at 25-45 Hz). Increases in Peak B connectivity and decreases in Peak A connectivity were associated with disease. Induction of mild disease was associated with several changes in connectivity: 1) the cortico-subthalamic connectivity from the L-PMC to L-STN decreased while the reciprocal L-STN to L-PMC increased, 2) both L-M1 to L-PMC and R-M1 to R-PMC causalities increased, and 3) a significant decrease in connectivity occurred from the R-PMC to R-M1. Few significant changes were seen between mild and moderate disease, except for increased bidirectional right-hemispheric cortico-cortical connectivity. Graph-theory analysis suggested that the network became more "efficient" at both local and global levels. Based on these results, it is hypothesized that: 1) premotor cortex-subthalamic nucleus interactions are altered in disease and play a role, directly or through mediating nodes, in generating excessive beta band synchrony, 2) the M1 became hyper-synchronized with the PMC, possibly leading to "locking" of neural information flow and disrupting the network's ability to desynchronize, 3) changes in modulation of R-M1 by the R-PMC may have either compensated for left hemispheric cortico-subthalamic changes or instead may have been an indirect effect of them, and 4) increased overall efficiency in the model may be related to excessive beta band synchrony induced in the Parkinsonian state. Increased understanding of connectivity within this network will hopefully increase knowledge of Parkinson's disease and improve treatments.

Title: Motor context modulates substantia nigra pars reticulata spike activity in patients with Parkinson's disease

Authors: *A. TEKRIWAL[1], G. FELSEN[2], S. G. OJEMANN[3], A. ABOSCH[5], J. A. THOMPSON[4];
[1]Neurosci. Grad. Program, Med. Scientist Training Program, [2]Dept. of Physiol. and Biophysics, [3]Dept. of Neurosurg., [4]Dept. of Neurosurgery, Dept. of Neurol., Univ. of Colorado Anschutz Med. Ctr., Aurora, CO; [5]Dept. of Neurosurg., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Objectives: The severity of motor symptoms in Parkinson's disease (PD) depends on environmental conditions. For example, the presence of external patterns such as a rhythmic tone can attenuate bradykinetic impairments. However, the neural mechanisms for this context-dependent attenuation remain unknown. Here, we investigate whether context-dependent symptom attenuation is reflected in single-unit activity recorded in the operating room from the substantia nigra pars reticulata (SNr) of PD patients undergoing deep brain stimulation surgery (DBS). The SNr is known to influence motor planning and execution in animal models but its role in humans remains understudied.
Methods: We recorded SNr activity while 9 subjects (4 male; 64 ± 7 years) performed cued directional movements in response to auditory stimuli under interleaved "patterned" and "unpatterned" contexts. SNr localization was independently confirmed with expert intraoperative assessment as well as post-hoc imaging-based reconstructions.
Results: As predicted, we found that motor performance was improved in the patterned context, reflected in increased reaction speed ($p = 0.0092$, 1-tailed Wilcoxon signed rank test (paired)) and accuracy ($p = 0.0173$, 1-tailed two-sample t-test (paired)) compared to the unpatterned context. These behavioral differences were associated with enhanced responsiveness of SNr

neurons – i.e., larger changes in activity from baseline – in the patterned context. Unsupervised clustering analysis revealed two distinct subtypes of SNr neurons: one exhibited context-dependent enhanced responsiveness exclusively during movement preparation, whereas the other showed enhanced responsiveness during portions of the task associated with both motor and non-motor processes.
Conclusions: Our findings indicate the SNr serves roles in motor planning and execution, as well as warrants greater attention in the study of human sensorimotor integration and as a target for neuromodulatory therapies.

Title: Alpha-synuclein and synaptic gene dysregulation in Huntington’s Disease

Authors: *A. WHITE[1], D. COATES[2], W. TSAI[1], R. GOMEZ-PASTOR[1];
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]The Pennsylvania State Univ., State College, PA

Abstract: Alpha-synuclein (α-syn) is a neuronal protein that regulates synaptic vesicle trafficking and subsequent neurotransmitter release. Alteration in the levels of α-syn has been previously associated with synaptic deficits and Parkinson’s disease (PD). Recently, we and others showed that Huntington’s disease, a disease caused by a poly-glutamine expansion in the huntingtin gene, is also influenced by the levels of α-syn, although its mechanisms of action are not known. α-syn is a cytoplasmic protein but it can be found in the nucleus under pathological conditions. Our previous data showed that α-syn serine 129 phosphorylation (pS129 α-syn), a posttranslational modification associated with enhanced α-syn toxicity and PD, was increased in the nucleus of HD neurons and it correlated with synaptic changes. However, whether altered α-syn abundance and/or phosphorylation participates in synaptic gene dysregulation is unclear. To further investigate the role of α-syn in synapse regulation in HD we have taken an *in vitro* approach using mammalian cultures from immortalized striatal cells derived from control ($STHdh^{Q7}$) and HD ($STHdh^{Q111}$) mice. RT-qPCR analyses for an array of synaptic genes revealed that SNCA (α-syn) was significantly downregulated in HD cells while genes such as Slc30a3 and Slc17a7 were abnormally induced. We then manipulated the levels of α-syn by

siRNA or ectopic overexpression and found that α-syn siRNA led to a further induction of synaptic genes already upregulated in HD and up-regulation of the same genes also in control cells. On the contrary, α-syn overexpression resulted in a significant down-regulation of the exact same genes in both control and HD cells. We also generated a phospho-mimetic (S129E) and a phospho-null (S129A) α-syn mutant cell line to directly explore the effect of pS129 α-syn on α-syn's modulatory role in synaptic gene regulation. RT-qPCR of S129A and S129E expressing cells showed dysregulation of the same set of synaptic genes previously tested. These results suggest that α-syn abundance and phospho-mediated nuclear mislocalization modulates synaptic gene expression, and that alterations in synaptic gene expression observed in HD may be driven by deficits in α-syn.

Title: Patch-seq reveals transcriptional correlates of impaired synaptic transmission in single striatal neurons in Huntington's disease

Authors: F. PARASKEVOPOULOU[1], P. PARVIZI[2], G. SENGER[2], N. TUNCBAG[2], C. ROSENMUND[1], ***F. YILDIRIM**[1];

Abstract: Progressive transcriptional dysregulation in brain is an early and central feature of Huntington's disease (HD) pathogenesis. We and others have previously reported extensive genome-wide changes in transcription and epigenetic modifications in cell and mouse models as well as patient IPSC-derived striatal neurons. Here, using Patch-seq, a technique that combines electrophysiological recordings and single cell RNA sequencing, we studied the effects of mutant huntingtin (Htt) on transcription and synaptic transmission in single striatal neurons in an *in vitro* model of HD. Expression of mutant *Htt* decreased the synaptic output and caused dysregulation of a large number genes in single striatal neurons. Of these, we identified a group of genes whose dysregulation were correlated with the physiological deficits in neurons expressing mutant Htt. Pharmacological inhibition of histone deacetylase 1 and 3 activities rescued several functional deficits and ameliorated the aberrant gene expression in mutant Htt

neurons. Collectively, our work indicates a number of gene expression-neuronal function relationships in HD, supports an important role for epigenetic mechanisms in HD pathology and demonstrates that Patch-seq technology can be utilized to better understand molecular mechanisms of complex neurological diseases at single-cell level.

Title: Wild type huntingtin reduction leads to an NMDAR-dependent loss of presynaptic sites

Authors: *J. BARRON, F. NAFAR, M. PARSONS;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Huntington disease (HD) results in a triad of motor, cognitive and psychiatric symptoms, and is caused by a CAG repeat expansion in the huntingtin (*HTT*) gene, which results in the production of a mutant HTT protein (mHTT). In addition to the production of mHTT, individuals living with HD also generate half the amount of wild type huntingtin (wtHTT). wtHTT has a well-known role in neurodevelopment, as its knockout is embryonic lethal in mice; however, its exact function in the adult brain is not well understood. Recent research has suggested that wtHTT plays a major role in synaptic homeostasis of adult neurons. For example, loss of wtHTT impairs presynaptic vesicle release and postsynaptic receptor localization, as well as fast axonal transport of proteins important for synaptic plasticity, such as BDNF. Long term potentiation (LTP) in the CA3-CA1 hippocampus is reliant on presynaptic glutamate release and NMDA receptor activation, as well as BDNF presence. We hypothesized that the synaptic impairments triggered by wtHTT lowering may lead to defects in NMDAR-dependent LTP. To test this, LTP was induced chemically using glycine (cLTP) in primary hippocampal cultured neurons and wtHTT levels were lowered by self-deliverable siRNA. Both presynaptic synaptophysin (SYP) and postsynaptic PSD-95 were labelled by immunofluorescence. Using super-resolution microscopy, we quantified SYP and PSD-95 puncta density from dendritic segments at the nanoscale level. cLTP induction revealed an activity-dependant decrease in SYP, but not PSD-95, density in wtHTT-lowered cells. These results signify a potential switch from synaptic potentiation to depression and subsequent loss of synapses during hippocampal NMDAR activation due to wtHTT lowering. Understanding the outcomes of wtHTT reduction in

the adult brain is critical as many HD genetic therapies in development further lower patient wtHTT levels.

Title: Excitatory synapse loss and its in vivo functional correlation with ^{1}H MRS in the knock-in zQ175 mouse model of Huntington's disease

Authors: *N. ZARATE[1], K. GUNDRY[2], B. YU[1], G. OZ[2], R. GOMEZ-PASTOR[1];
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Ctr. for Magnetic Resonance Res., Univ. of Minnesota Ctr. for Magnetic Resonance Res., Minneapolis, MN

Abstract: Huntington’s disease (HD) is a devastating neurodegenerative disorder caused by a trinucleotide (CAG) repeat expansion in exon 1 of the Huntingtin gene. HD is characterized by progressive motor, cognitive, and psychiatric impairments for which there are no effective therapies or cure. Medium spiny neurons (MSNs) are preferentially affected, causing synaptic perturbations that contribute to eventual neuronal death. Previous work in cell and mouse models of HD show changes in thalamo-striatal (T-S) synaptic stability before cortico-striatal (C-S) dysfunction, motor symptom onset, or cell death. Non-invasive imaging techniques, such as ^{1}H MRS, have been used in HD mouse models and patients to monitor key neurochemical changes associated with neuronal health. However, the molecular mechanism that connects brain neurochemical changes with functional decline is still unknown, limiting our understanding of how potential treatments that may affect synapse function translate into neurochemical changes. In this study, we conducted *in vivo* longitudinal ^{1}H MRS in the striatum followed by *ex-vivo* analyses of T-S excitatory synapse density using the knock-in zQ175 HD mouse model as well as zQ175 mice lacking one allele of CK2α’(henceforth referred to as zQ175:CK2α’$^{(+/-)}$), a kinase we previously showed to be detrimental in HD. We found age- and genotype-dependent neurochemical differences between WT and HD mice, consistent with previous observations by others. Longitudinal analyses of excitatory synapse density showed a significant reduction in T-S synapses at all time points in HD mice that was rescued in the zQ175:CK2α’$^{(+/-)}$ mice. Linear regression analyses showed T-S synapse number significantly correlated with alterations in a multitude of neurochemicals and neurochemical ratios, highlighting their potential use as

surrogate biomarkers to monitor synapse dysfunction in HD. Overall, these results show the benefits of using ^{1}H MRS in future HD pre-clinical studies as a non-invasive tool to monitor the efficacy of current therapeutic trials and their effects on excitatory synaptic function.

Title: Mdivi 1 protects against mutant huntingtin-induced impaired mitochondrial dynamics, defective bioenergetics/biogenesis, mitophagy and synaptic damage in Huntington's Disease

Authors: *P. REDDY[1], B. RAMASUBRAMANIAN[2], N. SAWANT[2], J. PRADEEPKIRAN[2], M. VIJAYAN[2], S. KUMAR[2], H. MORTON[2], L. E. BUNQUIN[2], S. KSHIRSAGAR[2];
[1]Intrnl. Med., [2]Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Abstract: The purpose of our study is to understand the protective effects of mitochondrial (mt) division inhibitor 1 (Mdivi 1) against mutant huntingtin (mHtt) induced mt abnormalities and synaptic damage in Huntington's disease (HD). Increasing evidence suggests that structural and functional abnormalities of mt and synaptic damage selectively found in medium spiny neurons in HD pathogenesis. Recently, we found mHtt-induced, impaired mt dynamics in striatal and cortical postmortem HD brains and BACHD and HD-knockin (HDKI) mouse models of HD. **Methods:** We treated BACHD and HDKI mice and non-transgenic wild-type (WT) mice with Mdivi 1 for six months. We performed behavioral analysis using rotarod (motor coordination), open field (locomotor activity), Y-maze (working memory) and tail suspension (neurological phenotype) in treated and untreated BACHD, HDKI (HD mice) and WT mice. Using a variety of techniques/methods, we studied cell, molecular, ultra-structural and dendritic spines in Mdivi 1 treated HD mice. **Results:** As expected, behavioral phenotype was significantly improved for all tests in Mdivi 1-treated HD mice relative to Mdivi 1-untreated HD

mice. These observations suggest that Mdivi 1 is a good compound to reduce mHtt-induced behavioral abnormalities. We also found mRNA and protein levels of mt fission genes were significantly reduced, mt fusion genes were significantly increased, mt biogenesis and synaptic genes were increased, autophagy and mitophagy genes increased. We also found increased dendritic spines in striatal, cortical, and hippocampal tissues of Mdivi 1-treated HD mice. Our electron microscopy data revealed increased mt length and reduced mt size in Mdivi 1-treated HD mice. **Conclusions:** These observations indicate that Mdivi 1 reduces mt fragmentation and enhances mitophagy and synaptic activities.

Title: Genes related to neurotrophin signaling are associated with clinical function and brain morphology in prodromal Huntington's disease

Authors: *N. ALEXANDER, R. R. BUTLER, III, W. SYRIANI, W. A. JOHNSON, B. LEHALLIER, D. A. SIMMONS, F. M. LONGO;
Neurol. & Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder caused by a mutation that expands the length of CAG repeats in the *HTT* gene, resulting in the mutant huntingtin (mHtt) protein. mHtt disrupts diverse cellular processes leading to preferential degeneration of the striatum. Effective HD therapeutics will likely require modulation of underlying mechanisms promoting degeneration along with attempts to mitigate mHtt expression. A major contributor to HD-related degeneration is mHtt-induced loss of neurotrophic support. Neurotrophin (NT) signaling networks largely overlap those disrupted by mHtt; thus, NT receptors (primarily TrkB and $p75^{NTR}$) have emerged as therapeutic targets. As such, it is of interest to determine if NT signaling-related genes affect disease progression in prodromal HD. Accordingly, a previous study showed that *NTRK2* (gene encoding BDNF’s receptor TrkB) influenced frontal grey matter preservation in the PREDICT-HD dataset, a longitudinal clinical

study of prodromal HD. The current study evaluated how SNPs from ~100 NT signaling-related genes affect HD progression in the PREDICT-HD cohort. We examined regional brain volumes and clinical function (motor and cognitive), adjusted for CAG-age product (CAP) score, gender and genomic PCs1-10, at baseline and longitudinally—derived from functional principal component analysis (fPCA)—using genome wide association (GWA) in PREDICT-HD cases (n=929). Gene-level GWA analysis using MAGMA and H-MAGMA replicated previous associations of known residual HD age of onset-related genes (*FAN1*, *PMS1*, *MLH1*, *MSH3*). Improved SNP-to-gene mapping implicated several NT signaling-related genes—including *TRAF5, RASGRF2, PTEN* and *ADAM17*—that showed preferential association with specific HD phenotypes: grey matter of the putamen, caudate, globus pallidus, and frontal and parietal cortices, as well as cognitive and motor function (Stroop, Trail making, Single Digit Modalities tests, total functioning capacity). This genomic data paired with matching eQTL loci (in GTEx v8 and BRAINEAC databases) in corresponding brain tissues supports the role of NT signaling in residualized regional brain volumes. Replicating these analyses in larger cohorts may reveal additional NT signaling-related genomic loci of smaller effect size that contribute to the observed prodromal changes in these residual phenotypes, supporting their use as biomarkers of progression and treatment. This work provides further support for targeting NT signaling as an HD therapeutic.

Title: Neuronal potassium-chloride cotransporter 2 (KCC2) function is altered in the indirect pathway of the basal ganglia in huntington's disease

Authors: *M. SERRANILLA, J. C. PRESSEY, M. A. WOODIN;
Univ. of Toronto, Toronto, ON, Canada

Abstract: Huntington’s disease (HD) is an inherited neurodegenerative disorder characterized by progressive motor dysfunction. Motor impairments result from extensive neurodegeneration of the basal ganglia (BG), a highly interconnected assembly of subcortical nuclei best-known for their role in movement-related functions. The primary site of degeneration is the striatum, the input structure of the basal ganglia which sends inhibitory projections to the surrounding nuclei

of the basal ganglia. The striatum consists primarily of D1 and D2 dopamine receptor-expressing neurons which make up the direct pathway (dSPNs) and indirect pathway (iSPNs), respectively. dPNs and iSPNs are known to exert opposing effects on motor output, whereby activation of the direct pathway promotes movement, while the indirect pathway inhibits unwanted movement. In HD, there is a preferential loss of iSPNs, biasing basal ganglia output towards the direct pathway, though the cause of this enhanced susceptibility remains unclear. Accumulating evidence suggests that impaired synaptic inhibition within the basal ganglia circuitry may underlie this specific pattern of degeneration. Synaptic inhibition in the mature brain is largely mediated through the neurotransmitter, gamma-aminobutyric acid (GABA). GABA exerts fast hyperpolarizing inhibition by binding to Cl- -permeable GABAA receptors. GABAergic inhibition requires low intracellular Cl - concentration ([Cl-]i), which is maintained by the potassium-chloride cotransporter, KCC2. However, when KCC2 function is reduced, [Cl-]i increases, subsequently weakening the GABAergic driving force and synaptic inhibition. Usinga combination of electrophysiology, biochemical and behavioural assays, we determined that KCC2 function was reduced and GABAergic signaling was impaired in the indirect pathway of symptomatic R6/2 mice, a transgenic mouse model HD. In R6/2 mice, iSPNs demonstrated a depolarization in the reversal potential for GABA compared to dSPNs. In addition, the neuronal response to GABA was altered, from inhibitory to excitatory in the Globus Pallidus externa, the output structure of the indirect pathway. Interestingly, pharmacological reduction of [Cl-]i with the FDA-approved diuretic bumetanide effectively delayed the onset of motor impairments in R6/2 compared to controls. These findings provide evidence that the early impairments in GABAergic transmission in the indirect pathway may be a key mechanism contributing to circuitry and motor defects in HD. As therapeutic treatments for HD are limited, this work demonstrates the use of KCC2 as a novel potential therapeutic target in the treatment of HD.

Title: Dynamic analysis of huntingtin interactomes in response to proteotoxic stress

Authors: *J. WEI[1], H. XU[1], E. BELIARD[1], E. CAPOBIANCO[2], M. LU[1];
[1]Florida Atlantic Univ., Boca Raton, FL; [2]Univ. of Miami, Miami, FL

Abstract: Huntingtin protein (Htt) is a large protein (~350KDa) whose exact function is unknown. Mutation in this protein causes Huntington's disease (HD), a devastating autosomal dominant fatal neurological disorder with no cure. It is critical to understand the functions of normal Htt and mutant Htt in order to decipher the molecular pathogenesis of HD. It is strongly suggested that Htt serves as a scaffold protein that regulates protein complexes formation for various purposes. Mutant Htt is implicated in perturbing protein-protein interactions (PPI) in association with normal Htt. However, given the pathological role of cellular stresses in HD, how Htt interactome changes in response to cellular stresses remains largely unknown. To identify the dynamic interacting partners, for both normal and mutant Htt, in response to cellular stresses, we established an ascorbate peroxidase (APEX2)-based proximity labeling platform to spatiotemporally label Htt-interacting proteins in live cells. We first generated stable clones expressing Flag-APEX2-NES (nuclear export sequence, NES), Flag-APEX2-fHtt23Q (Htt23Q) or Flag-APEX2-Htt145Q (Htt145Q) using the human neuroblastoma SH-SY5Y cell line. Since Htt is largely present as a diffusible cytosolic protein, NES samples were included as a spatial probe to identify random cytosolic proteins that are in close vicinity with APEX2 due to the nature of APEX2 labeling. To test whether the APEX2-based strategy can distinguish specific local protein interaction network for normal and mutant Htt in response to proteotoxic stress, we developed a multi-step workflow to identify and quantify the abundance of biotinylated proteins in control and MG132-treated (stress) samples by 10-plex TMT quantitative mass spectrometry (MS). We identified a total of 636 proteins from the 4 plexes. After applying stringent filtering steps, 94 proteins remained for further analysis. Our primary analysis indicated that muHtt is preferentially associated with components in the intermediate filaments. We validated some of the proteins by western blot and co-immunoprecipitation. Dynamic interaction networks of Htt/muHtt in response to proteotoxic stress are currently under construction.

Title: Understanding transcriptional dysregulation in ALS using RNA sequencing and computational approaches

Authors: *F. J. ARNOLD[1], A. GROMOVA[2], S. U. MCKINSTRY[3], U. RAYCHAUDHURI[1], Y. GOU[1], A. R. LA SPADA[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is an incurable neurodegenerative disorder characterized by the progressive loss of motor neurons in the brain stem and spinal cord. While the etiology of the vast majority of ALS cases remains unclear, study of inherited forms of ALS has highlighted dysregulation of RNA metabolism as a key contributor to disease. To better understand the changes in RNA processing that occur in ALS, we are utilizing RNA sequencing (RNA-seq) and computational approaches to identify transcriptional and structural alterations to the RNA landscape in cell and animal models of ALS. RNA-seq of lumbar spinal cord from a knockin mouse model of ALS4 (caused by mutations in the RNA/DNA helicase senataxin (SETX)) revealed upregulation of long non-coding RNAs and dysregulation of genes involved in axonal integrity and immune function. Additionally, we found that upregulated genes are highly expressed in microglia, while downregulated genes are highly expressed in motor neurons. To more deeply investigate transcriptional dysregulation in these key cell types, we isolated microglia from the spinal cord of ALS4 mice and performed RNA sequencing. In parallel, we sequenced induced pluripotent stem cell (iPSC)-derived motor neurons from an ALS4 patient and a gene-corrected isogenic control line. Finally, to determine if mutations in SETX directly alter its RNA binding function, we are performing UV-crosslinking and immunoprecipitation followed by RNA sequencing (CLIP-seq) of SETX from ALS4 iPSC-derived motor neurons and an isogenic control line. Using machine learning approaches to improve existing RNA secondary and tertiary structure prediction algorithms, we aim to determine the structural motifs that mediate SETX binding.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disorder characterised by a progressive loss of motor function. While it is known that the eponymous spinal sclerosis observed upon autopsy is the result of Cortico-Spinal Motor Neuron (CSMN) degeneration, it remains unclear why this neuronal subtype is selectively affected. To understand the unique molecular properties that sensitise deep-layer CSMNs to ALS, we performed RNA sequencing of 79,169 single nuclei from the frontal cortex of patients and controls. In unaffected individuals, we found that expression of ALS risk genes was most significantly enriched only in $THY1^+$ presumptive CSMNs and not in other cortical cell types. In patients, these genetic risk factors, as well as additional genes involved in protein homeostasis and stress responses, were significantly induced in $THY1^+$ CSMNs and a wider collection of deep layer neurons, but not in neurons with more superficial identities. Examination of oligodendroglial and microglial nuclei also revealed patient-specific gene expression changes We show microglial alterations can in part be explained by interactions with degenerating neurons. Overall, our findings suggest the selective vulnerability of CSMNs is due to a “first over the line” mechanism by which their intrinsic molecular properties sensitise them to genetic and mechanistic contributors to degeneration.

Abstract: Amyotrophic lateral sclerosis (ALS) is a rare multifactorial neurodegenerative disorder characterized by relentless lost of motor neurons (MNs),leading to progressive muscle paralysis and precocious death. ALS is mainly sporadic, but 10% of cases are familial. At present, ALS pathogenesis has not been completely elucidated and potential molecular biomarkers of this disease remain to be identified. MicroRNA (miRNAs) are small non coding RNA molecules with post-trascriptional regulatory role. Previous studies have shown that deregulation of miRNA expression is corelated with ALS, but the downstream pathological events associated with MNs degeneration have not yet been clarified. In this study we performed microRNA expression profile analysis of iPSC-derived MNs and related exosomes from familial patients and healthy subjects. We identified dysregulation of miR-34a, miR-335 and miR-625-3p expression in MNs and exosomes. Further, we tested the expression of key miRNAs (miR-625-3p, miR-34a-3p, miR-34a-5p, miR-335-3p and miR-335-5p) in the cerebrospinal fluid (CSF) of a cohort of 54 ALS patients with a mean age of 58.4 ± 11.5 years and 19 healthy controls with a mean age of 52.8 ± 17.4 years. CFS miR-625-3p, miR-34a-5p and miR-335-3p levels were significantly dysregulated in familial patients compared to controls; miR-625-3p levels predicted familial amyotrophic lateral sclerosis diagnosis with moderate accuracy. Furthermore, the expression of miR-625-3p and miR-34a-5p significantly differed among *C9orf72-carriers*, *SOD1-carriers* and sporadic subjects. These microRNAs regulate genes and pathways that correlate well with disease pathogenesis, suggesting that studying microRNA deregulation can contribute to confirm previously identified molecular mechanisms underlying the disease and to identify new ones. Investigating patient-derived MNs, exosomes and CSF in the same study have shed light on the common pathological mechanisms underlying MNs degeneration, confirming the relevance of miRNA modulation in ALS pathogenesis. This approach might pave the way for the identification of novel biomarkers for disease diagnosis, prognosis and response to treatment.

