Abstract: Chronic alcohol abuse is a serious public health issue that has recently been exacerbated as Americans sought refuge from the stress and isolation of the COVID-19 pandemic at the bottom of a glass of wine, beer, or liquor. Problematic drinking has been linked to a myriad of health issues and premature death. Neurobiologically, excessive drinking has been linked to widespread reductions in gray matter volume, aberrant functional activity, and consequently, impairments in a variety of cognitive domains. Spatial working-memory is one such domain with numerous studies reporting deficits in heavy drinking populations. To elucidate the relationship between spatial working-memory and chronic alcohol abuse 18 participants with Alcohol Use Disorder (AUD) and two non-AUD chronic heavy drinkers performed a spatial 2-back task during an fMRI scan. Individual-subject general linear modeling analysis was conducted to determine which voxels showed greater BOLD activity during correctly identified 2-back events (hits) compared to successful memory storage events (the trials two prior to a hit). A group level analysis was then conducted to determine which of the identified voxels correlated with drinking frequency (percentage of days where subjects drank as established by the Timeline Follow Back). This analysis revealed a cluster of 171 voxels primarily located in the right postcentral gyrus and edging into the right precentral gyrus which displayed a significant positive correlation ($r=0.715$, $p<0.001$) with drinking frequency. These results suggest that more frequent drinkers show higher BOLD activation in the right postcentral gyrus and right precentral gyrus more during successful memory storage than hits compared less frequent drinkers. This may indicate that frequent drinkers recruit these regions more heavily than infrequent drinkers in order in order to compensate for functional deficits resulting from frequent drinking.

Title: Multimodal social and emotional information across the superior temporal sulcus

Authors: *J. M. DENNING, A. S. PERSICHETTI, A. MARTIN;
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Humans are remarkably efficient and accurate at processing social and emotional information from multiple modalities. Other people's faces and voices are good cues to their identities and emotional states. Previous studies have shown that regions in the superior temporal sulcus (STS) represent social and emotional information while also being sensitive to auditory, visual or both modalities. However, the precise mapping of person and modality information, and how they overlap in the STS, is still not known. We scanned fifteen participants using high-resolution 7T fMRI with both univariate and representational similarity analyses (RSA) to ask how faces and voices are represented and integrated within the STS and in person-selective regions across the whole brain. During separate trials, participants either viewed images of faces or objects, listened to vocalizations or object sounds, or were presented with both visual and auditory stimuli at the same time. Specifically, the faces and voices are from nine individuals, each depicting three emotional states (laughing, neutral, and crying), while the objects and sounds are from nine inanimate objects that are either positive (e.g., champagne bottle), neutral (e.g., a broom), or negative (e.g., a gun). Presenting the stimuli in this way allowed us to dissociate neural representations of emotion and identity information related to people and objects that were either modality-specific or multimodal. Consistent with prior studies, our univariate results show that a known face-selective region in the posterior STS is sensitive to both auditory and visual modalities, while a region located in the middle of the STS exhibits a selective response to human vocalizations. In addition, RSA suggests that the vocalization-selective middle region of the STS represents emotional information in human vocalizations, while the face-selective posterior region shows a weaker preference towards emotions compared to identity information for both images and vocalizations. Furthermore, we found a general bias towards vocalizations and emotional information in the upper bank of the STS, and this effect is more prominent in the right hemisphere. Taken together, these results suggest that emotion information is represented in a category- and modality-specific format in the human STS.

Title: High socio-economic status is associated with low brain entropy

Authors: A. Q. WANG[1], ***Z. WANG**[2];
[1]Lower Merion High Sch., Ardmore, PA; [2]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Background and hypothesis: Socio-economic status (SES) drives many aspects of human life. Those of a higher SES often seem to perform better and be more successful. To find whether this is underlined by any brain mechanism, we characterized brain activity used brain entropy (BEN) mapping and assessed its associations with SES. Low BEN suggests high coherence of brain activity, which has been shown to be related to better brain function and neurocognition. A recent study has shown that better educated people have lower BEN than their counterparts and the associations were predominantly located in the frontal-parietal brain networks. Since education is related to socio-economic status too, we **hypothesized** that BEN in the frontal-parietal regions is inversely correlated with SES as measured by personal income. **Methods**: Preprocessed resting state fMRI (rsfMRI) data were downloaded from 1081 young healthy subjects from the Human Connectome Project. BEN maps were calculated from the rsfMRI data using BENtbx (https://cfn.upenn.edu/~zewang/BENtbx.php). BEN vs income correlation was evaluated using simple regression implemented in SPM12. Age, sex, and education years were included as covariates. Statistical significance was defined by $p<0.001$. Multiple comparison correction was performed with the permutation-based cluster size correction method. The cluster size was >150 ($q<0.5$). The mediation effect of education on the relationship between income and BEN was assessed. **Results**: Income was significantly related to education and fluid intelligence. Significant inverse correlation between income and BEN was found in the executive control network and the default mode network. The relation between income and BEN in these regions was significantly mediated by education. Personal income did not mediate the correlation between education and BEN. **Conclusion**: Higher SES is associated with better organized brain activity (lower BEN) in the frontal-parietal circuit, which is known to be related to fluid intelligence and higher-order function. The social-economic effects of BEN are caused by education. Our data suggests that low fronto-parietal BEN may represent a brain mechanism for the profound SES effects on brain cognition or human life. Future study will be required to assess the mediation effects of family income.

Title: Intrinsic markers of the (dis)honesty

Authors: *M. DELGADO-HERRERA, B. I. ARCE LÓPEZ, M. GIORDANO;
Dept. de Neurobiología Conductual y Cognitiva, Inst. de Neurobiología, UNAM, Querétaro, Mexico

Abstract: Honesty can be defined as acting in accordance with the moral rules and social norms of a community and it includes giving up the opportunity to make a profit, for example, by refraining from cheating to obtain money. (Dis)honesty can be influenced by intrinsic factors, that is, cognitive, psychological, and emotional individual differences that characterize each person. The aim of this research was to assess whether intrinsic factors such as intelligence, gender, executive functions such as working memory and inhibitory control, social cognition skills (including empathy and theory of mind), and personality traits are linked to (dis)honesty. Fifty-six neurotypical young adults participated in this experiment. (Dis)honesty was evaluated with a novel "Honesty task" based on whether the participants were or not were tempted to: a) review the answers that the researcher had "accidentally" given them and b) misreporting his/her knowledge in order to pretend to know more. An honesty index was created based on a qualitative analysis of the behaviors shown by the participants during the "Honesty Task". The honesty index ranged from one to four, that is, from honest to dishonest. Number one of the honesty index included a combination of behaviors that denoted with certainty the participant's honest decision making; conversely, number four included the behaviors most representative of dishonesty. We found a high percentage of participants in number four of the honesty index, which corresponds to the most dishonest behaviors. The honest group had higher scores for Empathic Concern and Neuroticism than the dishonest group. We performed a cluster analysis based on the normalized intrinsic factors scores. Differentiation into four clusters provided the clearest delineation. The results of the cluster analysis replicated the results of the group analysis (honest vs. dishonest). Cluster 1 (the honest group) was made up of participants with high Neuroticism, Empathic concern and Personal Distress scores and with low Conscientiousness scores, and these scores are opposite in the participants who made up Cluster 4 (the dishonest group). In conclusion, although dishonesty is a highly complex behavior that can be influenced by a wide range of both, contextual and intrapersonal factors, this research suggests that prosocial behaviors such as empathic concern, theory of mind skills and personal distress are a cornerstone of (dis)honesty.

Title: Neural coordination between participants during naturalistic perception: Towards a marker of social dysfunction in schizophrenia

Authors: *E. C. BAEK, R. HYON, K. LOPEZ, M. A. PORTER, C. PARKINSON, E. A. REAVIS;
UCLA, Los Angeles, CA

Abstract: The neural factors that allow humans to forge social bonds more readily with some people than with others remain poorly understood. In particular, very little is known about how individual differences in brain activity contribute to chronic deficits in the formation and maintenance of social relationships in clinical disorders such as schizophrenia. Recent evidence from functional magnetic resonance imaging (fMRI) suggests that healthy individuals forge social ties more readily with people who process the world in a particularly similar way to them than they do with others. Such work has suggested that two people are more likely to befriend each other if particular regions of their brains respond similarly to naturalistic movies (e.g., regions of the default mode network [DMN]). One can quantify the response similarity for particular brain regions and pairs of participants by calculating inter-subject correlations (ISCs) of fMRI time series. Although it is known that ISCs can predict social-bond formation in specific pairs of people, it is not clear how ISCs relate to more general measures of social dysfunction (e.g., social disconnection). Further, the feasibility of ISC research has not been established in schizophrenia, although it may be a useful tool for understanding social dysfunction in the disorder. We collected fMRI data during naturalistic perception in 64 healthy adults. We also piloted the same paradigm in 6 stable adult outpatients with a diagnosis of schizophrenia. We assessed ISCs in a set of anatomically-defined cortical and subcortical regions that span the entire brain. Participants also provided measures of social disconnection. In each group, ISCs exhibited expected stimulus-driven patterns (e.g., high ISCs in visual and auditory cortex; low ISCs in motor and somatosensory cortex), providing evidence in support of data validity in both groups. In the healthy group, across several brain areas (including DMN regions), participants with high subjective and/or objective measures of social disconnection (i.e., loneliness or having few friends, respectively) tended to have lower ISCs than well-connected participants. ISCs of individuals in the schizophrenia pilot sample were very low for the same regions. Our findings suggest that individuals who process naturalistic stimuli in idiosyncratic ways may have more difficulty forming social ties. Additionally, the preliminary data in the schizophrenia group demonstrates the feasibility and promise of the method in a new clinical population. They also hint at the potential for this approach to shed light on the neural determinants of social dysfunction in serious mental illnesses.

Title: Working memory load impairs tacit coordination and inter-brain EEG synchronization

Authors: *L. A. NEWMAN, M. K. VAN VUGT;
Univ. of Groningen, Groningen, Netherlands

Abstract: Accomplishing shared goals with others often requires the ability to relate their actions to underlying mental states such as intentions and beliefs (Theory of Mind; ToM). Working memory load has previously been found to impair ToM processing in single-participant paradigms where participants are presented with static, pre-given social scenarios. However, ToM processing in more naturalistic, dynamic multi-participant scenarios remains relatively unexplored. “Hyperscanning” is a promising method for studying multi-participant coordination, in which brain activity is measured in multiple participants simultaneously during live interaction. Previous hyperscanning findings show greater inter-brain synchronization (IBS) in interacting participants compared with non-interacting participants, especially in regions previously implicated in ToM, and in alpha and theta frequency bands associated with attentional gating processes. These findings suggest that IBS may reflect a correspondence between the mental states of one participant and the (ongoing updating of) representation of those mental states by another participant (via ToM and requisite working memory resources). We sought to make this widely-held but untested interpretation of IBS more explicit by investigating the relationship between IBS and performance in a multi-participant ToM task. Participant dyads performed a computerized ToM task in which they were presented with novel images each trial and were instructed to each choose the same image, with the chosen images shown at the end of each trial. In addition, participants in the high-load condition performed one trial of an ongoing n-back task at the beginning of each ToM trial, requiring them to update and maintain numbers in working memory while performing the ToM task. Significantly lower P3 ERP amplitude at image onset in the high-load condition indicated that allocation of working memory resources was attenuated during ToM processing. Linear Mixed Models and Generalized Additive Models revealed ToM performance and IBS in a small number of channels significantly decreased in the high-load condition, and increased more slowly across trials, as compared with a low-load control condition. These results indicate that, expanding on traditional single-participant paradigms, ToM loads on working memory in a two-person coordination task, and that IBS is sensitive to changes in ToM induced by working memory load.

Title: Am I speaking to a human, a robot, or a computer? Neural representations of task partners in communicative interactions with humans or artificial agents.

Authors: *D. PISCHEDDA[1], A. LANGE[1], M. KIRTAY[2], O. A. WUDARCZYK[3], R. ABDEL RAHMAN[3], V. V. HAFNER[2], A. K. KUHLEN[3], J.-D. HAYNES[1];
[1]Bernstein Ctr. for Computat. Neurosci., Charité – Universitätsmedizin Berlin, Berlin, Germany; [2]Dept. of Computer Sci., [3]Dept. of Psychology, Humboldt-Universität zu Berlin, Berlin, Germany

Abstract: When people speak, they adapt their language to the specific conversational partner (e.g., Brennan & Hanna, 2009). Partner-adapted language production has been associated with the ability to take another person's perspective (i.e., mentalizing; Frith & Frith, 2006). This skill is supported by a brain network including ventromedial prefrontal cortex (VMPFC), precuneus, and temporoparietal junction (TPJ, Molenberghs et al., 2016). Partner-adapted speaking requires high flexibility. The brain supports flexible behavior by pre-activating the cortical structures needed to perform an upcoming task (e.g., Pischedda et al., 2017; Sakai & Passingham, 2003). These include ventrolateral prefrontal cortex (VLPF) and parietal cortex (e.g., Pischedda et al., 2017). A previous study (Kuhlen et al., 2017) showed that VMPFC and VLPFC encode information about the intention to address a conversational partner (a human confederate) as compared to having no conversational partner (to test a microphone). This suggests an involvement of mentalizing when addressing a human partner. As artificial agents are becoming frequent conversational partners, we explore, at the neural level, the difference between communicating with artificial agents and human partners (e.g., Rauchbauer et al., 2019). Specifically, we investigate partner-specific neural representations when preparing to address different task partners: a human, a Pepper robot, or a computer. Fifty participants (32 female) worked on a spatial task together with their task partners while undergoing functional magnetic resonance imaging. On each trial, the participant instructed one of the partners to perform an action and observed the outcome of the partner's action. Instructions were identical across partners. This paradigm allowed us (1) to identify neural representations of task partners prior to speaking and (2) to assess differences between these representations. We applied multivariate decoding methods (Haynes, 2015) to identify brain regions encoding information about different

communication partners. We show that both VMPFC and VLPFC, as well as precuneus and parietal cortex, encode information about the specific task partner that is addressed. Moreover, univariate analyses revealed higher activation in TPJ when talking to a human as compared to Pepper. These results suggest that while some areas of the mentalizing network are specifically activated when addressing a human partner, others respond to robots as well. Identifying which critical features maximize activation of the mentalizing network will allow for designing robots that can be accepted as interaction partners in everyday life.

Title: Cognitive load and eye movement patterns during health literacy and executive functioning tasks

Authors: *G. CAVANAUGH[1], R. OWNBY[2], S. GRANT[2], M. ABREU[2], P. HARDIGAN[3], V. JOHNSON[4];
[1]Nursing, [2]Osteo. Med., [3]Allopathic Med., [4]Col. of Healthcare Sci., Nova Southeastern Univ., Ft Lauderdale, FL

Abstract: Introduction. Cognitive function decline is an expected consequence of aging; furthermore, risk factors, such as repeated exposure to stress, impact information processing and decision-making regardless of age. Many studies have been successful at evaluating cognitive processing in non-verbal individuals through eye-tracking measures, though to date, no studies have examined the impact of homelessness on executive functioning using eye-tracking measures. This study examines eye-movement and pupil diameter as an indicator of cognitive load during a computerized assessment of health literacy and executive function in two socioeconomic groups, proposing that individuals from disadvantaged backgrounds will demonstrate greater difficulty with executive functioning. **Methods.** The Montreal Cognitive Assessment (MoCA) and Fostering Literacy for Good Health Today (FLIGHT)/ Vive Desarollando Amplia Salud (VIDAS), a progressively more difficult health literacy tool, were used as the primary assessments; other assessments included grip strength and the Trail Making test. Participants were 85 adults (26-65 years old), 65 were homeless and compared to 20 persons

with stable housing. Participants completed assessments on a laptop mounted with a Tobii eye-tracker. Visualization and numerical data were exported from Tobii ProLab and were analyzed using SPSS v.27. **Results**. Mean baseline pupil diameter were 2.83mm ± 0.5329 (homeless) and 2.62mm ± 0.2366 (control). Both groups demonstrated significant pupil dilation from baseline while progressing through the tasks divided into 8 frames $F(8, 266156)= 1239.43$, $p = .000$. A visual analysis of the data suggests that the homeless group showed the greatest change, with more guessing events, more disorganized patterns of eye-movement, and more incorrect FLIGHT/VIDAS answers (mean score 11.34 vs 27.57). The homeless group's scattered eye-movement patterns were consistent with an increase in errors during the Trail Making Test, lower MoCA scores (M= 24.72 vs M= 27.1), and weaker grip strength. **Conclusions.** Results suggest that individuals who are homeless may have difficulty processing information from complex cognitive tasks. Furthermore, the homeless population may include individuals with unidentified and undocumented cognitive deficits that might prevent them from successfully processing information for better decision-making.

Title: Shared responsibility in collective decisions decreases the sense of agency in the human brain

Authors: *M. EL ZEIN[1], R. J. DOLAN[2], B. BAHRAMI[3];
[1]Univ. Col. London, London, United Kingdom; [2]Max Planck UCL Ctr., London, United Kingdom; [3]Ludwig Maximilian Univ., Munich, Germany

Abstract: Distributing responsibility among several individuals in social decisions helps minimize the burden of responsibility for the consequences of decisions. We investigated the neural correlates of this effect in a magnetoencephalography (MEG) study. Human participants performed a reward-based learning decision-making task in contexts where we parametrically modulated responsibility for decision outcomes and measured ratings of how responsible subjects felt after their decisions. Participants' subjective sense of responsibility decreased parametrically as a function of group size. An overall self-serving bias was evident in

participants consistently feeling more responsible for positive as compared to negative outcomes. Trial by trial regressions of MEG signals against responsibility contexts revealed both outcome-dependent and outcome-independent neural signatures that covaried with responsibility. Outcome processing was parametrically reduced with decreasing responsibility at 200ms post outcome onset, an effect centred on parietal and precentral brain regions. Prior to revealing an outcome, motor preparation for decisions at 500ms after stimulus onset was attenuated for social decisions. Interestingly, the boost in responsibility for positive outcomes was stronger in social contexts and associated with increased activity in regions related to social and reward processing, including orbito-frontal cortex and the superior temporal sulcus. Together, these results show that sharing responsibility with others reduces agency through an influence on pre-outcome motor preparation and post-outcome processing, while affording an opportunity to flexibly take credit for positive outcomes.