Title: A multi-analyte evaluation of cerebrospinal fluid biomarkers for amyotrophic lateral sclerosis

Authors: A. ALEXANDER[1], D. PERREGAUX[2], D. UNRUH[1], R. WELLER ROSKA[1], A. KUBIK[1], ***Y. NOAM**[2];
[1]Bio-Techne, Minneapolis, MN; [2]Bio-Techne, Wallingford, CT

Abstract: Background: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease characterized by muscle atrophy that leads to eventual paralysis and death. ALS symptoms and disease progression vary significantly from person to person and this heterogeneity poses challenges for prognosis as well as missed opportunities for personalized treatment. Thus, there is a clinical need for biomarkers that reliably track disease progression and aid in treatment evaluation of ALS patients. Various fluid-based ALS biomarkers have been proposed, and recently the axonal proteins neurofilament light (NfL) and heavy (NfH) chain have emerged as potential neurodegeneration biomarkers for ALS as well as for other neuro-pathologies. In this pilot study, we utilized an automated multi-plexed microfluidic approach to analyze cerebrospinal fluid (CSF) from ALS patients and healthy donors to determine if a combination of CSF proteins can improve biomarker utility in ALS. **Methods:** The study cohort included 15 sporadic ALS patients (ALSFS-R score 25-47) and 15 age-matched controls. A total of 20 candidate biomarkers were analyzed using the automated Ella^{TM} platform. A customized microfluidic design allowed for minimal to no cross-reactivity or interference while preserving CSF volume (<110 ul per donor). Statistical modeling was applied to determine the optimal biomarker panel. **Results and conclusion:** The most salient differences in CSF profiles were manifested as significantly elevated NfL and NfH levels in ALS patients. Median levels of NfL and NfH measured at 0.83 [IQR: 0.62-1.3] and 0.95 [0.89-1.22] ng /mL in controls, and 3.7 [1.9-9.6] and 4.0 [2.3-8.6] ng/mL in ALS patients. We also saw a modest increase in the glial marker YKL-40/CHI3L1 (Ctl: 387 [289-513], ALS: 529 [412-689] ng/mL). Principal component analysis showed distinct stratification of ALS patients from controls. To evaluate the utility of a multi-analyte panel, we built a predictive statistical model trained using a leave-one-out cross validation strategy. Comparing linear regression, logistic regression, and random forest classifier models, our logistic model performed best with 93.3% accuracy and a ROC AUC value of 1.00 [0.98-1.0, 95% CI]. This model utilized measurements of 7 analytes: CRP, NF-L, NF-H, LIPO-2, GFAP, TREM-2, and VCAM-1. Building a logistic regression model with either the NF-H or NF-L measurement alone resulted in 90.0% accuracy and ROC AUC values of 0.98 [0.94-1.0] and 0.96 [0.88-1.0], respectively. Overall, our data supports a strong biomarker utility for CSF neurofilaments in ALS, whereas an alternative 7-analyte panel provides modest improvement in accuracy.

Title: Neuron-to-neuron transmission of polyGR through extracellular vesicles causes degeneration in receiving cells.

Authors: *M. CICARDI[1], D. TROTTI[2];
[1]Thomas Jefferson university, Philadelphia, PA; [2]Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Amyotrophic lateral sclerosis (ALS) and fronto-temporal dementia (FTD) are two neurodegenerative disorders which belong to the same disease spectrum. The most common genetic cause of ALS-FTD is a hexanucleotide repetition (G_4C_2) present in the intron 1 of the C9orf72 gene. This mutation results in three main toxic events: C9orf72 protein reduction, RNA foci formation and aberrant repeat associated non-AUG translation (RAN-T). The products of RAN-T are five dipeptide repeat proteins (DPRs: polyGA, polyGP, polyGR, polyPA and polyPR). Employing a mouse model which conditionally expresses polyGR, one of the most toxic DPR, we found that a fraction of the extracellular vesicles (EVs) present in the serum encloses polyGR. EVs are double membrane organelles which are released by cells through different pathways and whose content varies according to cells' patho/physiological conditions. We thus analyzed whether neurons produce EVs loaded with RAN-T products. Indeed, DPRs were detected in neuronal EVs and glutamate stimulation was able to increase the number of polyDPR$^+$ EVs. Interestingly, we found higher percentage of polyGR$^+$ EVs compared to other DPRs. We then investigate if the internalization of polyGR$^+$ EVs elicited toxicity in recipient neurons. We treated cortical neurons with polyGR$^+$ EVs and by live imaging we found a significant reduction in cell viability compared to control EVs treated neurons paralleled by TDP-43 nuclear depletion which is hallmark of ALS-FTD pathology. When we performed *in vivo* experiments injecting polyGR$^+$EVs in mouse spinal cord we observed loss of NeuN positive cells, paralleled by astrocytes and microglial recruitment at the injection site. Treating human derived motor neurons (MNs) with polyGR$^+$ EVs and we found that only C9-ALS derived MNs show increased neurodegeneration possibly owing to polyGR$^+$ EVs induced RAN-T which we were able to measure thanks to a luciferase RAN-T reporter. In conclusion we demonstrated that polyGR reception into neurons was able to cause neuronal toxicity, TDP-43 nuclear depletion and increase in RAN-T substantiating the hypothesis that EVs mediated neuron-to-neuron spreading of polyDPRs is one of the possible pathways in which neurodegeneration spreads across the central nervous system of ALS-FTD patients.

Title: Neuronal stimulator of interferon genes pathway activation in amyotrophic lateral sclerosis

Authors: *C. MARQUES[1,3], K. DORFMAN[1,3], J. SUNG[1,3], A. HELD[1,3], M. ADLER[1,3], C. I. AGUILAR[1,3], D. H. OAKLEY[1,3,2], B. T. HYMAN[1,3], L. PETRUCELLI[4], C. LAGIER-TOURENNE[1,3], B. J. WAINGER[1,3];

Abstract: The type-I interferons (IFN) response is a well-established innate immune response to pathogens infection. However, this response has also recently been strongly implicated in neuroinflammation and neurodegeneration in diseases including Parkinson's and amyotrophic lateral sclerosis (ALS). The type-I IFN upstream regulator, stimulator of interferon genes STING, is increasingly appreciated to instigate this type-I IFN-mediated response. While much of this work has focused on activated immune cells themselves, cell-autonomous activation of innate immune signaling pathways within neurons can also occur and may play roles in neurodegenerative diseases. However, the role of STING signaling in driving this neuronal response remains unknown and represents the aim of this study. We hypothesize that STING signaling dysregulation within neurons contributes to their degeneration in the context of ALS, a rapidly progressing and fatal disorder of the motor nervous system. Approximately 10% of ALS cases are familial and result from mutations in any of the more than 30 ALS genes, of which the most common is the chromosome 9 open reading frame 72 (*C9ORF72*) intronic repeat expansion. To determine whether STING is functional within motor neurons, we performed molecular analyses on human-induced pluripotent stem cell (iPSC)-derived neurons as well as primary mouse cortical neurons subjected to modulators of STING activity. Treatment of neurons with a STING agonist or antagonist led to an increase or decrease of type-I IFN response genes expression, respectively. Thus, our data demonstrate the presence and functional integrity of STING signaling pathway in neurons. Using human iPSC lines from a range of familial ALS patients as well as mutations introduced by gene editing to create isogenic disease and control pairs, we showed a consistent increase in STING activation within ALS iPSC-derived neurons compared to control. To validate the findings *in vivo*, we used an adeno-associated virus mouse model of C9orf72 ALS and found increased STING levels in vulnerable layer V corticospinal motor neurons. To further confirm the relevance of these findings, we demonstrated similar increased STING protein in layer 5 cortical pyramidal neurons from ALS postmortem brains

compared to either Alzheimer's or non-neurological control ones. Thus, our studies demonstrate STING pathway activation in ALS neurons, with complementary findings among iPSC, mouse, and human post-mortem studies. This project is intended to provide insight into molecular pathways involved in ALS and identify targets for the development of therapeutic strategies for ALS.

Title: Als motor cortex communicate their disease state very early in disease via exosome mediated signals

Authors: *M. GAUTAM[1], E. F. XIE[1], J. BRENT[1], N. KOCAK[1], *O. GOZUTOK MOORE[1], H. SHIN[1], A. GUNAY[1], M. PLEBANEK[2], C. THAXTON[2], P. OZDINLER[1];
[1]Neurol., [2]Urology, Northwestern Univ., Chicago, IL

Abstract: Exosomes are small vesicles that transport important bio-molecular cargo (e.g. protein, RNA, miRNA and lipids) to recipient cells. They are a novel mediator of intercellular communication between different cells and organs in the body. Their ability to cross the blood brain barrier enables flow of information between central nervous system (CNS) and the periphery. Cortical dysfunctions are emerging to occur prior to symptom onset and one of the contributing factors for the initiation and progression of disease pathology in amyotrophic lateral sclerosis (ALS). This study was designed to reveal how ALS cortex communicate their diseased state via exosomes, and to reveal exosomal protein cargo that mediate the warning signal. The mice that develop ALS due to mSOD1 mediated toxicity and TDP-43 pathology are utilized together with wildtype healthy littermates. Exosomes secreted by cultured dissociated motor cortex obtained from diseased and healthy mice were isolated after 10 days of *in vitro* culture. Proteomic analysis of those exosomes suggested the presence of a common message sent out both by $hSOD1^{G93A}$ and $prpTDP\text{-}43^{A315T}$ motor cortex, which is modulated by a key transcription

factor. We performed gene modulation
experiments in both healthy and diseased neurons to investigate the impact of this transcription factor on neuronal survival. We find that the motor cortex of both hSOD1^{G93A} and prpTDP-43^{A315T} mouse models of ALS utilize exosomes to communicate their disease state even at postnatal day 3 (P3). In an effort to investigate whether this message is "protective" or "detrimental", we performed gene modulation. Our results suggest that proteins present in these exosomes appear to signal a message that codes for protection from upcoming neurodegeneration at this early age. This study unravels how cortex is involved in ALS early in the course of disease, and how exosomes can modulate key cellular events that may be targeted to overcome neurodegeneration.

Title: Roles of MFN2 in mitochondrial transport of human spinal motor neurons

Authors: *Y. MOU[1], J. DEIN[3], Z. CHEN[1], X.-J. LI[2];
[2]Dept. of Biomed. Sci., [1]Univ. of Illinois, Rockford, IL; [3]Univ. of Illinois Col. of Med. Rockford, Rockford, IL

Abstract: Charcot-Marie-Tooth (CMT) disease is one of the most common genetically inherited group of motor and sensory neurological disorders, with a global prevalence of 1 in 2500 people. CMT type 2A is one of axonal subgroups of CMT and is caused by dominant mutations in the mitofusin-2 (*MFN2*) gene. MFN2 is located in the outer mitochondrial membrane and regulates mitochondrial fusion, playing a critical role in the maintenance of normal neuronal functions. Although loss of MFN2 induces axonal neuropathy, the detailed mechanism by which MFN2 deficiency causes axonal degeneration of human spinal motor neurons remains largely unknown. In this study, we established MFN2-knockdown human embryonic stem cell (hESC) lines using lentivirus expressing MFN2 short hairpin RNA (shRNA). Using these hESC lines, we found that MFN2 deficiency did not alter the differentiation of spinal motor neurons from hESCs but induced fragmented mitochondria with abnormal function determined by live-cell imaging. Notably, MFN2-knockodwn spinal motor neurons recapitulated CMT2A disease related

phenotypes, including extensive perikaryal inclusions of phosphorylated neurofilament heavy chain (pNfH), accumulated axonal swellings, and increased pNfH levels in long-term cultures of spinal motor neurons. Importantly, MFN2 deficit impaired both anterograde and retrograde mitochondrial transport within axons by disturbing kinesin and dynein motor protein-associated gene expression. Taken together, our data reveal that MFN2 deficiency results in axonal degeneration and impairs mitochondrial morphology and function in human spinal motor neurons. The impaired mitochondrial transport in MFN2-knockdown spinal motor neurons is partially mediated by aberrant expression of motor proteins, which provides potential therapeutic targets for rescuing axonal neuropathy of spinal motor neurons in CMT2A disease.

Abstract: Answer ALS was conceived and organized as a comprehensive multi-omics approach to ALS to ascertain, at a population level, the various clinical-molecular-biochemical subtypes of ALS. This national program enrolled a combined total of 1047 ALS and ALS/FTD patients and

matched control subjects. Individuals were recruited at 8 national ALS centers and followed longitudinally over one year. A smartphone-based system was employed to collect deep clinical data including fine motor activity, speech, breathing and linguistics/cognition. In collaboration with IBM Research, analytics of speech pattens reveals a strong correlation between clinical progression indices and speech. In parallel, iPS motor neurons were derived from each patient and these cells underwent multi-omic analytics including whole genome sequencing, transcriptomics, ATAC-Seq and proteomics. HIPAA compliant cloud databases were employed to store all data. Open access to all clinical, biological and molecular data is central to the program as well as public release of all generated iPS cell lines The intent of this data is for the generation of integrated clinical and biological signatures using bioinformatics, statistics and computational biology to establish patterns that may lead to a better understanding of the underlying mechanisms of disease including subgroup identification. A web portal for open source sharing of all data was developed for widespread community-based data analytics. This community-based clinical and science program provides for the identification of distinct reliably identifiable subgroups among the sporadic and familial patients and the great utility in iPS based approaches to disease pathophysiology and therapy discovery.

Title: Identification of novel environmental inducers of TDP-43 aggregation linked to Amyotrophic Lateral Sclerosis

Authors: *G. FRAGOLA[1], J. M. WOLTER[2], T. J. COHEN[1];
[1]Dept. of Neurol., [2]UNC Neurosci. Ctr., Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Pathological aggregation of Transactive response DNA binding Protein 43 kDa (TDP-43) is a hallmark of Amyotrophic Lateral Sclerosis (ALS), a devastating neurodegenerative disease affecting upper and lower motor neurons. The overwhelming majority of ALS cases is sporadic, and the etiology likely stems from the interaction between age, genetics, and the environment. Recently, many environmental factors, including potentially damaging toxicants, have been linked to ALS through epidemiological studies, but a comprehensive identification of

all risk compounds that we as humans are exposed to has not been done. There is, therefore, an urgent need to identify environmental toxins causing TDP-43 aggregation. To address this need, we performed a high-content imaging screen by exposing cells expressing a GFP-tagged TDP-43 to a library of over 1,000 environmental compounds with high potential for human and ecosystem exposure and denoted as "at risk". This screen led to the identification of novel inducers of TDP-43 aggregation, which were validated in mouse primary neurons and in hiPSC-derived neurons. Mechanistic studies indicate that these novel compounds induce TDP-43 aggregation via new cellular and biochemical pathways and highlight unanticipated targets for therapeutic intervention. Moreover, the detection of these environmental risk compounds identifies human populations at high risk of developing ALS and other TDP-43 related diseases.

Abstract: Expansion of a GGGGCC repeat in the 5' region of the first intron of chromosome 9 open reading frame 72 (C9orf72) gene is the most common genetic cause of two major neurodegenerative diseases, amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). This mutation accounts for ~40% of familial ALS, ~25% of FTD as well as ~7% of sporadic ALS cases. Precise dissection of the cell-type-specific pathophysiological alterations in C9orf72-associated neurodegenerative disease may help illuminate disease mechanisms. However, most molecular, genomic, and epigenomic studies have used bulk brain specimens that represent mixed signals from diverse neuronal and glial cell types. Here, we profiled the cell type specific transcriptome and epigenomes in two brain regions, primary motor cortex (MCX) and medial prefrontal cortex (mPFC), using post-mortem tissue samples from controls (n=6), and

patients with C9orf72-ALS (n=6) and C9orf72-FTD (n=6). We used single-nucleus RNA sequencing (snRNA-seq) and assay for Transposase-Accessible Chromatin using sequencing (snATAC-seq) to identify transcriptomic and chromatin accessibility disruptions relevant to this mutation in specific cell types. We obtained high-quality molecular profiles from ~100k nuclei in snRNA-seq and ~120k nuclei in snATAC-seq, and identified distinct classes and subtypes of neuronal and glial cells in the two brain regions. We found that the transcriptome was most disrupted by both diseases in astrocytes and subtypes of excitatory neurons. Transcriptome alterations were accompanied by concordant changes of chromatin accessibility in the gene body or distal linked enhancers of differentially expressed genes. We confirmed these findings in purified populations of the major brain nuclei obtained by fluorescence activated nuclei sorting (FANS), as well as using protein level measurements for selected differentially expressed genes. In summary, our study represents the first comprehensive characterization of molecular alterations in C9orf72-associated ALS and FTD at the level of single brain cells. Our unexpected finding of considerable ALS/FTD-associated pathology in astrocytes suggests novel biological pathways and genes that are dysregulated in these diseases.

Title: Targeting H-Reflex Hyperexcitability after SCI with Repurposed PAK1-Inhibitor, Romidepsin

Authors: *S. KAUER, C. BENSON, M. L. REIMER, S. PATWA, S. LIU, S. G. WAXMAN, A. M. TAN;
Yale Univ., New Haven, CT

Abstract: Spasticity is a clinical symptom of hyperexcitability within the spinal stretch reflex system (or H-reflex), which presents as a velocity-dependent increase in tonic stretch reflexes with exaggerated tendon jerks (Lance,1980). Individuals living with spasticity may have difficulty engaging in physical rehabilitation, experience concomitant muscle-joint pain, and experience negative quality-of-life issues (Holtz et al., 2017). Over the past decade, we have documented a common structural motif of Rac1-PAK1 regulated dendritic spine morphology associated with hyperexcitability disorders, including spasticity (Bandaru et al., 2015; Zhao et al., 2016). In this study, we investigate the utility of "repurposing" romidepsin, a clinically available drug to disrupt PAK1, to relieve spasticity after SCI. Romidepsin is a potent HDAC inhibitor that reduces PAK1 activity without affecting its protein level. Importantly, we and others have previously highlighted PAK1 as a promising druggable target for chronic neurological disease. In agreement, we have shown that romidepsin treatment has a predictable effect upon cellular and structural correlates of chronic pain (Guo et. al., 2018). To assess the efficacy of romidepsin for addressing spasticity, we will use reporter mice expressing fluorescent YFP (Thy1-YFP). To induce spasticity, we will perform a mild contusion SCI using the Infinite Horizon (IH) impactor device. Romidepsin or vehicle will be administered as three intrathecal injections four-weeks after SCI or Sham surgeries. Blinded observers will perform all physiological and behavioral assessments for spasticity and locomotor function. To analyze protein expression levels for drug response, i.e., PAK1 activity, we will process spinal cord tissue using clearing methods. We will identify a-motor neurons using established morphological criteria (Bandaru et al., 2015; Tan et al., 2012). To determine the efficacy of romidepsin treatments on SCI-induced spasticity, anatomical and biochemical data will be correlated with spasticity outcomes. YFP-expressing dendritic spine morphology will be profiled in association with H-reflex excitability indicative of spasticity. To monitor *in vivo* bioavailability, we will use assess drug-response biomarkers from all animals before and after treatment with romidepsin. A positive romidepsin drug-response in tissue and reduced dendritic spine dysgenesis that correlates with reduced spasticity outcome will support our hypothesis regarding the efficacy of targeting PAK1 activity after SCI.

Title: Dynamically clamping human somatosensory neurons quantifies the roles of $Na_V1.8$ and $Na_V1.9$ in electrogenesis

Authors: *M. ALSALOUM[1,2], J. I. R. LABAU[1,2], S. LIU[1,2], M. R. ESTACION[1,2], P. ZHAO[1,2], F. B. DIB-HAJJ[1,2], S. G. WAXMAN[1,2];

Abstract: The inhibition of voltage-gated sodium (Na_V) channels in somatosensory neurons presents a promising novel modality for the treatment of pain. However, the precise contribution of these channels to neuronal excitability, the cellular correlate of pain, is unknown; previous studies using genetic knockout models or pharmacologic block of Na_V channels have identified general roles for distinct sodium channel isoforms, but have never quantified their exact contributions to these processes. To address this deficit, we have utilized dynamic clamp electrophysiology to inject precisely calibrated levels of $Na_V1.8$ and $Na_V1.9$ currents into induced pluripotent stem cell-derived sensory neurons (iPSC-SNs), allowing us to quantify how graded changes in these currents affect neuronal excitability and electrogenesis. We quantify and report direct relationships between $Na_V1.8$ current density and action potential half-width, overshoot, and repetitive firing. We additionally quantify the effect varying $Na_V1.9$ current densities have on neuronal membrane potential and rheobase. Furthermore, we examined the simultaneous interplay between $Na_V1.8$ and $Na_V1.9$ on neuronal excitability. Finally, we show that minor biophysical changes in the gating of $Na_V1.8$ can render human iPSC-SNs hyperexcitable, in a first-of-its-kind investigation of a gain-of-function $Na_V1.8$ mutation in a human neuronal background.

Title: Non-opioid treatments for neuropathic pain: PK/PD of strategically substituted agmatines

Authors: *B. CLEMENTS[1], C. PETERSON[2], K. KITTO[2], G. L. WILCOX[3], C. A. FAIRBANKS[4];
[1]Dept. of Pharmaceutics, [2]Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]Dept Neurosci, Pharmacol, Dermatol, Univ. Minnesota Med. Sch., Minneapolis, MN; [4]Depts Pharmaceut, Pharmacol & Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: Agmatine, an arginine metabolite, has been shown to reduce chronic pain in mice in a GluN2B receptor subunit-dependent manner, without motor side effects that are common for NMDA receptor antagonists. Various biopharmaceutical features, including short serum half-life, residence time, and limited blood brain barrier penetrance, challenge the utility of systemic delivery of agmatine. To address these limitations, we developed a series of substituted agmatines (SSAs), to increase lipophilicity and distribution to the CNS. We hypothesize that, relative to agmatine, SSAs reduce chronic pain with greater potency or efficacy with more ideal pharmacokinetic parameters. Assessment of the reduction of chronic pain behaviors was performed in male and female Sprague-Dawley rats following spared nerve injury (SNI). Tactile hypersensitivity was measured using von Fey monofilament stimulation. Intravenous strategically substituted agmatines dose-dependently reduced tactile hypersensitivity in nerve-injured subjects. Additionally, a reduction was seen at doses with no agmatine activity. Pharmacokinetic studies were performed in male and female rats, with serial blood collection via jugular catheters. Plasma was analyzed using LC-MS/MS, following novel analytical methods developed in our laboratory. At a dose of 13 nmol/kg, IV SSA-3 shows 2-phase distribution and elimination, with an elimination half-life of 36.7 ± 3.95 minutes. IV SSA-4 (13 nmol/kg) shows a similar distribution and elimination profile, with an elimination half-life of 38.3 ± 3.45 minutes. These data show a greater plasma half-life as compared to agmatine (9-15 minutes). When delivered orally in 5% DMSO, SSA-3 demonstrated oral bioavailability at 22.9%. Taken together we have observed that strategically substituted agmatines reduce tactile hypersensitivity arising from spared nerve injury with more ideal pharmacokinetic features.

Title: Mindfulness meditation-induced stress reductions predict pain relief

Authors: *J. DEAN[1], G. POSEY[2], G. RIEGNER[1], L. KHATIB[1], V. OLIVA[1], J. BAUMGARTNER[1], Y. JUNG[3], R. KRAFT[2], F. ZEIDAN[1];
[1]Univ. of California San Diego, La Jolla, CA; [2]Wake Forrest, Winston-Salem, NC; [3]Univ. of California, Davis, Davis, CA

Abstract: Stress and chronic pain disorders are highly comorbid conditions wherein stress reliably exacerbates pain. The perigenual anterior cingulate cortex (pgACC) and the amygdala are uniquely associated with modulating pain and stress. However, it is unknown if and how stress and pain are modulated by mindfulness meditation training.
Forty healthy, pain-free individuals were randomly assigned to our validated four session (20 minutes/session) mindfulness-based (n = 20) or a book-listening control (n = 20) regimen. Prior to intervention training, participants were administered four noxious heat series consisting of ten, 10 second plateaus of 49°C thermal stimulation to the right calf at the baseline session. After completing their respective interventions, participants underwent blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging (fMRI) imaging during heat. Two heat series were administered during rest (pre-manipulation) followed by two additional heat series (post-manipulation) during mindfulness or rest (controls). Visual analog stress and pain ratings (0 = "no pain/stress"; 10 = "worst pain/stress imaginable") were collected after each heat series, respectively.
A one-way analysis of variance (ANOVA) revealed no between group differences in pain intensity ($p = 0.80$) or stress ($p = 0.27$) ratings during noxious heat at the baseline session. A 2 (mindfulness vs. control) X 2 (pre- vs. post-manipulation) repeated measures ANOVA found that mindfulness meditation significantly reduced pain intensity (32% decrease, $p < 0.001$) and stress (39% decrease, $p = 0.023$) ratings in the mindfulness but not the control group. A simple linear regression found mindfulness-induced reductions in stress predicted reductions in pain intensity ($p = 0.01$, $R^2 = 0.30$).
The present study demonstrates that mindfulness-induced reductions in stress were associated with lower pain suggesting overlapping psychological and neural mechanisms. We postulate that stronger mindfulness-induced pgACC-amygdala connectivity will be associated with lower stress and pain.

Title: N-(1-benzylpiperidin-4-yl)-4-fluorobenzamide a new compound with antihyperalgesic and atiallodynic effect in neuropathic rats

Authors: *M. DECIGA-CAMPOS[1], G. NAVARRETE-VÁZQUEZ[2];
[1]Inst. Politécnico Nacional, Mexico City, Mexico; [2]Facultad de Farmacia, Univ. Autónoma del Estado de Morelos, Morelos, Mexico

Abstract: The σ_1 receptor (σ_1R) plays a pivotal role in the transmission of pain; σ_1R are located in the plasma membrane and subcellular membranes, particularly in the endoplasmic reticulum, where they play a modulatory role in intracellular Ca^{2+} signaling. This work describes the design and synthesis of a novel analog of haloperidol: *N*-(1-benzylpiperidin-4-yl)-4-fluorobenzamide (LMH-2) as well as its antihyperalgesic and antiallodynic effect in rats with neuropathy induced by chronic constriction injury of the *sciatic* nerve (CCI). LMH-2 was designed as a haloperidol analog, its structure was characterized by spectroscopic (^{1}H and ^{13}C NMR spectra) and spectrometric mass (electronic impact) techniques. Also, *in silico* predictions of pharmacokinetic, pharmacodynamic, and toxicological properties were obtained with promising results. The *in vivo* antihyperalgesic and antiallodynic activity was carried out using Wistar rats with CCI. Compound LMH-2 presented a high affinity for the σ_1R in an *in vitro* binding assay, showing a K_i = 6.0 nM and high σ_1R/σ_2R selectivity ratio (>30). Subsequently, molecular docking studies were carried out to determine the binding energy and to analyze LMH-2-protein interactions. Throughout an *in silico* pharmacological consensus analysis, LMH-2 was considered safe to evaluate rats with neuropathic pain. The dose-response curves of the antiallodynic and antihyperalgesic effects showed less antihyperalgesic and antiallodynic response with respect to Gabapentin used as a positive control. However, when comparing the potency of the effects it can be seen that the new designed compound LMH-2 is more potent than gabapentin because its ED_{50} is lower with respect to gabapentin, both in the antihyperalgesic effect (LMH-2, ED_{50} = 14.8 ± 2.1 mg/kg and GBP, ED_{50} = 29.9 ± 1.1 mg/kg) and the antiallodynic effect (LMH-2, ED_{50} = 9.0 ± 1.4, GBP, ED_{50} = 35.3 ± 2.3 mg/kg) this means that a lower dose is required for LMH-2 generate the same antihyperalgesic and antiallodynic response as gabapentin in the ICC model. LMH-2 administration produces antihyperalgesic and antiallodynic effects that probably result from an antagonism at σ_1R. LMH-2 may have potential as an analgesic drug in neuropathic pain.

Title: Strategically-substituted agmatines prevent the development of oxycodone self-administration

Authors: *C. PETERSON[1], C. BARAJAS[2], K. KITTO[1], G. WILCOX[1], C. FAIRBANKS[3];
[1]Neurosci., [2]Exptl. and Clin. Pharmacol., [3]Pharmaceutics, Univ. of Minnesota, Minneapolis, MN

Abstract: The glutamatergic system is shown to play a central role in opioid addiction, therefore its inhibition has been shown to prevent the development of opioid-seeking behavior in a rodent model of drug-seeking. A decarboxylated form of L-arginine, agmatine, has been demonstrated to preferentially antagonize GluN2B-containing NMDA receptors. We have designed a series of strategically-substituted agmatine compounds (SSA1-SSA4) with the goal of improving several biopharmaceutical features of the parent compound. To this end, we have evaluated these compounds as a more viable potential therapeutic for the treatment of opioid use disorders (OUD) and evaluated their risk of dependence with repeated administration. Self-Administration: Mice (F, 21-30g) were given access to operant chambers and allowed to press either for oral oxycodone reward or an inactive control. Daily, the mice were given either a pre-treatment of a strategically-substituted agmatine (SSA3) compound or vehicle control, i.p.. Daily lever-pressing was recorded as an indication of drug-seeking behavior. Additionally, this same cohort was allowed to lever press for food pellet reward following conclusion of oxycodone reinforcement. Area under the curve (AUC) was compared between SSA pre-treated and vehicle pre-treated groups. Pre-treatment with the SSA3 compound significantly decreased oxycodone seeking behavior, but had no impact on food-maintained responding. Additionally, SSA3 showed no impact on motor coordination or cardiovascular function, side effects of concern for glutamatergic compounds. Physical dependence: Rats (M/F, 200-380g) were injected twice daily for 28 days with only one of the following compounds: SSA1-SSA4, ketamine as an in-class control, morphine as a positive control, or vehicle. The rats were observed for an hour following each injection for behavioral alterations indicative of dependence. While morphine and ketamine developed symptoms consistent with dependence associated with their respective receptor classes, the SSA compounds showed no indication of overt dependence behaviors representative of either class of compound. These data indicate that a strategically-substituted agmatine compound is capable of significantly reducing opioid-seeking behavior with a wide therapeutic window, avoiding the motor impairment and cardiovascular impairment typical of drugs of this class.

Title: Approaches for optimizing temporal patterns of spinal cord stimulation (SCS) for treatment of chronic pain

Authors: *K. M. LAMBERT[1], T. ZHANG[2], J. GILBERT[1], M. MOFFITT[2], W. M. GRILL[1]; [1]Biomed. Engin., Duke Univ., Durham, NC; [2]Boston Scientific Neuromodulation, Valencia, CA

Abstract: Spinal cord stimulation (SCS) is an effective therapy for chronic pain used to treat tens of thousands of patients each year. There remain opportunities to improve SCS efficacy, as, in aggregate, SCS reduces pain scores by more than 50% in only ~60% of recipients, and recent clinical studies suggest that patterns of SCS beyond tonic stimulation may improve outcomes. Thus, we hypothesized that optimized temporal patterns of SCS may produce greater suppression of pain and greater reductions in spinal nociceptive neuron firing than frequency matched tonic SCS. We pursued two complementary approaches to produce optimized temporal patterns of stimulation - dual frequency SCS (dfSCS) and model-based optimization of patterned SCS. In both cases, we used a biophysical model of the dorsal horn network to test the ability of patterns to inhibit model wide dynamic range (WDR) neuron firing- a validated proxy for pain. In our dfSCS approach, two different frequencies of tonic SCS between 0-70 Hz were delivered separately to distinct populations of dorsal column axons originating from center and surround sensory receptive fields. Patterns were considered effective if they produced a 30% reduction in WDR firing rate compared to single frequency controls (higher, lower, and average) and pre-stimulation firing. The dfSCS parameter space was reduced by searching for frequency pairs that produced WDR firing rate reductions that were robust to the center-surround distribution of axons stimulated, and to loss of GABAergic and glycinergic inhibition known to occur during pain progression. Across all model states examined, the range of optimal surround frequencies was 40-70 Hz and center frequencies was 0-10 Hz. In our pattern optimization approach, we combined our computational model with a modified genetic algorithm to optimize temporal patterns of SCS that maximized a fitness function constructed to select patterns that were both more effective at reducing WDR firing rate than frequency-matched tonic SCS and more efficient than the clinical standard 50 Hz tonic SCS. In addition, patterns were evaluated for their ability to reduce WDR firing rate compared to frequency-matched stochastically generated patterns. The best performing patterns were often at average rates of ~30 Hz, with a majority of interpulse intervals between 20-30 ms or 40-50 ms, and an overall range of 1-70 ms. These patterns reduced model WDR firing rates compared to single frequency, 50 Hz, and stochastic

controls. The results demonstrate that model-based design of spatio-temporal patterns of SCS beyond tonic SCS is a promising approach to improving SCS therapy.

Title: Cannabinoid receptor modulation of Cav3.2 voltage-gated calcium channels

Authors: *E. K. HARDING[1,2], M. A. GANDINI[1,2], T. TRANG[1,2], G. W. ZAMPONI[1,2]; [1]Univ. of Calgary, Calgary, AB, Canada; [2]Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Cannabinoids represent a promising therapeutic avenue for treatment of chronic pain, however mixed results from both clinical and preclinical trials indicate that more work is needed to define the precise mechanism of action of cannabinoids in reducing pain symptoms. Cannabinoid receptor 1 (CB1R) is a $G_{i/o}$ coupled receptor that initiates complex signaling cascades within neurons, ultimately leading to inhibition. This occurs through interaction with a variety of proteins and ion channels, including presynaptic high voltage-activated calcium channels, which become inhibited upon CB1R activation. Low voltage-activated calcium channels such as Cav3.2 can also be present at some presynaptic terminals, including at primary afferent terminals in the superficial spinal dorsal horn, where they contribute to nociceptive processing. We therefore sought to determine whether CB1R activation by cannabinoids leads to inhibition of Cav3.2 channels. We first recorded from tsA-201 cells expressing pcDNA for Cav3.2 alone or in combination with CB1R. A time course of peak current amplitude was acquired during wash-in of the synthetic cannabinoid agonist, HU210. HU210 had no effect on Cav3.2 peak current alone up to concentrations of 5 µM. Similarly, HU210 at 1 or 5 µM did not

inhibit Cav3.2 peak current in cultures co-expressing CB1R. Positive controls performed in Cav2.2 and CB1R co-cultures showed inhibition by 1 µM HU210. We next wondered if expression of CB1R alone could affect Cav3.2 function. We found no significant differences in activation voltage or peak current density when comparing IV-curves between groups. However, comparison of steady-state inactivation curves revealed that co-expression with CB1R produced a significant ~10 mV hyperpolarizing shift in half-inactivation voltage. Our results therefore indicate that while the synthetic cannabinoid HU210 does not produce significant CB1R-mediated inhibition of Cav3.2, the expression of CB1R with Cav3.2 alone is sufficient to modulate Cav3.2 function. These results are the first indication that cannabinoid receptors can alter Cav3.2 channel gating to decrease the size of the window current. Future experiments will determine whether this is a result of constitutive activity of CB1R on Cav3.2, or a potential physical interaction between these two channels.

Title: Evaluation of pain reduction by RNA aptamers targeting glutamate receptors in a rat spinal cord injury model

Authors: *S. JERGOVA[1], Z. HUANG[2], A. EESWARA[1], A. PACHECO-SPIEWAK[1], L. NIU[2], J. SAGEN[1];
[1]Miami Project Cure Paralysis, Univ. of Miami, Miami, FL; [2]Dept. of Chem., Univ. at Albany, SUNY, Albany, NY

Abstract: Spinal cord injury (SCI)-related neuropathic pain remains difficult to treat with poor long-term prognosis. Given the high risk of using opioid analgesics as a primary treatment, there is an urgent medical need to develop new therapeutics. Studies in diverse pain models in rats have shown that AMPA/kainate receptor antagonists can significantly inhibit pain, without abuse potential. However, properties such as nonselective off-target effects through systemic administration, and poor water solubility which reduces CNS bioavailability, are problems prevalent in virtually all existing AMPA receptor inhibitors. In this project we have tested three RNA aptamers that act as AMPA or kainate receptor antagonists as a new class of potential analgesics in a rat SCI-induced pain model. These aptamers were previously identified using

systematic evolution of ligands by exponential enrichment (SELEX). Male and female Sprague Dawley rats underwent spinal clip compression to induce SCI-pain. Animals were tested for the presence of tactile and cold allodynia at 2hrs, 1D and 4D post injection, starting at 4 week post SCI. Each of the three aptamers (FN1008, FN1040, and FB9s-b or vehicle) was injected intrathecally at a 4-day interval at the A50 dose established by prior experiments. Conditional place preference (CPP) test was performed with iv gabapentin as the conditioning analgesic drug. Potential side effects (locomotor scores, reflexes, weight) with repeated aptamer injections were monitored. Both males and female rats developed hypersensitivity to tactile and cold stimuli by week 4 post SCI. Injection of aptamer FN1008 and FB9s-b significantly reduced hypersensitivity at 2 hrs after each injection, and robust and prolonged anti-allodynic effects were observed with aptamer FN1008 and FB9s-b, as compared with weak effects of FN1040. Aptamer FN1008 and particularly FB9s-b (a kainate receptor-selective aptamer) appeared to produce more sustained anti-allodynic effects after 3-5 repeated injections that did not reverse to baseline pain levels. In addition, both aptamers reduced gabapentin CPP, suggesting a reduction of ongoing pain in treated animals. Yet, no side effects were detected from aptamer-treated rats. Interestingly, the two effective aptamers are selective for distinct receptors (FN1008 for AMPA receptors, FB9s-b for kainate receptors), suggesting blocking both AMPA and kainate receptor activities may be even more useful in pain control. Our results demonstrate that FN1008 and FB9s-b are both efficacious and safe to use and the use of RNA aptamers is a promising treatment strategy for alleviating debilitating neuropathic pain due to SCI.

Title: A multi-region close loop BMI system for pain modulation

Authors: *G. SUN, F. ZENG, Q. ZHANG, H. XU, Y. LIU, Z. CHEN, J. WANG;
New York Univ., New York, NY

Abstract: Effective treatments for chronic pain remain limited. Conceptually, a closed-loop neural interface that combines sensory signal detection with therapeutic delivery can produce timely and effective pain relief. Such systems have been challenging to develop due to difficulty in accurate pain detection and ultra-fast analgesic delivery. Pain has sensory and affective

components, encoded in large part by neural activities in the primary somatosensory cortex (S1) and anterior cingulate cortex (ACC), respectively. Meanwhile, studies have shown that stimulation of the prefrontal cortex (PFC) produces descending pain control. Here we designed a brain-machine interface (BMI) that combines automated pain detection based on simultaneously recorded local field potential (LFP) signals from the S1 and ACC with optogenetic activation or electrical deep brain stimulation (DBS) of the prelimbic PFC in freely behaving rats. Our multi-region neural interface accurately detected and treated acute evoked pain and, more importantly, spontaneous pain associated with chronic pain. This neural interface performed with minimal delay and remained stable over time. Given the clinical feasibility of LFP recordings and DBS, our findings demonstrate the promising potential of BMI therapeutics for the treatment of pain and related neuropsychiatric diseases.

Title: Reduction of NMDA-stimulated calcium signaling by decarboxylated arginine (agmatine) using two-photon calcium imaging

Authors: *T. XIE[1], C. D. PETERSON[2], G. L. WILCOX[3], L. VULCHANOVA[2], C. A. FAIRBANKS[4];

Abstract: Chronic pain is a critical public health concern and effective long-term treatments are still needed. One of the targets for chronic pain management is inhibition of synaptic plasticity in the spinal cord via antagonism of the NMDA receptors (NMDAr). Specifically, antagonism of the GluN2B subunit in spinal cord dorsal horn is involved in the central sensitization and the development of chronic pain. Our previous studies have demonstrated that the intrathecal administration of agmatine, an endogenous aminoguanidine that preferentially antagonizes GluN2B-containing NMDArs, inhibits and reverses the tactile hypersensitivity without causing motor side effects. In this study, we investigated the spinal modulatory effect of agmatine at the cellular level utilizing calcium imaging. Calcium imaging is an established imaging technique to

visualize intracellular Ca^{2+} representing an indirect measure of neuronal activation, but NMDA-stimulated calcium transients have not been reported in spinal cord dorsal horn. The aim of this study is to develop NMDA-stimulated calcium transient assay in ex vivo mouse spinal cord dorsal horn and examine the effect of agmatine in this assay. Our hypothesis is that agmatine can dose-dependently inhibit NMDA-stimulated calcium transients in mouse spinal cord dorsal horn. Female and male ICR mice (4-6 weeks) were perfused before spinal cord extraction and ex vivo spinal slices were loaded with the calcium indicator dye Fluo-4. Intracellular Ca^{2+} was visualized by single plane two-photon microscopy. Time-lapse of images were acquired and the peak amplitude and AUC of Fluo-4 fluorescence intensity were analyzed by Student's t-test and ANOVA test. We observed that NMDA-stimulated calcium transients were elicited by an NMDA drug mixture containing NMDAr agonists (NMDA, glycine) and AMPA receptor antagonists (NBQX). We further demonstrated that the 5mM agmatine incubation significantly inhibited NMDA-stimulated calcium transients compared to control. Increasing agmatine concentration (0.5, 1, 2.5, 5, 10 mM) showed dose-dependent inhibition of NMDA-stimulated calcium transients. These data suggest that agmatine is an effective inhibitor of NMDArs in the spinal cord dorsal horn, and agmatine inhibited NMDA-stimulated calcium transients, consistent with our previous research demonstrating that agmatine is an effective inhibitor of NMDAr in the spinal cord dorsal horn.

Title: Behavioral detection of optogenetic stimulation in macaque inferior temporal cortex is influenced by visual input

Authors: E. LOPEZ[1], S. BOHN[2], R. AZADI[1], A. AFRAZ[1];
[1]NIH, Bethesda, MD; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Anecdotal evidence from electrical stimulation of the human fusiform cortex suggests that the visual perceptual event induced by stimulation of a given cortical position varies in amplitude depending on the visual input to the eyes. This is not compatible with the intuitive view, associating a singular phosphene-like perceptual event with stimulation of a given position on the visual cortex. Here we systematically put this question to test. In two macaque monkeys,

we chronically implanted LED arrays over the central inferior temporal (IT) cortex where we had previously injected Adeno Associated Virus 5 engineered to express excitatory opsin C1V1. We also implanted the array on the opposite IT cortex where no virus injection was performed. Each behavioral trial started by fixation on a target followed by presentation of an object image randomly drawn from a set of 40 for 1 second. In half of the trials, randomly selected, a 200ms illumination impulse was delivered to the IT cortex in the middle of image presentation. Then the animals indicated if the trial contained a cortical stimulation impulse or not by looking at one of the two consequently presented targets to receive liquid reward. The two animals learned this task significantly above chance level within 17 and 8 days respectively. The analysis of results revealed a strong effect of image on the animals' ability to detect cortical stimulation ($p < 0.001$ for all) with their performance ranging from 88% to 52% for various objects. Detection of cortical stimulation was near its minimum for both animals, when no stimulus (except for a sound cue) was presented to the fixating animal during cortical stimulation (<56% for both animals). The animals were not able to detect cortical illumination over control areas with no virus transduction. In a separate experiment, we showed that detectability of optogenetic stimulation increases as the intensity of LED activation increases, and that the slope of this increase is different for various objects ($p < 0.02$ for all). Our results show that detectability of optogenetic stimulation of the IT cortex varies across different visual inputs and drops significantly when no visual stimulus is presented. This is consistent with human observations and suggests that the perceptual events induced by artificial activation of the IT cortex, highly depend on the content of vision.

Title: Visibility of visual input strongly modulates detectability of optogenetic stimulation of inferior temporal cortex

Authors: *R. LAFER-SOUSA, K. WANG, A. AFRAZ;
NIH, Bethesda, MD

Abstract: Stimulation of visually sensitive regions of ventral temporal cortex in humans has been shown to cause changes in perception, yet the precise nature of these effects remains unclear. In some cases, cortical stimulation while an object or image is being viewed suggests an

additive effect wherein a hallucinatory image is superimposed on the image that has been streaming from the retina (e.g. Schalk et al. 2017). Other cases suggest such stimulation causes a distortion of the contents of the visual input (e.g. “your face metamorphosed, your nose got saggy and went to the left” Ragarajan et al. 2014). Clarifying the nature of these perturbations is critical to understanding the role these brain regions play in behavior and perception. In order to systematically test whether stimulation of inferior temporal (IT) cortex causes additive versus distortive effects, we carried out optogenetic stimulation in macaque monkeys performing a stimulation-detection task while viewing images of objects that varied in visibility. Hypothetically, if stimulation causes an additive effect, varying visibility of the visual input should not affect detectability of stimulation. If anything, stimulation should be easier to detect when the visual input is less visible since there would be no underlying image to parse from the hallucinatory percept. If on the other hand cortical stimulation has a distortive effect, it should be easier to detect when the visual input is more visible, as the effect would necessarily be a function of the visual input. Hence, the stimulation-detection task is well-suited to distinguish between the distortion model and the additive model. Two macaque monkeys were implanted with arrays of LEDs over a region of their IT cortex transduced with the depolarizing opsin C1V1. In each trial, following fixation an image was displayed on the screen for 1s. In half of the trials, randomly selected, an LED was turned on for 200ms half way through image presentation, and the animal was rewarded for correctly identifying whether the trial did or did not contain cortical stimulation. The image set consisted of objects that degraded in contrast, saturation, and spatial frequency to near gray in 4 steps. Visibility of the visual input had a significant effect on stimulation detectability (ANOVA, M1 $p = 0.0036$, M2 $p = 1 \times 10^{-6}$). Consistent with the distortion model, the animals were more accurate at detecting stimulation when the visual input was more visible.

Title: Perceptography: behavior guided graphical reconstruction of phosphenes induced by electrical stimulation of the primary visual cortex

Authors: *T. MA[1], E. SHAHBAZI[1], A. BOWMAN[2], A. AFRAZ[3];
[1]Natl. Inst. of Hlth., North Bethesda, MD; [2]NIMH, Kensington, MD; [3]NIH, Bethesda, MD

Abstract: Is it possible to take a picture of a visual perceptual event induced by stimulation of the visual cortex? While the question sounds philosophically impenetrable, we have developed a concept, perceptography, to approximate such pictures; perceptograms. We define a perceptogram as an altered image, which is indiscriminable for the observer from the state of being cortically stimulated in a given visual area, while viewing the original image. To test the concept, we chose the primary visual cortex (V1) as a testbed because the perceptual events resulting from stimulation of area V1, known as phosphenes, are well studied in both humans and monkeys, yet loosely characterized in regards to their shape, timing, and luminance. A macaque monkey was trained to behaviorally detect short electrical impulses (250 μA, 40Hz bipolar square wave, 200 ms) delivered to its V1 via a Utah array while fixating at a dynamic pattern of low-frequency enhanced white noise subtending 23 degrees. Each trial lasted 1s, included 5 refreshments of the noise pattern, randomly included cortical stimulation halfway through the trial and was followed by two response targets for the monkey to indicate if the trial was "stimulated" or not. We only used stimulation in one position in the cortex for collecting each batch of data. We then marked the trials that led to a false alarm (12% of trials). We hypothesized that a false alarm is more likely if a pattern of noise happens to mimic the visual timing and features of the electrically induced phosphene. Thus, at first pass we averaged all the noise patterns that led to ~800 FAs across ~6000 behavioral trials and 3 cortical positions. For different cortical positions on V1, we found light and dark phosphenes significantly standing out of the noise (mean difference from average gray 4.6%, St.D 0.22, $p<0.01$, corrected for multiple comparisons). These phosphenes matched the location and timing of the saccades induced by electrical stimulation of their corresponding cortical position with the fixation condition relaxed. They also matched the location of the receptive field of the neurons directly under the stimulated shaft of the array.

Title: Perceptography, behavior guided reconstruction of visual percepts induced by stimulation of the inferior temporal cortex.

Authors: E. SHAHBAZI[1], T. MA[1], M. PERNUS[2], R. AZADI[3], W. SCHEIRER[4], *A. AFRAZ[1]; [1]NIH/NIMH, Bethesda, MD; [2]Fac. of Electrical Engin., Univ. of Ljubljana, Ljubljana, Slovenia;

Abstract: Cortical stimulation in high-level visual areas induces complex perturbations in visual perception. Understanding the nature of stimulation-induced visual percepts is necessary for characterizing visual hallucinations in psychiatric disease and for the development of visual prosthetics. While most of the evidence comes from anecdotal observations in human patients, systematic study of the topic has been severely limited in the absence of language faculty in nonhuman primates. We developed a new method, perceptography, to take pictures of complex visual percepts induced by optogenetic stimulation of the inferior temporal (IT) cortex in macaque monkeys. Each trial started with the animal fixating on the screen, followed by a 1s presentation of a natural-looking image produced by a generative adversarial network (GAN). Halfway through the image presentation, we briefly altered the image features. In half of the trials randomly selected, a ~1x1mm area of IT cortex was optogenetically stimulated, for the same duration as the image alteration, via an implanted LED array using the excitatory opsin C1V1. The animals were trained to report cortical stimulation with eye movements following the image offset. The animals learned to discriminate image feature alterations from those induced by cortical stimulation and were rewarded only for successful detection of the latter. Under the hood, two deep learning systems, DaVinci (GAN) and Ahab (Deep learning feature extraction pipeline), controlled image alterations and tracked the animals' behavioral responses, respectively. We hypothesized that false alarms (FA) are more likely to happen when an image alteration shares common features with the percept induced by cortical stimulation. In a functional closed loop with the animal, Ahab guided DaVinci to make image alterations that reduce the discriminability between stimulated and nonstimulated trials, thus increasing the chances of FA. While the baseline FA rate for nearly all image alterations remained at ~2.5%, within 10,000 trials(5 days), the pool of Ahab optimized images evolved to induce 8-10% FA. Among these were five images that induced 55-79% FA (cross-validated, $p<0.01$). We would like to call these images Perceptograms of IT, as the state of seeing them is hard for the animal to discriminate from the state of being cortically stimulated.

Title: Models of category-selective brain regions recapitulate key findings and enable high-throughput tests of selectivity

Authors: *N. RATAN MURTY[1], A. ABATE[1], P. BASHIVAN[2], J. DICARLO[1], N. KANWISHER[1];

Abstract: Cortical regions apparently selective to faces, places, and bodies have provided important evidence for domain-specific theories of human cognition, development, and evolution. But these claims of category selectivity are not quantitatively precise and remain vulnerable to empirical refutation. To address these limitations, we constructed deep convolutional artificial neural network (ANN) -based encoding models that accurately predict the observed fMRI response to novel images in the FFA, PPA, and EBA, outperforming both descriptive models and experts in the field. Even though not explicitly trained to do so, the models recapitulate several key findings in the literature (eccentricity and curvilinearity bias etc.) and provide important clues about the specific image features that drive the responses in these regions. We further used these computational models to subject claims of category selectivity to their strongest tests, by screening for and synthesizing images predicted to produce the highest response in each region. We found that the high-response-predicted images were all unambiguous members of the hypothesized preferred category for each region. Together these results provide highly accurate, image-computable encoding models of each category-selective region which we provide to the community as implementable online code. The results from our experiments also strengthen evidence for domain specificity in the human brain, and point the way for future research characterizing the functional organization of the brain with unprecedented computational precision.

Title: Opto-array: a chronically implantable led array designed for behavioral optogenetic experiments in nonhuman primates

Authors: *R. AZADI[1], E. LOPEZ[1], R. RAJALINGHAM[2], M. SORENSON[3], S. E. BOHN[4], A. AFRAZ[1];

Abstract: Optogenetics has revolutionized the landscape of systems neuroscience by enabling the scientist to perturb neural activity with precise spatial and temporal resolution and cell-type specificity. We developed the Opto-Array, a novel chronically implantable array of LEDs that can reliably deliver light in optogenetic experiments in large brains, specifically nonhuman primates. The OptoArray contains a 5x5 grid with 24 LEDs and one thermal sensor on a PCB encapsulated with a transparent parylene and silicone coating. The 2D configuration of LEDs enables perturbation of a large range of surface areas from (~1x1mm) for only one active LED to (~5x5mm) for the entire array turned on. The thermal sensor monitors the heating of the cortical tissue from light delivery to avoid any potential damage. The chronic nature of Opto-Array allows highly stable behavioral experiments, in which data can be pooled over months. Moreover, this tool provides a safer alternative to acute methods (i.e. using optical fiber and direct illumination), minimizing the tissue damage as well as the risk of infection associated with open cranial windows and chambers. Here we explain the surgical techniques and procedures for implantation of Opto-Array in macaque monkeys.

Title: Awake functional ultrasound imaging reveals rigidity of brain dynamics in reversible Shank3 mutant mice

Authors: *T. HENSCH[1], C. ORAM[2], T. WATANABE[3];
[1]Harvard Univ., Cambridge, MA; [2]Boston Children's Hosp., Boston, MA; [3]IRCN, Tokyo, Japan

Abstract: Human fMRI studies suggest that autism is underpinned by aberrant brain dynamics (Watanabe & Rees, 2017). To probe these mechanisms and their potential reversibility, whole-brain imaging from awake animals is required. We established a functional ultrasound (fUS) imaging paradigm for head-restrained wildtype (WT) and Shank3-deficient mice behaving freely on a ball while monitored for arousal state by concurrent pupillometry. Long-range resting state maps revealed a significant hypo-connectivity that was more prevalent in Shank3 heterozygous mice and at low arousal state. In parallel, we expanded the energy landscape analysis used previously for human fMRI data to deal with time-series data recorded from a relatively large number of neural areas. By applying the extended energy landscape analysis to the mouse fUS data, we examined the effects of Shank3 expression on brain state dynamics. First, we identified that the genetic disruption of Shank3 significantly deteriorated the flexibility of brain state dynamics (Cohen's $d > 6.0$; $P < 10\text{-}7$) due to significantly unstable minor brain states (Cohen's $d > 1.8$; $P < 0.0003$), which is consistent with our previous study of autistic human subjects (Watanabe & Rees, 2017). Instead, the duration of major brain states was unchanged in Shank3 mutants, unlike for high-functioning autistic subjects where it was elevated in parallel with their IQ. Notably, we found that Tamoxifen-induced re-expression of Shank3 in adolescent (P22-42) mice could recover their rigid brain state dynamics by stabilising the minor brain states (Cohen's $d > 1.7$; $P < 0.0005$), while not rescuing static resting-state connectivity. Thus, fewer neural transitions due to an unstable intermediate state may predict the severity of autism in both man and mouse. More broadly, it is now possible to bridge pre-clinical models of ASD at the whole-brain level to analogous non-invasive fMRI datasets from human subjects.