Title: Paired creative idea generation and behavioral synchrony

Authors: *M. SLAYTON[1], A. RAGNHILDSTVEIT[2], N. RINCON[1], J. IBARRA[1], C. TAN[1], A. ADHIKARI[1], R. BEATY[3], J. SCHOOLER[4], T. WHEATLEY[5], P. WHITEHEAD[1], P. SELI[1]; [1]Dept. of Psychology & Neurosci., Duke Univ., Durham, NC; [2]Dept. of Psychology, Univ. of Utah, Salt Lake City, UT; [3]Dept. of Psychology, Pennsylvania State Univ., University Park, PA; [4]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA; [5]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The capacity to share creative ideas enables humans to communicate, work together, and produce novel solutions necessary for social development. This study aimed to examine how interpersonal neural synchrony affects creativity in dyadic pairs who are engaged in a brainstorming discussion. Dyads performed a modified alternate uses task (AUT) virtually over Zoom. We then assessed level of creativity (measured by creativity rank, ideas, and idea length) as well as interactivity (measured by speaker switching, pause, pause length, overlaps/interrupts, acknowledgements, and content) unrelated to the task. Each dyad completed four one-minute rounds, first responding to a conventional AUT prompt followed by prompts that built off the previous. Creativity was strongly correlated with off-task chatting ($r = 0.65$, $P = 0.02$) and verbal acknowledgment (e.g. ‘yeah’ or ‘uh-huh’) ($r = 0.52$, $P = 0.07$), and moderately correlated with speaker switching ($r = 0.41$, $P = 0.16$). These findings are consistent with previous research

indicating that group interaction improves creative performance among pairs, and further implicates underlying interactive mechanisms that may be responsible. Future work will explore temporal dynamics of creative cognition in dyads using EEG hyperscanning while participants complete a group AUT.

Title: Fixation duration and location differences between change blindness task phases for adolescents with ASD

Authors: J. SNIDER[1], S. HACKER[2], S. LIU[3], *L. CHUKOSKIE[4];
[1]Inst. for Neural Computation, UCSD, La Jolla, CA; [2]Neurosciences, [3]UC San Diego, La Jolla, CA; [4]Northeastern Univ., Boston, MA

Abstract: The ability to detect and respond to changes in a visual scene is essential for functional orienting in our dynamic natural world. We are interested in how unique visual and social perceptual abilities affect the way people explore changing scenes. We used a change blindness task to characterize eye movements and fixations both in adolescents with an Autism Spectrum Disorder (ASD) and Typically Developing (TD) adolescents. Social and non-social changes were made in each of 16 natural scenes. These changes were balanced for low-level salience, eccentricity, and size. For each presentation, participants first freely viewed a static image for 6s (admire). Then, a modified image alternated with the original for 1s each with a 200ms black mask appearing between alternations to mitigate motion artifacts. Participants had up to 60s to identify the change (search). To encourage young participants, we simplified the task after 17s, decreasing the mask duration by 50ms after every other alternation.
We compared the gaze behavior and reaction time responses of ASD and TD participants. We observed that participants with ASD had significantly shorter fixation times than their TD peers in the search portion of each trial, but that this effect is weaker in the "admire" portion of each trial. We observed no between-group differences in search success or time to success. Similarly, we observed no consistent differences in speed or success of search for social or non-social

targets overall or by group. However, when the scene was divided into social versus non-social content regions, there was a consistent and large difference in fixation dwell time in both groups. The fixation dwell times for social content were longer during both the admire and search phase, but the effect was stronger in the search phase of the task. During the admire phase, both groups preferentially looked at the social content in the first second and the rest of the scene over the next 5s. For the first two alternations of the search phase, TD participants looked at social regions, but participants with ASD continued to search the scene. The tendency to look at the social regions gave TD participants a slight advantage in identifying social changes, at the cost of a slight advantage for participants with ASD for non-social changes.
These results reveal that the nature of the task has substantial effects on content-specific fixation times that are durable across groups. Also, while both groups indistinguishably preferred social content during free viewing, TD participants preferred to look at social regions during the search phase even in the absence of a task-related benefit.

Title: Social media use experience escalates news sharing behavior: Behavioral Experiments on infodemics

Authors: *H. ONISHI, K. I. KOBAYASI;
Doshisha Univ., Kyoto, Japan

Abstract: In recent years, there has been a phenomenon called infodemic, which is the sharing and spreading of fear-inducing and untrue news, and it has become a major social problem, especially in the era of the Covid-19 pandemic. In other words, infodemics arise from the sharing of news. A factor involved in the active sharing of news is the experience of using social media. Social science research suggests that as people become more experienced in using social media, they are more willing to share the news. Considering neuroplasticity, it is conceivable that the more experience we have with social media, the more our neural circuits will be suited to it, however, it is not clear how this affects infodemics. We hypothesized that the experience of using social media to communicate one's opinions to the public was a factor in the infodemics. To replicate the subjects' actual use of social media, we conducted a behavioral experiment that mimics social media. Participants were presented with 60 different news articles and instructed to perform three actions on them: "Like", "Share", and "Comment". The stimuli were news related to Covid-19 and other topics, and these articles consisted of 20 positive news, 20 negative

news, and 20 neutral news. We divided our subjects into two groups: those who had at least one year of experience using social media to communicate their opinions to the public ("experienced group") and those who did not ("naïve group"). The experiment was divided into two phases: the first 30 sessions were conducted under the assumption that one's actions would be shown to the world (public condition), and the second 30 sessions were conducted under the assumption that one's actions would only be shown to one's friends (private condition). Our results showed that subjects expressed significantly more "like" for positive articles, which suggests that the use of social media was replicated in the experiment. In the experienced group, a significant increase in the number of comments to news about Covid-19 in the public condition trials was observed, compared to the condition of the private trials. This suggests that people with experience in using social media are publishing their own opinions, which may be the cause of the infodemics. Interestingly, in the experienced group, a significant increase in the number of “shares” of positive news in the public condition trials was observed, but not in negative news. From these results, we suggest that the experience of usage of social media affects the news sharing behavior, and it can act as a positive influence on the public, rather than causing the infodemic by promoting the negative news sharing.

Title: Acute stress acts as a safeguard against social influence in risky decision-making

Authors: *L. KLUEN[1,2], M. BOGDANOV[1,3], L. SCHWABE[1];
[1]Cognitive Psychology, Univ. of Hamburg, Hamburg, Germany; [2]Humanities and Social Sci., Caltech, Pasadena, CA; [3]Psychology, McGill Univ., Montreal, QC, Canada

Abstract: Acute stress is well-known to affect decision-making under risk. However, previous work has mostly investigated this effect in individual subjects making isolated decisions, neglecting other potential sources of decision biases, such as the social context. Given that providing information about other people’s choices may nudge individuals’ decisions to conform with the observed behaviour, we here aimed to test how stress impacts the effect of social influence on decision-making behaviour.To this end, 86 participants underwent the Trier Social Stress Test (TSST) or a non-stressful control manipulation before they completed a social decision-making task, in which they were asked to choose between a risky and a safe gamble

option with different expected value propositions. During ‘information’ trials, information about how two ‘mock’ participants decided about the gambles was provided to the actual participant. In two thirds of the trials, this social information could be either expected value congruent (i.e., ‘mock’ participants chose the gamble with the higher expected value) or incongruent. Results revealed that participants’ choices in the control condition were indeed biased in the direction of the social information provided, whereas acute stress diminished the social influence on decision-making behaviour. This difference was most clearly pronounced at the beginning of the task. Interestingly, even when ‘mock’ participants chose the gamble with the lower expected value, participants in the control condition were also more likely to follow this behaviour and thus acting against their own interest. This was not seen in stressed participants as their choice behaviour did not differ between trials in which the social information was expected value conform or was not. Our findings provide the first insight into how stress may affect, i.e. reduce, the influence of social impact on risky decision-making behaviour. Possibly acting as a protective mechanism to reduce negative choice impact.

Title: Dynamics of hidden brain states when people solve a verbal puzzle

Authors: *Y. YU[1], Y. OH[2], J. KOUNIOS[2], M. BEEMAN[1];
[1]Northwestern Univ., Chicago, IL; [2]Drexel Univ., Philadelphia, PA

Abstract: Dynamics of hidden brain states when people solve a verbal puzzle
When people try to solve a puzzle, they go through distinct steps: encoding the problem, retrieving the meaning, ideation, evaluation, etc. Those steps often occur recurrently and spontaneously in varying orders. To extract the discrete dynamics that can characterize such multi-stage solving processes, we applied an unsupervised machine learning method to continuously recorded EEG data. EEG was recorded for 39 participants when they attempted Compound Remote Associates problems (CRA, Bowden & Jung-Beeman, 2003). CRA problems are verbal puzzles that can be solved in either insight-leaning or analysis-leaning manner. Self reports for insight or analytic solving processes have been widely used to study neural substrates underlying those strategies (e.g., Becker et al., 2020; Kounios et al., 2006). We fitted a Hidden Markov Model to the time-frequency transformed EEG signals and decoded each trial as a time-

resolved state sequence. The model identified several hidden states where each state is characterized by a distinct, spectrally-resolved power topography. For example, one of the states features widespread activation in alpha-band frequency (8-9 HZ and 10-13 HZ) but neutral in other frequency bands, while some states feature localized theta-band activation. The probability of this state peaks before stimulus onset and decreases before response. Interestingly, this "alpha-dominated state" is more likely to be visited and maintained in a trial solved by insight than one by analysis, echoing the earlier findings on alpha power at posterior parietal electrodes before response (Jung-Beeman et al., 2004). Our analysis further suggested that the steeper decline in the probability of this state before response is associated with reporting a solution by insight, compared to a solution by analysis. Overall, the hidden brain states exhibit different transition patterns through various stages of a trial and can be related to behavioral outcomes. This paradigm provides a way to extract dynamic features that characterize creative problem solving and potentially provide a novel window into the nature of the underlying cognitive processes.

Title: Memory retention period-dependent human hippocampal processing during learning

Authors: *M. KWON[1], S.-H. LEE[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of

Abstract: The capability to maintain important information for a long time is essential for survival. Here we investigate why some memories are forgotten in a few days while other memories remain for a month or more, although both types of memory are referred to as long-term memory. Given that the hippocampal activity during learning is correlated with subsequent memory performance, we focused on whether these memories are differentially processed in the hippocampus from learning stage. Using functional magnetic resonance imaging (fMRI) and trial-by-trial pattern similarity analysis, we tracked how hippocampal representations of associated information changed during repeated association learning. We found that the representations for associated stimuli in the hippocampus changed dynamically during learning

and that this dynamic representational change was related to the subsequent memory performance. Remarkably, while the degree of shared representations for pairs remembered for at least four weeks were increased and maintained during learning, the shared representations for pairs forgotten before four weeks were observed only temporarily. Furthermore, for long-lasting pairs but not for short-lived pairs, shared representations during learning were also observed in the ventromedial prefrontal cortex. These results suggest that there are two types of long-term memory with different degrees of maintenance and that which type is expressed depends on how information is processed in the hippocampus and prefrontal cortex during learning.

Title: The medial temporal lobe in developmental amnesia: structure and anatomo-functional correlations

Authors: *L. J. CHAREYRON[1], W. K. KLING CHONG[2], M. MISHKIN[3], N. BURGESS[4], R. C. SAUNDERS[3], F. VARGHA-KHADEM[1];
[1]Cognitive Neurosci. and Neuropsychiatry, [2]Developmental Imaging and Biophysics Section, Univ. Col. London Great Ormond Street Inst. of Child Hlth., London, United Kingdom; [3]Lab. of Neuropsychology, NIMH, Bethesda, MD; [4]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: BACKGROUND: Early-life episodes of hypoxia-ischemia can target the hippocampus and lead to developmental amnesia (DA). Patients with DA exhibit severe episodic memory impairment, but their semantic memory is largely preserved. It is not clear, however, whether the residual hippocampus plays a role in encoding and/or retrieval of new information, or the surrounding neocortical areas rescue hippocampal function after early injury.
AIMS: We aimed to investigate anatomo-functional correlations between cognitive performance and the volumes of (a) residual hippocampal subregions, and (b) parahippocampal gyrus in patients with DA.
METHODS: We used manual segmentation on MRI acquisitions to estimate the volume of three hippocampal subregions: uncus, CA-DG (including CA fields and dentate gyrus) and subicular complex; and the volume of three surrounding cortical areas: entorhinal, perirhinal and

parahippocampal cortices, in an exceptionally large cohort of 23 patients with DA and 32 controls of comparable age. The groups were assessed on: i) the Four Mountains Test, which provides measures of spatial perception and immediate spatial memory, and ii) the Doors and People Test, which provides equated measures of verbal and visual recognition and recall. RESULTS: In patients with DA, the level of CA-DG and subicular complex atrophy was about 40% while the atrophy of the uncus was moderate (−26%). In contrast, the entorhinal and perirhinal cortices showed only a mild (−5%) volume reduction in patients with DA and the volume of the parahippocampal cortex was not statistically different from controls'. Patients' spatial perception and spatial memory performance correlated negatively with the volume of the Subicular complex. Also, patients' recall, but not recognition memory performance, correlated negatively with the volume of the Uncus. We did not observe correlations between the volume of the entorhinal, perirhinal and parahippocampal cortices and either patients', or controls' performance.
CONCLUSIONS: Based on our findings, we propose that following early hippocampal damage preserved cortical areas surrounding the hippocampus rescue the encoding and storage of decontextualized memoranda depending on the extent of damage to the hippocampal subregions. Thus, the greater the damage, the more likely that the rhinal cortices rescue memory processes. However, irrespective of this rescue and the extent of damage, the critical hippocampal-dependent function of recall remains irreversibly compromised.

Title: Awake ripples enhance emotional memory encoding in the human brain

Authors: *H. ZHANG[1,2], I. SKELIN[2], S. MA[2], M. PAFF[3], M. A. YASSA[4,5,2], R. T. KNIGHT[6,7], J. J. LIN[1,2,4];

Abstract: Multiple mechanisms have been proposed to support the prioritized encoding of emotional experiences, including neuromodulatory effects on plasticity and interplay between the hippocampus and the amygdala. Sharp-wave/ripples (SWRs) are transient hippocampal oscillations (80-150 Hz), associated with synchronous neural activation in the hippocampus and the amygdala and implicated in binding anatomically distributed memory traces. Moreover, behaviorally relevant reactivation of emotional memory occurs during awake SWRs (aSWR), and aSWR disruption immediately post-experience interferes with memory utilization. In this study, we tested the hypothesis that post-encoding aSWRs could facilitate better emotional memory discrimination, through the coordinated hippocampal-amygdala memory reinstatement. Using the simultaneous intracranial electroencephalographic (iEEG) recordings in the human hippocampus and the amygdala (n = 17, 20 electrodes respectively) in 7 presurgical epilepsy patients (4 females, age 33 +/- 16) performing an emotional memory encoding and discrimination task, we first show stimuli with higher arousal were associated with better discrimination memory ($p = 0.047$, logistic linear mixed-effect model). Next, we demonstrated that during the immediately post-encoding period (i.e., shortly after stimulus presentation and before the next stimulus), the number of aSWR is predictive of both stimulus arousal ($p = 0.03$) and probability of later discrimination ($p = 0.03$, Wilcoxon signed-rank test). Next, we implemented representational similarity analysis to quantify memory reinstatement for each trial. We observed that the post-encoding aSWR is associated with reinstatement in the hippocampus and the amygdala ($p < 0.05$, permutation test). Moreover, the reinstatement exhibits region-specific double dissociation. Specifically, amygdala reinstatement is associated with higher arousal ($p = 0.035$), whereas hippocampal reinstatement is linked to later correct discrimination ($p = 0.008$, cluster-based permutation test). Finally, we tested if the memory reinstatement occurs simultaneously in the amygdala and hippocampus, by computing the outer product of regional reinstatement traces for individual aSWR events. The aSWR-locked joint memory reinstatement during the post-encoding period was predictive of memory discrimination ($p < 0.05$, permutation test). Together, these findings suggest the aSWRs-mediated memory reinstatement in the amygdala and hippocampus as a putative mechanism accounting for better remembering emotional experiences.

Title: Human visual cortex supports recognition memory for simple, visual stimuli.

Authors: *N. M. DE LA ROSA-RIVERA[1], R. A. COWELL[2];
[1]Neurosci. and Behavior, Univ. of Massachusetts Amherst, Amherst, MA; [2]Psychological and Brain Sci., Univ. of Massachusetts, Amherst, MA

Abstract: Most theories of memory assume that long-term, declarative memory relies primarily on the medial temporal lobes (MTL). In contrast, the Representational-Hierarchical (RH) Account - challenges this claim, replacing it with two assumptions: (1) the brain contains a hierarchy of stimulus representations, from simple features (lines, blobs) in visual cortex, to conjunctions of features (which make up objects) in the temporal lobe, to high-dimensional associative representations in hippocampus; and (2) any region in the hierarchy can support memory for the information that it represents. The RH Account thus predicts that long-term, declarative memory for simple, purely visual stimuli should recruit regions outside of the hippocampus, specifically, in visual cortex. In this study, participants studied a set of simple visual stimuli for 10-20 days via visual search training. Stimuli were built from conjunctions of shape and fill pattern. At test in the MR scanner, subjects saw Studied items, Recombination items (novel recombinations of features of studied items), and Novel items. Participants responded “Old”, “Recombo” or “New”. Preliminary fMRI analyses contrasting "New" vs. "Recombo" trials (a “feature memory” signal, because only the features of these stimuli differ in familiarity; the conjunctions are novel in both) show widespread recruitment across visual cortex. Analysis of the *distribution* of voxel activations to New, Recombo and Old stimuli suggest that patterns elicited by Old and Recombo stimuli have reduced variance: voxels highly active to New stimuli "drop out" once stimulus features are learned. This occurs more prominently in later visual regions (e.g., LO, TO), hinting that visual feature memory may be localized to mid-level visual cortex.

Title: Perirhinal cortex automatically tracks recent and lifetime experience with objects regardless of decision relevance

Authors: *H. YANG, S. KOHLER;
Western University, Brain and Mind Inst., London, ON, Canada

Abstract: A large body of evidence points to a critical role of the perirhinal cortex (PrC) in recognition memory, i.e. the ability to recognize prior occurrence of objects. Most of this work in humans has focused on recognition of recent occurrence in a study phase. Neurophysiological studies with non-human animals have shown that the PrC tracks not only recent but also cumulative long-term exposure. In prior research from our laboratory we have developed a paradigm that allows for probing of responses to cumulative prior exposure on both time scales. Using this paradigm with words denoting concrete objects, an fMRI study with healthy participants revealed that activity in PrC tracks judged degree of recent and lifetime exposure, in line with the non-human neurophysiological findings. In the current study, we asked whether this response occurs automatically or whether it is tied to a requirement to make memory decisions on the relevant time scale. In an initial study phase, healthy participants (N=30, age range 18-40, 7 males, all right-handed) provided animacy judgement about object concepts that were repeated at different frequencies. In the test phase, participants rated relative presentation frequency of the recently studied concepts, as well as cumulative lifetime familiarity of non-studied concepts. Cumulative lifetime familiarity of the previously studied concepts was probed in a third phase. We again found that left PrC tracks judged degree of recent and lifetime exposure. Critically, our results revealed that these responses were not tied to a requirement for memory decisions on the relevant time scale. They also occurred when participants judged prior exposure on the other time scale, and even when no judgments of prior occurrence were required at all (in the study phase). This pattern of findings suggests that PrC automatically tracks prior occurrence across multiple time scales, and that the specific evidence on which pertinent memory decisions rely is computed in cortical regions other than PrC.

Title: Dissociations among three functional subnetworks in prefrontal cortex and resolution of the exploration/exploitation dilemma through interactions with hippocampus

Authors: *A. E. PAPALE[1], M. N. HALLQUIST[2], A. Y. DOMBROVSKI[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Psychology and Neurosci., Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Interactions between hippocampus and ventromedial prefrontal cortex/orbitofrontal cortex (vmPFC/OFC) are thought to contribute to decision-making by optimizing future choice given past experience. The vmPFC has been shown to signal scalar value signals in neuroeconomic tasks and OFC has been broadly implicated in abstract state space representation. These structures facilitate rapid and adaptive transitions between exploration and exploitation. Prior work in our lab suggests that hippocampus helps to resolve the explore-exploit dilemma—posterior hippocampus encourages exploration through encoding of reward prediction errors and global value maximum locations, and anterior hippocampus facilitates exploitation strategies by encoding global uncertainty (value entropy) signals. However, the role of vmPFC/OFC, in association with hippocampus, in resolving the exploration-exploitation dilemma remains undetermined. Here, we investigate the role of fMRI signals in healthy human subjects from ventral prefrontal and orbitofrontal subnetworks (cognitive control, default mode network—DMN, and limbic network) on the clock task, a decision-making task where action values vary along a temporal interval with visuospatial cues. We used a reinforcement learning model that compresses value information based on the entropy of the value distribution (i.e., the agent selectively remembers preferred action values). We find that DMN activity correlates with negative entropy during exploitation, while limbic network activity correlates with the global value maximum location, suggesting a role in exploration. While control and limbic networks display positive correlation with reward prediction errors, strikingly, DMN displays a negative correlation. We further investigated how anterior and posterior hippocampus interact with these prefrontal networks in the context of exploration/exploitation. Preliminary findings suggest that anterior hippocampus activity post-reward is followed by a global increase in vmPFC/OFC activity. Posterior hippocampal activity following a negative entropy change also correlates with vmPFC/OFC activity. Both subdivisions of hippocampus convey information about entropy to the DMN and link the location of the value maximum to vmPFC/OFC activity. In summary, the DMN ventral prefrontal subnetwork is activated by hypothesis confirmation signals and receives hippocampal inputs that signal the spatial and temporal statistics of the environment.

Abstract: Development, aging, and neurodegenerative pathologies are known to affect medial temporal lobe (MTL) subregions differently, selectively, and in a complex progression. Characterizing MTL subregional changes using high-resolution MRI may provide greater insight into these processes and better biomarkers for neurodegenerative disease. However, substantial differences in MTL subregion definition has hindered the ability to compare results across laboratories or draw robust conclusions. The Hippocampal Subfields Group (HSG) is an international organization seeking to address this issue by developing a histologically valid, reliable, and freely available segmentation protocol for high-resolution T2-weighted 3T MRI (http://www.hippocampalsubfields.com). Our workflow consists of four steps: 1) collecting histology samples labeled by multiple expert neuroanatomists to form a novel reference dataset to guide the development of the MRI segmentation protocol, 2) developing boundary definitions for each segment of the hippocampus (head, body, and tail) and MTL cortices on MRI, 3) assessing HSG community agreement with boundary rules using online questionnaires, and 4) testing reliability of the protocol definitions. We have developed a preliminary subfield segmentation protocol (i.e., completed steps 1-2) for the hippocampal head, body, and tail. With respect to the outer boundaries of the hippocampal body, i.e., boundaries of the hippocampus with neighboring regions, 29 labs reached consensus for all segmentation rules (step 3). We are

now assessing community agreement with segmentation rules for the inner boundaries of the hippocampal body, such as those between the cornu ammonis fields. Once consensus is reached, we will begin conducting reliability testing for both the inner and outer boundaries of the body (step 4). Similarly, we will assess community agreement with the head and tail segmentation rules, followed by reliability testing. Once completed, the harmonized protocol will significantly facilitate cross-study comparisons and provide increased insight into the structure and function of MTL subregions across the lifespan and in disease.

Title: The effective connectivity of the human hippocampal memory system

Authors: *E. T. ROLLS[1], G. DECO[2], C.-C. HUANG[3], J. FENG[4];
[1]Oxford Ctr. For Computat. Neurosci., Coventry, United Kingdom; [2]ETIC, Univ. Pompeu Fabra, Barcelona, Spain; [3]East China Normal Univ., Shanghai, China; [4]Univ. of Warwick, Coventry, United Kingdom

Abstract: The anatomical connections of the human hippocampus shown with tractography appear to be more extensive with many cortical areas than was previously known (Huang et al 2021), and this has implications for understanding the operation of human memory (Rolls 2021). Here this is developed with effective connectivity measurements based on the resting state BOLD signal which reveal the directionality and strength of the connectivity. The new asymmetric effective connectivity algorithm was developed from a previous approach (Deco et al 2019), and was used with a modified Human Connectome Project atlas (Glasser et al 2016). In 172 participants in the HCP imaged at 7T, it was found that a ventral ‘what’ hippocampal stream involves the temporal lobe cortex, perirhinal and parahippocampal TF cortex, and entorhinal cortex with generally stronger forward connectivity to the hippocampus than backwards. A

dorsal ‘where’ hippocampal stream connects parietal cortex with posterior and retrosplenial cingulate cortex, and with parahippocampal TH cortex, which in turn project to the presubiculum, which connects to the hippocampus. Thus some separate ‘what’ and ‘where’ streams can converge in the hippocampus, from which backprojections return to the sources. However, unlike the simple dual stream hippocampal model, there is some cross-connectivity between these systems before the hippocampus is reached; and the hippocampus has some effective connectivity with earlier stages of processing than the entorhinal cortex and presubiculum. For example, the human hippocampus receives effective connectivity from the posterior and retrosplenial cingulate cortex, and parietal cortex. This effective connectivity is consistent with the anatomical tractography, but goes beyond it by providing evidence about the directionality and strength of the connectivity. These findings provide the foundation for new concepts on the operation of the hippocampal memory system in humans, given that the connectivity allows for pre-hippocampal cortical areas to become specialized for particular functions, rather than primarily acting as serial gateways to and from the hippocampal system. A good example is the ventromedial visual area / TH system where spatial scenes are represented.

Abstract: Some recent work on the neural representation of episodic memory in the human hippocampus has identified a memory signal reflecting the generic status of test items (novel vs. repeated) whereas other work has identified another memory signal reflecting the repeated status of specific test items. Here, we investigated the co-existence and mnemonic functions of both episodic memory signals in the same experiment. We recorded single-unit activity from four brain regions (hippocampus, amygdala, anterior cingulate, and prefrontal cortex) of epilepsy patients as they completed a continuous recognition task. The generic signal was found in all four brain regions, whereas the item-specific memory signal was detected only in the hippocampus and reflected sparse coding. That is, for the item-specific signal, each hippocampal neuron responded strongly to a small fraction of repeated words, and each repeated word elicited strong responding in a small fraction of neurons. The fact that this neural code was sparse, pattern-separated, and limited to the hippocampus accords with longstanding computational models. We suggest that this item-specific episodic memory signal is fundamental, with the generic memory signal likely being derived from it.

Title: Patterns of distributed neural firing code for perceptual and semantic features

Authors: *C. T. WEIDEMANN[1], P. N. STEINMETZ[2], J. JACOBS[1];
[1]Dept. of Biomed. Engin., Columbia Univ., New York, NY; [2]NeurTex Brain Res. Inst., Dallas, TX

Abstract: Intracranial recordings from neurosurgery patients have revealed that the spiking activity of individual neurons reliably predicts performance in episodic memory tasks. We investigated the extent to which the pattern of neural activity across multiple simultaneously recorded units revealed additional information about task performance. A total of 121 patients

with implanted micro-electrodes participated in at least one of 7 distinct tasks probing recognition memory and perceptual decisions. Across a total of 258 experimental sessions we identified 20,578 units which were predominantly located in medial temporal lobe structures. For each stimulus presentation in a given experimental session, we constructed a vector of neural firing from each unit's total number of spikes during the stimulus presentation. We quantified the similarity of the firing pattern associated with two stimulus presentations by calculating the cosine similarity between the corresponding vectors. The firing pattern across these units were similar for repeated items, but this similarity did not indicate whether participants would recognize the repetition. Additionally, we observed increased similarity of neural firing patterns for non-identical stimuli belonging to the same category, with higher similarity for stimulus pairs sharing a narrower category. The pattern of neural activity thus reflected the perceptual and semantic stimulus features rather than an episodic memory signal. These findings are consistent with a highly distributed neural code for perceptual and semantic stimulus features.

Title: Adaptive Stimulus Selection for Consolidation in the Hippocampus

Authors: *S. TERADA, J. O'HARE, T. GEILLER, Z. LIAO, B. VANCURA, A. LOSONCZY; Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY

Abstract: Associative memories guide behavioral adaptation by binding together outcome-predictive sensory stimuli. However, in a feature-rich environment, only a subset of stimuli may predict a desired outcome. How neural circuits enable behavioral adaptation by selectively and durably representing subsets of sensory stimuli pertinent to a specific outcome is not known. We investigated this feature selection process in the hippocampus during memory acquisition and subsequent consolidation. Two-photon calcium imaging of CA3 axonal projections to CA1

combined with simultaneous local field potential recordings revealed that CA3 projections encoding behaviorally-informative sensory stimuli were selectively recruited during the memory replay events that underlie hippocampal memory consolidation. These axonal projections formed sequential assemblies conjunctively linking sensory features to spatial location and thus reward proximity. By contrast, axons encoding uninformative, peripatetic sensory cues were notably suppressed during memory replay. Thus, while hippocampus comprehensively encodes real-time sensory environment, it implements a flexible filtering mechanism to maximize utility of memories destined for long-term storage. We propose utility-dependent recruitment of sensory experience during memory consolidation as a general coding principle for associative learning.

Title: Characterizing Direct Cortical Influences on Hippocampal region CA1 in Behaving Mice

Authors: *J. BOWLER, A. LOSONCZY;
Columbia Univ., New York, NY

Abstract: Characterizing Direct Cortical Influences on Hippocampal region CA1 in Behaving Mice
The hippocampus plays critical roles in navigation and episodic memory, with the most prominent neural correlate of these behaviors being “place cell” activity. It is widely assumed that afferent excitatory inputs to the hippocampus carry critical information required for generating and tuning these navigational and memory-related changes in hippocampal network dynamics. Two subregions of the Entorhinal Cortex(EC) have been particularly implicated in this process by providing distinct input streams to the hippocampus. Specifically, the medial EC (MEC) is thought to be involved primarily in processing spatial information, while the lateral EC (LEC) is thought to primarily process information related to individual items and how they have been arranged spatially or paired with a context. Despite these activity patterns having been well studied in the EC, a detailed understanding at the circuit level of the entorhinal influence on hippocampal population dynamics is still lacking. The direct projections from MEC and LEC to

CA1pyramidal cells (CA1PCs) offer a tractable bridge to this knowledge gap. Chronic, subcellular-resolution two-photon functional imaging of identified EC afferents during head-fixed virtual reality navigation and learning provides an opportunity for direct observation and characterization of the information transferred between the EC and CA1. These experiments test the hypothesis that CA1PCs receive spatial and sensory information from both MEC and LEC inputs which instruct CA1PC's population dynamics. Results indicate that it is possible to decode various navigationally relevant variables from the activity observed in the EC projections to CA1 including position, velocity and context. Increased activity is also observed in these afferents in response to task relevant salient cues as well as to goal proximity or anticipation. The direct EC to CA1 projection provides input to CA1PCs capable of evoking an abundance of both spatial and episodic representations, as observed in the hippocampus.

Title: Compartment-specific tuning of hippocampal dendritic feature selectivity by intracellular Ca^{2+} release

Authors: *J. K. O'HARE[1], Y. HIRABAYASHI[3], V. L. HEWITT[1], H. BLOCKUS[1], M. SZOBOSZLAY[1], S. V. ROLOTTI[2], T. C. GEILLER[1], A. NEGREAN[1], V. CHELUR[2], A. LOSONCZY[1], F. POLLEUX[1];
[1]Zuckerman Mind Brain Behavior Inst., [2]Dept. of Neurosci., Columbia Univ., New York, NY; [3]Sch. of Engin., Univ. of Tokyo, Tokyo, Japan

Abstract: Dendritic Ca^{2+} is critical in determining how neurons respond and adapt to patterns of incoming excitation. The endoplasmic reticulum sequesters high concentrations of Ca^{2+} which it can release into the cytosol in response to strong synaptic activation; a phenomenon known as intracellular Ca^{2+} release (ICR). Given the centrality of Ca^{2+} to synaptic plasticity, these

feedforward release events have been suggested to shape and drive plasticity mechanisms underlying learning. Up to now, a number of methodological obstacles have prevented the investigation of ICR in mammalian neurons *in vivo*. By taking a combinatorial approach comprising single-cell electroporation of custom DNA cocktails, simultaneous *in vivo* imaging of dendritic and somatic activity during spatial navigation, optogenetic induction of spatial receptive fields, and an acute genetic approach to augment ICR itself, we were able to gain insight into the *in vivo* role of this subcellular process in pyramidal neurons of hippocampal area CA1. We found that ICR supports the establishment of dendritic feature selectivity and ultimately shapes dendritic integrative properties determining output-level receptive fields. This was particularly true of apical dendrites, which integrate distinct streams of information originating from a nonidentical set of afferent regions compared to basal dendrites. Thus, ICR, a subcellular postsynaptic process, acts cooperatively with circuit- and systems-level architecture *in vivo* to regulate behaviorally-relevant plasticity in a compartment-specific manner.

Title: Hebbian plasticity of GABAergic synapses sufficient for consolidation of world structure by CA3 replay

Authors: *Z. LIAO[1], D. HADJIABADI[2], S. TERADA[1], I. SOLTESZ[3], A. LOSONCZY[1]; [1]Neurosci., Columbia Univ., New York, NY; [2]Stanford Univ., Palo Alto, CA; [3]Sch. of Med., Stanford Univ., Stanford, CA

Abstract: The replay of previously learned sequences during sharp-wave ripples at rest, a process required for memory consolidation, represents a defining computational feature of hippocampal population dynamics. However, the content of these replay episodes, and in particular whether specific experiences or an abstracted, utilitarian representation of the world are consolidated, remains controversial. Recent experimental work has shown that experience-specific representations are suppressed in sharp-wave ripples, while conserved, recurring representations are adaptively recruited. We propose a succinct but novel mechanism for this phenomenon: the reuse of the symmetric spike-time dependent plasticity rule (sSTDP), previously reported at CA3 excitatory synapses, to remodel inhibitory synapses as well. We show using three levels of modeling—random network, detailed biophysical, and abstract normative—that Hebbian plasticity of GABAergic synapses is sufficient to accurately reproduce the experimental findings. We make the key prediction that inhibitory plasticity is not only sufficient but necessary to functionally filter noisy observations in order to learn the latent statistical structure of the world. We further predict that ablating inhibitory plasticity leads to the disruption of replay and the emergence of pathological offline dynamics. Finally, we propose a number of experiments to validate these predictions in both physiological and pathological conditions. Our theoretical work here outlines a potential direct link between the synaptic and cognitive levels of memory consolidation, with implications for both normal learning and neurological disease.

Title: Behavioral state-dependent electrical signaling of neuronal dendrites

Authors: *A. NEGREAN[1], Z. LIAO[1], D. LI[1], C. YANG[1], N. E. MCCLAIN[1], D. HOLDER[1], G. ZHANG[2], S. W. EVANS[2], M. CHAVARHA[2], M. Z. LIN[2], A. LOSONCZY[1];
[1]Neurosci., Columbia Univ., New York, NY; [2]Neurobio., Stanford Univ., Stanford, CA

Abstract: Excitation, inhibition and a variety of ion-channels interact at the level of dendrites to shape neuronal output. Studying this input-output transformation is a formidable technical challenge. In the awake behaving animal, sharp electrode and path-clamp based dendritic recordings are hampered by movement artifacts and development of optical means of measurement is in great need. Calcium imaging offers sufficient signal-to-noise ratio to measure neuronal output and suprathreshold dendritic activity, however, relying on depolarization, it provides only a limited view of dendritic excitability and its role in synaptic integration.
Recent advances in membrane potential imaging using ASAP-based genetically encoded voltage sensors demonstrate the feasibility to record somatic membrane potential changes in the awake behaving mouse [1]. Recent work from our group [2] showed that we can resolve suprathreshold dendritic activity in hippocampal CA1-area pyramidal neurons in awake mice running on a treadmill.
With the goal to understand how different behavioral states influence the electrical activity of dendrites, we further characterize ASAP3b sensor kinetics at 37C through a Markov-chain model and extend voltage measurements over the entire dendritic tree and across several electrophysiologically defined behavioral states: immobility with and without sharp-wave/ripples and locomotion-dependent theta oscillations. During locomotion on a cued belt we find multiple electrically place tuned compartments tiling the entire belt. During sharp wave/ripples, we find the cell body and the dendritic tree to be, on average, hyperpolarized, while local field potential theta-oscillations have a corresponding intracellular membrane potential oscillation distribution within the dendritic tree.