Title: Whole-brain network switching by arousal requires cholinergic MeCP2 expression

Authors: *P. ARTONI[1], C. ORAM[1], J. LEBLANC[2], V. VINCI[1], C. A. NELSON[2], M. FAGIOLINI[1], T. K. HENSCH[3];

Abstract: Whole-brain networks continuously balance between modes of integration and segregation. While integration occurs when different brain areas work cooperatively, segregation arises as individual domains emerge to perform specific tasks. By combining large-scale functional ultrasound (fUS) imaging in awake, behaving mice during visual stimulation with network analysis, we found that arousal state transitions reversibly switch between a dorsal integration pathway and bottom-up sensory specialization. In contrast, the MeCP2-deficient mouse model of Rett Syndrome (RTT) failed to toggle their whole-brain networks efficiently. Selective restoration of MeCP2 within cholinergic (but not noradrenergic) circuits was sufficient to rescue cortical network dynamics and their associated multiplicative gain both globally and at single-cell resolution. The aberrant sensory gain trajectory in MeCP2-deficient mice was recapitulated by regression stage in RTT patients. Therapeutic strategies tracking arousal states and targeting cholinergic circuits may thus pre-empt deficits of systems-wide network dynamics in the etiology of neurodevelopmental disorders.

Title: Mesoscopic landscape of cortical functions revealed by through-skull wide-field optical imaging in marmoset monkeys

Authors: *X. SONG[1], Y. GUO[2], H. LI[2], C. CHEN[2], J. LEE[3], Z. SCHMIDT[2], X. WANG[3]; [1]Johns Hopkins Med. Institutions, Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD; [3]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: The primate cerebral cortex is organized into specialized areas representing different modalities and functions along a continuous surface. The functional maps across the cortex, however, are often investigated a single modality at a time (e.g., audition or vision). To advance our understanding of the complex landscape of primate cortical functions, here, we developed and applied to awake primates a polarization-gated wide-field optical imaging method for measuring cortical functions through the un-thinned intact skull. In awake marmoset (*Callithrix jacchus*)—a primate species featuring a smooth cortex—adjacent auditory, visual, and somatosensory cortices were noninvasively parcellated in individual subjects with detailed tonotopy, retinotopy, and somatotopy. A new pure-tone-responsive tonotopic gradient was discovered in the auditory cortex and a face-patch sensitive to motion in the lower-center visual field was localized near an auditory region representing frequencies of conspecific vocalizations. These adjacent cortical regions may form a network coordinating audiovisual information such as vocalization sounds and month movement for vocal communication. This through-skull landscape-mapping approach opens new opportunities for understanding how the primate cortex is organized and coordinated to enable real-world behaviors.

Title: Gaze and body tracking of freely moving marmosets for visual neurophysiology during naturalistic perception-action cycles

Authors: *V. SINGH[1], A. HUK[2], J. L. YATES[2], V. NGO[1], S. M. SHIELDS[2], C. MILLER[1]; [1]UCSD, San Diego, CA; [2]The Univ. of Texas, Austin, TX

Abstract: Recently, there has been a surge of interest to investigate behaviour in freely moving animals as brain activity in the freely-moving vs constrained (e.g., head-fixed) states may not necessarily be identical. Marmosets are an emerging animal model of choice because of their small size, fast development, exquisite visual systems, and membership in the same taxonomic order as humans. However, reliable systems for gaze and body movement tracking in freely-behaving marmosets are not yet available. Leveraging current advancements in Single-Board-Computers (SBC) and artificial neural networks (ANNs), we report methods in two distinct but integrated domains. First, we developed a novel wireless, head-mounted eye tracking system with an eye camera and a scene camera that are calibrated, allowing estimation of where the animal is looking in the scene while being freely foraging in an open arena. We then use a semantic segmentation ANN to determine the gaze dynamics. The data streams from the eye-tracking cameras are synchronized with wireless neural recording. Second, we use another ANN environment (DeepLabCut) to estimate the location and movements of the animal when the animal is hunting for food (field crickets) in a large arena with multiple cameras on each side of the room. These approaches have substantial implications for the feasibility of using freely-moving nonhuman primates in navigational studies, visual neuroscience and other domains where the inherent constraints of the head-fixed preparation limit opportunities to elucidate key dimensions of brain function. In the case of our visual neuroscience projects, this integrated set of hardware and ANN-based analysis allow for detailed, quantitative characterizations of visual processing during natural behaviors.

Title: Visuomotor Integration for Natural Hunting Strategies in Wild Marmosets

Authors: V. NGO[1], F. DE LA FUENTE[2], J. GORMAN[1], A. SOUTO[3], A. HUK[4], N. SCHIEL[2], *C. MILLER[1];
[1]UC San Diego, La Jolla, CA; [2]Univ. Federal Rural de Pernambuco, Recife, Brazil; [3]Univ. Federal de Pernambuco, Recife, Brazil; [4]Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: Marmoset monkeys (*Callithrix jacchus*) are prolific hunters. This arboreal New World primate employs a range of dynamic strategies tailored specifically to the distinct strategies needed to successfully prey on a diversity of different insects, ranging from terrestrial ants to flying beetles and dragonflies. Here we sought to quantify the visuo-motor integration that occurs during these different behavioral strategies for successful prey capture in wild marmosets at the Baracuhy Biological Field Station (Cabaceiras, Brazil) employ. We analyzed ~600 high-resolution video recordings of hunting events and quantified how individuals coordinate their limbs, head, and body to successfully visually identify, monitor, and attempt grasps of their target prey. Our preliminary analyses show that hunting strategies were dependent on several factors including prey size, their relative position on the substrate to the prey, the area in which they hunt, and whether conspecifics were nearby. We observed that when marmosets hunt in trees, they typically reach for prey with two hands while extending their body more than half their original body length during a coordinated ballistic grasp. While when hunting on the forest floor, their body extension was significantly less due to their body position when grasping and animals typically retrieved insects with their mouth. We are currently employing modern computer vision technology -DeepLabCut - to more accurately quantify the visuomotor integration that occurs during two of the more dynamic hunting strategies. Notably, the most frequent hunting strategy marmosets employed was a two-handed ballistic grasp following a behavioral pause for motor-planning and visual optimization in the arboreal substrate. A second strategy analyzed here involved rapid head-gaze tracking behavior of fast flying beetles which involved either one- or two-handed capture mid-air. Overall, data suggests that distinct visuo-motor integration strategies for prey capture were implemented based on the stability of the substrate and optimization of pre-attack positional behavior. The marmoset's natural prey-capture behavior offers an exciting opportunity to investigate active vision in a nonhuman primate, including the opportunity to quantify visuo-motor integration in the wild and under more controlled laboratory conditions.

Abstract: Early life experience sculpts thalamic axons carrying sensory information to the cortex. Here, we identify the thalamo-cortical (TC) targets that initiate the rewiring process which manifests in altered cortical oscillations. Monocular deprivation (MD) acutely induced a transient (<4hr) peak in EEG gamma (~40Hz) power specifically within mouse visual cortex, but only under conditions of open critical period plasticity (juvenile or adult dark-reared wildtype, adult Lynx1- or GAD65-deficient mice with diazepam). Concomitant, immediate loss of thalamic input onto fast-spiking (FS) GABA neurons (but not pyramidal cells) was observed within hours of MD using a TC slice preparation of the mouse visual pathway - again only if the critical period was open. Computational modeling of the TC pathway suggests that the emergent 40 Hz rhythm in response to MD is the result of a cortical interneuronal gamma (ING) rhythm in networks of FS neurons. Conditions for ING, including the presence of interneuronal gap junctions, appear at the start of the critical period, rapidly forming a rhythm when TC input is imbalanced by MD. The ING rhythm effectively dissociates thalamic input from cortical spiking leading to a rapid loss of previously strong TC-to-FS connections through standard spike-time dependent plasticity rules. A direct consequence of weakening the dominant TC input is that, on a slower time-scale, previously silent TC-to-FS connections are allowed to strengthen. Thus, ING enables cortical dynamics to transition from being dominated by the strongest TC inputs prior to MD to sensing the statistics of the population TC input after the networks have stabilized following MD. Our network model further captures the gradually increasing gamma frequency

and eventual fade-out of the rhythm as it evolves over time, suggesting that the fleeting ING accompanying MD can serve as a readout of the TC network state. Our findings reveal the first synaptic events underlying critical period plasticity and identify gamma oscillations induced by brief sensory challenge as a robust biomarker with which to probe disrupted developmental trajectories, such as in cognitive disorders like autism and schizophrenia.

Title: Distinct laminar profiles in V1 for 'hallucinated' and accurately detected gratings

Authors: *J. HAARSMA[1], N. CORBIN[2], M. F. CALLAGHAN[1], P. KOK[1];
[1]Univ. Col. London, London, United Kingdom; [2]Ctr. de Résonance Magnétique des Systèmes Biologiques, Bordeaux, France

Abstract: In order to make meaning of the noisy sensory world, it is thought that the brain integrates prior expectations with sensory input. Distinct cortical layers are believed to play different roles in achieving this, with agranular layers receiving feedback connections to provide contextual input, whereas the granular layers are thought to provide bottom-up sensory input. However, the exact computational roles of the distinct layers in balancing sensory inputs and internal signals remains unclear. Here we use layer-specific fMRI to study the cortical microcircuitry underlying perception and hallucination in healthy individuals. On the first day, we trained human participants (N=24) on a forced two choice perceptual discrimination task, where participants were presented with noisy grating stimuli, and had to decide whether they perceived a clockwise or anti-clockwise tilted grating, as well as report their confidence that a grating was perceived. On the second day participants performed the task while ultra-high-resolution fMRI (0.8mm) was used to measure brain activity. Importantly 50% of trials on the second day contained noise only, which allowed us to explore detection of gratings embedded in noise, as well as false percepts of gratings in noise ('hallucinations'). We found that, whilst participants were able to perform the task with high accuracy, they were unaware upon debriefing that 50% of trials did not contain gratings, with participants estimating there to be

10% of noise trials on average instead. Similarly, participants reported seeing gratings with higher-than-average confidence on 32% of noise trials. A logistic regression model revealed that previous responses and percepts, as well as an auditory cue that signalled the most likely orientation to the participant during training, contributed significantly to hallucinated gratings. Crucially, the laminar profile of perceived and hallucinated gratings in V1 was strikingly different. Specifically, we found a strong interaction between confidence and layer on stimulus trials, where high confidence responses on accurate trials was related to stronger middle layer activity. In contrast, hallucinated gratings on noise trials were particularly related to superficial layer activity. We conclude that despite subjectively similar experiences, the laminar profile of accurately detected and hallucinated gratings are distinct, where the input layers are the key-determinant in driving perceptual confidence in stimulus trials, it is the superficial layers which combine feedback activity from higher regions with input from the middle layers to create a false percept.

Title: Whole-brain reconstruction of different types of single spiny neurons in the visual cortex of mice

Authors: *Y. WANG[1], H.-C. KUO[1], X. KUANG[2], P. LESNAR[1], Y. LI[2], W. XU[1], L. AHMADINIA[1], Y. YU[1], A. LI[3], H. GONG[3], Q. LUO[3], S. A. SORENSEN[1], H. ZENG[1]; [1]Allen Inst. for Brain Sci., Seattle, WA; [2]Wenzhou Med. Univ., Wenzhou, China; [3]Huazhong Univ. of Sci. and Technol., Hubei, China

Abstract: Excitatory neurons are the majority in visual cortex (VC) including primary region (VC1) and high functional regions (VC2), which have been intensively studied and defined into many types in different layers using brain slices. Full neuronal morphologies are still unknown for these neuron types. To describe and classify these neurons based on complete morphologies, we performed computation-assisted morphological reconstructions to obtain full dendrites and axons of single neurons across all layers of VC using Vaa3D-TeraVR from a high resolution whole brain image stack acquired with a two-photon fluorescence micro-optical sectioning tomography system (*2p*-fMOST). We sparsely labeled neurons using tamoxifen-inducible Cre driver lines crossed to a bright GFP reporter. Based on whole brain reconstruction, we described

preliminary results for excitatory neurons in VC1 and VC2. In total, 169 neurons (89 in VC1, 80 in VC2) were reconstructed, including 18 types from layer 2 to layer 6. Tufted PCs in layers 2, 3 and 4 ***(L2TPC, L3TPC, L4TPC)*** had a balanced number of two subtypes with ipsilateral (***TPC_ips***) and bilateral (***TPC_bi***) projections to multiple cortical regions. The TPC_bi cells formed asymmetrical axonal clusters between the two hemispheres predominantly to the ipsilateral side. In layer 4, ipsilateral subtypes were predominant among neuron types studied (***L4TPCs***, ***L4UPCs***); Small tufted PCs in layer 5 (***L5SPCs***) featured long axonal collaterals along pial, and had ipsilateral and bilateral subtypes, forming multiple projections in the cortex. ***L5SPC_bi*** cells were the predominant type in VC2 and formed asymmetrical richer axonal clusters between two hemispheres. They projected predominantly in the ipsilateral side, which often projected to a subcortical region. Featured by thick tufted apical dendrites with a later bifurcated tuft, simple L5TPC cells (***L5TPC_sim***) were the only thick tufted PC type in VC1 and the predominant type in VC2 where complex L5TPCs (***L5TPC_com***, with an early bifurcated tuft) were encountered occasionally. A narrow PC type in layer 6 (***L6NPCs,*** L6CT cells) in both VC1 and VC2 consistently had a single projection to thalamus but targeted different subregions. Featured with two big dendrites, bipolar PCs in layer 6b (***L6bBPCs***) also have ipsilateral and bilateral subtypes forming multiple projections in the cortex. ***L6bBPC_bi*** neurons had symmetrical axonal arbors between the two hemispheres. These results indicate that individual excitatory neuron types in VC typically have ipsilateral and bilateral subtypes; their soma locations and local dendritic and axonal morphologies are correlated with their axonal projections at whole brain level.

Title: Whole dorsal cortex dynamics and behavioral correlates in the International Brain Lab task

Authors: *C. S. KRASNIAK[1,2], A. POUGET[3], .. INTERNATIONAL BRAIN LABORATORY[4], A. M. ZADOR[1];
[1]Neurosci., Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Cold Spring Harbor Lab. Sch.

of Biol. Sci., Cold Spring Harbor, NY; [3]Univ. of Geneva, Geneva, Switzerland; [4]The Intl. Brain Lab., London, United Kingdom

Abstract: Making a decision is a complicated process that includes processing current sensory information, integrating the current information with prior information, planning a motor output, and executing that motor command. Prior information has a strong influence over decision-making behavior. However, how prior information influences the neural activity underlying the different processes in decision-making remains unclear. Here we use the task standardized by the International Brain Laboratory (IBL) to investigate the neural basis of how sensory evidence is combined with prior information in the process of making decisions. The IBL task requires head-fixed mice to report whether a visual stimulus appears on the left or right side of a screen by turning a wheel left or right. In addition to this simple decision task, the prior probability of the stimulus appearing on one side switches, in blocks of about 50-100 trials, from 80% on one side, to 80% on the other. The IBL as a whole is investigating the brain-wide correlates of this task in single-unit neuropixels probe recordings. However the number of simultaneously recorded areas across the brain is relatively small in such recordings. Here we have used an alternative physiological approach to assess neural activity in many brain areas simultaneously, in order to probe how these areas represent and integrate the neural activity underlying this behavior. We used widefield GCaMP6s calcium imaging to record the activity of the whole dorsal cortex during task performance. We find neural activity in general to be highly correlated across the brain. These correlations arise through a combination of extrinsic (task-associated) and intrinsic correlations. Despite these strong correlations, we can still use neural activity to decode task variables such as action selection and stimulus side. The performance of this decoding varies based on which brain areas the model uses. Remarkably, the performance of the decoder nearly matches the behavioral performance when using neural activity in V1, M2, and to a lesser extent, M1, however, the activity in other areas is less predictive of behavior despite strong global correlations. Current work now focuses on the effect of the prior on neural activity in different areas. The ability to probe multiple brain areas simultaneously provides a powerful approach to understanding how multiple brain areas coordinate to represent and solve decision making tasks.

Abstract: We study the neural basis of probabilistic binary decision making in mice performing the International Brain Lab task, which combines perception of noisy stimuli with tracking a slowly shifting bias in the probability that one of the two possible actions is correct. Performing well at this task requires performing hierarchical inference over disparate timescales separated over 1-2 orders of magnitude. We generate hypotheses for how the brain might solve the task by training a continuous-time recurrent neural network. The model makes four key predictions we seek to test: First, the encoding of two key latent variables, stimulus side and bias side, is non-orthogonal, enabling interaction between the latent variables in a way that subserves hierarchical inference. Second, within-trial sensory evidence moves the neural state in the appropriate direction along both dimensions, albeit with different amplitudes that is related to the difference in timescales between the latent variables. Third, feedback from the previous trial, which in principle should enable more accurate inference of the bias, should have no effect on the integration of information. Fourth, that movement in the two-dimensional plane should display two kinds of dynamical behavior: within trials, sensory evidence drives the neural state to one of two discrete fixed points to infer one latent variable, whereas between trials, the neural state relaxes to a line attractor to infer the other latent variable. We test these predictions by first analyzing behavior from 342 sessions, quantifying performance metrics and showing a wide distribution of performance across mice. Next, we perform preliminary analyses of brain-wide Neuropixels recordings from 3 high-performing mice, and find they match these four predictions, with both model and mice exhibiting similar sub-optimalities relative to optimal Bayesian agents. Our findings shed light on the neural mechanisms involved in hierarchical probabilistic inference.

Title: Coding of vision, action initiation, action selection, and expectation in single neurons across the brain in The International Brain Lab dataset

Authors: *Y. SHI[1], N. ROTH[2], N. A. STEINMETZ[2], T. ENGEL[1], .. INTERNATIONAL BRAIN LABORATORY[3];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Biol. Structure, Univ. of Washington, Seattle, WA; [3]The Intl. Brain Lab., London, United Kingdom

Abstract: Vision, action selection, action initiation, and prior expectation arise from neuronal activity that may be distributed across brain regions. Here we delineate the spatial distribution of single-cell neuronal activity that is relevant for these processes. To achieve this, we introduce a dataset of brain-wide Neuropixels recordings from mice performing a visual discrimination task in which they turn a wheel left or right to indicate the location of a presumed visual stimulus. In each recording session, the probability of stimuli appearing on the left vs. right is 80% (or 20%) in blocks of consecutive trials. As of July 2021, the recordings consist of 756 penetrations across the mouse brain, covering 278 brain regions. To visualize the neural activity across the brain, we computed the peristimulus time histograms of average neural activity in each brain region for specific stimulus conditions. To quantify the sensitivity of single neurons to the behavioral task (baseline vs. task), visual stimulus (left vs. right location), action selection (left vs. right direction of turning), action initiation and prior expectation (left vs. right block-side), for each of these conditions, we computed the sensitivity metric of given condition based on the condition-combined Mann-Whitney U statistic. Specifically, we compared the firing rates from each trial of one condition value to each of the other values, while fixing the other conditions, and then combined all comparisons into one number per neuron. In this way, we could isolate the influence of individual conditions on neural activity. To estimate statistical significance, we used a shuffle test in which trial labels were randomly permuted within the condition 3000 times. To control for spurious correlations due to serial dependencies in the task variables, we also used the

pseudo-session approach for the block-side, visual stimulus and action selection. We then computed the fraction of neurons in each brain region significant for behavioral task, visual stimulus, action selection, action initiation and prior expectation, and identified brain regions that are most relevant for these conditions. To further study the encoding of visual information of single neurons across the brain, we analyzed the receptive fields of neurons that are sensitive to visual stimuli and compared these responses to visual responses during the task. We also compared the activity during the task to activity while the same stimuli are presented in a passive-viewing paradigm. Consistent with prior work, we observed widespread coding of action initiation but substantially more restricted representations of visual and choice coding.

Cybernetcs, Tuebingen, Germany; [6]Univ. Col. London, London, United Kingdom; [7]Ctr. for Learning and Memory, UT Austin, Austin, TX; [8]Univ. of Geneva, Geneva, Switzerland

Abstract: In the IBL task, a head-fixed mouse is trained to move a wheel to the left or right, depending on the side of a Gabor patch shown on a screen in front of the animal. The probability of a stimulus being on one side is 80% (20%) in blocks of consecutive trials before switching in an unsignalled manner. The animals' action selection (including on trials with 0% contrast input which are directly revealing of any bias) indicates that they are sensitive to this preponderance. We are currently examining neural correlates of this partly persistent sensitivity.
Here we explore aspects of the pre-stimulus behavior of the subjects to see if information about

the currently favored side (crudely a 'prior') is present in such a way that might confound or at least complicate our neural analysis. We investigated kinematic correlates, such as body posture or paw position on the wheel, and dynamic correlates such as laterally-dependent whisking, tongue movements/licking, or motion of the wheel. To do this, we had to control for the substantial autocorrelation in the favored side (and the aspects of this prior to which the animals' behavior shows to be sensitive).
We found that in a measurable fraction of animals, whisker movement between trials is modulated by block type, meaning that there is for example more whisking when a right stimulus is more likely to appear. Here we report the prevalence of such kinematic and dynamic correlates of the prior.

Title: Task-relevant population dynamics in the international brain lab dataset revealed by manifold analysis

Authors: *C. LANGDON[1], M. SCHARTNER[2], E. DEWITT[3], K. D. HARRIS[4], I. FIETE[5], P. DAYAN[6], T. INTERNATIONAL BRAIN LABORATORY[4];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Champalimaud Ctr. for the Unknown, Lisbon, Portugal; [3]Champalimaud Res., Lisbon, Portugal; [4]Univ. Col. London, London, United Kingdom; [5]MIT, Boston, MA; [6]Max Planck Inst. Tübingen, Tübingen, Germany

Abstract: How animals use prior beliefs about their environment to make perceptual decisions is an important question in neuroscience. We analyze data from the IBL consisting of 583 Neuropixel recordings from mice performing a binary perceptual discrimination task (stimulus on left or right) in which the stimulus side probability varies across blocks of trials. Using unsupervised and supervised linear dimensionality reduction methods, we characterize the low-dimensional subspaces in which neural activity is confined, identify subspaces encoding key task-relevant variables, and analyze their within-trial population dynamics. To obtain task-

relevant subspaces we use a combination of two approaches. In the first, we compute averaged PSTHs by partitioning trials based on task variables, then apply principal component analysis to obtain a low-dimensional projection of task-relevant neural activity. We use a pseudo-session approach to assess the significance of distances between trajectories. This approach identifies sessions in which post-stimulus, pre-action trajectories for left and right choices are significantly separated, revealing the temporal evolution of stimulus integration and choice selection within the population. We also found a significant separation of trajectories prior to stimulus onset, possibly reflecting an internal bias based on the block. Our second approach uses linear discriminant analysis to obtain low-dimensional subspaces in which each axis discriminates a distinct task variable. We restrict these analyses to individual brain regions and identify regions in which there is significant discrimination of block side and action selection. We then project neural activity onto the subspace spanned by the discriminants for these variables. By identifying regions with significant discrimination of both block side and action selection, we consider how these two variables covary by analyzing within-trial trajectories in this subspace. This analysis reveals an effect of block in the action discriminant prior to stimulus onset and an effect of action selection on the block discriminant following stimulus onset. We find qualitatively similar dynamics across several brain regions.

Title: Dissecting Motor Representations by Video Analysis Using Deep Learning

Authors: *Z. WANG[1], S. CHEN[2], L. D. LIU[3,2], Y. LIU[1], B. KANG[1], H. HOU[2], L. NUO[3], K. SVOBODA[2], S. DRUCKMANN[1];
[1]Stanford Univ., Stanford, CA; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [3]Baylor Col. of Med., Houston, TX

Abstract: Neural representations in cognitive tasks are typically considered in terms of abstract cognitive performance, yet it is known that cognitive and emotional states can be associated with typical movements, e.g., pacing when nervous, creating difficulty in the assignment of neural representation to the internal state or the movement. Here we analyze simultaneous neural recordings across multiple brain areas and highspeed videos of behavior in a short-term memory (STM) task (see Susu Chen et al SFN 2021). We test a series of approaches to relate neural activity to ongoing movements, from markers of facial features, through convolutional auto-encoder applied to videos to full end-to-end learning.
We found that areas more associated with motor control (e.g., the medulla for facial movements), had higher single-trial explained variance than areas related to motor preparation (e.g., the Anterior Lateral Motor cortex, ALM, part of M2). We find that more expressive models more accurately predicted neural activity. Auto-encoder embeddings were more accurate than facial markers, and end-to-end learning more accurate than embeddings.
We varied the time offsets between the behavior used for prediction and neural activity and found that offsets vary across brain regions and within layers in brain regions. We found that shallower layers in ALM were more associated with sensory activity than deeper layers, consistent with previous circuit mapping findings from Hooks et al. J. Neuroscience 2013. and Economo et al. Nature 2018. We tested the relation between trial-type selectivity of neurons and their predictability from video. We find that neurons that are more associated with trial-type rather than upcoming choice were harder to predict from videos, consistent with a more sensory representation. We demonstrate that the structure of neuronal correlations changes across subspaces of activity that are well or poorly predicted by behavioral representations.
We directly predicted upcoming choice from behavior representations. We find that upcoming choice was predictable, but accuracy was highly variable across animals. By examining the accuracy of different behavioral features we find that the movements predictive of future actions varied across animals.
These results shed light on the relation between movements and neural activity in STM tasks and demonstrate important steps in the effort to link neural representations to movement.