Title: The functional architecture of glutamatergic release onto CA1 neurons

Authors: *J. R. CLIMER[1], M. D. ADOFF[2], H. DAVOUDI[1], J. S. MARVIN[3], L. L. LOOGER[3], D. A. DOMBECK[1];

Abstract: Area CA1 of the hippocampus is necessary for spatial memory and hosts place cells, pyramidal neurons that fire as mice visit distinct locations in an environment. They are surrounded by silent and non-place cells, which may be place cells when the mouse is in a different context. Place cells receive inputs from spatial and non-spatial neurons in other regions, notably cells in hippocampal area CA3. In contrast to other regions containing neurons with well-defined receptive fields, there is no anatomical organization to the arrangement of the tuning of place cells. Thus, many models of place firing rely on random presynaptic inputs being amplified post-synaptically to generate selective firing. Advances in functional indicators and in vivo subcellular two-photon imaging provide means to examine the presynaptic inputs. Using resonant scanning two photon microscopy and the florescent glutamate sensor SF-iGluSnFR.A184S, we mapped glutamate release onto the dendrites of CA1 pyramidal neurons with micron scale resolution as mice navigated a linear track in virtual reality. By following these dendritic recordings with calcium imaging from the parent somas (using the red-shifted calcium indicator jRGECO1a), we determined how excitatory inputs contribute to the type and tuning of somatic output. Place cells receive more spatially tuned inputs than their non-place peers, and this input arrives preferentially in the receptive field of the neuron. This tuned input is anatomically organized along the dendrites, arriving in functional clusters along the dendrite. To examine the moment-by-moment transformation of inputs to the place cell outputs, we then imaged the dendrites and soma of neurons simultaneously. Overall, our results implicate increases in total excitatory input and co-activation of anatomically clustered synaptic input in place firing. Since they largely inherit their fields from upstream synaptic partners with similar fields, many CA1 place cells appear to be part of multi-brain-region cell assemblies forming representations of specific locations.

Title: Spatial information transfer in hippocampal place-cell models depends on biophysical heterogeneities, trial-to-trial variability, and symmetry of place-field firing

Authors: *A. ROY, R. NARAYANAN;
Indian Inst. of Sci., Bangalore, India

Abstract: The relationship between the feature-tuning curve and information transfer profile of individual neurons provides vital insights about neural encoding. However, the relationship between the spatial tuning curve and spatial information transfer of hippocampal place cells remains unexplored. Here, employing a stochastic search procedure spanning 12000 morphologically realistic models, we arrived at 127 conductance-based place-cell models that matched 22 intrinsic somato-dendritic measurements with their electrophysiological counterparts, and were endowed with sharp place-field tuning profiles (high peak firing rate and low spatial width). The parametric values exhibited neither clustering nor strong pairwise correlations. We introduced trial-to-trial variability (activity-dependent and activity-independent) in responses and computed model tuning curves and information transfer profiles, using stimulus-specific (SSI) and mutual (MI) information metrics, across locations within the place field. We found spatial information transfer to be heterogeneous across models, but to reduce consistently with increasing degrees of variability. Importantly, whereas reliable low-variability responses implied that maximal information transfer occurred at high-slope regions of the tuning curve, increase in variability resulted in maximal transfer occurring at the peak-firing location in a subset of models. Moreover, experience-dependent asymmetry in place-field firing introduced asymmetries in the information transfer computed through MI, but not SSI, and the impact of activity-dependent variability on information transfer was minimal compared to activity-independent variability. Biophysically, we unveiled a many-to-one relationship between different ion channels and information transfer. We also demonstrated critical roles for *N*-methyl-d-aspartate receptors, transient potassium and dendritic sodium channels in regulating information transfer via virtual knockout models (VKMs). Our results emphasize the need to account for trial-to-trial variability, tuning-curve shape and biological heterogeneities while assessing

information transfer, and demonstrate ion-channel degeneracy in the regulation of spatial information transfer.

Title: Motor-sensory integration punctuated by attentional-shifts as a key strategy to map navigational boundaries by zebrafish placed in a novel environment

Authors: *B. SANGHERA[1,2], M. GADDAM[2], J. S. KANWAL[2];
[1]Univ. of Miami, Coral Gables, FL; [2]Dept. of Neurol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Movement is essential for gaining new information about one's environment, particularly in the relative absence of external sensory inputs. By integrating bouts of movement with a stream of sensory inputs, animals can begin to construct a spatial frame-of-reference within which to navigate. Here we tested whether time-segments of movement culminate in acquisition of allocentric cues to facilitate motor-sensory integration. Individual zebrafish (n = 9) were placed in a small (17 x 17 cm) tank with a smooth, curved and opaque surface. Video recordings were initiated immediately after fish placement and continued for 10 min. Machine-learning software packages for pose- and behavior-tracking (DeepLabCut, B-SOiD and VAME) elucidated up to 20 motifs that included forward glide, reorientation, and turns. Distance of animals from the center of the tank during exploratory swimming revealed that zebrafish spend more time along the edges of the tank during the first vs. the last minute. For mapping navigational boundaries, zebrafish employed a strategy of reorientations and forward glides terminating in two or more successive contacts with the tank wall followed by a sharp turn and free-swim back to the initial location. As the fish became familiar with its environment, bout frequencies of reorientations and their transitions to forward glides and sharp turns decreased by 26.6% and 20.8% (n = 7), respectively. The frequency of forward glides increased by 9.1%. Markov chain analysis revealed systematic transitions between these six swim patterns. Forward glides frequently terminated in contact with the tank wall followed by either reorientation or forward glide (transition probabilities of 22%, 22% and 58%, respectively). Reticular and reticulospinal neurons that control swim and turn movements in fish have complex touch-

sensitive receptive fields (Kanwal & Finger, 1997) and neurons in the lateral pallium encode the edges of the environment, head direction, swimming speed, and the swim velocity-vector (Vinepinsky et al., 2020). Moreover, fish can encode order for a series of spatially linked sensory inputs (de Perera, 2004). Together, these reports and our observations on zebrafish swim strategy suggest that fish are capable of employing a "go-and-touch" strategy to map navigational boundaries within a novel environment. In our working model, motor-sensory integration is coupled with bouts of sustained attention to create a neural representation of space. We hypothesize that attentional shifts (reorientations) triggered by the pallium and habenula may be critical for timely activation of brainstem mechanisms for action selection and specification.

Title: Fruit flies use a spatial heuristic to navigate the environment

Authors: N. MEDA[1], G. M. MENTI[1], *A. MEGIGHIAN[1], M. A. ZORDAN[2];
[1]Biomed. Sci. and Padova Neurosci. Ctr., [2]Biol. and Padova Neurosci. Ctr., Univ. of Padova, Padova, Italy

Abstract: Animals rely on multiple sensory information systems to make decisions. However, strategies that shorten decision-making time by taking into account more essential elements of information are preferred to strategies involving complex analyses. These "shortcuts to decision" are also termed "heuristics". It remains unclear whether animals can apply the exact same heuristics that humans employ. The identification of heuristic principles in species phylogenetically distant to humans would shed light on the evolutionary origin of speed-accuracy trade-offs and offer the possibility to investigate the brain representations of such trade-offs. During experiments on spatial learning, we observed that the search strategies of the invertebrate *Drosophila melanogaster*, the common fruit fly, resembled a spatial heuristic. Single fruit flies (adult males, aged 6-10 days, n = 40) were trained to find relief from a negative stimulation (optogenetic bitter taste) in a square virtual area close to a visual marker. Every time the visual marker changed position, the animal faced a cue conflict regarding where the following negative stimulation could be stopped: either in the spatial location where it was last experienced or in proximity to the new visual marker. Here we show that fruit flies learn the visual marker – relief association. However, their first, fast and frugal strategy to find relief relies

on the “Nearest Neighbour Rule” heuristic. That is, the fly visits the salient location closest to its current position to hopefully stop the negative stimulation. Only if this strategy proves unsuccessful, the animal then uses other learned associations to avoid bitter taste. The acknowledgment of a heuristic in *D. melanogaster* supports the view that invertebrates can leverage ‘economic’ principles when making choices, and that the existence of heuristics in evolution dates to at least 600 million years ago, the estimated time of metazoan divergence.

Title: Spatial cognition in the cane toad (Rhinella marina)

Authors: *D. SHAYKEVICH, L. O'CONNELL;
Biol., Stanford Univ., Stanford, CA

Abstract: The field of spatial cognition continues to grow increasingly robust with the characterization of spatial coding in the brains of species across different classes of animals. Since the initial description of place cells in the rodent hippocampus in the 1970’s, scientists have been able to study neurons with similar functions in other mammals, birds, and fish. However, how space is encoded in the amphibian brain is unknown, leaving an incomplete understanding of how the neural structures supporting spatial coding evolve. We are using the cane toad (Rhinella marina), a common species in South America and a successful invader in many other parts of the world, to identify the brain regions and neural signatures of spatial cognition. We conducted field-based translocation studies of cane toads within their native range in French Guiana and found that toads can navigate back to their home range after being moved 500 m from their home range, suggesting advanced navigational abilities. As our field studies with wild toads do not allow us to disentangle motivation and experience in contributing to navigational abilities, we are conducting spatial behavior assays in the laboratory and have found that half of the toads tested can learn to find a goal location based on allocentric visual cues within a four-arm maze. We are using immunohistochemical detection of pS6 as a proxy for neural activity to test the hypothesis that the medial pallium, a putative homolog of the mammalian hippocampus, has more active neurons in toads that have learned the correct exit from the maze compared to toads that did not meet learning criteria. Finally, the anuran brain has

large movements within the skull, and as their movement involves hopping and jumping, in vivo recordings of neural activity in freely moving frogs is challenging. Here, we report on the use of mesh electronics to record neural activity from the amphibian brain in a way that allows for large brain movements within the skull. We are currently testing if there are cells that fire with respect to spatial or environmental features. This technology that allows neural recordings from freely moving amphibianas will also open the doors for many other research programs studying amphibian behavior.

Title: Spatial learning and memory in the naked mole-rat (Heterocephalus glaber)

Authors: *N. HITE[1], D. K. SARKO[2];
[2]Dept. of Anat., [1]Southern Illinois University, Sch. of Med., Carbondale, IL

Abstract: The Hebb-Williams maze is a behavioral paradigm that is commonly used to test the learning and spatial working memory capabilities of animal models. Mouse and laboratory rat species have proven to be particularly adept at navigating such a task, particularly when visual cues and effectively motivating rewards are presented. The naked mole-rat, a less common but increasingly utilized animal model, is a subterranean rodent that presumably has well-developed spatial learning and memory skills in order to thrive within its natural habitat of extensive underground burrows and tunnel systems. However, the spatial learning and memory capabilities of this species remain to be tested. In addition, for a species with sensory adaptations that greatly diverge from those of rats and mice, it is necessary to develop a maze design and set of motivators that are more customized to naked mole-rats in order to facilitate their successful completion of the maze task and to more accurately elicit a true representation of their spatial learning and memory capabilities. Using animals from our laboratory colonies, housed in a vivarium setting that mimics the tunnel systems that naked mole-rats would experience in the wild, we developed a behavioral paradigm aimed to effectively assess the spatial working memory of naked mole-rats, including analysis of learning curves associated with maze performance and testing of memory retention in subsequent weeks. Using a modified Hebb-Williams maze, adult naked mole-rats underwent three days of training, consisting of five trials per day wherein they were allowed to freely explore the maze in search of the reward chamber.

Memory retention was then tested one day, one week, and one month following the last day of training. Performance was analyzed based on latency to the reward chamber and the number of errors made prior to reaching the reward chamber. Overall, the goal of this study was to establish a behavioral paradigm for maze navigation in naked mole-rats, including optimization of rewards and environmental motivators in order to best assess spatial learning and memory in this species. Future studies are aimed at investigating changes in learning and memory that result from sensory plasticity.

Title: Environmental and procedural aspects that influence navigational strategy usage in a dual solution plus maze

Authors: *L. ANDREOLI[1], J. R. WICKENS[3], K. Z. TANAKA[2];
[2]Memory Res. Unit, [1]Okinawa Inst. of Sci. and Technol., Onna, Japan; [3]Neurobio. Res. Unit, OKINAWA INSTITUTE OF SCIENCE AND TECHNOLOGY, Onna-son, Japan

Abstract: Navigation is a fundamental behaviour for all animals, whether it is to find food, shelter, or a mate. It is thought to occur through three different processes: piloting, place strategy, and response strategy (Chersi, 2014 arXiv preprint arXiv). When animals follow a salient sensory cue which leads to a goal location, they are piloting. When the animal follows a flexible representation or a cognitive map of the space in which it is navigating, uses place strategy. Alternatively, animals use response strategy when they base their navigation in a sequence of actions to go to a specific place. It has been shown that both humans (Iaria et al, 2003 J Neurosci) and rodents (Packard et al, 1996 Neurobiol Learn Mem.) rely initially on place strategy and, after navigating several times in the same environment, start utilizing a more automatized response strategy. The dual-solution plus maze have been used to study the change in navigational strategy from place to response learning. In a plus-shaped maze, animals train to go from a South arm to West arm to get a reward. They can be probed after training from the opposite arm (North). Animals that undergo short training tend to use place strategy, and will

turn to the previously baited arm (West), making a different body turn than they did in training. After prolonged training, they tend to use response strategy, making the same body turn, and going to the previously non-baited arm (East). This project aims to elucidate environmental and training aspects that influence usage of place or response strategy. For that we trained animals in a protocol based on Wang et al. (2011 Neuron) in which they showed that majority of wild type mice displays place strategy with short training and response strategy for long training. We trained 11 mice (7 C57/BL6 and 4 pTRE-H2B-GFP) during short (5 sessions, 10 trials per session) and long training (10 sessions, 10 trials per session), to elicit place and response strategy, respectively. Although the animals learned the task (i.e., maintained performance above 70% for two consecutive days), all animals behaved as response learners during short training phase. We are currently testing which aspects (animal strain, number of trials per session, number of sessions, habituation process) can influence animals to behave as response learners after short training. With this work we hope to contribute to the understanding of how different training protocols and behavioural setups can influence usage of navigational strategy.

Title: TrkB antagonist ANA-12 decreases rats' use of place strategies in problem solving

Authors: *L. M. BUYNACK[1], J. A. WILLNER[2];
[1]Psychology, Concordia Univ., Montreal, QC, Canada; [2]Radford Univ., Radford, VA

Abstract: Brain-derived neurotrophic factor (BDNF) and its receptor, tropomyosin receptor kinase B (TrkB), are important not just for initial development of the nervous system, but also for synaptic plasticity in the adult nervous system. BDNF and TrkB play an important role in the cellular changes that mediate long-term potentiation (LTP) in hippocampus. Changes in BDNF and TrkB levels and expression in hippocampus are correlated with acquisition of place learning tasks that depend on this system. The present study examined the effects of ANA-12, a noncompetitive antagonist for TrkB, on rats' use of "place" and "response" strategies in an appetitive T-maze task that could be solved using either strategy. Male Long-Evans rats (75-120 days of age, N = 57) were initially handled, adapted to food restriction, and assigned to groups that received intraperitoneal injections of either 0.5 or 1.0 mg/kg ANA-12 in isotonic saline, or

saline alone 4 hours before each maze session. Rats were first adapted to the T-maze and allowed to explore and eat cereal reinforcers on the maze for two consecutive days (two 10 min sessions/day). The next day, the rats began reinforced training in which they were placed on the start arm of the maze and rewarded with a cereal reinforcer for choosing the goal arm opposite their initial side preference. The rats were trained to a criterion of 7 correct choices in 8 consecutive trials, with daily sessions of 20 training trials (1 min ITI). Training continued until a rat had reached criterion or received 4 days of training (80 trials), at which time it was dropped from the study. One minute after reaching criterion, the rat received a probe trial in which the maze was rotated 180° to pit place and response strategies against one another. The rat was placed on the maze and allowed 3 min to choose a goal arm; rats that went to the location where food was previously found were classified as using a place strategy, whereas those that made the same body turn as during training were classified as using a response strategy. Result show that administration of ANA-12 did not impair rats' ability to learn or perform the T-maze task; analysis of choice latencies and trials to criterion failed to reveal any significant between-groups differences during acquisition of the task. Significant differences were found on the probe trial, however, with ANA-12 decreasing rats' use of place strategies in a dose-dependent manner. These results support the idea that BDNF and TrkB are critical for place learning and memory.

Title: Novel measures of Morris water maze performance that use vector field maps to assess accuracy, uncertainty, and intention of navigational searches

Authors: *M. PRABOD KUMAR[1], D. MEHROTRA[1], N. N[1], D. ALMEIDA-FILHO[2], Y.-S. LEE[4], A. J. SILVA[3], B. JAYAPRAKASH[5];

Abstract: Most commonly used behavioural measures for testing learning and memory in the Morris water maze (MWM) involve comparisons of an animal's residence time in different quadrants of the pool. Such measures are limited in their ability to test different aspects of the animal's performance. Here, we describe novel measures of performance in the MWM that use vector fields to capture the motion of mice as well as their search pattern in the maze. Using these vector fields, we develop quantitative measures of performance that are intuitive and more sensitive than classical measures. First, we describe search patterns in terms of vector field properties and use these properties to define three metrics of spatial memory namely Spatial Accuracy, Uncertainty and, Intensity of Search. We demonstrate the usefulness of these measures using four different data sets including comparisons between different strains of mice, an analysis of two mouse models of Noonan syndrome (Ptpn11 D61G and Ptpn11 N308D/+), and a study of goal reversal training. Importantly, besides highlighting novel aspects of performance in this widely used spatial task, our measures were able to uncover previously undetected differences, including an animal model of Noonan syndrome, which we rescued with the mitogen activated protein kinase kinase (MEK) inhibitor SL327. Thus, our results show that our approach breaks down performance in the Morris water maze into sensitive measurable independent components that highlight differences in spatial learning and memory in the MWM that were undetected by conventional measures.

Title: Mice learn multi-step routes by memorizing subgoal locations

Authors: *P. SHAMASH, P. IORDANIDOU, T. BRANCO;
Sainsbury Wellcome Ctr., Univ. Col. London, London, United Kingdom

Abstract:

The behavioral strategies that mammals use to learn multi-step routes are unknown. Results from maze-learning protocols and open-field environments have emphasized two possibilities: the cognitive map (model-based) and taxon (model-free) strategies. However, it is unknown how well this dichotomy explains the rapid learning profiles and non-random exploration patterns that characterize spatial learning in natural settings. Here we investigated how mice develop efficient escape routes to a shelter when the direct path is blocked by an obstacle. Capitalizing on the robustness and intrinsic motivation of threat-evoked escape, we examined spatial learning in four ways: analysis of exploration and escape routes; comparison of 14 different arena geometries; dynamic reconfiguration of the arena; and acute manipulation of neural activity during exploration. We found that mice at first escaped inefficiently, running toward the shelter and negotiating the obstacle using sensory cues. Within twenty minutes, they developed a subgoal strategy: escaping directly to the obstacle edge before heading to the shelter. Mice continued to escape in this manner even after the obstacle was removed, indicating use of spatial memory. However, neither the taxon nor cognitive map theory could explain how subgoals were memorized. Instead, mice used a hybrid approach. As with an internal map, they achieved all-or-none learning of allocentric locations; but similar to model-free behavior, subgoals inflexibly persisted even after shortcuts opened up, and learning occurred during ‘practice runs’ rather than investigation. To test the hypothesis that running to obstacle edges during exploration generates subgoals, we used a closed-loop optogenetic manipulation; interrupting these movements by stimulating premotor cortex successfully prevented subgoal learning. These results suggest that subgoal memorization - i.e., learning allocentric subgoal locations during instinctive practice runs - is itself a fundamental strategy by which rodents compute multi-step routes in new environments.

Title: Innate heuristics and fast learning support flexible action selection during escape

Authors: *F. CLAUDI[1], D. CAMPAGNER[2], T. BRANCO[3];
[1]Sainsbury Wellcome Ctr. (UCL), London, United Kingdom; [2]Sainsbury Wellcome Centre, UCL, London, United Kingdom; [3]Sainsbury Wellcome Ctr., London, United Kingdom

Abstract: When faced with imminent danger, animals must rapidly take defensive actions to reach safety. In species such as mice, knowledge about the spatial environment is used to select appropriate defensive actions, as well as to plan and execute efficient flights. Natural environments often present multiple possible routes to refuges and to maximize survival the choice between them must be rapid and accurate (i.e., selecting the option with highest adaptive value). Relying on extensive trial-and-error learning would be maladaptive because errors could be deadly. Escape path selection thus poses a challenging learning and decision-making problem, and how animals solve this problem is not well understood.
In this work we have investigated how mice choose escape routes to a shelter when there are multiple possible paths of varying length and geometry. Using a series of new behavioural assays together with high-resolution quantification of behaviour and theoretical modelling, we find that mice integrate both direct and path distance to shelter to compute route choice. Furthermore, mice display this choice strategy upon the first encounter with threat after only a few minutes of exploration in a novel environment. This shows that the action selection process leverages rapidly acquired spatial knowledge and uses innate heuristics to assign value to different options. The combination of learned and innate knowledge leads mice to preferentially select escape paths that minimize threat exposure with minimal learning requirements, providing an evolutionary advantage. Comparing the behaviour of mice with the performance of different classes of reinforcement learning agents shows that only model-based agents endowed with innate heuristics can accurately replicate the animals' choice behaviour. This suggests that sophisticated learning and decision-making strategies underly innate escape path selection behaviour in mice.
Our results provide an entry point for understanding the mechanisms behind the unequalled

learning abilities of the mammalian nervous system, and how the brain integrates acquired and innate knowledge to generate decisions. They may also inspire the development of more efficient learning algorithms for artificial agents.

Title: Hippocampal signatures of avoidance of a moving object as revealed by immediate-early gene imaging

Authors: *J. SVOBODA, B. KRAJCOVIC, D. CERNOTOVA, N. AHUJA, S. KUBIK, A. STUCHLIK;
Inst. of Physiol. of the Czech Acad. of Sci., Praha, Czech Republic

Abstract: Animals can efficiently organize their spatial behavior with respect to other moving animals or objects but the underlying neural substrate is poorly understood. To model spatial interactions between an animal and moving object, we developed an aversive task in which a rat placed on a circular arena must avoid a 25cm distance from a small programmable robot to keep itself from a mild footshock. Our previous work showed that dorsal hippocampus plays a vital role in this process. Bilateral muscimol inactivations of the dorsal hippocampus impaired avoidance of a moving but not stable robot. In addition, unit recordings from CA3 found neurons responding to the mutual position of a rat and the robot. In the present experiment, we aimed at investigating the neural substrate in more detail using immediate-early gene imaging. Male Long Evans rats either underwent training to avoid a stable (S) or moving (M) robot in four 20-min daily sessions. On the last day, they either continued in this condition (SS group, MM group), or the condition changed (SM group, MS group). Control group remained in the cage on the last day (CG). Fifty minutes after the last session, rats were sacrificed and perfused. Brains were either stained for the presence of c-fos protein or the expression of other immediate-early genes, Homer1a and Arc, was determined using cellular compartment analysis of temporal activity by fluorescence in situ hybridization (catFISH). In all but the control group, we found increased c-fos activity in the dentate gyrus, followed by a less active CA1. Interestingly in CA3 and CA1, groups initially trained to avoid a mobile robot (MM, MS) displayed higher activity than groups trained with the stable robot (SS, SM), irrespective of the condition in the last day. These data

suggest that CA3 and CA1 plasticity may be related to experienced knowledge of the mobility of the robot. Detailed analysis of catFISH data is in progress.

Title: Orienting eye movements during REM sleep

Authors: *Y. SENZAI, M. SCANZIANI;
Univ. of California, San Francisco, San Francisco, CA

Abstract: REM sleep is accompanied by vivid visual dreams and characterized by rapid eye movements, from which this phase of sleep gets its acronym. It has been proposed that rapid eye movements during REM sleep represent orienting of the gaze in the virtual environment of dreams. While some behavioral studies in humans and animals support this hypothesis, other studies suggest that eye movements during REM sleep are simply the consequence of the random activation of the pontine nuclei. In order to address this controversy, we recorded from head direction (HD) cells in the anterodorsal thalamus (AD), a population of neurons whose activity reports the head direction of the animal. Previous work has shown that during REM sleep, the population activity of HD cells is similar to that during actual navigation, in that it maintains a coherent representation of HD, i.e. a “virtual HD”. Because fast eye movements are coupled to head movements during gaze shifts in awake freely moving animals, we hypothesized that during REM sleep rapid eye movements may predict changes in the virtual HD. To this end, we monitored eye movements during REM sleep while recording ensembles of HD cells from the AD. We trained a Bayesian decoder with the activity of HD cells to decode HD of mice navigating in the open field, and then applied the decoder to the spontaneous activity of HD cells during REM sleep to decode virtual HD. We focused our analysis on rapid eye movements occurring in isolation, i.e. separated by at least 400 ms intervals from preceding eye movements. We discovered that, during REM sleep, the direction of eye movements predicted the direction of the changes in virtual HD. Furthermore, the amplitude of rapid eye movements correlated with amplitude of changes in virtual HD. Importantly, such correlation between rapid eye movements

and virtual HD was similar to the relationship between fast saccade-like eye movements and HD representation in the AD of awake mice. This study provides the first physiological evidence that rapid eye movements represent gaze shifts in the virtual world during REM sleep.

Title: The neural correlates of spatial disorientation in head direction cells

Authors: *R. M. GRIEVES, M. SHINDER, L. ROSOW, M. S. STEVEN, J. S. TAUBE; Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Spatial disorientation is an experience that one does not easily forget. While the brain has likely evolved robust mechanisms to combat this affect, the neural underpinnings of these mechanisms are yet to be uncovered. To explore this, we monitored the activity of head-direction (HD) cells in the anterodorsal nucleus (ADN) of the thalamus under different conditions associated with disorientation: 1) while rats underwent uni- or bi-directional rotations in the light, or 2) while blindfolded, and 3) during passive restraint or while freely moving. We sought to determine if periods of presumed disorientation led to HD cell quiescence, random firing, or bursts of activity dissociated from HD. HD cells did not become quiescent in darkness or when animals were restrained suggesting that active locomotion and visual inputs are not necessary to drive HD cell activity. HD cells also continued to fire during rotations but average firing rates and burst frequency were reduced. Bursts during rotations were not associated with a particular HD, however, coherence remained high between co-recorded cells suggesting that the hypothesized attractor network remained intact but was decoupled from external stimuli. Peak firing rates and directionality (Rayleigh vector length) also decreased during rotation sessions, especially when rotations were fast, conducted in darkness, or while rats were passively restrained. Initially, HD cells maintained their directionality during rotations in darkness, however, with each revolution, tuning curves shifted in the direction of rotation, suggesting that the HD system was underestimating angular rotation. This result is consistent with the insensitivity of the vestibular system to accurately track constant unidirectional rotation. Lastly, after passive rotations in the dark, HD cells continued to fire in bursts and these bursts matched the frequency of rotation. This phenomenon is similar to post-rotational "nystagmus": the repetitive, oscillating movement of the eyes which occurs after sustained rotation and during

spatial disorientation. During rotations disorientation effects were reduced when visual cues were available, suggesting that while the generation of the HD signal is undoubtedly vestibular in origin, visual inputs provide a functional role in directional tuning. Thus, one of the ways the brain overcomes spatial disorientation is through multisensory integration of different inputs. These findings allow us to better understand not only the HD signal but also the systems of spatial orientation and navigation that subserve and depend upon it.

Title: Anesthesia disrupts Head Direction Cell activity in freely-moving rats.

Authors: *G. MUIR, I. AARRESTAD, H. CABASCO, N. WEITERMANN;
Psychology, St. Olaf Col., Northfield, MN

Abstract: Head direction (HD) cells in the rat provide navigational information by increasing their firing rates when the rat's head points a specific direction in the horizontal plane. Some evidence exists to show that during sleep, HD cells stop firing with such directional specificity, but maintain their firing relationships to each other consistent with an attractor network hypothesis. In this study, we investigated the effects of Isoflurane and Nembutal anesthesia on HD cell activity to see if these properties would be consistent by recording from HD cells while rats were 1) unconscious on a rotating platform, and as they woke up and recovered from anesthesia (Isoflurane), and 2) as they went from an awake to an unconscious state under anesthesia (Nembutal). Results showed that under both forms of anesthesia, HD cells cease to fire directionally and began firing tonically in all directions as the rat was rotated. Additionally, HD cells' average and peak firing rates significantly decreased while under anesthesia. In the moments before the rats regained consciousness, HD cells showed a dramatic increase in firing rate. Most HD cells quickly recovered their original directional tuning following the rats' initial movement post-anesthesia in the presence of a polarizing cue card, but adopted a random firing direction in the absence of the cue. Cells were, however, less directional, on average, while recovering from Isoflurane than during the preceding baseline trial. We suggest this inconsistency could result from continued effects of isoflurane or short recovery sampling times. These results show, for the first time, how HD cells behave under anesthesia, and invite further

comparison with HD cell activity across other unconscious states. In addition, these results may be interpreted as supporting intrinsic attractor network dynamics in the HD cell network.

Title: Prospective goal representation in monkey OFC during 3D virtual reality foraging

Authors: *M. WANG[1], B. Y. HAYDEN[2];
[1]NIH, Bethesda, MD; [2]Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: During natural foraging, animals exhibit goal-directed behavior to learn the structure of the environment and obtain reward. Prospective goal state representation and navigational planning are essential to this process. Although neural activities for route planning have been well-studied in hippocampus, the neural underpinnings for goal state encoding, which potentially informs route-planning and guide subsequent behavior, is still unknown. We hypothesized that goal simulation, i.e. reactivation of goal-related state in neural populations, is the key to use prospective goal representation to plan for subsequent action. We developed a 3D virtual reality foraging task to test this hypothesis. In this task, a jackpot reward is hidden at a random location in the virtual maze (goal location) for each session, while other maze configurations stay the same across all sessions. On each trial, the subject is teleported to another random location (start location) during the inter-trial interval. The subject then navigates through the virtual maze with a joystick to forage for the hidden jackpot reward. Subjects took significantly longer search time (from start to goal location) and less efficient travelled paths during pre-learning than during post-learning trials. We recorded large ensembles of OFC neurons (~55 units simultaneously/session) and found that: (1) OFC neurons showed mixed selectivity and encoded navigation and goal-related information, such as place, egocentric movement, allocentric moving direction, and relative relation between self and the goal. (2) Goal state representation was simulated right before the start of navigation and during navigation. (3) Goal-state simulation predicted subsequent goal-approaching behavior. (4) OFC goal state representation predicted learning. Together, we found that OFC showed neural signature of using goal simulation to guide behavior.

Univ., Seoul, Korea, Republic of

Abstract: Nanoscale imaging of biomolecules broadly facilitates biological findings. Various nanoscale imaging techniques for intracellular biomolecules in cells have been used and developed including super-resolution fluorescence microscopy (e.g. STED, STORM, and PALM), and electron microscopy accompanied by ultrathin sectioning or focused-ion beam (FIB) milling. However, current nanoscale imaging methods are still not widely used in typical biological laboratories, as high instrumental requirements, skilled personnel, or complicated sample preparation are needed. Herein, we demonstrate a new molecule-specific nanoscale imaging method based on scanning electron microscopy (SEM), termed DecoM (Development of silver on gold nanoparticles for correlative fluorescence and scanning electron Microscopy). In DecoM, secondary antibodies bearing both fluorophores and gold nanoparticles (AuNPs) are used to label target proteins, and in-situ silver development proceeds, followed by simple drying under ambient conditions. This simple sample procedure enables the imaging of labeled molecules with SEM at a resolution of 68 nm without any additional slicing technique, such as ultrathin sectioning using ultramicrotome or FIB milling. Multiplexed nanoscale imaging can be demonstrated by labeling two proteins with antibodies bearing different fluorophores and overlaying fluorescence microscopy and SEM images. Finally, we show DecoM to visualize the nanoscale changes in microtubules in cultured cells overexpressing microtubule-severing proteins, which are associated with multiple diseases. DecoM makes researchers who perform antibody staining routinely obtain molecule-specific nanoscale imaging in their study immediately.

Title: Picasso: ultra-multiplexed imaging of the brain through blind unmixing of spectrally overlapping fluorophores

Authors: *J. SEO[1], Y. SIM[3], J. KIM[2], H. KIM[1], I. CHO[1], Y.-G. YOON[2], J.-B. CHANG[1]; [1]Dept. of materials science and engineering, [2]Sch. of electrical engineering, Korea Advanced Inst. of Sci. and Technol., DAEJEON, Korea, Republic of; [3]Dept. of biomedical engineering, Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Fluorescence microscopy has been used as a useful tool for studying the spatial information, expression pattern, and molecular architecture of biomolecules in highly heterogeneous systems. However, its multiplexing capability is limited to 4-5 molecules due to the spectral overlap of fluorophores. To accomplish a much higher level in multiplexing with fluorescence microscopy, diverse techniques where spectrally overlapping fluorophores could be unmixed to their signals into each one have been developed. The reference-based unmixing (e.g., linear unmixing and spectral phasor) enables to unmix signals of spectrally overlapping fluorophores using preknowledge of fluorophores' emission spectra. However, particularly in highly organized specimens, precise measurements are challenging because emission spectra are possibly fluctuated by the degree of photobleaching, subregions of the specimen, and light scattering altered by the depth of the fluorophore. Therefore, the large volumetric imaging of more than 10 biomolecules has not been reported with reference-based unmixing. The non-reference-based unmixing (e.g., non-negative matrix factorization (NMF) and clustering-based unsupervised machine learning) has provided the unmixing without the preknowledge. NMF does not present a unique solution, so establishing human interventions and proper constraints are critical for multiplexed imaging. Moreover, NMF typically requires that the number of images (N) is sufficiently larger than the number of fluorophores (F) for reliable unmixing. Otherwise, the clustering-based unsupervised machine learning can achieve the unmixing, even if the N is fewer than the F. However, since it allocates each pixel into one of the multiple clusters results in zero-value in other clusters, it shows a low unmixing performance when

multiple biomolecules are spatially overlapped. Here, we propose PICASSO which can achieve more than 15-color multiplexed imaging without reference measurements through mutual information minimization. Even though PICASSO is a non-reference-based unmixing technique, it only requires that *N* is equal to *F*. Also, it presents a high unmixing performance even when it unmixes spatially overlapping biomolecules. We show diverse demonstrations of multiplexing *via* PICASSO including 3D and large area imaging, mRNA imaging, and FFPE sample imaging. We expect that PICASSO could be a helpful tool for mapping the spatial information or interactions of biomolecules and discovering new neuronal cell subtypes in a nervous system.

Title: FRACTAL: Multiplexed signal amplification of immunofluorescence via cyclic antibody staining

Authors: *H.-M. YEON[1], Y. CHO[1], J. SEO[1], Y. SIM[2], J. CHUNG[3], C. PARK[1], C. PARK[2], D. KIM[3], J.-B. CHANG[1];

Abstract: Amplification of immunofluorescent (IF) signal became an important issue in imaging field owing to its capability of high-resolution imaging of low-abundance target proteins and reducing imaging time for large-volume IF imaging. Also, simultaneous imaging of multiple markers is crucial for identifying the overall spatiotemporal distribution and relations of the target proteins. In this study, we demonstrate fluorescent signal amplification via cyclic staining of target molecules (FRACTAL), a technique that does not require custom optimization or repetitive activation and inactivation process for multiplexed imaging. FRACTAL only requires commercialized primary antibodies and secondary antibodies for IF signal amplification. We amplify the IF signals of cultured cells, clinical specimens, and tissue slices by more than nine-fold using only fluorophore-conjugated antibodies. We also show that cyclically applied secondary antibodies form uniform layers around a target protein using stochastic optical reconstruction microscopy (STORM) imaging. Theoretically, FRACTAL can be applied to the

multiplexed imaging if the cross-reactivity between the orthogonal secondary antibodies are eliminated. Here, we also demonstrate that simultaneous multiplexed signal amplification using FRACTAL is possible through simple antibody affinity purification process to prevent cross-reaction between the orthogonal secondary antibodies, using NHS-activated agarose gel spin column. The fluorescent signals of Lamin A/C, myelin basic protein (MBP), and glial fibrillary acidic protein (GFAP) in the mouse brain samples were amplified through simultaneous cyclic staining of purified secondary antibodies from six different host species, rabbit-donkey, rat-mouse, and chicken-goat pairs, respectively. We also show that multiplexed FRACTAL is compatible with protein-retention expansion microscopy (pro-ExM) technique and represents higher post-expansion fluorescent signal than that of the samples with conventional indirect IF staining. These results provide an effective shortcut for multiplexed signal amplified imaging of in-vivo target proteins of interest.