Title: Comparing cognitive models of dynamic reward learning in the head-fixed mouse

Authors: *J. OH[1], K. J. MILLER[1,2], A. LEBEDEVA[1], K. D. HARRIS[1];
[1]Univ. Col. London, London, United Kingdom; [2]Google Deepmind, London, United Kingdom

Abstract: Comparing cognitive models of dynamic reward learning in the head-fixed mouse Jin Oh, Kevin J Miller*, Anna Lebedeva, Kenneth D Harris*
To characterize the behavioral strategies of reward-based learning, we quantitatively fit multiple cognitive models to behavioral data from head-fixed mice performing a two-armed bandit task. In this task, the start of each trial is signaled by an auditory cue, after which the mouse turns a wheel to the left or right side to earn a liquid reward. The mouse is rewarded with a 80% probability for choosing the favored side, and 20% probability for the unfavored side. The favored side flips randomly after 125 -175 trials.
We considered six different cognitive models, each representing a possible strategy mice might use to solve the task. The models were standard Q-learning (Sutton and Barto, 1998), optimistic Q-learning (Lefebvre et al., Nat. Hum, 2017), generalized local matching law (Baum, J. Exp. Anal. Behav.,1974), forgetting Q-learning (Barraclough et al., Nat. Neurosci, 2004), differential forgetting Q-learning (Ito et al., J Neurosci, 2009), and a mixture-of-agents model (Miller et al., bioRxiv, 2021). We assessed model fit in two different ways. First, to characterize which specific features of the data each of the models gets right, we created synthetic behavioral datasets using each model with parameters optimized separately for each mouse. We compared these synthetic datasets to the true behavioral dataset using multiple summary statistics, including trial-history regression (Lau et al., J Exp Anal Behav, 2005), bout distribution, and learning curves. Second, to obtain a single numerical score quantifying each model's fit, we used cross-validation: the model parameters were fit by maximum likelihood on one half of the data and evaluated by their likelihood on the other half. Based on these assessments, we found that the differential forgetting Q-learning and a mixture-of-agents model fit the mouse datasets better than the other cognitive models that we considered. We are currently exploring several additional models. Future work correlating the internal variables of these models with neuronal population recordings may help uncover the brain mechanisms of reward-based learning.

Title: Recording neurons across the brain during a two-armed bandit task

Authors: *A. LEBEDEVA, K. J. MILLER, J. OH, Y. WANG, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Learning from rewards in order to optimize behavior in a changing world is a key component of cognitive flexibility. In animals, this capacity is often studied using the "dynamic two-armed bandit" task. In each trial of this task the animal selects one of two possible actions, each of which is associated with a different time-varying probability of reward. A large body of work has sought to understand the neural mechanisms of reward learning using tasks of this kind, but studies have typically focused on a relatively small number of brain regions.
Here, we developed a version of the two-armed bandit task for head-fixed mice. The start of each trial was signalled by an auditory cue, after which the mouse chose to spin a steering wheel either to the left or to the right. On each trial, one of these (left or right) was designated the better choice, and followed by liquid reward with high probability, while the other was followed by reward only with low probability. The identity of the better choice flipped periodically throughout each behavioural session, requiring mice to continually learn in order to optimize the rate of rewards. Mice did this successfully, altering their choice on average within ~10 trials after the flip.
We used high-density Neuropixels probes to make acute extracellular recordings from ~21000 neurons across 15 brain regions (such as primary and secondary motor cortices, prelimbic and infralimbic cortex, caudoputamen, hippocampus, nucleus accumbens and others). Analysis of the data revealed that choice and reward coding was widespread, but that an interaction between choice and reward was most strongly encoded in the secondary motor cortex (MOs). This suggests that MOs plays a special role in reward-guided learning. To investigate this region in more detail, we implanted probes chronically, allowing us to record the activity of the same MOs neurons each day for multiple weeks, while animals were learning the task and as they performed the task after learning. In this dataset as well, we found a large number of MOs neurons encoding the interaction between reward and choice. Currently, we are developing reinforcement learning models of mouse behaviour in this task, and using them to search for correlates of cognitive variables such as correlates of expected reward. We are also investigating the role of the secondary motor cortex using causal methods, using optogenetic silencing on a subset of trials to determine whether neural activity in this region is necessary for trial-by-trial reward learning.

Title: Intrinsic timescales as an organizational principle of neural processing across the whole rhesus macaque brain

Authors: *A. M. G. MANEA[1], A. ZILVERSTAND[2], S. R. HEILBRONNER[1], J. ZIMMERMANN[1];
[1]Dept. of Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN; [2]Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Intrinsic timescales (ITs) are rhythmic dynamics of neuronal fluctuations that serve to integrate and support neural processing on different timescales. Thought to reflect the amount of temporal integration of a brain area, they are closely related to cortical and subcortical functional hierarchy. Traditionally, they have been investigated using electrophysiology in nonhuman primates (Murray et al., 2014; Cavanagh et al. 2016; Cirillo et al., 2018; Fascianelli et al., 2019; Nougaret et al., 2021). However, this method is not suitable for understanding whole brain dynamics, nor is it straightforward to apply it in humans. Functional magnetic resonance imaging (fMRI) could solve these issues, since it allows for whole brain inquiries in both species. It has not been clear up until this point whether ITs can be assessed using fMRI. Because prior IT work has been done in nonhuman primates, here we assess whether previously identified IT hierarchies can be extracted from macaque resting-state fMRI. We analyzed ultra-high field (10.5T) resting-state fMRI from macaques (N=9). ITs were computed by estimating the autocorrelation function of each voxel's fMRI signal. We tested the fMRI replication of electrophysiological ITs in 18 regions from previously published studies. In nearly all cases, hierarchical IT patterns were replicated in fMRI. For example, sensory areas had the lowest and prefrontal cortex (PFC) the highest ITs. Because of this, we took the opportunity to interrogate ITs across the whole brain. We then compared IT maps with fine-grained resting-state functional connectivity (FC) gradients, which provide a mapping of FC similarity profiles. Since gradients interrogate FC similarity profiles across the brain, and hence its functional architecture, linking

them to the IT hierarchy can demonstrate that the underlying functional architecture of resting-state FC is not only based on low frequency synchrony, as is widely accepted, but rather reflects a more intricate “timescale hierarchy”. To establish this, gradients were estimated by applying diffusion mapping to the voxel-wise FC matrix of the area under investigation. We then established a relation between FC gradients and ITs by correlating both maps. For example, among others, ITs and gradient maps were highly correlated in the parietal lobe ($r = 0.56$), medial PFC ($r = 0.70$), and motor cortex ($r = 0.68$). We therefore propose that ITs underlie the functional architecture of resting-state FC, as measured by FC gradients, and that ITs describe the macroscale functional organization of the brain, both in terms of connectivity and intrinsic temporal fluctuations.

Title: Representation of task variables in mouse frontal cortex during delayed decisions based on vision and value

Authors: *L. E. WOOL[1], E. SVAHN[1], R. TERRY[1], A. RITOUX[1], A. LAK[2], M. CARANDINI[1], K. D. HARRIS[1];
[1]Univ. Col. London, London, United Kingdom; [2]Oxford Univ., Oxford, United Kingdom

Abstract: [Introduction] During visually guided decision-making, the brain must optimally combine sensory evidence, reward value, and action timing to make the appropriate choice. However, it is not clear how, and where, these task variables are combined. In the mouse, frontal cortical area MOs is an important region for sensory-based decision-making (Coen et al., 2021; Zatka-Haas et al., 2021) and may encode upcoming choice in delayed-response tasks (Guo et al., 2014). [Methods] We asked whether MOs combines neural representations of task variables. To investigate this, we trained mice in a visually guided instructed delay task. Head-fixed mice report the location of a visual grating of variable contrast by steering a wheel left or right (Burgess et al., 2017) after an enforced delay period of 0.8-1.0 s. The volume of water rewarded

for correct choices differed twofold between correct left and correct right choices, and alternated over blocks of ~200 trials (Lak et al., 2020). We used two-photon calcium imaging to measure the activity of thousands of L2/3 cortical excitatory neurons in MOs while mice performed the task. [Results] Performance on a given trial depended on both stimulus contrast and expected reward. Psychometric curves shifted between blocks, favoring choices promising larger rewards. Furthermore, the proportion of impulsive choices (reports made before the end of the delay) increased with expected reward and stimulus contrast. MOs neurons heterogeneously coded multiple task variables. A minority of neurons exhibited contralateral visual responses at the time of stimulus onset. Most neurons showed nonselective modulation at movement onset, but many were also choice-direction-selective. Neurons with significant contraversive or ipsiversive choice preference were found in both MOs hemispheres. Some neurons were modulated by trial outcome in the feedback period, encoding the presence or absence of reward and/or licking activity. Other neurons were differentially modulated by whether the animal delayed their choices or moved impulsively. Yet other neurons appeared to be modulated by task-independent variables such as whisking. Some MOs neurons exhibited mixed selectivity to multiple task variables. [Conclusions] Our preliminary findings suggest that excitatory MOs neurons heterogeneously encode features of a visually guided choice delay task, as well as task-independent features such as whisking. Moreover, some MOs neurons encode multiple features, suggesting a role in combining representations of task variables during decision-making.

Abstract: During natural behavior, contingencies between stimuli and outcomes often depend on context, and animals must flexibly adjust their behavioral strategies accordingly. Changes in

brain state are known to influence performance during fixed-contingency sensory tasks, and we hypothesize that brain state dynamics underlie an animal's ability to behave in a flexible, context-appropriate manner. To capture context-dependent brain state dynamics, we mapped behavioral states during a paradigm where mice must flexibly adjust their strategy in a context dependent manner. In our paradigm, head-fixed mice discriminate between frequencies of tone clouds or angles of drifting gabor patches, while we measure pupil size, whisker pad motion, and locomotion. We analyzed task performance using a Hidden Markov Model with states parameterized by a Generalized Linear Model (GLM-HMM). The GLM-HMM revealed that each mouse used multiple strategies throughout task performance, and the model identified transitions between the distinct decision-making states on a trial by trial basis. We used this framework to interrogate the relationship between decision-making strategies and measured behavioral variables. In parallel with developing our behavioral paradigm, we have implemented high density electrophysiological recordings and single-cell resolution neural imaging across broad regions of the temporal and dorsal cortical surface. Combining these recording techniques with our state-based description of task performance will enable us to observe context-dependent changes in neural response dynamics across cortical regions. These efforts will build an understanding of the brain states that underlie behavioral flexibility.

Title: Additive audiovisual integration in the mouse superior colliculus

Authors: *F. TAKACS[1], P. COEN[2], M. ROBACHA[2], K. D. HARRIS[2], M. CARANDINI[2]; [1]Sainsbury Wellcome Ctr., [2]Univ. Col. London, London, United Kingdom

Abstract: [Introduction] To guide actions, the brain usually integrates information from multiple senses. For instance, an object can be located more accurately by combining visual and auditory cues to its position. In multiple species, neural correlates of spatially selective audiovisual integration have been found in the superior colliculus (SC, Stein & Meredith, Science, 1983, Knudsen,J.Neurosci,1982, King et al., J. Comp. Neur., 1985). How prevalent are audiovisual

neurons in the SC of the mouse? Are they spatially selective for auditory stimuli? Do they integrate audiovisual signals nonlinearly (Ito et al., bioRxiv, 2021) or additively as has been seen in the frontal cortex (Coen et al., bioRxiv, 2021)? [Methods] To address these questions, we recorded the activity of neural populations (~2,400 neurons) in SC of awake, head-fixed mice using multishank Neuropixels 2.0 probes, in response to checkerboard visual stimuli and pink noise auditory stimuli presented at varying azimuths, alone or in combination. [Results] We found neurons selective for visual stimuli (26% of neurons) mostly in the superficial layers, and neurons selective for auditory stimuli (20%) mostly in intermediate and deep layers. 8% of neurons responded to both stimuli. While essentially all visual neurons were spatially tuned following a topographic visual spatial map, only 21% of auditory neurons were spatially tuned, and the tuning of these auditory neurons did not form a spatial map. We found that 95% of neural responses were captured by an additive model. The remaining neurons tended to be visual rather than multisensory, with visual responses modulated nonlinearly by the presence of sounds. [Conclusions] Overall, these results suggest that the SC, like the frontal cortex, combines signals from the different senses additively. This strategy is optimal under broad statistical assumptions. We are currently testing whether this additive combination holds only during passive stimulus presentation or also during audiovisual behavior (Coen et al., bioRxiv, 2021).

Title: Mouse frontal cortex mediates additive multisensory decisions

Authors: *P. COEN[1], T. P. H. SIT[2], M. J. WELLS[1], M. CARANDINI[1], K. D. HARRIS[1]; [1]Univ. Col. London, London, United Kingdom; [2]Sainsbury-Wellcome Ctr., London, United Kingdom

Abstract: [Introduction] To interpret the world and make accurate perceptual decisions, the brain must combine information across sensory modalities. For instance, it must combine vision

and hearing to localize objects based on their image and sound. Probability theory suggests that evidence from multiple independent cues should be combined additively, but it is unclear whether mice and other mammals do this, and the cortical substrates of multisensory integration are uncertain. Here we show that to localize a stimulus, mice combine auditory and visual spatial cues additively, a computation supported by unisensory processing in auditory and visual cortex and additive multisensory integration in frontal cortex. [Methods] We developed an audiovisual localization task where mice turn a wheel to indicate the joint position of an image and a sound. The stimuli can be auditory, visual, or a combination of the two, presented in coherent or conflicting locations. In a set of mice, we performed optogenetic inactivation of different spots across dorsal cortex while mice performed this task. We then focused our recordings on frontal cortex, recording >10,000 neurons with Neuropixels probes during behaviour. [Results] In this task, mice integrated auditory and visual cues independently in all conditions. An additive model, with independent weights for audio and visual stimuli, predicted the mean response of mice to all cue combinations. Optogenetic inactivation of different spots across dorsal cortex while mice performed this task demonstrated that auditory and visual areas contribute unisensory information, whereas frontal cortex (secondary motor area, MOs) contributes multisensory information to the mouse's decision. Of the frontal areas recorded, only MOs activity could predict the mouse's upcoming choice. Consistent with the mice's additive behavior, neural activity in MOs reflected an additive combination of visual and auditory signals. Furthermore, an accumulator model applied to the sensory representations of MOs neurons reproduced behaviourally observed choices and reaction times. [Conclusions] Frontal area MOs integrates information from multiple sensory cortices additively, providing a signal that is then transformed into a binary decision by a downstream accumulator.

Title: Additive multisensory integration across species and modalities

Authors: *M. CARANDINI, T. SIT, K. D. HARRIS, P. COEN;
Univ. Col. London, London, United Kingdom

Abstract: [Introduction] To make accurate perceptual decisions, the brain must combine signals from different sensory modalities. A simple way to combine these signals is to add them. This procedure is optimal if the signals are statistically independent and may be a useful heuristic if they are not. We recently found that mice use this heuristic when combining sounds and images to localize a target (Coen et al, *bioRxiv* 2021). Here we ask whether this heuristic could also describe multisensory integration in different modalities and species. [Methods] We analyzed published data from studies where rats, macaques, and humans perform a two-alternative discrimination task that encourages the combination of two sensory modalities, and we used the "GRABIT" function in Matlab to estimate the values from the published psychometric data. These studies involved (1) a task where macaques used visual and vestibular cues to determine the direction of heading (Gu et al, *Nature Neurosci*, 2008); (2) a task where rats and humans used visual and auditory cues to estimate stimulus rate (Raposo *et al, J. Neurosci*, 2012, and Pisupati et al, *eLife*, 2021); (3) a task where rats combined visual and tactile cues to determine the orientation of a grating (Nikbakht et al, *Neuron*, 2018). [Results] In all these studies, the psychophysical data appeared to be well fit by a simple additive model in which the log odds of choosing one option vs. the other are the sum of the log odds estimated from one sensory modality and the log odds estimated by the other sensory modality. This was particularly clear when replotting the psychometric curves in log odds scale: in this representation, the responses to stimuli in each modality fall on a straight line and summing those two lines yields the responses to stimuli involving both modalities. [Conclusions] These results resemble those we obtained in mice that used visual and auditory cues to determine the location of a stimulus (Coen et al, *biorXiv*, 2021). Addition of sensory signals from different modalities, therefore, seems to be a heuristic that can quantitatively explain the way multisensory evidence is combined across multiple species and behavioral tasks. It may thus represent a default mechanism by which the brain integrates signals across modalities.

Title: Behavioral responses to auditory and visual stimuli in mice

Authors: *T. P. H. SIT[1], C. BIMBARD[2], M. ROBACHA[2], P. COEN[2], M. CARANDINI[2], K. D. HARRIS[2];
[1]Sainsbury-Wellcome Centre, Univ. Col. London, London, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: [Introduction] Multisensory responses are apparently found throughout the brain, even in areas that were thought to be devoted to particular sensory modalities. However, assigning this neural activity to sensory variables per se is confounded by the fact that much of the brain exhibits activity related to movement, which can be evoked by sensory stimuli. Based on results in (Bimbard et al 2021, BioRxiv), we hypothesize that many of the stimuli commonly used in sensory research evoke movement responses that were not robustly characterized. Here we sought to characterize the diversity of movement found in mice in response to sensory stimuli commonly used in audio and visual neuroscience.
[Methods] We presented head-fixed mice with a large set of auditory, visual and audiovisual stimuli. Stimuli were drawn from studies in sensory and multisensory neuroscience, and include drifting gratings, moving bars, looming discs, pure tones, chirps, ultrasonic recordings of mice, and naturalistic movies. At the same time, we filmed mice with three cameras capturing the whiskers, eye, paws, and torso and monitored their breathing with flow sensors.
[Results] Sounds such as pure tones consistently triggered an onset movement response. This response persisted both within an experiment across the span of hours and between experiments across weeks. Visual looming discs elicited movement responses that are more pronounced at a specific range of looming speed, and there was an asymmetry in elicited movement between white looming discs presented with a black background and black looming discs presented with a white background. Naturalistic sounds elicited complex movement responses that could not be easily predicted from their spectrotemporal properties. These more complex relationships varied across mice.
[Conclusion] We conclude that auditory and visual stimuli commonly used in neuroscience research can evoke different magnitudes and types of movement in mice, which can sometimes be hard to predict from basic properties of the stimuli. These movements persist after habituation to the stimuli, so they are likely to affect all recordings, even after habituation. These results highlight the importance of controlling for movement variables when studying the correlates of neural activity.

Title: Behavioral origin of sound-evoked activity in mouse visual cortex

Authors: *C. BIMBARD, T. P. H. SIT, A. LEBEDEVA, K. D. HARRIS, M. CARANDINI; Univ. Col. London, London, United Kingdom

Abstract: [Introduction] Many studies suggest that all of sensory cortex, including primary sensory areas, is multisensory. For instance, mouse primary visual cortex (V1) appears to be influenced by auditory signals. This influence may be due to projections from the auditory system to the visual cortex. However, there is a possible alternative explanation for these apparent multisensory signals. Sounds can change internal state and evoke uninstructed body movements. Internal state and body movements correlate with activity in many brain regions, including V1. It is thus possible that sounds affect visual cortex because they change internal state or behavior.
[Methods] To test this possibility, we asked whether sound-evoked signals in mouse V1 could be predicted by uninstructed sound-evoked movements. Using Neuropixels probes, we recorded the responses of hundreds of V1 neurons to audiovisual stimuli, while filming the mouse. We monitored internal state through pupillometry, as well as specific body and face movements.
[Results] We observed that V1 encoded a low-dimensional representation of sounds (different neurons showing similar responses), in contrast to the encoding of videos, which was high-dimensional (different neurons showing different responses). The time courses of the sound responses in this low-dimensional space were tightly correlated to the body movements evoked by these sounds. Different sounds evoked different temporal patterns of movement, which were stereotyped across trials and across mice, and these movements could predict the sound responses of V1 neurons.
[Conclusion] We conclude that the apparent representation of sounds in visual cortex can be explained by uninstructed yet stereotyped sound-evoked movements. This result suggests that the multisensory activity that has been widely observed across the brain may have a simpler, behavioral origin.

Title: Spiral waves of activity in the cortex of awake mice

Authors: *Z. YE, N. A. STEINMETZ;
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Travelling waves are often observed in large scale population activity in different brain areas and in various brain states. However, the detailed spatiotemporal patterns of wave propagation have not been well characterized in awake mammals. Using widefield imaging of the dorsal cortex in awake GCaMP7-expressing transgenic mice, we robustly observed spiral waves in the 2-8Hz frequency range. Spiral centers were detected using optical flow methods applied to phase data after Hilbert transformation. These spirals were usually mirrored on the left and right hemispheres with opposing rotation directions. Similarly, we frequently observed simultaneous mirrored spirals split along the S1/M1 border within the same hemisphere. Spirals tended not to occur during overt movements of the mouse, and were more prevalent during periods of quiet wakefulness, which are also characterized by high 2-8Hz power. Spirals were also present in epochs during which mice actively consumed rewards, though primarily in between moments of reward licking. The presence of spirals in wild-type mice was separately validated with 4-shank Neuropixels 2.0 probe recordings in the cortex. These results demonstrate the cortical activity in the mouse has more complex spatiotemporal patterns, including distinctive spirals, than previously known.

Title: Active translation signals underpin sensory-motor mismatch responses in the mouse primary visual cortex

Authors: M. VELEZ-FORT, L. COSSELL, ***T. MARGRIE**;
Sainsbury Wellcome Ctr., London, United Kingdom

Abstract: To accurately navigate, animals must integrate multiple types of information whilst locomoting - that is, moving from one place to another. Importantly, motor commands must be constantly compared with ongoing feedback about the actual motion of the head (and eyes) as well as external visual motion. The primary visual cortex in mice receives both motor and vestibular input that is presumably combined with visual information during locomotion and navigation. Here, we have for the first time investigated neural activity in V1 recorded during locomotion in its most basic form: running forward in a single dimension.
Using a novel setup in head-fixed mice that allows us to independently manipulate the 3 fundamental elements of locomotion - motor/running (R), translation (T) and visual flow (VF) - we found that 74% of V1 neurons increase their activity during locomotion (i.e., when the speed of running, translation and visual flow are matched) compared to standing still. To understand the contribution of translation to overall locomotion activity, we first compared neural responses while animals were not permitted to run (treadmill locked), but experienced visual flow (VF) or passive translation with visual flow (T+VF). We found that in 59.5% of all recorded V1 cells, firing rates during T+VF motion were significantly greater than firing rates during VF alone, suggesting the existence of widespread translation-based input to V1. However, the modulation of activity due to translation was strongly attenuated during active locomotion. Only 6% of V1 cells showed any difference in motion-evoked activity when comparing running with visual flow (R+VF) to active locomotion (R+T+VF). This suggests that although V1 has access to translation signals, during locomotion, translation-based activity in V1 is largely attenuated.
To explore the functional role that these translation inputs may play, we randomly introduced brief (250ms) mismatch events by increasing the gain in both translation (T) and visual flow (VF) while the animal was engaged in active locomotion. These ‘slip’ events triggered strong responses across V1. At a single cell level, 20% of cells showed a significant change in firing rate. These responses couldn’t be explained by the mismatch between running speed (R) and visual flow (VF) alone, since omitting translation led to a complete absence of mismatch-related firing rate changes.
Taken together, these results suggest a circuit motif that enables attenuation of translation-based signals by motor input that serves as the substrate for a locomotion-related mismatch signalling and that V1 is acutely sensitive to un-expected movement of the head.

Title: Multisensory integration in superior colliculus and primary visual cortex of awake behaving mice

Authors: *K. DOERENKAMP[1,2], P. S. GRAFF[3,2], G. NABBEFELD[1,2], T. RÜLAND[4,1,2], S. BRILL[1], B. M. KAMPA[1], S. MUSALL[3];

Abstract: The Superior Colliculus (SC) is a key area for the integration of multisensory stimuli and involved in numerous cognitive functions. Inputs from different modalities reach the SC either directly or via the cortex. Yet, how multisensory integration in SC differs from cortex is not well understood. We therefore performed Neuropixels recordings in visual cortex (V1) and SC of awake mice while presenting visual, auditory and tactile stimuli. A majority of V1 neurons responded to visual stimuli but a large fraction also responded to auditory and tactile stimulation. In SC, responses were more evenly distributed with a small preference for visual and tactile over auditory stimuli.
To quantify multisensory integration in V1 and SC neurons, we compared responses to unisensory stimuli to different multisensory combinations. Here, multisensory were mostly larger than unisensory responses for all stimulus combinations. Interestingly, multisensory enhancement was more common in V1 while SC neurons showed a larger variety in either enhancement or depression, suggesting a more detailed representation of multisensory stimuli. Accordingly, SC neurons were also more sensitive to spatially incongruent multisensory stimuli which promoted multisensory depression in SC but not in V1.
To assess the role of cortical inputs for responses in SC, we optogenetically stimulated either V1 or primary somatosensory cortex (S1). Excitation of V1 or S1 reliably activated SC neurons with short latencies, confirming that they were driven by direct cortical projections. Optogenetic inhibition of V1 or S1 strongly reduced corresponding sensory responses in the SC, suggesting that cortex is the primary source for sensory responses in SC. S1 stimulation also drove V1 neurons but with significantly longer latencies, suggesting that tactile responses in V1 are due to indirect S1 inputs. Lesions in the rostrolateral visual area RL strongly reduced all tactile responses in V1.
Lastly we tested how multisensory integration is affected by behavior. We thus trained mice in a multisensory discrimination task where visual gratings and tactile stimuli had to be integrated to obtain a reward. Mice performed the task with high accuracy and we compared multisensory responses in V1 and SC in naive versus trained animals. Here, multisensory responsiveness was stronger in trained mice.
Our results demonstrate that multisensory integration in the SC largely depends on cortical inputs but is more sensitive to incongruent stimuli. This and its increased multisensory responsiveness emphasizes its importance for multisensory perception and behavior.

Title: Pan-cortical state-dependent activity exhibits complex spatiotemporal structure during spontaneous and stimulus-evoked behavior

Authors: *E. D. VICKERS, D. G. WYRICK, P. PARKER, C. NIELL, L. MAZZUCATO, D. A. MCCORMICK;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: The flow of neural activity across cortex during active sensory discrimination is constrained by task-specific cognitive demands. During spontaneous behavior, the brain is free to sample widely from a vast repertoire of activation motifs. Understanding how local and global activity motifs are selected by task demands in a modality-dependent manner will require in-depth study of densely sampled spontaneous activity at single neuron resolution across large regions of cortex. Here we show 2-P Ca^{2+} imaging data from two novel *in vivo* preparations that enable mesoscale imaging of up to 7500 individual neurons simultaneously at ~3 Hz across a 6 x 6 mm FOV. In total, we imaged more than a half-million neurons over 200 sessions, each lasting ~45 min, across 20 mice. We recorded state variables of walk speed, pupil diameter, and whisker motion energy. Preliminary analyses revealed heterogeneous distributions of neurons with large correlations to behavioral state variables, and some neurons with no apparent correlation to arousal or movement. Exploration of the heterogeneity of state-dependence with partially supervised k-means clustering revealed diverse spatiotemporal patterns of activity (e.g. dense, widespread, and temporally structured) that were not evident with sorting by principal components, and had clear relationships to state variables (e.g. ON / OFF, transient / sustained). To test for directed causal interactions of putative long-range functional connections, we developed a novel statistical method called functional causal flow (FCF). Preliminary FCF analysis of widefield GCaMP6s imaging data from dorsal cortex revealed strong state-dependent modulation of inter-areal causal functional connectivity during passive visual stimulation relative to periods of darkness. We are currently performing similar FCF analysis of 2-P mesoscope data. In the future, we will explore how engagement, strategy and cognitive flexibility in a switching audiovisual 2-alternative forced choice (2-AFC) discrimination task act to further shape and select the subset of activity patterns present under spontaneous and passive conditions.