Abstract: An unbiased investigation of the entire organism at sub-cellular resolution is needed to understand neural systems from a systematic perspective[1]. The microbiota-gut-brain axis, for instance, full spatial coverage over the whole organism is essential for investigating different bidirectional communication paths between the central and the enteric nervous system. In contrast, a high spatial resolution is needed for elucidating the underlying molecular mechanisms of the effects of the microbiota on our brains and behavior[2]. Various imaging methods, including tissue clearing[3-5], computed tomography[6], and electron microscopy[7], have been utilized to visualize the anatomical structures of biological systems, but their resolution or throughput is not high enough for nanoscale imaging over multiple scales[6]. Here we present a whole-body super-resolution microscopy imaging technique, which can visualize anatomically relevant structures at a lateral resolution of 60-nm over the whole vertebrate model animal *via* non-specific labelling of proteins and expansion microscopy. Expansion microscopy is a super-resolution imaging technique of cultured cells and tissue slices and can achieve nanometer resolution with conventional microscopy through the physical expansion of specimens. Wholebody-ExM is based on expansion microscopy and functional-group-directed fluorescent labeling, which non-specifically labels proteins inside specimens with fluorophores without any target-specific labeling techniques. Using wholebody-ExM, we successfully visualized the major anatomical structures of vertebrates over the intact zebrafish larva and mouse embryo without any high-affinity antibodies, ultra-thin sectioning, and specialized instruments. We also demonstrated that wholebody-ExM retains the fluorescence signals of fluorescent proteins, and its resolution is high enough to visualize various structures that can be imaged only with electron microscopy. With these advantages, wholebody-ExM would be highly useful for studying transgenic lines showing anatomical abnormalities or studying the nanoscale neuro-morphological changes occurring in different brain developmental stages.

Title: Expansion microscopy of a single mixed synaptic contact reveals additional components of electrical synapses

Authors: *S. CARDENAS-GARCIA, S. IJAZ, A. E. PEREDA;
Albert Einstein Col. of Med., Bronx, NY

Abstract: Auditory afferents terminate as "Club endings" on the teleost Mauthner cells that contain specializations for electrical and chemical transmission. In 4-6 dpf larval zebrafish, these terminals are easily identifiable by immunolabeling with anti-connexin (Cx) antibodies as oval contact areas of about 2 microns in diameter. However, their size does not allow for visualization of the spatial distribution of various synaptic proteins within each terminal. For this purpose, we applied expansion microscopy, which allowed us to reveal the presence of, and the spatial relationship between, multiple synaptic components by immunolabeling. By using the proExM protocol, we are able to expand the diameter by up to 5x the original size of these terminals. Expansion with Cx and GLUR2/3 antibodies revealed that, while multiple gap junction (GJ) plaques are distributed throughout the entire contact area, a much smaller number of glutamatergic synapses are restricted to the periphery. Antibodies for the fish homologs of the mammalian Cx36, Cx35 and Cx 34, showed that they co-localize at each punctum, as GJs in club ending terminals are formed by heterotypic channels made by these proteins. Strikingly, expansion also increased the distance between pre- and postsynaptic sites, exposing the lack of co-localization between labeling for the presynaptic Cx35 and ZO1, the latter of which is a scaffolding protein restricted to the postsynaptic hemiplaque. Electron microscopy of these terminals (Kimmel et al., 1981) showed the presence of adherens junctions in the vicinity of GJs. Therefore, we explored their incidence and spatial distribution within the terminal using N-cadherin and Beta catenin antibodies, in combination with Cx labeling. N-cadherin labeling was distributed throughout the contact area and was mutually exclusive with Cx labeled puncta, suggesting a possible functional relationship between these two proteins and structures. Thus, our results indicate that an electrical synapse might operate with multiple GJs and include the contribution of additional structural components such as adherens junctions.

Matrisome is defined as the ensemble of ECM components and ECM-associated proteins. Alterations of the matrisome reflect the development of various diseases. However, it has not been well studied due to its insolubility and complexity. Brain tissue has a higher cell density and weaker mechanical strength than other tissues in the human body. When removing cells using a general decellularization method to produce scaffolds and obtain ECM proteins, various problems must be considered because tissues are easily damaged. In this study, we performed decellularization in combination with polymerization to retain the brain shape and ECM components. We immersed mouse brains in oil for polymerization and decellularization via CASPER (Clinically and Experimentally Applicable Acellular Tissue Scaffold Production for Tissue Engineering and Regenerative Medicine) and then isolated matrisome using sequential matrisome preparation reagents (SMPRs), namely, RIPA, PNGase F, and concanavalin A. Adult mouse brains were well preserved with our decellularization method. Western blot and LC-MS/MS analyses revealed that core matrisome proteins, including collagen and laminin, were isolated efficiently from decellularized adult mouse brains using SMPRs. Our method will be helpful to obtain matrisome data and perform functional studies using adult mouse brains and other tissues.

Title: A neurochemical atlas of the brain

Authors: *J. ARCHIBALD[1,4], E. L. MACMILLAN[2,5], J. L. K. KRAMER[3,4,6];
[1]Exptl. Med., [2]Radiology, [3]Anesthesiology, Pharmacol. and Therapeut., Univ. of British Columbia, Vancouver, BC, Canada; [4]Intl. Collaboration on Repair Discoveries, Vancouver, BC, Canada; [5]Philips Hlth. Canada, Vancouver, BC, Canada; [6]Djavad Mowafaghian Ctr. for Brain Hlth., Vancouver, BC, Canada

Abstract: Neurological conditions are a growing concern and evidence-based treatments represent a research priority. Central to these are advanced neurophysiological techniques, which are used to examine neurological conditions including neurodegenerative (e.g., Alzheimer's) and psychiatric conditions (e.g., schizophrenia). These approaches focus on function in terms of electrophysiology and blood flow. Yet measurement of neurochemicals via proton-magnetic resonance spectroscopy (^{1}H-MRS) provides a unique opportunity to evaluate neurochemicals, colloquially termed *The Virtual Biopsy.* Mapping neurochemicals in the brain is desirable, to gain insight into biochemical processes in health and disease. The cingulate cortex is involved in cognition functions (e.g., attention, processing, reward, processing of somatic sensations). Thus, it has become a popular technique to examine behaviour, function and clinical conditions. The distribution, typical ranges and variability of neurochemicals have not been examined making the decision of where to collect the data from challenging. To address this, we have performed a metabolic map of the cingulate cortex at 3T. Timing of the scan, food intake and menstrual cycle were standardized across participants. Preliminary results from five healthy participants (1f, age= 22.7 ± 5.5) show a coefficient of variation (CV) of 22% creatine, 7.4% glutamate, 10.3% NAA, across the cingulate gyrus between subjects. The CV for each metabolite was calculated within subjects across the different locations on the cingulate gyrus and ranged from 15.1-29.7% for creatine, 4.2-9.7% for glutamate, and 3.3-18% for NAA. These findings will be examined in a larger sample size, further analysis will examine sex differences and cortical thickness, as well as other neurochemicals. As MRS moves towards becoming a standardized technique, answering these questions will provide an important basis for understanding the human brain’s biochemical environment.

Title: Cerebrovascular Smooth Muscle Disease Causing ACTA2 Arginine 179 Pathogenic Variants disrupt Actin polymerization altering cell proliferation and migration.

Authors: *C. A. LUSK[1], C. L. LINO CARDENAS[2], S. K. MCCARTHY[1], C. G. BERGEN[1], M. E. LINDSAY[2], P. L. MUSOLINO[1];

Abstract: The ACTA2 gene encodes for alpha smooth muscle actin isotope 2 (α-SMA) which is preferentially expressed in vascular and visceral smooth muscle cells (SMC). ACTA2 Arginine 179 (Arg179) pathogenic variants cause multi-systemic smooth muscle dysfunction and childhood onset of cerebrovascular disease. Narrowing of cerebral vessels appears to be at expense of intima hyperplasia (SMC proliferation) that leads to white matter and arterial ischemic injury. Previous in-silico 3D modeling has suggested that ACTA2 Arg179 variants (Arg179H and Arg179C) may alter the polymerization of actin from Globular Actin (G-Actin) to Filamentous Actin (F-Actin) but to date no cellular, molecular or functional studies in human cells have been done to determine the underlying mechanisms of intima hyperplasia in ACTA2 Arg179 mutant cells. Here, we characterized ex-vivo control and patient-derived myofibroblasts through G/F Actin ratio quantification via western blot, determined changes in cytoskeletal assembly by high resolution immunofluorescent microscopy, and assessed migration and proliferative function in wound healing assays. Mutant cells showed a significantly higher ratio of G-Actin to F-Actin and an abnormal response to transforming growth factor beta (TGF-β) compared to controls. Through immunocytochemistry, we confirmed disruption of stress fibers and F-Actin associated with the accumulation of G-Actin in the cytoplasm. Moreover, wound healing assays showed that mutant cells close the gap sooner than controls by increasing their cell numbers rather than their migratory capacity. Our findings suggest a dominant negative effect of mutant protein on actin polymerization that leads to decreased migration and compensatory proliferation of smooth muscle cells. These deficits may underlie the intima proliferation associated with cerebrovascular disease and ischemic injury seen in ACTA2 Arg179 pathogenic variants. This ex-vivo model provides a robust molecular and functional phenotype for studying the underlying cellular mechanisms of ACTA2 Arg179 mutations and provides an opportunity to test potential therapeutic interventions in the future.

Title: Alteration of H3K9-acetylation in the mesocorticolimbic system after the development of cocaine sensitization

Authors: *D. CONSUEGRA GARCIA[1], C. CALO-GUADALUPE[1], K. Y. BOSQUE CORDERO[2], R. VAZQUEZ-TORRES[1], M. S. BRODIE[3], C. JIMENEZ-RIVERA[1];
[1]Univ. Of Puerto Rico Med. Sci. Campus, San Juan, PR; [2]Biol. Dept., Univ. of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico; [3]Dept Physiol & Biophys M/C901, Univ. Illinois-Chicago, Chicago, IL

Abstract: Addictive substances are known to induce changes in the brain's mesocorticolimbic system (MCL). The MCL is made of various structures which process pleasurable and reinforcing stimuli. Drugs of abuse cause long-term transcriptional changes, known to be produced by epigenetic modifications in the brain and contributing to the individual's vulnerability to develop addiction. Among the modifications that can change brain function by altering gene expression are histone post-translational modifications (PTMs). Histone acetylation, a type of PTM, is one of the most studied epigenetic modifications in the field of substance use disorder (SUD). One group of enzymes that control histone acetylation are histone deacetylases (HDACs), which regulate gene expression. Hyperpolarization activated cyclic nucleotide (HCN) channels are widely expressed in the MCL and are the molecular structure that is responsible for the expression of I_h current. Previous results from our laboratory demonstrated that cocaine behavioral sensitization, a non-contingent cocaine administration model, increased HCN2 subunit's expression in the ventral tegmental area (VTA), nucleus accumbens, prefrontal cortex (PFC) and hippocampus (HIP). We also demonstrated an I_h reduction in putative VTA DA neurons from cocaine-sensitized rats' concomitant to a decrease in surface expression of HCN2 subunits. Our preliminary data shows that I_h reduction can be reverted to baseline levels after in vitro incubation with an HDAC inhibitor (SAHA), indicating that histone acetylation is a major mechanism controlling HCN adaptation during cocaine sensitization. Our hypothesis is that acetylation profiles in other MCL structures are also altered by cocaine sensitization. Using the western blot technique, we investigated total protein concentration of H3K9-Ac, a histone modification marker, in MCL regions known to express I_h. Animals were sensitized for 7-days and 24-hours after the last cocaine injection were sacrificed and tissue punches of the PFC and HIP were collected. Densitometric analysis demonstrate that cocaine sensitized animals have a decrease H3K9-Ac expression in the PFC and HIP compared to saline controls. These results could indicate that cocaine sensitization causes alterations in histone modification in MCL structures that controls the expression of HCN and other neuroadaptations. Knowledge of epigenetic cocaine-induced changes in I_h within the MCL can ultimately identify new targets for the development of agents to treat SUD. Currently, CUT & TAG studies are being performed to view H3K9-Ac levels in gene promoters responsible for the modulation of HCN.

Title: Down-regulation of KCNQ3 in suicide: A post-mortem human brain proteomic study

Authors: *M. VELDIC[1], A. CABALLO-ARREOLA[2], M. HO[2], A. OZERDEM[2], A. B. CUELLAR-BARBOZA[3], M. U. KUCUKER[2], C. A. STOCKMEIER[4], G. RAJKOWSKA[4], M. A. FRYE[2], D.-S. CHOI[2];

Abstract: Introduction
Global rates of suicide are estimated at >800,000 annually. The dorsolateral prefrontal cortex (DLPFC) has been an important area of interest in suicide research due to evidence of morphometric changes and neurotransmitter abnormalities.
Objectives
We aimed to identify proteomic profile and biological pathways in the DLPFC of suicide victims employing mass spectrometry-based non-biased untargeted proteomics.
Methods
DLPFC from age-matched male mood disorder suicide cases (n=5) and non-suicide cases (n=5) were compared. Proteome was subjected to trypsin digestion and analyzed by liquid chromatography coupled to tandem mass spectrometry. Protein identification and quantitation was achieved using MaxQuant and in-house software. Proteins that differed between groups at false discovery rate (FDR) corrected *p*-values (Benjamini-Hochberg-Yekutieli) <0.3 and absolute log2 fold change (FC) >0.4 were considered statistically significant and were subjected to pathway analysis by Qiagen Ingenuity software. Validation of two proteins of the top canonical pathway was performed using Western blot.
Results

In the suicide cases, 33 of the 5644 detected proteins showed significantly altered expression. The top differentially expressed proteins were potassium voltage-gated channel subfamily Q member 3 (KCNQ3) (log_2 FC=-0.481, p=2.10E-09, FDR<0.001), metallo-beta-lactamase domain-containing protein 1 (MBLAC1) (log_2 FC=-1.011, p=1.16E-06, FDR=0.002), and tripartite motif containing 36 (TRIM36) (log_2 FC=0.614, p=2.31E-06, FDR=0.003). The top canonical pathway enriched was the GABA-receptor signaling (p<0.001). We validated the downregulation of KCNQ3 by Western blot (p=0.045).

Conclusions

Here we report for the first time a reduction in the levels of KCNQ3 in the DLPFC of suicide victims. Future studies with larger sample and equal gender representation are needed.

Title: Blood based protein biomarkers for the diagnosis and differentiation of acute stroke using a discovery based SWATH-MS proteomics approach: Results from the Discovery phase

Authors: *S. MISRA[1], P. SINGH[5], D. BHALLA[1], P. TALWAR[1], R. CHAKRABORTY[5], M. NATH[1], S. SENGUPTA[5], P. KUMAR[1], A. KUMAR[1], P. AGGARWAL[2], A. K. SRIVASTAVA[1], A. K. PANDIT[1], D. MOHANIA[3], A. GULATI[4], K. PRASAD[1,6], D. VIBHA[1]; [1]Neurol., [2]Emergency Med., [3]Dr. R.P. Ctr., [4]Clin. Epidemiology Unit, All India Inst. of Med. Sci., New Delhi, India; [5]CSIR-Institute of Genomics and Integrative Biol., New Delhi, India; [6]Neurol., Rajendra Inst. of Med. Sci., Ranchi, India

Abstract: Background: Rapid diagnosis of stroke and its subtypes is essential in early stages. Due to unavailability of neuroimaging in developing nations and time-sensitive nature of revascularization therapies, blood biomarkers are required to aid clinical decision making. Recent developments in high-throughput proteomics approach have shown potential to discover biomarkers for diagnosing acute stroke.

Objective: To determine blood based protein biomarkers for the diagnosis & differentiation of

ischemic stroke (IS) from healthy controls and intracerebral hemorrhage (ICH) within 24 hours of symptom onset using a discovery based SWATH-MS proteomics approach.
Methods: An ongoing diagnostic test study conducted at Department of Neurology, All India Institute of Medical Sciences, New Delhi, India. In the discovery phase, serum samples were collected within 24 hours from acute stroke (IS & ICH) patients & healthy controls and were subjected to SWATH-MS based untargeted proteomics. A spectral ion library for serum proteins was generated by analysing SCX fractionated tryptic peptides in data dependent mode and UniprotKB database was searched using Proteinpilot™ software 5.0.1 for SWATH analysis. Peak processing and area extraction was performed using SWATH 2.0 in PeakView 2.2 software at 1% peptide false discovery rate (FDR). Significant proteins were selected using the following criteria: >1.5 foldchange for upregulated, <0.67 for downregulated, p-value<0.05 and confirmed/tentative selection using Boruta random forest. Protein-protein interactions and pathway analysis were conducted using STRING version 11. Statistical analysis was conducted in R version 3.6.2.
Results: Our study included 80 subjects; 40 total stroke cases (20 IS, 20 ICH) within 24 hours of symptom onset [mean age: 50.4(10.38)] and 40 age, sex, hypertension and diabetes matched healthy controls [mean age: 49.64(10.64)]. Total 251 proteins were identified in Proteinpilot™ search with 5% global FDR. Through SWATH analysis, we quantified 210 proteins. In IS cases, 17 proteins compared to ICH and 12 proteins compared to healthy controls were significantly differentially expressed. Sixteen proteins were significantly differentially expressed in total stroke compared to control subjects. The network for 13 proteins was highly connected showing molecular interactions with other proteins with high confidence.
Conclusion: Our study identified potential protein biomarker candidates for the diagnosis and differentiation of acute stroke. These biomarkers will further be validated in a large sample to determine their diagnostic potential in the ongoing validation phase of the study.

Title: Screening more vs. less mutagenic targets among 129 kinases of the druggable genome

Authors: I. MCKNIGHT[1], R. RAINES[1], H. WHITE[1], ***J. SHIM**[2];
[1]Biomed. engineering, [2]Marshall Univ., Huntington, WV

Abstract: Aim: Several factors have been reported to be associated with high mutation rates, including recombination rate, proximity to a telomere [F(i)], and high adenine and thymine (A+T) content [F(ii)]. Among these factors, we have previously shown that F(i) and F(ii) can explain some of the genetic mutations linked to neurological disorders, such as congenital hydrocephalus. Here, we analyzed 129 kinases in the Druggable Genome if they meet these two aforementioned factors. **Methods**: A list of understudied proteins has been reported by *the Illuminating the Druggable Genome Project* (IDG) of the NIH. Among 390 understudied proteins associated with cancer and neurological disorders, we tested how many previously known genes match with (i) proximity to telomeres or (ii) high A+T content in 129 kinases. The genomic information was extracted using a genome data viewer. **Results**: Out of the 129 genes of the understudied druggable kinases we examined, 74% (95 of 129) were of sufficient proximity to their telomeres at less than 50 million bases (Mb). Roughly 25% (32 of 129) of the kinases contained A+T content higher than 59%, which is the human genome-wide average. Furthermore, 106 of 129 kinases (82%) satisfied either telomere proximity (F(i)) or high A+T content (F(ii)), while 23 of 129 genes (18%) met neither of the two factors. Thus, these 23 kinases have a relatively lessened chance of deleterious mutations. **Conclusion**: Our initial results reveal that 129 understudied kinases proposed as druggable proteins by the IDG are highly susceptible to germline or somatic mutations. This suggests that 82% of the listed druggable kinases (n=129) are prone to high mutation rate due primarily to their proximity to telomeres and/or nucleotide compositions and that 23 of 129 kinases (18%) are relatively less mutagenic as druggable targets.

Title: Genetically targeted proteomics identify compositional and phosphoproteome of corticostriatal axons across postnatal development

Authors: *V. DUMRONGPRECHACHAN[1,2], R. B. SALISBURY[3,4], L. BUTLER[1], M. L. MACDONALD[3,4], Y. KOZOROVITSKIY[1,2];
[1]Northwestern Univ., Evanston, IL; [2]Chem. of Life Processes Inst., Evanston, IL; [3]Univ. of Pittsburgh, Pittsburgh, PA; [4]Biomed. Mass Spectrometry Ctr., Pittsburgh, PA

Abstract: The basal ganglia (BG) process information from the cerebral cortex, thalamus, and limbic structures, essential for goal-directed behaviors including motor learning, action selection and habit formation. The striatum is the largest input to BG that receives diverse cortical and thalamic glutamatergic inputs. Innervating glutamatergic afferents form synapses onto dendritic spines of spiny projection neurons (SPNs), the output neurons of the striatum. Corticostriatal axon innervation begins in the embryonic stage and continues to develop postnatally in the rodent brain. Little is known about the molecular basis contributing to circuit formation including the innervating axon guidance systems, synapse formation, and their regulations. Abnormal development of striatal circuits has been implicated in the pathogenesis of many neurological disorders such as autism spectrum disorders (ASD) as well as Tourette's and obsessive-compulsive disorders. Studying the axonal proteomes of any neural system remains challenging. Axonal compartments are difficult to isolate. Suboptimal techniques such as fluorescent sorting of synaptosomes and axon growth cones require extensive tissue dissociation and result in loss of cell-type specific information. Here, we use a novel APEX2 reporter mouse line and proximity labeling proteomics to map compositional and phosphoproteome of corticostriatal axons across postnatal development.

Title: Characterizing alternative splicing in the hippocampus and cortex of the ENCODE4 mouse postnatal time course using bulk and single-nucleus long-read RNA-seq

Authors: *F. REESE[1,2], E. REBBOAH[1,2], B. A. WILLIAMS[3], H. LIANG[1,2], M. GANTUZ[1,2], B. J. WOLD[3], A. MORTAZAVI[2,1];
[1]Ctr. for Complex Biol. Systems, [2]Developmental and Cell Biol., Univ. of California, Irvine, Irvine, CA; [3]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Alternative isoforms that arise from alternative splicing as well as transcription start site (TSS) or transcription end site (TES) choice are known to play key roles during postnatal development especially in the brain, which is commonly known as the organ with the highest alternative splicing rates in humans. However, many of these isoform changes have been characterized using short-read sequencing techniques that were not comprehensive and did not probe the full length identity of each isoform. Furthermore, the cell-type specificity of these isoforms can be difficult to deconvolve from bulk or short-read single-cell data.
As a part of the 4th phase of the ENCODE Consortium, we collected hippocampus and cortex from male and female C57BL6J/Castaneus F1 hybrid mice at 8 postnatal timepoints (P4, P10, P14, P25, P36, P2mo, P8mo, P18-20mo). These samples were probed using multiple sequencing technologies within the consortium including DNase-seq, microRNA-seq, and RNA-seq. Notably, we sequenced these timepoints using bulk long-read RNA-seq as well as a form of single-cell long-read RNA-seq (LR-Split-seq). We are analyzing this full-length transcriptomic dataset in concert with the additional data modalities to characterize the landscape of alternative isoform usage as well as the regulatory influences such as haplotype, epigenetic state, and miRNA expression landscape that drive alternative isoform expression across tissues, timepoints, and cell types. We are also probing our long-read transcriptomes for genes that exhibit isoform, TSS, or TES switching across tissues, timepoints, and cell type. We are further querying our transcripts that have altered open reading frames or may be subject to nonsense-mediated decay with a specific focus on the genes that are found to display evidence of isoform switching.

Brain Sci., Seattle, WA

Abstract: The BRAIN Initiative Cell Census Network (BICCN) is a consortium of laboratories generating high value data to profile various phenotypic aspects of cell types in mouse, human, and non-human primate brain with a goal to generate, map, and share brain cell data with research communities. The Brain Cell Data Center (BCDC) organizes the diverse data, tools, and knowledge and provides public access to data and multimodal classification of cell types. The BCDC, as part of its mission, focuses on ensuring that data outputs of the consortium are made accessible and strives towards the FAIR data principles (findable, accessible, informative and reusable).
BICCN Data Inventory. BICCN projects and data collections are served to the public in the BICCN Data Inventory. This resource allows the community to find relevant datasets for their research. Metadata regarding specimens profiled in this effort are staged in a public repo prior to presentation on in the Data Inventory. This resource also points to data archive locations for high resolution data and protocols.
Ontology development. The BCDC maintains an ontology for relevant fields for metadata collection, including specimen types, techniques, and other relevant fields. The BCDC is incorporating the cell type ontology being developed for the BICCN and neuron phenotypes.
Research Resource IDs (RRIDs). The consortium has encouraged BICCN participants to register their research resource identifiers relevant to the consortium to improve the identification and citability of resources and support reuse.
Data and resource documentation. Through a coordinated effort with data-generating centers, data archives and analysis tools, the BICCN generated a multimodal cell census and a cell atlas of the mammalian primary motor cortex. The teams synthesized a holistic framework to define the cell type composition of neural circuits. These datasets and others are described with detailed information about projects and data collections in a searchable format, with links to data repositories and other relevant tools in our new searchable Project Summary pages.
FAIR Data Pipelines. The BCDC works with consortia members to transition processing pipelines used in publications to cloud native implementations publicly available in Terra. These pipelines are installed in a cloud and ready to use with documentation, test data sets and outputs. The pipelines support community standards including GA4GH data standards, RRIDs, use of standard workflow languages, open licensing, open source code (public GitHub repositories) and deposition in Dockstore (a community resource for bioinformatics workflows).

Title: Head to foot: the role of brain peptides in diabetic wound healing.

Authors: L. THURA[1], ***K. PHILIBERT**[3], X. SHAO[4], C. YANG[2], S. WU[1], M. J. GLUCKSMAN[4];
[1]Scholl Col. of Podiatric Medicine, Ctr. for Lower Extremity Ambulatory Res., [2]Midwest Proteome Ctr., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [3]Ctr. for Proteomics and Mol. Therapeutics., [4]Ctr. for Proteomics and Mol. Therapeut., Chicago Med. School/RFUMS, North Chicago, IL

Abstract: Diabetes mellitus is a metabolic disease accompanied by potentially debilitating complications creating major health problems for a significant population. Almost 20 million people worldwide develop diabetic foot ulcers (DFUs) annually that begin with peripheral neuropathy and susceptibility to wounds with accompanying inflammation. DFUs often exhibit impaired healing, placing patients at an increased risk of infection often progressing to lower limb amputation and increased morbidity and mortality. Biomarkers are utilized as an objective biologic measurement and evaluation of normal versus pathological biological processes. More specifically, we compare those diabetic patients who will heal with those who will not. Utilizing biochemical, genomic and proteomic approaches with clinical samples, we identify biomarkers of wound healing in DFU to allow improved clinical diagnosis, prognoses and targeted treatments by stratifying patient outcomes. We utilize a high throughput proteomics approach starting with patient serum from the wound site during debridement for the discovery phase. After immunodepletion of the 12 most common protein components in serum, there is a large-scale and high throughput separation by UPLC and mass spectrometry to quantify differences in patient groups. Lastly, the bioinformatics data handling, including meta-analyses of several of our studies is comprised of PEAKS data with transformation by Stata to gauge patterns in sampling or linkage in gene and protein pathways. Neuropeptides, such as neurotensin, and their enzymatic regulators, including neurolysin, as well as other proteins found in the nervous system have been implicated in the pathophysiology of diabetic foot wounds by virtue of neuropathic processes as well as the wound healing process from inflammation to migration/proliferation and

remodeling through wound closure. We enter the validation phase of identified biomarkers representing potential differences between diabetic healers and non-healers characterized by our multipronged workflow.

Title: Proteomic analysis of heat-stable proteins revealed an increased proportion of proteins with compositionally biased regions

Authors: *H. PARK[1], T. YAMANAKA[2], N. NUKINA[1];
[1]Lab. of Structural Neuropathology, Sch. of Brain Science, Doshisha Univ., Kyoto, Japan; [2]Dept. of Neurosci. of Dis., Brain Res. Institute, Niigata Univ., Niigata, Japan

Abstract: Intrinsically disordered proteins (IDPs) have been in the spotlight for their unique properties, such as their lack of secondary structures and low sequence complexity. Alpha-synuclein and tau are famous disease related IDPs with compositionally biased regions in their sequences, accumulating in the brains of patients with Parkinson disease and Alzheimer disease, respectively. Out of the various properties of known IDPs, their heat resistance in particular was what attracted our attention. We assumed that there exist many other unidentified proteins that are extremely resistant to heat, referred to as heat-stable proteins, which would also have low sequence complexity. In this study, we identified heat-stable proteins in the soluble fraction of mouse brains and found that most of the heat-stable proteins had low sequence complexity with biased amino acid composition. Found in abundance in human brains, IDPs can undergo different types of post-translational modifications (PTMs) leading to various human diseases. We then investigated the heat-stability and aggregation of phosphorylated synuclein and tau with different phosphorylation sites. We suggest that PTMs can be important factors that determine the heat-stability and aggregation property of a protein. Complete understanding of IDPs and their role in the pathogenesis of human diseases requires characterizing the features and properties of heat-stable proteins.

Title: Anodal Transcranial Direct Current Stimulation Affects Rat Cortex and Hippocampal Protein Expression in an Intensity-Dependent Manner

Authors: *S. H. JUNG[1,2], S. HARSHMAN[1], C. HATCHER-SOLIS[1], J. MARTIN[1];
[1]Cognitive Enhancement and Biodynamics, U.S. Air Force Res. Lab., Dayton, OH; [2]ORISE, Oak Ridge, TN

Abstract: Prevailing evidence indicates transcranial direct current stimulation (tDCS) affects learning and memory in a region specific and intensity-dependent manner, but the regulatory mechanisms remain unclear. Previously, we provided evidence that tDCS enhances memory consolidation by modifying plasticity-associated proteins in the hippocampus and genes in the cortex. Here, we examined the impact of tDCS current intensity on proteomes in the rat cortex and hippocampus. A single session of anodal tDCS was applied for 30 minutes (near bregma 0-5 mm) at the current intensity of 0, 250 or 500uA, and the brain regions were collected after 2 hours (n = 5/group). Synaptoneurosomes were isolated and bottom-up liquid chromatography mass spectrometry was used to profile proteomics. The Proteome Discoverer software was used to search proteomic data with a target false discovery rate of 0.05. The normalized data of about 3000 proteins were analyzed. Functional enrichment analysis showed unique and similar pathways and functions were significantly enriched by tDCS when compared between cortex and hippocampus. Protein-protein interaction and Ingenuity pathway analyses resulted in significant pathways and functions when compared between different current intensities and different brain regions. Canonical pathway analysis showed that synaptogenesis signaling pathway was significantly affected by tDCS in hippocampus but not cortex: p values for 250uA intensity of anode and cathode polarities and 500uA intensity of anode and cathode polarities are 4.19E-12, 3.07E-04, 0.0026, & 0.023, respectively. However, no statistical significance was detected from the cortex. Neuritogenesis function was significantly affected by anodal 250uA in both hippocampal (p = 1.95E-16) and cortical (p = 1.12E-05) and only cathodal 250uA in hippocampal (p = 7.51E-09) synaptosomes. We detected overlapping proteins that were significantly modified between the two different current intensities and brain regions that were examined. For example, NUBP1 was significantly decreased by anodal 250uA and 500uA in both hippocampal (p = 0.0419 & 0.0391) and cortical (p = 0.0021 & 0.0216) synapses. However,

only cortical synapse showed a significant change in the NUBP1 expression by cathodal tDCS. In conclusion, our data show similar tDCS-induced alterations in cortical and hippocampal synaptosomes across 2 different current intensities: especially beneficial effects by the 250uA current intensity. Thus, our data provide supporting evidence that tDCS-induced enhancement of cognitive performance may be associated with tDCS-induced modifications in cortical and hippocampal synaptosomes.

Title: Identifying epigenomic and transcriptomic alterations in human brain evolution at cellular resolution

Authors: *E. CAGLAYAN[1], F. AYHAN[2], T. M. PREUSS[4], S. YI[5], G. KONOPKA[3];
[1]UT Southwestern Neurosci. Grad. Program, Dallas, TX; [2]UT Southwestern Med. Ctr., Lewisville, TX; [3]UT Southwestern Med. Ctr., Dallas, TX; [4]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA; [5]Georgia Inst. of Technol., Atlanta, GA

Abstract: Human evolution is marked by an enlarged brain and increased cognitive ability. It is hypothesized that such traits must be genetically encoded, motivating decades of research to find human specific molecular traits linked to specific genetic modifications. Early approaches that compared humans to closely related species - primarily chimpanzees - showed that the majority of human specific molecular traits are likely caused by alterations in non-coding regions, leading to altered gene expression patterns. To understand both non-coding and gene expression patterns specific to humans at cellular resolution, we performed single-nuclei ATAC-seq (snATAC-seq) and single-nuclei RNA-seq (snRNA-seq) in human, chimpanzee and macaque adult cortex. This yielded ~73000 nuclei in snATAC-seq and ~150000 nuclei in snRNA-seq. We reproduced many previously identified neuronal subtypes and found certain neuronal subtypes to be more human specific than others indicating heterogeneity of human evolution at finer cellular resolution.

Through motif analysis on human specifically accessible regions, we were able to pinpoint human specific transcription factor activity for each cell type, including neuronal subtypes. We also found that human specific molecular features were more enriched in cognitive diseases compared to chimpanzees at the gene regulatory level and highlight certain cell types with increased disease enrichment. Taken together, our results demonstrate the epigenomic and transcriptomic features of human brain evolution and uncover their potential link with cognitive diseases at the cellular level.

Title: Tracing of cardiac, pulmonary and recurrent laryngeal fascicle groups in porcine vagus nerve to inform selective vagus nerve stimulation (SPARC)

Authors: *N. THOMPSON[1], E. RAVAGLI[1], S. MASTITSKAYA[1], F. IACOVIELLO[2], J. PERKINS[4], A. V. GOURINE[3], P. SHEARING[2], K. ARISTOVICH[1], D. HOLDER[1];
[1]Med. Physics and Biomed. Engin., [2]Chem. Engin., [3]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom; [4]The Royal Vet. Col., Hatfield, United Kingdom

Abstract: Vagus nerve stimulation (VNS), a promising treatment for numerous conditions, often results in off-target effects due to the unknown fascicular organisation of the cervical vagus nerve and thus nonspecific nature of stimulation. In this work, we determine the fascicular anatomical representation of the recurrent laryngeal, cardiac and pulmonary branches of the vagus nerve at the mid-cervical level of VNS cuff placement in the vagus nerve in pigs using micro-computed tomography (microCT).
The left vagus nerves of four domestic female 60-70 kg pigs were dissected from the cervical region to the branches of the target organs, fixed in neutral buffered formalin, sectioned into 4 cm lengths with appropriate landmarks for registration left in place and soaked in Lugol's solution (1% total iodine) for five days for sufficient contrast staining. For scanning, the sections of nerves were blotted dry, and placed in a 3D printed mount within the microCT scanner (Nikon XT H 225, Nikon Metrology). A molybdenum target was used and the scanning parameters for all scans were set to the following: 7 μm voxel size, 35 kVp energy, 114 μA current, 4 W power,

0.25 fps in 4 s exposure time, and 3176 projections. Scans were reconstructed in CT Pro 3D (Nikon Metrology) and analysed in ImageJ. Fascicles of the three target organs/fascicle groupings were segmented and traced with Neurolucida 360 (MBF Bioscience) from the point of branching to the mid-cervical level of the vagus (20-25 cm total length per nerve).
Three distinct regions, with minimal overlap only between a small number of pulmonary and recurrent laryngeal fascicles (~5%), were identified within the cross-section of the cervical vagus nerves with the three identified fascicular groupings remaining mostly discrete at the cervical level (~30%, 30% and 4% of total vagus nerve area for pulmonary, recurrent laryngeal and cardiac fascicle groups, respectively). The cardiac fascicle(s) remained completely separate from the other fascicular groups. This confirmed an organotopic organisation of the cervical vagus nerve according to organ/function when looking at these three fascicular groupings. Further studies are required to identify the organisation of the fascicles carrying information to the other organs innervated by the vagus nerve. Knowledge of the functional anatomical organisation of the vagus nerve will enable accurate selective VNS ultimately allowing for the avoidance of off-target effects and improving its overall therapeutic efficacy. Work in progress is to extend the approach to delineate the functional anatomy at the cervical level of excised vagus nerves of humans.