Title: Elucidating sex differences in the expression of aromatase in the brains of young adult rats by fluorescent in-situ hybridization

Authors: *J. IMMENSCHUH, S. B. THALHAMMER, E. COMASCO;
Sci. for Life Laboratory, Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: The enzyme aromatase (*Cyp19a1* gene) catalyzes the biosynthesis of estrogens from androgens. Of interest, aromatase seems to be involved in non-reproductive functions in the brain, such as regulation of neurogenesis, synaptic transmission and neuroprotection. Sparse evidence points to expression in specific brain regions that are of relevance to emotional and cognitive functions, and in a sex-dependent manner. Investigation of its expression throughout the brain has shown to be outdated and imprecise, and is lacking the identification of sub regions in both males and females. Additionally, little is known about the identity of the neurons expressing aromatase. The present study sought to confirm and map the expression pattern of *Cyp19a1* throughout the brain of young adult rats of both sexes and elucidate sex differences, as well as characterize in an exploratory fashion the cell types expressing this gene. Brains of male and female Sprague-Dawley rats (n=12) were collected on postnatal week ten and sliced coronally. *Cyp19a1* mRNA was mapped by use of fluorescent in-situ hybridization (FISH) and regions of interest were identified. Automated quantification of the number of positive cells per ROI was computed using CellProfiler. In the male rat brain, *Cyp19a1* was highly expressed in the posterior medial amygdaloid nucleus (MeP) and the bed nucleus of stria terminalis (BNST). Intermediate expression levels were found in the medial preoptic area (MPA), the Cornu Ammonis field 3 (CA3) of the hippocampus and the posterior cortical amygdalohippocampal area (AHi). Low expression was detected in the anterior caudate putamen (CPu), the nucleus accumbens (Acb) and the ventromedial hypothalamus (VMH). In the female rat brain, similar expression patterns were detected. However, the expression was significantly lower than in the males in the BNST, VMH, MeP, AHi and the CA3 field. Co-expression with cell markers was scrutinized with double FISH to examine the identity of *Cyp19a1* mRNA expressing cells. The majority of the *Cyp19a1*-positive cells were GABAergic, some also expressing somatostatin, in all regions except for the cortical amygdala and the anterior AHi where the highest co-expression

was found in glutamatergic cells. A smaller fraction of cells was shown to co-express *Slc1a3* especially in the amygdala and the VMH, suggesting expression of *Cyp19a1* also in astrocytes. No co-expression was observed with *Gfap, Slc18a2, Chat, Mbp, Th* or *Pvalb*. These findings suggest a sex-specific expression pattern of aromatase in the brain of young adult rats and that *Cyp19a1* is expressed region-specifically in several neural cell types.

Title: Sex differences in androgen receptor, estrogen receptor alpha, and c-Fos co-expression with corticotropin-releasing factor expressing neurons in restrained mice

Authors: *K. A. RYBKA, J. J. LAFRICAN, Z. J. ROSINGER, D. O. ARIYIBI, M. R. BROOKS, J. J. JACOBSKIND, D. G. ZULOAGA;
Psychology, Univ. At Albany State Univ. of New York, Albany, NY

Abstract: Prevalence rates of anxiety and depression are nearly twice as high in women when compared to men, with suggested mechanisms involving sex-dependent gonadal hormone exposure and hypothalamic-pituitary-adrenal (HPA) axis dysregulation. Actions of gonadal hormones through androgen receptor (AR) and estrogen receptor alpha (ERα) have been implicated in the regulation of HPA axis responsiveness and anxiety behaviors, while corticotropin-releasing factor (CRF) is known to regulate the HPA axis, anxiety, and depression. Using Crh-IRES-Cre::Ai9 (tdTomato) reporter mice we first tested whether CRF neurons co-localize AR in mice and if this differed by sex. High co-localization of AR in CRF neurons was found within the medial preoptic area (MPOA), bed nucleus of the stria terminalis (BST), medial amygdala (MeA), and ventromedial hypothalamus (VMH), while moderate CRF/AR co-expression was found within the central amygdala (CeA) and low levels in the paraventricular hypothalamus (PVN). Sex differences in CRF/AR co-expression were found in numerous brain regions including the BST, CeA, and VMH where males showed higher levels of co-expression within these regions. We next investigated CRF co-localization with ERα, where generally less CRF/ERα co-localization was found relative to CRF/AR co-localization. High co-expression was found within the MPOA and VMH, while moderate levels were found in the arcuate nucleus and low levels in the PVN and CeA. Sex differences in CRF/ERα were found in the MPOA and PVN, where females showed higher levels of co-localization. Finally, we restrained mice for 30

minutes to assess neural activation of CRF cells within these regions during psychogenic stress by assessing co-localization with the neural activation marker cFos. Greater CRF/cFos co-expression was found in females when compared to males in the principal nucleus of the BST, with no other sex differences found in other regions. Given the known role of CRF in the regulation of anxiety, depression, and the HPA axis, the presence of AR and ERα and sex-specific activation of discrete CRF cell groups indicate potential mechanisms for the mediation of sex differences in these functions.

Title: Functional characterization of hippocampal regulation of CRF+ PVN neuronal activity

Authors: *A. B. COLE[1], S. M. THOMPSON[2];
[1]Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Corticotropin-releasing factor-positive (CRF+) neurons in the paraventricular nucleus of the hypothalamus (PVN) drive activity of the hypothalamic-pituitary-adrenal (HPA) axis. The release of CRF from these cells initiates the neuroendocrine stress response that ultimately leads to elevation of circulating glucocorticoids and exerts effects on a wide range of body systems. This systemic and powerful response therefore demands tight regulation of the HPA axis, carried out by brain regions upstream of the PVN as well as negative feedback within hypothalamic, pituitary, and adrenal cells. Circulating glucocorticoid levels exhibit a complex and dynamic pattern of activity that respond to numerous physical and psychological stimuli, suggesting regulation by multiple brain regions. Although this negative feedback is crucial to the proper functioning of the HPA axis and ultimately an organism's health, certain psychiatric conditions have been linked to dysregulation of this negative feedback. One of the most consistent biological findings in patients with major depression is dysregulation of the HPA axis. Investigating links between these conditions and the dysregulation of the HPA axis may lead to important insights of the underlying biology of these conditions. The hippocampus is suggested as a prime candidate for contributing to regulation of HPA activity. Removing hippocampal

inputs to PVN leads to increased activity of the PVN, suggesting a net inhibitory influence. The exact nature of this regulation is unclear, and the complexity of HPA axis overall suggests that the answer may not be as straightforward as lesions studies suggest. The presented work utilizes patch clamp electrophysiology to record the activity of CRF+ PVN cells in response to electrical and optical stimulation of hippocampal inputs to the PVN. Results suggest that the hippocampus provides both monosynaptic excitatory and disynaptic inhibitory input to CRF+ neurons of the PVN, with the bed nucleus of the stria terminalis serving as an inhibitory relay for hippocampal excitatory output. Inhibitory postsynaptic potentials (eIPSCs) elicited with high frequency stimulation of hippocampal efferents maintained a fairly consistent amplitude in CRF+ cells, whereas excitatory postsynaptic potentials (eEPSCs) decreased in amplitude. The functional consequences of this input were studied in vivo, using optogenetic stimulation of hippocampal efferents and determination of plasma corticosterone levels. The BNST may thus represent a site of sign reversal, allowing glutamatergic hippocampal efferents to exert negative feedback on the HPA axis.

Title: Changes in Cortisol Levels Across the Lifespan in Common Marmosets (Callithrix jacchus)

Authors: *M. LOPEZ[1,2], A. SEIDL[1], K. A. PHILLIPS[1,2];
[1]Neurosci., Trinity Univ., San Antonio, TX; [2]Southwest Natl. Primate Res. Ctr., Texas Biomed. Res. Inst., San Antonio, TX

Abstract: Human aging is associated with senescence of the hypothalamic-pituitary-adrenal axis, which leads to progressive dysregulation and increased cortisol exposure. This key hormone is implicated in the pathogenesis of many age-related diseases. Common marmosets display a wide spectrum of naturally-occurring age-related pathologies that compare similarly to humans, and are increasingly used as translational models of aging and age-related disease. Our previous work has shown cortisol concentration decreases in marmosets from juvenile to adult ages. Whether the marmoset hypothalamic-pituitary-adrenal axis also shows senescence with increasing age is unknown. To address this question, we analyzed hair cortisol concentration

(HCC) across the lifespan of captive common marmosets via a cross-sectional design. We collected shaved hair from the upper back from 48 marmosets from five developmental stages: infant (n=8), juvenile (n=10), adult (n=10), older adult (n=10), and geriatric (n=10). For all age classes an equal number of males and females were sampled. Samples were processed and analyzed for cortisol using enzyme immunoassay. HCC ranged from 1416 to 12408 pg/mg. We found significant main effects of age and sex (age: $F(4,38) = 7.74$, $p = .001$; sex: $F(1,38) = 7.00$, $p = .012$). Infants had significant higher levels of HCC compared to all other age groups. Females had higher HCC than males. The interaction between sex and age was not significant. These results indicate marmosets do not show dysregulation of the HPA axis as they age.

Title: Neural circuitry for oxytocin release and maternal behavior

Authors: *S. VALTCHEVA[1], H. A. ISSA[1], K. A. MARTIN[1], K. JUNG[2], H.-B. KWON[2], R. C. FROEMKE[1];
[1]Skirball Inst. for Biomolecular Med., New York Univ. Sch. of Med., New York, NY; [2]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Parenting behaviors emerge from complex neural circuits conferring sensitivity to infant needs to ensure survival of the species. One important molecular signal for the maternal brain is oxytocin (OT), a nine amino acid peptide produced mainly in the hypothalamus (Althammer 2017; Jurek 2018; Valtcheva 2019). Oxytocin is believed to powerfully enhance parental behaviors by increasing the salience of sensory cues from the offspring (Dölen 2015; Grinevich 2018; Froemke 2021). However, it remains unexplored what sensory cues from infants can activate OT neurons in new mothers. Here we describe a neural circuit routing auditory

information about infant vocalizations to the OT system in maternal mice (dams). By performing in vivo cell-attached and whole-cell recordings from optically-identified OT neurons, as well as fiber photometry of OT cells in awake dams, we found that OT neurons, but not other hypothalamic cells, are activated following playback of pup distress vocalizations. Using anatomical tracing and channelrhodopsin-assisted circuit mapping (Petreanu et al., 2007), we identified the projections and brain areas (from inferior colliculus and auditory cortex to the posterior intralaminar thalamus, PIL) relaying auditory information to OT neurons. We identify the PIL as a major auditory input to OT cells. In hypothalamic brain slices, we found that optogenetic activation of PIL fibers led to long-term depression of synaptic inhibition in OT neurons mediated by postsynaptic internalization of GABAARs via dynamin signaling. Therefore, persistent activation of OT neurons following pup calls in vivo is likely mediated by disinhibition. Using a genetically-encoded OT sensor (Mignocchi et al., 2020), we demonstrated that pup calls, but not pure tones, were efficient in triggering OT release in downstream areas such as the VTA. Finally, inhibiting PIL projections to hypothalamus with chemogenetics, perturbed pup retrieval behavior in dams by decreasing the amount of pups retrieved and increasing the latency of retrieval over multiple trials. These findings suggest that the thalamus-hypothalamus noncanonical auditory pathway may be a specific circuit for the detection of social sounds, important for disinhibiting OT neurons, gating OT release in downstream brain areas, and sustaining maternal performance over time.

Title: Oxytocin-paired anogenital stimulation in neonatal mice

Authors: N. M. FERNANDEZ, E. R. FORTI, *E. HAMMOCK;
Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) is a neuropeptide best known for its roles in parturition, lactation, and maternal care, and the modulation of adult social behavior. OXT is present in maternal saliva and OXT receptors (OXTR) are present in the external anogenital area of male and female neonatal mice. Studies in rats have demonstrated the importance of anogenital licking and grooming of pups by dams during development, assisting in urination and defecation and

influencing typical neurodevelopmental outcomes. Artificial anogenital stimulation of rat and rabbit neonates with a paint brush, mimicking maternal licking and grooming, has led to increased c-Fos immunoreactivity in the hypothalamus. Therefore, the goal of this experiment is to determine if exogenous OXT applied at the peripheral site of anogenital sensory stimulation modulates brain activation in infancy. Male and female post-natal day 8 OXTR-EGFP reporter mice were randomized to treatment group which included a "holding" control or anogenital stimulation delivered by a paint brush dipped in one of three OXT manipulation conditions (saline vehicle, 1 μM OXT, or 1 μM OXTR antagonist — atosiban). Ninety minutes after the stimulation, neonates were perfused with 4% paraformaldehyde and brains processed for c-Fos immunoreactivity. Preliminary analyses indicate that, like in rats and rabbits, anogenital stimulation enhances hypothalamic c-Fos immunoreactivity in neonatal mice. Data collection is ongoing. The final analyses will be sufficiently powered to detect medium to large effect sizes, including treatment × sex interactions.

Title: Oxytocin and vasopressin 1a receptors are functional in both sexes at embryonic day 16.5 in mice

Authors: *E. J. SOMMER, H. K. CALDWELL;
Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstract: There is mounting evidence that the oxytocin (Oxt) and vasopressin (Avp) systems contribute to early brain formation. Specifically, work in transgenic mice as well as the embryonic manipulation of the Oxt system suggests that signaling through the Oxt receptor (Oxtr) during embryonic development affects behavior in adulthood. Unfortunately, at this time, very little is known or understood about what the roles of these systems during embryonic development. What is known is that, in mice, the Oxtr is present in both sexes as early as embryonic day (E) 16.5, while the production of Oxt is temporally offset between females and males. In females, Oxt mRNA is found as early as E12.5, but in males it is not transcribed until postnatal day 2. In contrast, mRNA transcripts for Avp are found as early as E13.5 and the Avp 1a receptor (Avpr1a) is available in both sexes at E14.5. While it is not clear why there would be a receptor without an obvious ligand for the Oxtr in males, the question of what is activating the

Oxtr or the Avpr1a is premature without knowing whether the receptors are even functional during embryonic development. So, in order to assess the functionality of the Oxtr and Avpr1a in both sexes at E16.5, we performed an Oxtr- and Avpr1a-stimulated g-protein coupled receptor binding assay. We hypothesized that the Oxtr and Avpr1a were functional in both sexes and would be stimulated by Oxt and Avp, respectfully. In this assay, functionality was measured by applying an Oxtr or Avpr1a agonist to tissue sections then determining if there is a decrease in the binding of an ^{35}S radiolabeled GTP; which would occur if there was a conformational change in the receptor, resulting in GDP being released from the Gα subunit. We found both that the Oxtr and Avpr1a are functional at E16.5 in both sexes within the same, but specific, brain regions. For the Oxtr, functional binding was observed in the ventricular and subventricular zones of the cortical neuroepithelium, but not the ventricular or subventricular zones of the septal neuroepithelium or the amygdalar area. For the Avpr1a, functional binding was observed in the nucleus of the vertical limb of the diagonal band of Broca, but not the fornix, olfactory tubercle, indusium griseum, or the ventral hypothalamic area. It is important to note that while this experiment cannot provide information about the nature of the ligand utilized in the developing brain, such as Avp acting at the Oxtr or Oxt acting at the Avpr1a, the data do suggest that Oxtr and Avpr1a signaling have the ability to impact embryonic brain development.

Title: Cyp11a1 isoforms in the mammalian central nervous system

Authors: *Y. LIN, V. PAPADOPOULOS;
Dept. of Pharmacol. & Pharmaceut. Sci., Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA

Abstract: Neurosteroids are steroid hormones synthesized by the nervous system, which have essential roles in brain function, neuroinflammation, and neuroprotection. Although the steroid biosynthesis pathway has been assumed to be identical between peripheral steroidogenic organs and the CNS, there are discrepancies between steroidogenic enzyme levels and neurosteroid concentrations in the brain. In particular, cytochrome P450 11A1 (CYP11A1) - the enzyme catalyzing the first step of steroid formation - has been challenging to detect in the human brain even though its product, pregnenolone, is found in high levels in the brain. Although there is one

CYP11A1 found in rats, two CYP11A1 isoforms are present in humans and mice. However, the differences in expression, function, and localization between the isoforms are unknown. Current literature has focused exclusively on CYP11A1 isoform a (i.e., the classical isoform), while isoform b has not been studied.
Given that the classical CYP11A1a isoform has been challenging to detect in the CNS, we hypothesized that the major CYP11A1 isoform found in the CNS might differ from that present in the periphery. qRT-PCR analysis of mouse tissues revealed that the RNA expression of isoform b is approximately two-fold higher in the brain and spinal cord compared to that of isoform a. In contrast, in peripheral steroidogenic tissues in mice, RNA expression levels of *Cyp11a1* isoform a are 100-fold higher than that of isoform b. In the human brain and spinal cord, the RNA expression levels for *CYP11A1* isoform a appear to be higher than those of isoform b. However, there appears to be a truncation in the brain mRNA transcript for *CYP11A1* isoform a localized between exons 1 and 2. No such truncation was seen in the adrenal or testes. To further characterize the localization and function of different isoforms, we transfected CYP11A1 isoforms a and b into MGM-1 human glioma cells. Although both isoforms appear to be localized to the mitochondria, only the classical isoform a is involved in steroidogenesis. Our results suggest that the human brain expresses a CYP11A1 isoform different from the currently known isoforms. The expression of this alternate CYP11A1 isoform may be under different regulatory mechanisms and it may be involved in different functions than the classical CYP11A1 isoform.

Title: Shared genetic susceptibility across multiple types of chronic pain implicates brain and neuroendocrine systems

Authors: *K. ZORINA-LICHTENWALTER[1], C. BANGO[2], M. C. KELLER[1], L. VAN OUDENHOVE[3], M. CEKO[4], M. A. LINDQUIST[5], N. P. FRIEDMAN[1], T. D. WAGER[2]; [1]Univ. of Colorado Boulder, Boulder, CO; [2]Dartmouth Col., Hanover, NH; [3]Dept. of Chronic Dis. and Metabolism and Leuven Brain Inst., KU Leuven, Leuven, Belgium; [4]ICS, Boulder, CO; [5]Dept. of Biostatistics, Johns Hopkins Univ., Baltimore, MD

Abstract: Current conceptualizations of chronic pain rely heavily on body site and symptom-based groupings. However, pain conditions show substantial phenotypic and genetic overlap, which suggests shared underlying pathophysiology. We characterized the genetic component of this shared risk across 24 chronic pain conditions in the UK Biobank dataset (N=500,000). We conducted a genome-wide association study (GWAS) on each condition and estimated genetic correlations (indicative of shared genetic risk) among them. We used confirmatory factor analysis (CFA) within a genomic structural equation modeling (gSEM) framework to compare groupings in three ways: (1) by body site, (2) by putative etiology, and (3) using results derived from exploratory factor analysis (EFA, a data-driven method). The EFA-CFA pipeline was validated using a split-genome approach with model discovery and validation in odd and even autosomes, respectively. As a complement to factor analysis, we subjected the genetic correlation matrix to graph theoretic analyses, characterizing the network properties and community structure. All analyses pointed to a common genetic factor that confers shared risk across pain conditions. GSEM results showed evidence of a bifactor structure, with a prominent general factor explaining most of the shared genetic variance and two body site-specific factors related to musculoskeletal and cranio-visceral disorders. Network visualization revealed a single dominant community of 17 highly interconnected conditions that share genetic associations. Common factor loadings and network betweenness centrality showed arthritis, back, and neck pain to be the top conditions in terms of shared genetic variance. A GWAS on the common factor showed 163 genome-wide significant loci, which we investigated using FUnctional MApping (FUMA) pathway and annotation analysis. FUMA revealed associations with high expression levels in the pituitary gland and several brain tissues -- particularly hippocampus, cerebellum, and nucleus accumbens -- as well as associated gene overlap with behavioral phenotypes: mood, sleep, and cognition. Overall, these results indicate broad genetic vulnerability across pain disorders and suggest involvement of common neural circuits and neuroendocrine pathways.

Title: Thyroid hormone T4 mitigates TBI-induced accumulation of lipid droplets in liver

Authors: *M. KHANDELWAL[1], G. KRISHNA[1], Z. YING[1], F. GOMEZ-PINILLA[1,2];
[1]Dept. of Integrative Biol. and Physiol., [2]Dept. of Neurosurg., UCLA, Los Angeles, CA

Abstract: Traumatic brain injury is the most common cause of death and disability. Most of existing efforts have been devoted to understand the TBI pathology in the brain without consideration that the periphery can modulate TBI pathogenesis. In particular, given the role of liver in detoxification and processing of lipids and proteins important for brain function, it is crucial to determine the action of liver on TBI pathogenesis. We are following up previous results that TBI influences fatty acid metabolism and that these effects are exacerbated by fructose ingestion. Oil Red O staining revealed a widespread accumulation of large lipids droplets in rats either receiving fructose or TBI injury, and an even larger accumulation in fructose rats exposed to TBI. Lipid droplets in hepatic tissue are involved in the storage of lipids such as triglycerides, steryl esters and retinyl esters. Lipid droplets are crucial for lipid and energy metabolism; however, excessive accumulation of lipid droplets in organelles is linked to various metabolic disorders such as obesity, fatty liver and atherosclerosis. We have studied the action of T4 thyroid hormone based on results of single cell genomics (Gomez-Pinilla and Yang; Nature Communications, 2018) pointing out thyroid hormone as an important metabolic modulator of TBI and a potential therapeutic target. T4 administration significantly reduced the size, intensity and number of lipid droplets. Additionally, T4 administration reduced the LXR II levels (marker for lipid droplets) in fructose fed TBI rats. In fructose fed-TBI animals the levels of Fatty acid synthase (FAS) were increased and this could be the cause of triglycerides accumulation in liver tissue. FAS is a key lipogenic enzyme involved in fatty acid metabolism such that elevated levels of FAS results in accumulation of triglycerides thereby causing oil droplet formation. We observed significant reduction in FAS levels in T4 administered animals. Thus, thyroid hormone (T4) could be a promising therapeutic agent in treating individuals suffering from TBI and consume high fructose diet.

Title: A systematic review and meta-analysis on the effects of exercise on the endocannabinoid system

Authors: *S. DESAI[1], B. BORG[1], C. CUTTLER[5], K. M. CROMBIE[6,7], C. A. RABINAK[1,2,3,4], M. N. HILL[8], H. A. MARUSAK[1,4];

Sci., [4]Merrill Palmer Skillman Inst. for Child and Family Develop., [1]Wayne State Univ., Detroit, MI; [5]Washington State Univ., Pullman, WA; [6]Univ. of Wisconsin-Madison, Madison, WI; [7]Univ. of Texas at Austin, Austin, TX; [8]Univ. of Calgary, Calgary, AB, Canada

Abstract: The endocannabinoid (eCB) system plays a key role in maintaining homeostasis, including regulating metabolism and stress responses. Chronic stress may blunt eCB signaling, and disruptions in eCB signaling have been linked to stress-related psychiatric disorders and physical health conditions, including anxiety, depression, posttraumatic stress disorder (PTSD), diabetes, and obesity. Pharmacological and non-pharmacological behavioral interventions (e.g., exercise) that target the eCB system may be promising therapeutic approaches for preventing and treating stress-related diseases. Here, we perform a systematic review and the first meta-analysis to examine the impact of exercise on circulating eCB concentrations. Thirty-three articles (reporting on 51 samples) were included in the systematic review, and ten were included in the meta-analysis. The majority of samples that measured anandamide (AEA) (73.5%) showed a significant increase in AEA concentrations following acute exercise, whereas effects on 2-arachidonoylglycerol (2-AG) were inconsistent in the systematic review. However, the meta-analysis revealed a consistent increase in both AEA and 2-AG following acute exercise across modalities (e.g., running, cycling), species (e.g., humans, mice), and in those with and without pre-existing health conditions (e.g., PTSD, depression). There was substantial heterogeneity in the magnitude of the effect across studies, which may relate to exercise intensity, physical fitness, timing of measurement, and/or fasted state. Effects of chronic exercise were inconsistent. Potential interpretations of exercise-induced mobilization of eCBs, like replenishment of energy stores, along with possible implications, like mediating analgesic and mood-elevating effects of exercise, are included. Our review highlights the ability of exercise to activate the eCB system and mobilize eCBs. We offer recommendations for future work and discuss exercise as a behavioral intervention to prevent and treat stress-related psychopathology.

Title: Novel sexually-differentiated cell populations in the preoptic area of a sex-changing fish, Amphiprion ocellaris, characterized by single-nucleus RNA sequencing

Authors: *C. G. PARKER[1], Z. V. JOHNSON[2], B. E. HEGARTY[2], G. W. GRUENHAGEN[2], J. T. STREELMAN[2], J. S. RHODES[1];
[1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Across vertebrate species, sex differences in cell number and phenotype in the preoptic area of the hypothalamus (POA) are essential to regulating sex-specific reproductive physiology and behavior. In mammals, male POA differentiation can be traced back to the presence of gonad-derived androgens, while female POA differentiation (feminization) does not have a clear trigger to mark its beginning and proceeds without gonadal influence. As such, POA feminization is less amenable to laboratory manipulation in mammal models, and is generally not as well understood. In anemonefish like the common clownfish *Amphiprion ocellaris*, POA feminization follows a clear trigger and proceeds without gonadal influence, providing a complementary model for the study of POA feminization. Anemonefish display natural male-to-female sex change, and sex change is easily induced in the lab. Previous work in *A. ocellaris* identified a sexually-differentiated cell population in the anterior POA that is more numerous in females than males. In order to identify potential phenotypes for this cell population, and identify other sexually-differentiated characteristics in the anemonefish POA, we carried out single nucleus RNA sequencing on POA-containing brain tissue from mature male (n=6) and female (n=6) *A. ocellaris*. Libraries were prepared from pooled samples and individual fish were recovered (demultiplexed) using scSplit. Clustering produced 49 clusters, which were then classified as representing major cell classes (e.g. excitatory neurons, inhibitory neurons, radial glia, microglia) using canonical markers. After recovering individuals from pooled samples we tested which clusters differed significantly between the sexes on the basis of cell number. We found 12 clusters to be sexually differentiated, of which 7 were female-biased and 5 were male-biased. One of the male-biased clusters was found to be strikingly differentiated (prominent in males and almost absent in females) and contained a high proportion of cells expressing an androgen receptor gene, suggesting a potential role in brain-pituitary-gonad signaling. Possible homology of the identified sexually dimorphic cell populations in the fish POA with mammalian POA will be evaluated by statistical comparisons with mouse POA single cell data (publically available). Results provide clear cellular composition endpoints for sexual differentiation of the POA that is accomplished during sex change. Further studies will explore the time-course, gonad-dependence/independence, signaling cascades, and epigenetic programming involved in active feminization of the POA in the novel anemonefish model.

Title: Social acute stress activates different areas in the chicken central extended amygdala

Authors: A. PROSS[1,2], A. H. METWALLI[1,2], J. A. MORENO[1], *L. MEDINA[1,2], E. DESFILIS[1,2];
[1]Univ. of Lleida, Lleida, Spain; [2]IRBLleida, Lleida, Spain

Abstract: Stress is a major problem in poultry farms and research animal facilities due to its negative impact on animal growth, reproduction, susceptibility to disease and welfare. Neural regulation of the stress response has been extensively studied in mammals, highlighting a critical role of the central extended amygdala (EAce) as a major controller of the hypothalamic-pituitary-adrenocortical axis and the sympatho-adrenomedullary system. There is high conservation on the hypothalamic and brainstem centers that trigger the stress response between species, but very little is known on the regulation of the stress response by the amygdala in non-mammals. Using an evolutionary developmental biology approach, our group identified several areas in the chicken telencephalic subpallium, which include cell populations likely homologous to those of mammalian EAce. Our goal was to study if the putative EAce of domestic chicken (*Gallus gallus domesticus;* White Leghorn) is involved in the stress response. We used a previously described paradigm of acute social isolation in seven-day-old chickens, which leads to increased distress vocalizations and corticosterone levels, as reliable markers of biological stress. Fertilized eggs were obtained from a farm and incubated in the laboratory at standard temperature, lighting and humidity conditions. After hatching, chicks were housed in groups, in pens, with food and water ad libitum. On day 7, pairs of same sex animals were treated as follows: one was immediately sacrificed, while the other was isolated from the group for 30 minutes and then sacrificed. Brains were rapidly dissected, and samples were collected, using 1mm-diameter punches, from three different EAce areas: lateral bed nucleus of the stria terminalis (BSTL), peri-intrapeduncular island field and oval central amygdala nucleus (pINP-Ov), and capsular central amygdala (CeC). These samples were analysed using quantitative retrotranscription PCR to detect differential expression of the immediate early gene cFos, comparing isolated with control animals. Two different housekeeping genes (GAPDH and HPRT1) were used to normalize the value. We found a significantly higher cFos mRNA expression in BSTL and CeC but not in pINP-Ov in the stressed animals compared to controls. The activation in BSTL and CeC supports a role of these areas in acute social stress. These

results suggest a conservation of function between avian and mammalian EAce, and open the venue for future studies of the specific cell populations that become active following acute social stress.

Title: Examining sex differences and the role of corticotrophin-releasing factor in how acute stress impacts reward learning and dopamine release in rats

Authors: *M. P. JOHNSTON[1], B. HAMAUEI[2], C. E. STELLY[2], M. J. LEFNER[3], M. J. WANAT[4];
[1]Univ. of Texas At San Antonio Dept. of Biology/Neurobiology, San Antonio, TX; [2]Biol., Univ. of Texas, San Antonio, San Antonio, TX; [3]Univ. of Texas At San Antonio, San Antonio, TX; [4]Neurosciences Inst., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Exposure to stress can exert long-lasting consequences on behavior. Recent findings demonstrate that acute stress elicits a persistent elevation in Pavlovian conditioned responding in male rats. This stress-enhanced reward learning occurs due to elevated reward-evoked dopamine release in the ventral lateral striatum (VLS). However, the stress-related signaling that mediates the impact of acute stress on reward learning is unknown. One likely candidate is corticotrophin-releasing factor (CRF), which is released in the ventral tegmental area (VTA) during stress whereby modulating dopamine-dependent behaviors. While there are known sex differences in CRF signaling and behavioral responses to stress, it is unclear if there are also differences in how acute stress and CRF signaling impacts reward learning and dopamine release. This project has two primary goals: (1) determine the role of CRF signaling in the VTA during stress-enhanced reward learning and (2) identify whether sex differences exist in how acute stress influences reward learning and dopamine release in the VLS. Our preliminary findings indicate that antagonizing CRF receptor signaling within the VTA blunts stress-enhanced reward learning. Ongoing experiments are utilizing *in vivo* fast-scan cyclic voltammetry recordings to examine how stress and the stages of the estrous cycle influence VLS dopamine release and reward

learning. The results of this project will provide valuable insights on the interaction between stress, reward learning, and dopamine release in male and female rats.

Title: Elucidating the Differences in Underlying Pathways of Varying Types of Acute Stress

Authors: T. SALTZ[1,2], *A. B. LIPSHUTZ[3,2], K. R. ANDERSON[2,4], A. MANGANARO[2,4], D. DUMITRIU[2,4];
[1]Neurosci., Williams Col., Williamstown, MA; [2]Developmental Neurosci., New York State Psychiatric Inst., New York, NY; [3]Neurosci. & Behavior, Barnard Col., New York, NY; [4]Pediatric Psychiatry, Columbia Univ. Irving Med. Ctr., New York, NY

Abstract: Elucidating the underlying neurocircuitry of acute stress may provide insight into the causes and predispositions of many neuropsychiatric disorders. Understanding the neurocircuitry that underlies acute stress will allow greater understanding of how different types of stressors are processed in the brain via the activation of discrete neural circuits. While the amygdala has been implicated in the pathophysiology of acute stress, many of the neural pathways and brain areas that project to the amygdala at the time of acute stress remain unknown. Previous data show significant differences in motor function of C57 mice after undergoing acute stress (velocity of 8.29 ± 0.29 cm/s, n = 132) as compared to their paired controls (velocity of 9.68 ± 0.45 cm/s, n = 62). We thus hypothesize a connection between acute social and psychomotor stress though we predict that the two are processed differently in the brain via discrete projections to the amygdala. In order to evaluate this hypothesis we will perform Acute Social Defeat Stress (ASDS) and Tail Suspension Test (TST) in two separate subject groups to induce social and psychomotor stress, respectively. Using the genetic mouse line, TRAP2, as well as validated retrograde tracing tools we will observe projections to neurons that were active at the time of each behavior. TRAP2 mice have Cre expression under a cFos promoter which can be activated with an injection of tamoxifen. A virus containing floxed, inactive TVA-G proteins will be injected bilaterally into the amygdala of TRAP2 mice. When Cre is expressed and activated in cFos neurons, TVA-G proteins are expressed. Injections of tamoxifen will be administered in a controlled time window prior to the behavioral paradigm in order to activate Cre which will induce the expression of TVA-G proteins in neurons that are active at the time of the behavior. A glycoprotein-deleted pseudorabies virus will be used to retrogradely trace monosynaptic

projections to neurons that were active during behavior in the amygdala in order to determine the upstream neural populations that project to these neurons. The glycoprotein-deleted pseudorabies can only infect cells that have TVA-G expression. Therefore, projections will only be traced in neurons that were active and expressed cFos at the time of behavior. We hypothesize that distinct patterns of projections to the amygdala will be distinguishable in comparing social stress versus psychomotor stress.

Title: Live versus robotic predatory threat on foraging by bed nucleus of the stria terminalis GABA neurons

Authors: *A. LY, A. BARKER, E. PREVOST, D. MCGOVERN, D. ROOT;
Univ. of Colorado Boulder Dept. of Psychology and Neurosci., Boulder, CO

Abstract: The motivation to venture outside a safe context in search for food, in spite of potential threats, is essential to survival. GABA neural activity in the bed nucleus of the stria terminalis (BNST), is implicated in stress and fear response. However, the underlying relationship between GABA BNST activity and changes in foraging behavior in response to a threat experience is unclear. Here, we compared changes in foraging behavior in response to a live or robotic predator threat. In addition, we utilized chemogenetic inhibition in order to investigate the role of GABA BNST activity in predatory threat response. Male and female VGaT::Cre mice received viral delivery of Cre-dependent FLEX-GFP or FLEX-hM4Di to the anteromedial BNST (AP+0.3,ML±0.6,DV-4.05). Mice were trained on a foraging task to search for food at discrete and incrementally greater distances in a brightly lit arena. After obtaining food, mice learned to retreat into a dark, enclosed “nest” safe context. The mice were then exposed to either a robotic land predator or a live predator positioned in front of a food source at the farthest distance. In our findings, both live and robotic predatory threat increased latency of successful foraging during the threat exposure itself. In the post-48 hour period after threat exposure, while robotic predator threat increased time spent in the safe context, live predator threat did not change time spent in the safe context but instead increased the number of head entries to the foraging zone from the nest, which was decreased with chemogenetic inhibition of

VGaT neurons in the BNST. The results demonstrate similarities between the effects of live and robotic predatory threat on foraging behavior during the threat itself but differential effects on foraging response in the 48 hours after the exposure, of which BNST GABA neurons have a selective regulatory role.

Title: Effect of social defeat on medial amygdala activity during social behavior

Authors: *A. RITGER[1], N. FERRARA[2], J. ROSENKRANZ[3];
[1]Neurobio. of Stress Resilience and Psychiatric Disorders, Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]Neurobio. of Stress Resilience and Psychiatric Disorders, Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [3]Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci. Chicago Med. Sch., North Chicago, IL

Abstract: The medial amygdala (MeA) regulates social behaviors and responses to social cues. Social stress can contribute to depression and there is evidence for reduced MeA volume and connectivity in depression. Repeated social defeat stress in rats results in negative long-term behavioral outcomes including social avoidance and anhedonia, and increases MeA immediate early gene expression. A clearer understanding of how and when MeA neuronal activity is engaged during social investigation following social stress would help delineate a role of the MeA in stress-induced changes in social behavior. The goal of this study was to determine the effect of social defeat on MeA activity during a social preference test (SoPT) in rats. We hypothesized that repeated social defeat stress would decrease social preference and increase MeA activity during a novel social encounter compared to control. MeA activity was measured using fiber photometry in adult male Sprague Dawley rats during the SoPT prior to and after repeated social defeat stress exposure. The SoPT consisted of a 3-chamber apparatus with a novel conspecific rat and a novel object enclosed in small cages in opposite chambers. We measured social preference as the ratio of time spent investigating the novel rat cage compared to the novel object cage. During social defeat, rats were exposed to 5 days of social defeat with a retired breeder Long Evans rat using the resident-intruder paradigm, and control rats were placed in a transport cage for the same amount of time. Following social defeat, MeA calcium transients

were then quantified during the SoPT during the time the rat spent exploring either the novel rat cage or the novel object cage. While preliminary results did not demonstrate a difference in social preference between social defeat and control groups, we did find that social defeat increased MeA activity while investigating the novel rat compared to novel object and compared to baseline recordings before stress. There was little change in MeA activity in the control group during novel rat or object investigation, or between recordings. These results suggest that the MeA response to social stimuli is increased relative to non-social stimuli following social defeat. This indicates that MeA responsiveness is sensitive to prolonged social stressors and is altered in response to novel social contexts following social stress. These results may help elucidate the neural mechanisms underlying social withdrawal symptoms in patients that have experienced significant social stress.

Title: Hypothalamus-projecting amygdala neurons link glycemic and behavioral responses to stress via the liver

Authors: *K. DEVARAKONDA[1], A. SHTEKLER[1], V. E. LEHMANN[2], M. JIMENEZ-GONZALEZ[1], A. ALVARSSON[3], R. LI[3], R. HAMPTON[3], P. J. KENNY[4], S. STANLEY[3]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Neurosci., [3]Diabetes, Obesity and Metabolism Inst., [4]Dept. of Pharmacol. and Systems Therapeut., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: When faced with a threat, animals must rapidly mobilize energy stores to support adaptive behavioral responses. Many brain regions mediate the autonomic, endocrine, and behavioral responses to stress. Limbic system brain sites such as the prefrontal (cingulate) cortex, amygdala, and hippocampus coordinate behavioral responses to acute and chronic stressors in a top-down manner by transmitting stress-relevant sensory, emotional, social, and environmental information to hypothalamic and hindbrain stress regions. In contrast to hypothalamic and hindbrain circuits, little is currently known about limbic contributions to glycemic and metabolic responses to stress or their involvement in maintenance of blood glucose homeostasis during non-stress periods. This is important because limbic system dysfunction is

heavily implicated in stress-induced mood disorders, which in turn are associated with increased risk of type II diabetes (T2D) and other abnormalities in blood glucose homeostasis. Here, we investigated the role of the medial amygdala (MeA) in coordinating metabolic responses to stress. First, we show that restraint and fasting stress recruit neural activity in anterior and posterior subdivisions of the MeA. Then, using anterograde and retrograde viral tracers, we identify a population of stress-responsive MeA neurons that project to the ventromedial hypothalamus (VMH). Chemogenetically stimulating VMH-projecting MeA neurons induces stress-like hyperglycemia and facilitates counterregulatory responses to fasting stress whereas their selective lesioning attenuates the hyperglycemic response to psychosocial stressors and impairs the counterregulatory response to an insulin challenge. Importantly, we show that these stress-related glycemic actions of VMH-projecting MeA neurons occur independent of changes in adrenal and pancreatic glucoregulatory hormones and instead operate through their polysynaptic connections to the liver via the celiac ganglia. Together, our findings identify a amygdala-regulated limbic-hepatic circuit that coordinates glycemic responses to stress.

Title: Divergent electrophysiological and morphological properties of hypothalamic paraventricular nucleus neurons between the common marmoset and the mouse

Authors: *J. K. SUNSTRUM[1,3], S. A. MESTERN[1,3], R. PRZY[1], S. EVERLING[2,3,4], J. C. MARTINEZ-TRUJILLO[2,3,4], W. INOUE[2,3,4];
[1]Neurosci., [2]Physiol. and Pharmacol., Western Univ., London, ON, Canada; [3]Robarts Res. Inst., London, ON, Canada; [4]Brain and Mind Inst., London, ON, Canada

Abstract: The release of stress hormones via the hypothalamic-pituitary-adrenal (HPA) axis is thought to be preserved across mammals. The apex of the HPA axis is formed by parvocellular neuroendocrine neurons in the paraventricular nucleus of the hypothalamus (PVN) that release corticotropin releasing hormone (CRH). While PVN-CRH neurons have been extensively studied in rodents, studies in primates remain scarce. It is possible that the diurnal activity cycle and complex social lives of primates have exposed them to different stressors, and PVN-CRH

neurons have evolved new features under evolutionary pressures. In this exploratory study, we compared PVN neurons between mice and the common marmoset (Callithrix jacchus), a New World primate that has emerged as a promising model in neuroscience. Using patch clamp electrophysiology in acute brain slices, combined with post-hoc morphology reconstruction and immunohistochemistry, we characterized marmoset PVN neurons (N = 10, n= 252) and compared them to their mouse counterparts. Marmoset PVN parvocellular neurons showed stereotyped electrophysiological features well-established in rodents and were distinct from other PVN neuron-types. However, marmoset PVN parvocellular neurons exhibited substantially larger sag-current and shifted membrane resonance due to hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. Interestingly, female (N = 5) parvocellular neurons exhibited greater voltage sag compared to male in marmosets but not mice. Further, morphological analysis revealed that marmoset PVN parvocellular neurons exhibit more dendritic spines compared to mice. These distinct features of marmoset PVN parvocellular neurons may reflect fundamental differences in synaptic integration adaptive for the lifestyle and stressors of primates.

Title: Pituitary adenylate cyclase activating polypeptide (PACAP) neurons in the bed nucleus of the striaterminalis (BNST) and their projections

Authors: *M. AKTAR[1], L. LEPEAK[2], V. MAY[4], S. E. HAMMACK[3];
[1]The Univ. Of Vermont, Burlington, VT; [3]Psychological Sci., [2]Univ. of Vermont, Burlington, VT; [4]Dept Neurolog. Sci., Univ. of Vermont Col. of Med., Burlington, VT

Abstract:
Pituitary adenylate cyclase activating polypeptide (PACAP) neurons in the bed nucleus of the stria terminalis (BNST) and their projections Mahafuza Aktar, Lauren Lepeak, Victor May and Sayamwong E. Hammack
Abstract
Pituitary adenylate cyclase activating polypeptide (PACAP) is a highly conserved neuropeptide playing pivotal roles in numerous physiological functions. We have demonstrated that PACAP

release in the bed nucleus of the stria terminalis (BNST) is critical for many of the behavioral and physiological consequences of stressor exposure. BNST PACAP may be signalingfrom several sources, including afferent fibers that originate in the lateral parabrachial nucleus (LPBn) as well as local PACAP-positive neurons residing within subregions of the BNST. Our prior in-situ hybridization studies have suggested that local PACAP production may be increased following chronic stress, and the activation of BNST PACAP neurons may play roles in coordinating behavioral and physiological stress responses. To determine the projection targets of these local BNST PACAP neurons, we infused AAV/EF1a-DIO-mCherry reporter vector into the BNST region of PACAP-ires-Cre mice to identify BNST PACAP-expressing neurons. Consistent with our previous work, we identified robust PACAP expression in local BNST neurons. PACAP neurons were found in anterior, posterior and ventral regions of the BNST and we traced some of their long distance fibers projections through the stria terminalis to amygdala subregions. Apart from the amygdala, we also identified novel BNST PACAP projections to the anterior forebrain and the medial habenula (MHb). These observations support the literature suggesting BNST PACAP activation is critical for many of the consequences of stressor exposure, and further clarify the neural circuits involved.

Title: Chronic alcohol intake compromises cholinergic modulation of striatal glutamatergic transmission and reduces behavioral flexibility

Authors: *Z. HUANG[1], T. MA[1], X. XIE[1], Y. CHENG[1], X. ZHUANG[1], H. GANGAL[1], X. WANG[1], L. SMITH[1], R. SMITH[2], Y. ZHOU[3], J. WANG[1];

Abstract: Exposure to addictive substances impairs flexible decision-making. Striatal cholinergic interneurons (CINs) are associated with behavioral flexibility. However, whether and how chronic alcohol intake alters behavioral flexibility and CIN-mediated control of striatal output remain unclear. Here, we report that chronic alcohol consumption and withdrawal impairs

reversal of instrumental learning. The alcohol-mediated behavioral inflexibility is associated with several electrophysiological alterations. First, the spontaneous firing of CINs was increased by chronic alcohol consumption. Second, chronic alcohol intake reduced excitatory inputs from the thalamic parafascicular nucleus to CINs in the dorsomedial striatum (DMS). Thalamic excitation triggers a burst-pause response in DMS CINs, which is critical for reversal learning. Third, the burst-pause responses of CINs were also altered by chronic alcohol intake. Moreover, chronic alcohol consumption impaired CIN-mediated inhibition of glutamatergic transmission in dopamine D1 receptor-expressing medium spiny neurons (D1-MSNs), which drive "Go" actions, and impaired CIN-mediated facilitation of glutamatergic transmission in D2-MSNs, which control "No-Go" behaviors. These results demonstrate that chronic alcohol intake reduces thalamic inputs to striatal CINs, compromising their regulation of glutamatergic transmission in MSNs, which may contribute to alcohol-mediated behavioral inflexibility. These results provide a potential neural mechanism underlying alcohol use disorder.

Title: Investigation of cortical and striatal dopamine contributions to binge- and compulsive-like alcohol intake

Authors: *E. A. SNEDDON, K. M. SCHUH, A. M. NADER, M. A. MUENCH, B. M. MASTERS, K. A. FENNELL, N. SHAND, S. C. MONROE, A. K. RADKE;
Psychology, Miami Univ., Oxford, OH

Abstract: Binge- and compulsive-like alcohol intake are markers of alcohol use disorder. Dopaminergic projections and mesocorticolimbic structures such as the medial and lateral orbitofrontal cortices (mOFC; lOFC), the ventral tegmental area (VTA), and nucleus accumbens core (NAcc) have all been implicated in alcohol drinking behaviors. Here we used chemogenetics and knockout mice to determine the roles of the mOFC, lOFC, VTA-NAcc projection, and dopaminergic contributions to ethanol (EtOH) drinking behaviors. Experiment 1:

The viral vector, AAV-hSn-hM4D(Gi)-mcherry was injected into the mOFC (n = 20) or lOFC (n = 15). Infected neurons expressed the Designer Receptor Exclusively Activated by Designer Drugs hM4Di. Clozapine-N-oxide (CNO) binds to hM4Di to cause neural inhibition. Post-surgery, mice self-administered 15% EtOH and water in a limited access drinking in the dark paradigm for 2 h/day. Escalation took place across 12 sessions. CNO was given to mice on session 11 to assess the effects of neuronal inhibition on EtOH drinking. Quinine (100 µM) was added to the EtOH bottle on sessions 13 - 15. Mice randomly received either CNO or vehicle (VEH) injections on sessions 13 or 15 in a crossover design. Experiment 2: The retrograde viral vector, AAV-hSn-DIO-hM4Di (Gi) was injected into the NAcc of DAT-Cre transgenic mice (n = 28, Cre+ = 16, Cre- = 12) to allow neuronal inhibition in dopaminergic neurons projecting from the VTA to NAcc. Mice were tested in the same paradigm described in Exp. 1. Experiment 3: A DAT knock-out (KO) transgenic line of mice (n = 29, HET = 17, WT = 12) self-administered 15% EtOH or water in a 48-h continuous access paradigm across 10 drinking sessions. Mice self-administered 15% EtOH for 24 h for one baseline day, then, quinine was added to the EtOH bottle in escalating concentrations: 12.5, 25, 100, and 250 µM. Each concentration of quinine was presented for four 24-h sessions, then mice were re-exposed to 15% EtOH for three 24-h sessions between each quinine presentation. For Exp. 1, inhibition of the mOFC did not alter binge- or compulsive-like EtOH intake. Inhibition of the lOFC increased consumption of 15% EtOH but not quinine + EtOH. For Exp. 2, preliminary data suggest that inhibition of the VTA-NAcc does not alter EtOH intake but may increase consumption of quinine + EtOH ($p = 0.067$). For Exp. 3, no differences between groups were observed on EtOH- or compulsive-like intake. All mice showed compulsive-like intake at 12.5 and 25 µM quinine. These results validate the role of the lOFC in the regulation of EtOH drinking and suggest a role for dopaminergic projections from the VTA to NAcc in compulsive-like EtOH drinking.

Title: Adolescent-onset ethanol drinking produces long-lasting COX-2-mediated changes on methamphetamine relapse in female adolescent rats.

Authors: *H. L. KLINE, B. K. YAMAMOTO;
Pharmacol. & Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Ethanol (EtOH) and Methamphetamine (Meth) are co-abused drugs but little is known about how they interact to affect behavior. Existing models of co-abuse employ EtOH self-administration and investigator-administered Meth in adult males, but few studies have examined adolescent-onset EtOH drinking and chronic Meth self-administration in female populations. This study aimed to determine the effects of EtOH drinking on later Meth abuse and the role of cyclo-oxygenase 2 (COX2), the enzyme involved in the synthesis of prostaglandins, in serial drug use in female adolescent rats. Rats drank EtOH or water (H2O) for 21 days during adolescence (PD28-49) followed by 21 days of Meth or saline self-administration via jugular vein catheter (PD49-70). Rats then underwent a 7-day Meth abstinence before a cue-primed Meth seeking challenge. Rats were then euthanized and brains were analyzed for changes in COX-2 by Western blot. Prior EtOH drinking had no effect on Meth self-administration. In the cue-primed Meth seeking test, H2O/Meth rats (n=10) pressed a lever previously associated with Meth 124±11.2 times (Mean±SEM) during challenge day, while EtOH/Meth rats (n=10) pressed 91.3±11 times, a 26.3% reduction ($p<0.05$; 2-way ANOVA). EtOH/Meth rats (n=10) had a 73.8% increase in COX-2 immunoreactivity in the striatum compared to H2O/Meth rats (n=9) ($p<0.05$). In a subsequent experiment, adolescent female rats underwent the same serial drug exposure protocol but were treated with the COX-2 inhibitor nimesulide or vehicle during the 7-day Meth abstinence period. In the cue-primed Meth seeking challenge, EtOH/Meth rats that were treated with nimesulide (n=9) had 97.2±9.7 presses, approximately equivalent to H2O/Meth/nimesulide rats (n=9) that pressed 99.5±9.7 times. Both nimesulide treated groups had significantly elevated pressing compared to H2O/Meth/vehicle (n=8, 73.2±9.3 presses) and EtOH/Meth/vehicle (n=8, 80.3±11.1 presses) ($p<0.05$). Overall, EtOH drinking during adolescence attenuated cue-primed drug seeking behavior and produced a long-term increase in COX-2 in the striatum. Conversely, nimesulide inhibition of COX-2 during Meth abstinence restored cue-primed Meth seeking in EtOH drinkers to a rate equivalent with that of H2O drinking rats implicating a role for COX-2 during abstinence from Meth on cue-primed Meth seeking. Based on the role of prostaglandin synthesis in inflammation, future studies will examine how EtOH drinking during adolescence contributes to possible changes in microglia.

Title: Effect of long-term permanent sugar consumption on ethanol preference in adolescent and adult rats

Authors: *M. RESÉNDIZ-FLORES, M. I. MIRANDA, G. VERA, A. RANGEL;
Neurobiología conductual y cognitiva, Inst. De Neurobiología, UNAM, Querétaro, Mexico

Abstract: The exacerbated sugar consumption and its cognitive processing involve the activation of the brain's reward system that mediate learning and behavior related to reinforcing the consumption of sweet and addictive substances. However, few studies have analyzed the impact of persistent sugar consumption and its relationship with the intake of addictive substances, such as ethanol, mainly when it is present in sugary alcoholic mixtures. On the other hand, it is known that the late maturation of frontal cortical areas during adolescence is related to the early intake of addictive substances such as ethanol. Given that alcohol intake usually begins in adolescence through sugary alcoholic mixtures, the objective of this study was to evaluate, in adolescent and adult rats, the effects of prolonged and permanent sugar exposure on the later preference for sugary ethanol.Male and female adolescent and adult Wistar rats were housed individually and kept at 23°C, in a reverse light-dark cycle. Food was available ad libitum. Rats were randomly assigned to the groups: Naive (N) or Chronic (C), with access to water or sugar, respectively, as the only liquid available for 24 h/21 days. Bodyweight, fluid, and food intake were recorded daily. After 21 days, the chronic group was divided into a group with continuous access to sugar (CS) and a group deprived of sugar, with access only to water (CD), between each of the four sugary ethanol (10%ethanol-10% sugar) vs. water preference tests (24 h each). In groups CS and CD adolescent and adult of both sexes, the chronic sugar consumption induced a suppressive intake effect of the sugary ethanol solution (S-EtOH); however, only the adolescent CD rats increased their consumption of sugar-ethanol mixture along with the preference tests. Furthermore, the data of adult rats also exposed to S-EtOH during adolescence (e.g., double exposure), the deprivation effect lasts into adulthood; since the CD double exposure adult consumed more S-EtOH than the CD adults that only consume S-EtOH in adulthood. Altogether, these results suggest that adolescent rats are more susceptible to sugar deprivation, independently of sex. The susceptibility could be related to late brain maturation and its implications on increased impulsive and risk-seeking behaviors such as the initiation in the use of addictive substances. Moreover, sugary ethanol mixture consumption during adolescence, both by females and males deprived of sugar, can facilitate its intake during adulthood.

Title: Assessment of Grouped and Individual Effects in Coadministration of Nicotine and Ethanol using Behavioral Economics Approach

Authors: *T. W. ALLEN[1], C. L. ROBISON[1], V. M. MADORE[1], N. COVA[1], H. MANNING[1], E. O'KEEFE[1], A. KALINOWSKI[1], J. MULLIGAN[1], K. BABINA[1], B. STARR[1], S. T. BARRETT[2], S. CHARNTIKOV[1];
[1]Psychology, Univ. of New Hampshire, Durham, NH; [2]Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Alcohol and nicotine are two commonly coadministered and abused legal substances. Estimates place global annual deaths at 3 and 8 million for alcohol and nicotine respectively. Global economic burden of alcohol is estimated at 210-665 billion USD whereas that of nicotine is estimated 422 billion USD. Studies indicate that 80-90% of individuals with alcohol use disorder also smoke cigarettes and tend to smoke more than those without alcohol use disorder. Although recent evidence indicates that nicotine potentiates reward value of appetitive stimuli in animal models, the relationship between alcohol and nicotine use is not fully understood. To address this, we designed a study with two objectives in mind. First, to determine the economic demand for nicotine and ethanol alone and then assess the relationships between two demand variables using grouped and individual levels of assessment. Second, to assess the effect of each substance on consumption of the other substance. Our findings show that overall, rats had highest initial demand for sucrose (*essential value*), followed by sweetened ethanol, ethanol alone, and nicotine. The alpha parameter for nicotine was highest, followed by ethanol, sweetened ethanol, and sucrose. Contingent but not non-contingent access to ethanol decreased nicotine self-administration. Both contingent and non-contingent nicotine administration increased ethanol self-administration. Importantly, parameters derived from individual demand for nicotine predicted responding for ethanol when nicotine was available contingently. This study demonstrates how coadministration of substances can be assessed on grouped and individual levels using behavioral economics approach. Future research needs to further explore how behavioral economics approach can be used to define substance use vulnerable phenotype and response to treatment on individual level.

Title: Sex differences in punished EtOH responding in an operant paradigm

Authors: *K. A. FENNELL[1], E. A. SNEDDON[2], J. DEMEDIO[3], S. BHATI[3], J. SETTERS[3], S. C. MONROE[3], K. M. SCHUH[4], N. SHAND[3], J. HOFFMAN[3], A. K. RADKE[5];

Abstract: Alcohol Use Disorder (AUD) is the third leading cause of preventable deaths in the United States, and causes an estimated number of 95,000 deaths in the United States per year. AUD has been shown to have more severe negative consequences for women. Thus, it is necessary to investigate mechanisms that may contribute to sex differences that may arise in alcohol drinking. Compulsive alcohol seeking, a characteristic of AUD, has been modeled in rodents with paradigms that punish drinking with aversive stimuli. Previous studies have found that females are more resistant to quinine punishment when seeking ethanol (EtOH) in an operant paradigm but sex differences in responding for EtOH punished with foot-shock have not been assessed. Thus, we examined whether male and female mice differ in foot-shock-resistant EtOH seeking and the role of mGluR5 receptors in the NAc core in mediating sex differences in punishment resistance. To test for sex differences, C5BL/6J mice were food-restricted to 85% of their free-feeding weight and trained to respond for a 10% sucrose solution on a fixed ratio 1 (FR1) schedule in an operant chamber. Once mice learned to respond, they were transitioned to a fixed ratio 3 (FR3) sucrose fading procedure with 3-5 days of 10% sucrose, 10% sucrose and 10% EtOH, 5% sucrose and 10% EtOH, and 10% EtOH solutions. When responding for the 10% EtOH solution was stable, a foot-shock (0.25 or 0.35 mA) was delivered. A second group followed the same sucrose fading procedure but was administered a 0.35 mA foot shock. A third, group self-administered 10% only and was punished with a 0.25 mA foot-shock. Males and females continued to respond for EtOH but reduced responding for sucrose when a 0.25 mA shock was delivered. Furthermore, males reduced response rates at the 0.35 mA shock while females did not. Additional follow-up experiments suggest these effects are not due to sex differences in foot-shock sensitivity. In a final experiment, mice were implanted with chronically indwelling cannulae in the NAc core and trained to respond for 10% EtOH as described above. The mGluR5 receptor antagonist, MTEP, or vehicle (VEH) was infused prior to delivery of a 0.25 mA foot-shock. Analysis of the effects of MTEP on punishment resistance is ongoing. Together, these results demonstrate that females are more likely to participate in punished EtOH

seeking. Glutamatergic signaling in the NAc core contributes to compulsive-like alcohol drinking and may drive the sex differences observed in this behavior.

Title: Effects of Sex Chromosomes on Compulsive-Like Alcohol Drinking in Four Core Genotype Mice

Authors: *B. M. MASTERS, E. A. SNEDDON, K. A. FENNELL, J. DEMEDIO, L. RASZIER, A. K. RADKE;
Miami Univ. Dept. of Psychology, Oxford, OH

Abstract: Approximately 15 million people in the United States suffer from Alcohol Use Disorder (AUD), 5.5 million of whom are women. Research has shown females to be more susceptible to AUD and to aversion-resistant alcohol consumption compared to males. Yet despite the high prevalence of women with AUD, female vulnerability to alcohol is understudied. Compulsive alcohol seeking is a defining characteristic of AUD that has been modeled using an aversion resistance paradigm known as Drinking in the Dark (DID) in which the bitter tastant quinine is added to ethanol (EtOH). To investigate mechanisms of sex differences in aversion-resistant drinking, we used the Four Core Genotypes (FCG) mouse model. This model includes four genotypes, two of which do not express the Sry gene and develop ovaries (XX/Sry- and XY/Sry-) and two of which express the Sry gene and develop testes (XX/Sry+ and XY/Sry+). In experiment 1, female (Sry-) FCG mice (n = 14, XX/Sry- = 7, XY/Sry- = 7) self-administered 15% EtOH or water in a 2-bottle limited access DID paradigm for four hours each session totaling 15 sessions. Each session began three hours into the dark phase of the mouse circadian cycle. Quinine was then added to the 15% EtOH solution in increasing concentrations of 100 µM, 250 µM, and 500 µM for 5 sessions at each concentration. During each session, bottles were weighed at the 0 h, 30 min, 2 h, and 4 h marks. Estrous cycle monitoring was conducted for 4 sessions at each quinine concentration. As a control, mice self-

administered a 2.5% sucrose solution about 2 weeks after the last EtOH + quinine session. Quinine was then added to the 2.5% sucrose solution in increasing concentrations of 100 µM, 250 µM, and 500 µM for 1 session at each concentration. A water control was conducted using this same DID procedure in a subset of mice who self-administered either plain water or water with quinine. Quinine was added to the second water bottle in increasing concentrations of 100 µM, 250 µM, and 500 µM for 1 session at each concentration. For experiment 2, the same procedure was followed using male (Sry+) FCG mice (n = 14, XX/Sry+ = 7, XY/Sry+ = 7), excluding estrous monitoring. Results of experiment 1 showed that the XY chromosome compliment promotes aversion-resistant EtOH consumption and EtOH preference in mice with ovaries (Sry-). Results of experiment 2 showed that XY/Sry+ mice consume more EtOH overall than XX/Sry+ mice. Although the mechanisms that underly female vulnerability to compulsive drinking are still unknown, these data can be used in future research to investigate potential genetic contributors to sex differences in alcohol drinking behaviors.

Title: Individual response to intermittent-swim stress predicts economic demand for ethanol in male rats

Authors: *S. CHARNTIKOV, C. ROBISON, V. MADORE, N. COVA;
Univ. of New Hampshire, Durham, NH

Abstract: Worldwide, alcohol use disorder results in 3 million deaths every year, which translates to 5.3 % of all deaths. Risk factors like physical or emotional trauma have been previously linked to alcohol consumption. However, not everyone responds the same way to stress; there is evidence of both individual vulnerability as well as individual resilience to stress. With that in mind, our study was designed to test whether the magnitude of individual response to stress can predict a magnitude of economic demand for self-administered ethanol. Wistar rats were trained to self-administer sucrose, sweetened ethanol, and ethanol alone prior to the exposure to stress, and the economic demand was derived for each substance. Rats were then subjected to intermittent-swim stress (n=32) in cold water or sham-stress (n=10) exposure. Ethanol demand was reassessed after a 10-day incubation period. In addition, plasma

corticosterone levels were assessed before and immediately after the traumatic stress exposure. Our main finding shows that a magnitude of corticosterone response to a traumatic stressor predicted an increase in economic demand for ethanol following a traumatic stress episode. We also show that the initial economic demand for ethanol in combination with stress-induced corticosterone response explain 54 % of the variance in economic demand for ethanol after the exposure to stress episode. Our study demonstrates for the first time the utility of the behavioral economics approach in assessing individual response to traumatic stress and stress-induced alcohol consumption. We also demonstrate for the first time that stress can significantly change established ethanol taking with rats vulnerable to stress exhibiting higher levels of post-stress consumption.

[1]Paradromics Inc., Austin, TX; [2]Francis Crick Inst., London, United Kingdom; [3]Caeleste, Mechelen, Belgium; [4]Electrical and Computer Engin., UCSD, La Jolla, CA

Abstract: Two predominant paradigms exist for processing electrical recordings of neuronal action potentials. The first aims to preserve raw data; in this paradigm the signal is amplified, filtered, and digitized, after which advanced signal processing is performed in the digital domain. This approach is energetically expensive because it involves digitizing and transmitting high bandwidth data. The second approach is targeted toward motor-prosthetics; in this approach signals are amplified, filtered, and then thresholded to create a binary stream of events. That processing can be performed in the analog domain, which can greatly reduce total power consumption, but it comes at the expense of spike waveform information.Here we describe a third possible approach that preserves spike waveform information but digitizes only a fraction of the raw data. We have implemented an optimized set of analog filters for detecting action potentials from intracortical electrode recordings. The filters are designed using Principal Component Analysis, based on a library of previously recorded spike data, and are instantiated in a CMOS analog circuit that fits within a 125 µm by 250 µm area and consumes 2.0 µW per

channel. The resulting output of n filters represents an n-rank approximation of the signal where each output is a continuously varying PC score, which is sampled at the moment when the spike peaks. This scheme reduces Spike Error Rate as compared to thresholding the output of 2nd order bandpass filters, especially in noisy conditions. We also show that 3 PC score outputs provide enough information to allow for spike sorting that is indistinguishable from that performed by experts on raw data. In conclusion, this technology will enable a new generation of brain-machine interfaces that are less subjected to trade-offs between data quality and power consumption.

Abstract: Extracellular recordings from behaving animals allow for investigating functions of brain circuits. While ease of access to the cortical surface allows for precise targeting of most cortical structures, accurate targeting of deep brain regions remains a challenge. In addition, whereas chronic cortical recording methods are well established (Roussy et al., 2020), methods for chronic recording of deep brain regions are scarce. As opposed to acute, chronic methods have the advantage of reducing chances of infection (Dotson et al., 2017), requiring less daily preparation, and allowing for longitudinal monitoring of the same population of neurons (McMahon et al., 2014). Here we describe a chronic and semi-chronic electrode implantation method for targeting of Basal Amygdala (BA) in macaque, utilizing the *Brainsight* neuronavigation toolkit and surgical methods borrowed from human SEEG (Stereoelectroencephalography) procedures. Anatomical images (MRI and CT) of two rhesus macaque were used for selection of implantation trajectories targeting BA, as well as designing of a custom cranial cap. Neuronavigation procedures require the co-registration of subject and image space (e.g. MRI), allowing for real-time navigation of anatomical images during the surgical procedure. To perform this co-registration, cranial cap screws were used as fiducial markers: homologous anatomical landmarks on the subject and the images, which when matched, transform the subject space into image space. Co-registration allowed for matching of pre-determined trajectories using image-guided navigation. Performing a 2.4mm craniotomy along the trajectory provided a minimally invasive entrance to the brain. An anchor-bolt (*Ad-Tech Medical*) was used as a small chamber, allowing a custom-made microdrive (monkey Ma) to be mounted, before passing of a polyimide guide tube to above target. Lastly, a 32 (monkey Ma) or 64 channel (monkey Mi) microwire brush array (*Microprobes*) was inserted by hand through the guide tube and lowered into the BA with the microdrive (monkey Ma) or by hand (monkey Mi).
Post implantation CT scan of each subject, co-registered with the T1 MRI, allowed for assessing of the targeting accuracy. Total targeting error of monkey Ma was 2.32mm (Euclidean distance) from the tip of the electrode (2.2 mm medial-lateral, 0.7 mm anterior-posterior, 0.3 mm superior-inferior), while monkey Mi had a total error of 1.44 mm (Euclidean distance; 0.5 mm medial-lateral, 0.9 mm anterior-posterior, 1.0 mm superior-inferior). In summary, our method provides a minimally invasive protocol for implantation of deep brain structures with an average targeting error of 1.88 mm (n=2).

Title: Optimal High Density Micro-ECoG Design

Authors: *A. SINGH[1], T. STERN[1], R. J. EDGINGTON[1], K. SAHASRABUDDHE[1], M. R. ANGLE[1], V. GILJA[2];

Abstract: For individuals with communication-limiting neurological disorders, surface grid electrocorticography (ECoG) based devices have the potential to enable the development of neural prostheses to help restore communication ability. Recent advances in microfabrication processes allow for higher density ECoG with smaller microscale contacts. This reduction in scale can ease the implantation process and provide a more granular spatial measurement of neurophysiological processes. We evaluate the potential of microscale ECoG by recording neural activity from the cortical surface of anesthetized sheep (N=3) with dense arrays of >20,000 18 µm diameter platinum iridium electrodes. Electrode pitch is 50 µm on average and spans an area over 12x12 mm^2 in the auditory cortex of anesthetized sheep (N=3). Electrode spacing (50µm to 1mm), electrode count (N=10 to 2000) and area coverage (1 to 100 mm^2) parameters are evaluated by subsampling and averaging individual electrode responses to estimate optimal parameters with respect to decoding auditory stimuli. Spectral power features are extracted with a preprocessing pipeline and a regularized, cross-validated linear regression model predicts the frequency of 19 presented pure tones from bandpassed high gamma activity. Decoding performance is evaluated by computing the tonal error in octaves between the tone presented and the tone predicted. When considering electrode pitch for a 7.5mm^2 area array, a minimum tonal error of 0.8 octaves is found at a 100 µm pitch (750 electrodes); tonal error is 1.4 octaves at 300 µm pitch and 2 octaves at 1mm pitch. Increasing array area decreases the density of electrodes needed to achieve similar performance, for example 1 octave tonal error can be achieved at 1 mm pitch with 100 mm^2 area coverage, dropping to 30 mm^2 for 300 µm pitch and area coverage less than 10 mm^2 requires 100 µm pitch density. Electrode contact sizes were simulated by averaging the response of multiple physical electrodes over an area of 8 mm^2. Increasing density and decreasing surface size achieved lower tonal error, with optimal performance (<1.32 octaves) for areas less than 0.3 mm^2 at their highest density. These findings suggest that specific neural states may be estimated with similar fidelity by either covering a larger spatial area with larger, sparsely placed electrode contacts or by covering a smaller spatial area with smaller, sparsely placed electrode contacts. These design tradeoffs are a critical consideration in the design of implantable systems for the development of next-generation brain-computer devices to enable functional restoration for individuals with communication disorders.

Title: Chronic intraspinal neural recording & electrical stimulation with braided multi-electrode probes in rats

Authors: *T. KIM[1], A. P. BORISYUK[1], T. BEZDUDNAYA[1], L. ZHOLUDEVA[3], J. WALKER[1], B. SHERMAN[2], M. R. DETLOFF[1], M. A. LANE[1], P. J. REIER[4], S. F. GISZTER[1]; [1]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Drexel Univ. Col. of Med., Phiadelphia, PA; [3]Gladstone Inst., San Francisco, CA; [4]Dept Neurosci, Rm L1-100K, Univ. Florida Col. Med. Brain Inst., Gainesville, FL

Abstract: We have designed a novel braided multi-electrode probe (BMEP) comprised of an ultrafine microwire bundle in a tubular braid form for use as a neural interface to record signals or stimulate neural tissue. The BMEP provides not only high mechanical flexibility to follow tissue motions and deformation, but also 6 ~ 24 channels for recording/stimulation in maximum 200μm diameter. The tubular BMEP has a removable tungsten needle to temporarily increase the stiffness of the braid for better tissue penetration and then restore its high flexibility after removal. Based on this mechanism, the probe-type BMEP is designed for easy insertion and release into any region of the central nervous system (CNS). One example is the spinal cord which, due to its length and flexibility, can frequently generate severe tissue motions which cause conventional electrodes to often severely damage tissue. Historically, only few chronic intraspinal recording trials with single microwires have been successful. In early studies our flexible BMEPs were able to chronically record intraspinal neural signals from freely jumping frogs. We are now pursuing three projects requiring chronic intraspinal implants with BMEPs for recordings or electrical stimulation (E-Stim). One is to investigate the therapeutic potential of combining E-Stim and stem cell transplantation after spinal cord injury (SCI) using a chronically implanted BMEP. To explore feasibility, cervical spinal hemi- contusions were followed with spinal neural progenitors being introduced into the lesion cavity a week later. Next, a 6 x 9.6μm BMEP in 2mm length was perpendicularly inserted into the graft region. Daily E-Stim was performed for 4 weeks (5 days / week). For E-Stim and neural recordings, we use a bidirectional

neural interface, Neurochip 2, which is a portable 2ch recording/3ch stimulation device developed by Fetz et al. (2011, IEEE Trans Neural Syst Rehabil Eng **19**(4): 427-435). We confirmed that the implanted BMEPs performed well for chronic recordings and E-Stim. This project is still on-going. The second project is to test an oblique insertion (35~40°) of 6 x 9.6µm long BMEPs (length:6~10mm) below a spinal transection at T10/11 and chronic intraspinal recording with the obliquely inserted BMEPs at L1/2. The oblique insertion seems more mechanically stable for lumbar cord applications than regular vertical insertions. Histological and electrophysiological tests are in progress. The last project tests changes in intraspinal neural activity before and after a SCI in a cervical area. This project has just been initiated and we are testing the quality of chronic neural signals with BMEPs.

Title: High resolution, transcutaneous peripheral nerve interface for quantitative tracking and visualization of nerve activity

Authors: M. MCKINNON[1], A. PREYER[1], R. BLUM[1], C. K. FRANZ[2], *I. CLEMENTS[1]; [1]BioCircuit Technologies, Atlanta, GA; [2]Biologics, Shirley Ryan Abilitylab, Chicago, IL

Abstract: Improved capabilities for non-invasive sensing and manipulation of neuromuscular activity would advance areas of clinical diagnostics, therapeutic stimulation, and neural prosthetics. Typical electrodiagnostic techniques are technically challenging and involve repeated repositioning of large surface electrodes by a highly trained clinician. Here we describe a multichannel transcutaneous recording and stimulation platform for targeted monitoring and manipulation of human nerves and muscles.
This platform was optimized for high-quality electrophysiological recordings in noisy environments (e.g., hospitals). Flexible, adhesive arrays of hydrogel electrodes were customized to target specific peripheral nerves and muscles. Custom software was written to simplify acquisition and data processing of raw signals. Meaningful physiological parameters (e.g., conduction velocity, nerve trajectory) were extracted from processed data by novel algorithms. We were able to track median nerve activity continuously from wrist to elbow with sufficient

resolution to calculate conduction velocity using a custom recording array. Innovative visualization methods were used to display propagating nerve activity intuitively and succinctly. Another electrode array was designed to conform to the elbow for precise spatial recording of ulnar nerve activity. This configuration could enable localization of focal conduction slowing with relevance to cubital tunnel syndrome. The same platform was used to acquire high density surface EMG recordings from skeletal muscle (soleus recruitment in response to tibial nerve stimulation) as part of a reflex operant conditioning therapy. We also recorded diaphragm contraction in response to phrenic nerve stimulation, which could be used to diagnose phrenic neuropathy resulting from severe COVID-19 infection.
A non-invasive, array-based system for peripheral nerve interfacing and quantitative assessment of nerve/muscle function was designed and validated within a variety of clinically-oriented applications. Ultimately this platform has the potential to advance neuromuscular research, neuromodulation, bioelectronic medicine, and neural prosthetics.

Title: Dual-sided probes for high spatiotemporal resolution recordings of spiking networks

Authors: *F. WU[1], A. LEVI[2], D. LEE[1], H. E. SLOIN[2], L. SPIVAK[2], S. SOMECK[2], E. STARK[2];
[1]Diagnos. Biochips, Glen Burnie, MD; [2]Tel Aviv Univ., tel aviv, Israel

Abstract: Cortical neuronal networks are responsible for various functions: decoding sensory input, encoding motor action, maintaining memories, and many more. Determining which neurons partake in a common function and what network connectivity patterns facilitate functionality is a major goal of neuroscience research. Planar silicon probes enable linking network activity patterns with cognitive function in intact subjects by simultaneously recording

hundreds of neurons within a local network at high spatiotemporal resolution. However, due to the planar structure of present probes, it is still impossible to record the entire neuronal population within a sphere around the probe.
We developed two types of dual-sided hybrid polyimide-silicon probes. In one design ("Dual-sided64"), each probe consists of two dual-sided shanks, each with 16 electrodes spaced 20 μm apart per side. The second design ("Dual-sided128") includes six dual-sided shanks, and every side is equipped with 10-11 electrodes spaced 15 μm apart. The distance between electrodes on opposite sides is 30 μm. A fiber-coupled LED was attached to every dual-sided shank, and then the entire device was mounted on a microdrive and implanted in a freely-moving CaMKII::ChR2 mouse. Recordings were performed in the neocortex and hippocampus of three mice over several months, and compared to recordings carried out under equivalent conditions using single-sided probes.
The dual-sided probes enabled four advances. First, the number of neurons recorded from a given piece of cortex increased, enabling monitoring a larger fraction of local circuit neurons. Second, dual-sided recordings showed higher density of inter-neuronal connections. Third, dual-sided probes allowed 3D triangulation of neuronal somata. Together with connectivity mapping, an imaging-like reconstruction of network structure and connectivity was achieved, without losing the temporal resolution made possible by electrophysiology. Finally, using the dual-sided probes we simultaneously recorded electrophysiological signature of different cellular compartments of the same neuron (soma, dendrites, and axon) on different sides of the same shank.
Dual-sided probe technology is a step towards monitoring all neurons within a small piece of the brain. The dual-sided probes allow reconstructing a neuronal network deep within the brain of freely-moving subjects at high spatial and temporal resolutions. In the future, dual-sided probes could be used to provide a better understanding of local network activity during performance of cognitive functions including learning, memory, and decision making.

Title: Flexible electrode technologies for mapping sensory-driven cellular and subcellular activity from the cortical surface in awake, behaving animals

Authors: *D. L. GONZALES[1], S. R. PLUTA[2], K. JAYANT[1];
[1]Weldon Sch. of Biomed. Engin., [2]Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: Dendrites exhibit diverse modes of regenerative potentials that shape perception, sensory tuning, and reward reinforcement. In mouse cortex, for example, Layer 5 (L5) pyramidal neuron burst-mode firing drives large, all-or-nothing calcium spikes in the apical dendrites that are critical for stimuli detection and object localization. However, the small size of dendrites renders scalable electrical readouts in behaving animals unfeasible with traditional electrodes. Thus, mapping subcellular activity and its relationship to neural computations and animal behavior remains notoriously difficult. Here, we discuss our efforts to develop a flexible and transparent neural interface with arrays of micro- and nano-scale electrodes tailored to map subcellular activity. Specifically, we hypothesized that a soft probe with high-density, thin-film electrodes would conform to the cortical surface and enable a scalable platform for monitoring activity in L5 apical dendrites near the surface of the brain. In mouse barrel cortex, we recorded both local field potentials and single-unit activity from awake animals during sensory stimulation. To determine the origin of these signals at the brain surface, we used simultaneous depth recordings. Silicon probe recordings across cortical layers revealed that field potentials at the cortical surface largely mirror deep-layer activity; however, specific signatures of the LFP remain unique to the upper cortical layers. Furthermore, preliminary experiments in which we performed simultaneous two-photon calcium imaging allowed for monitoring either somatic or dendritic calcium activity while performing electrophysiology at the cortical surface. These initial results suggest a strong dendritic component (possibly apical dendrite calcium spikes) in the LFP at the cortical surface that can be mapped on a scalable platform across barrels in behaving mice. We discuss key control experiments to ascertain the origin of the surface potential measurements and present design considerations of our technology to enable precision sub-cellular activity mapping with minimal invasiveness.

Title: Nucleus Accumbens Core and Shell Analysis using Deep Brain Stimulation through functional Magnetic Resonance Image in rat

Authors: *H.-J. KIM[1], R. S. CLEMENT[2], R. BAGWELL[2], N. N. TIRKO[2], Y.-Y. I. SHIH[1], S.-H. LEE[1];
[1]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Actuated Med. Inc, State College, PA

Abstract: NAc (Nucleus accumbens) is known as the backbone of the brain's reward circuit, which consists of substructures of the core and shell. In this study, deep brain stimulation (DBS) was used with simultaneous functional magnetic resonance imaging (fMRI) to directly map their functional connectivity circuits. After inserting vertically aligned 16-channel flexible electrodes to be positioned over the core and shell simultaneously, three 10 sec blocks of electrical stimulation pulses (65 Hz) were sequentially delivered to each channel during each session and analyzed by the general linear model (GLM). (Fig. 1A-E). As a result, stimulation of the shell region of NAc showed strong BOLD signal elevation within unilateral medial prefrontal cortex (mPFC), anterior cingulate, and amygdala, while stimulation of core region showed strong BOLD signal elevation of bilateral mPFC and orbital prefrontal cortex regions. (Fig 1F, n=15) The activity map was parceled with a data-driven functional atlas obtained through our other study and subsequently clustered into 3 modules, the mPFC circuit, amygdaloid circuit, and default mode network (DMN). The data was time-locked at stimulus onset to investigate the dynamics of network-level interactions (Fig 1G-I). The results present that the stimulation of the shell induced a significant and immediate increase of BOLD signal in the Amygdala compared to the core, suggesting strong connectivity between structures. Interestingly, the stimulation of the NAc core derived the significant DMN activation in a delayed manner. We expect that the time-locked analysis of DBS-fMRI with multipoint stimuli can be a useful tool for future studying the dynamics of network interactions in mesoscale circuit regions with functionally distinct substructures.