Title: Structural connectivity of the fore- and mid- brain in prairie voles

Authors: *K. R. GOSSMAN[1], B. DYKSTRA[1], K. TA[1], A. S. SMITH[2];
[2]Dept. of Pharmacol. & Toxicology, [1]Univ. of Kansas, Lawrence, KS

Abstract: Structural Connectivity of the Fore- and Mid- Brain in Prairie Voles
Kyle R. Gossman, Benjamin Dykstra, Kyle Ta, & Adam S. Smith.
Department of Pharmacology and Toxicology, University of Kansas, Lawrence, KS, USA
The socially monogamous prairie vole (Microtus ochrogaster) has been used for three decades to study the neurobiology of pair bonding. This has led to well-defined behavioral characterization

of partner affiliation and stranger aggression influences by particular neurochemicals and certain brain regions. However, limited knowledge is known about the overall neural circuity and interregional connections of vole brain. Neuroanatomical tracing methods remain fundamental for elucidating the complexity of brain circuits. Here in the present study, we used the highly gregarious prairie vole and cholera toxin subunit-B retrograde tracers (488nm, 555nm, 594nm, and 647nm) to map out the ipsilateral and contralateral fore- and mid- brain physical connections of the regions associated with the Social Decision-Making Network (SDMN) with the addition of the paraventricular nucleus of the hypothalamus (PVN) and the anterior cingulate cortex (ACC). In addition to limited work, these results will significantly expand our knowledge of the neural circuity of the vole brain and act as a guide for interregional connections for future research.

Title: Long range axonal projections of individual neurons in mouse layer 2/3 barrel cortex

Authors: *Y. LIU[1], G. FOUSTOUKOS[1], S. CROCHET[2], C. C. PETERSEN[3];
[1]École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; [2]EPFL, Lausanne, Switzerland; [3]École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: Neurons primarily communicate through release of neurotransmitter from presynaptic specialisations along their axonal arborisations. To understand the functional role of a specific neuron, it is thus important to know the structure of its axon. In particular, long-range axonal projections are thought to be important for communication between different brain regions. The mouse whisker system provides unique opportunities to investigate structure function relationships in the mammalian neocortex. The whisker primary somatosensory cortex (wS1) of mice contains a somatotopic map such that each whisker on the snout is individually represented by an anatomically-defined ‘barrel’. Each barrel column in wS1 primarily processes tactile sensory information from its homologous whisker. However, pyramidal neurons in wS1 signal information to many downstream targets, and even a single whisker deflection can evoke sensory signals across many brain areas. Here, in order to examine the structure of individual neurons, we used *in vivo* single-cell electroporation to express green fluorescent protein in layer 2/3 pyramidal neurons in wS1. After several days of expression, the mouse brains were fixed,

incubated in modified Cubic solutions, embedded in agarose, and then imaged using a two-photon tomographic microscope (Ragan et al., Nat Methods 2012). Semi-automated tracing of axons, allowed three-dimensional reconstruction of dendritic and axonal arborisations. Finally, registering the brain volume and the annotated morphology with the Allen Institute's Reference Atlas provided precise identification of long-range axonal targets (Han et al., Nature 2018). Although we were able to trace extensive axonal projections using this methodology, the signal-to-noise ratio was limited, likely giving rise to incomplete reconstructions. Our next goal is to obtain more complete axonal morphologies using iDISCO (Renier et al., Cell 2014), involving tissue clearing, immunolabelling and imaging with light sheet microscopy. (The first two authors contributed equally to this work)

Title: Posteromedial cortex projections to the striatum in the macaque

Authors: *M. MONKO, S. R. HEILBRONNER;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The Posteromedial Cortex (PMC), comprised of the posterior cingulate, retrosplenial cortex, and the precuneus, make up the posterior hub of the default mode network. Abnormal connectivity of the default mode network has been seen in a wide variety of psychiatric diseases. We are interested in how the interactions of the PMC with decision-making circuitry. To investigate this, we use a combination of tract tracing techniques and high-field resting-state fMRI in macaques. We examined the topography of the PMC to the striatum using bidirectional tract-tracers injected into the PMC. The resulting striatal terminal fields were charted and subsequently transformed into a 3D model registered to an MRI-generated reference space. These PMC-striatal cases were compared with other corticostriatal cases that have been implicated in decision-making. We also analyzed the functional connectivity of the PMC and striatum and compared this against our anatomical tracings. The PMC projects primarily, but not

exclusively, to the dorsomedial striatum, sharing striatal territory with prefrontal terminal fields involved in goal-directed decision making. These results contribute to growing literature about the involvement of the PMC in decision-making, as well as examining the relationship between anatomical and functional connectivity of corticostriatal circuitry.

Title: Implementation of a Novel Intersectional Viral Tracing Technique to Characterize Ventral Tegmental Area Dopamine Projection Neurons of the Olfactory Tubercle

Authors: *R. C. PAULY[1], J. PARK[1], R. V. BHIMANI[2], C. E. BASS[3];
[1]Biotechnical and Clin. Lab. Sci., [2]Neurosci., [3]Pharmacol. and Toxicology, Univ. at Buffalo, Buffalo, NY

Abstract: Ventral Tegmental Area (VTA)-dopamine(DA) innervation of the ventral striatum, the nucleus accumbens (NAc), and olfactory tubercle (OT), is known to play a critical role in reward/aversion processes as well as drug addiction. While the majority of studies have focused on the anatomical connections between the VTA and NAc, very little is known about VTA-DA projections to the OT despite it receiving some of the densest DA in the brain. Furthermore, recent reports have highlighted that similar to the NAc, the OT is compartmentalized into different subdivisions that have distinct roles in reward learning and addiction. In this study, we integrated a novel intersectional viral targeting approach in wild-type rats to restrict Red Fluorescent Protein (RFP) transgene expression to VTA-DA-OT projection neurons to selectively determine the density and distribution of VTA-DA projection neurons to the medial (m) and lateral (l) OT. This approach has distinct advantages over traditional tracing techniques by allowing for selective determination of projections based on neuronal phenotype. Expression of effector virus infused in the VTA encoding RFP in a Double Inverted Open (DIO) reading frame is dependent upon co-administration of retrograde targeting virus infused in the OT encoding a Cre recombinase, floxing the RFP sequence after selectively transfecting VTA-DA cell bodies. Thus RFP expression is confined to VTA-DA-OT neurons quantitatively measured through immunohistochemistry. Viral selectivity was also confirmed through immunofluorescence verification of TH and RFP co-expression in the VTA. Our findings highlight dense VTA-DA innervation of the *m*OT relative to the *l*OT through quantitative

measurements of VTA projection neurons. Through anatomical and neurochemical evidence, our data display that dense VTA-DA innervation of the *m*OT plays a key role in encoding reward and addiction.

Title: Collateral network of corticospinal neurons projecting to thoracic/lumbar spinal cord mapped by light-sheet microscopy and retrograde AAV vector

Authors: *T. LU[1], M. SHINOZAKI[1], N. NAGOSHI[2], M. NAKAMURA[2], H. OKANO[1];
[1]Dept. of Physiol., [2]Dept. of Orthopaedic Surgery, Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Thoracic spinal cord injury (SCI) in adult mice leads to damage of hindlimb function. Our previous studies have achieved certainly hindlimb function recovery in subacute phase of 10th thoracic (T10) SCI models by using induced pluripotent stem cell-derived neural stem/progenitor cells (iPSC-NS/PCs) therapy. However, neural circuits of the supraspinal neurons projecting to rostral and caudal sites of T10 level in intact rodents are still unclear, due to lacking effective neural tracing technology and global connectivity of brain-spinal inputs. Here, we found the distinct location of descending pathway (corticospinal tracts, rubrospinal tracts, and reticulospinal tracts) projecting to the 9th thoracic (T9) and lumbar enlargement (T13) in intact mice using retrograde AAV vector. Mapping of these neurons revealed the broader cortex area of corticospinal neurons (CSNs) projecting to T9 compared to T13. Interestingly, we noticed some double-labeled CSNs from T9 and T13, suggesting that they projected both to the lower thoracic spinal cord and to the lumbar enlargement. AAV2-Retro is known in targeting projection neurons through uptake at axonal terminals and retrograde transport of their payload to the cellular nuclei. However, little is known about axon collateral network of CSNs projecting to precise spinal segment. Using FLEX system, we revealed complex axon collateral network of labeled CSNs project to T9/T13 distributed in brain and spinal cord. Using tissue clearing and light-sheet microscopy we presented the global brain-spinal map of axon collaterals originating from these CSNs. Together, these findings revealed a new neuroanatomic insight in the collateral network of the descending pathway project to thoracic and lumbar enlargement, which would provide a new therapeutic targeting on functional recovery of hindlimbs after SCI.

Title: Monosynaptic anterograde circuit tracing with vesicular stomatitis virus (VSV) vectors

Authors: *X. MA[1], C. L. CEPKO[2];
[1]Harvard Med. Sch., Boston, MA; [2]Harvard Med. Sch/HHMI, Boston, MA

Abstract: A map of the connectivity patterns of the nervous system is fundamental to our understanding of the principles underlying normal function, as well as disorders. Previously, we developed the vesicular stomatitis virus (VSV) as a polysynaptic anterograde circuit tracer in a wide range of organisms (Beier et al., 2011; Mundell et al., 2015). For greater interpretability, we wished to develop monosynaptic anterograde VSV tracers (VSVdG). To achieve this, we have needed to overcome several challenges, including toxicity of the VSV glycoprotein (G), toxicity of viral replication, and innate immune system inhibition of VSV replication. First, to alleviate G protein toxicity, G is delivered by an AAV, and its expression is controlled by by Cre or Flp encoded by VSVdG. This prevents the fusion-active G protein from killing the AAV infected cells before trans-synaptic spread occurs. Second, we use a VSV vector encoding a mutant VSV matrix protein (Md) to avoid host cell transcription shut off, usually carried out by wild type M. Although this eliminates some of the toxicity of viral replication, the VSVdG-Md loses the ability to block the expression of interferons and several other cytokines, which inhibit VSV replication. Therefore, the third adaptation is to deliver a gene that encodes an inhibitor of cytokine signaling, encoded by another AAV, which is delivered at the same time as AAV-VSVG. Fourth, an immune-deficient strain of mice was found to be essential for efficient transsynaptic spread. Combining these four adaptations, the efficiency of this strategy was evaluated in the circuitry of the basal ganglia of mice. AAV and VSVdG were injected into the striatum, and VSVdG was observed to spread efficiently to a distant anterograde target, the substantia nigra (SN).

Title: Cell-type specific viruses transduce oxytocin and vasopressin neurons more effectively than ubiquitous promoters in mice and rats

Authors: *A. LEITHEAD[1], K. THIRTAMARA RAJAMANI[1], M. BARBIER[1], M. KIM[1], M. PERUGGIA[1], A. LEFEVRE[2], L. BARTECZKO[2], V. GRINEVICH[2], H. HARONY-NICOLAS[1]; [1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]German Cancer Res. Ctr., Heidelberg, Germany

Abstract: Recent technological advances in viral vectors and the development of transgenic rodent models have allowed for targeted gene expression to study the functions of specific cell populations and brain circuits. Studies concerning the hypothalamic oxytocin (OXT) and arginine-vasopressin (AVP) systems have begun to utilize these advanced methods to further characterize their roles across a range of physiological and behavioral functions. However, the efficacy of widely used viral constructs has not yet been systematically evaluated in these neural populations. Here, we injected viral vectors of different promoter and serotype combinations into the paraventricular nucleus of the hypothalamus in rats and mice then performed immunohistochemistry to determine specificity. We found that (1) ubiquitous promoters were not, on their own, effective at driving expression of a down-stream fluorescent protein in OXT or AVP neurons, (2) the OXT promoter efficiently drove gene expression in OXT neurons and this efficiency was attributable to the promoter and not the viral serotype, and (3) using a Cre recombinase-dependent system, in combination with a virus that expresses Cre recombinase under the control of OXT promoter, significantly improved the efficiency of viral transduction in OXT neurons. Finally, we demonstrate the utility of the OXT promoter for conducting circuit tracing studies to identify inputs to OXT neurons in mice by using a novel modified rabies virus system with specificity to OXT neurons. We conclude that extreme caution is needed when employing non-neuron-specific viral approaches/promoters to study neural populations within the hypothalamus.

Abstract: Techniques for directional tracing of neural circuits will propel our understanding of the organization and function of the brain. We adapted trans-Tango, a powerful genetic approach for anterograde circuit tracing in Drosophila, to a vertebrate nervous system, that of zebrafish. trans-Tango involves a synthetic signaling pathway introduced into all neurons. Specificity comes from genetically defined neurons presenting a tethered ligand at the synapse. Binding of ligand to a G protein-coupled receptor activates the pathway in post-synaptic neurons, resulting in recruitment of an arrestin-protease fusion protein, site-specific proteolysis of the receptor, and release of the QF transcription factor allowing its translocation to the nucleus. There QF binds to upstream regulatory sequences (QUAS) to drive expression of genes such as fluorescent reporters, which label and identify post-synaptic cells. The trans-Tango components were modified for zebrafish by placing receptor and arrestin fusion protein constructs downstream of the elavl3 promoter in Tol2 transposition vectors. Ligand variants differing in their pre-synaptic targeting sequences were also cloned into Tol2 plasmids under control of the Gal4 transcription factor. To test functionality, plasmids encoding ligand, receptor and arrestin, as well as Tol2 transposase RNA, were co-injected into 1-cell stage embryos, the progeny of a Gal4 driver that promotes strong expression of Tg(UAS:GFP) in the hindbrain mated with the Tg(QUAS:mApple-CAAX) reporter. Confocal imaging revealed GFP labeled axon terminals closely apposed to mApple labeled neurons, suggesting that trans-Tango is effective in transient expression assays. With such assays, we determined the optimal ligand for activating the receptor in post-synaptic neurons without off-target labeling. We are currently characterizing trans-synaptic labeling in stable transgenic lines with verified expression of trans-Tango components. We are also using optogenetics and calcium imaging to confirm that identified connections are functional synapses and developing a related configuration for retrograde circuit tracing. This work lays the foundation for mapping neural connectivity in vivo for both invertebrate and vertebrate nervous systems.

Title: Axonal Barseq, Novel Technique for High-Throughput Mapping Single-Cell Projections in Situ

Authors: *L. YUAN, X. CHEN, A. M. ZADOR;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Neurons are heterogenous and assembled into complicated circuits in the brain. To understand the underlying structure of circuits, it is essential to understand the long-range connectivity of neurons. However, neuronal processes are thin and intertwined, which presents a technical challenge for reconstructing long-range axons optically for large numbers of neurons. We previously developed BARseq to map long-range projections with high throughput and cellular resolution (Chen et al, 2019, Cell, 179: 772-786). In BARseq, each neuron is labeled with a unique RNA barcode that replicates and fills up the neuron. Barcodes in somas are sequenced *in situ* and matched to barcodes in potential projection target areas to reveal the projections. The target areas, however, are resolved by manual dissection, thus limiting the ability of BARseq to resolve projections to fine divisions in brain areas. Here we overcome this limitation by axonal BARseq, which uses *in situ* sequencing to resolve the barcodes in the axons. As a proof of principle, we mapped the projections of thousands of neurons in 2 mm area of mouse primary auditory cortex. We identified major cell types using projection targets and axonal trajectory. Moreover, axonal BARseq identified two clusters of intratelencephalic neurons with different soma and axonal lamina patterns. Thus, axonal BARseq is a promising technique for high-throughput mapping of long-range projections at high spatial resolution and single cell resolution.

Title: A computational platform for extracting and reconstructing images of single neurons in 3D from multi-colour labelled populations in iDISCO cleared brains

Authors: *N. MILOSAVLJEVIC[1], C. A. PROCYK[2], J. ROGERS[3], E. ZINDY[4], R. J. LUCAS[3];
[1]The Univ. of Manchester, Manchester, United Kingdom; [2]King's Col. London, London, United Kingdom; [3]Univ. of Manchester, Manchester, United Kingdom; [4]Ctr. for Microscopy and Mol. Imaging (CMMI), Gosselies, Belgium

Abstract: A fundamental aim in biology is to describe the morphology and connections of individual cells within tissue ensembles. Multi-reporter labelling technologies, such as Brainbow, apply stochastic expression of several fluorescent proteins to allow visualization of cell populations with single-cell resolution. However, extending this approach to generating objective quantification of anatomical features is more difficult and has to a large extent awaited the development of analysis platforms capable of extracting images of single cells in 3D. The main challenge of Brainbow method is the currently unavoidable variation in recorded fluorescence intensity (‘pseudo-colour variability’) within individual neurons making it challenging to trace and reconstruct individual cells with currently available tools. We present a computational platform - BRIAN (BraInbow Analysis of individual Neurons) that allows objective identification of voxels clusters, and their subsequent extraction to produce 3D images of single neurons. We show that BRIAN allows multi-reporter samples to be analysed using existing tracing technology (Filament Tracer, Imaris), to efficiently recreate single neurons. We show the successful application of BRIAN to retinal tissue by reconstructing individual cells (intrinsically photosensitive retinal ganglion cells, ipRGCs, and depolarizing ON bipolar cells) in densely labelled tissue with sufficient anatomical resolution for sub-type classification. Moreover, we demonstrate the successful application of BRIAN in Brainbow labelled brain

tissue to describe dendritic projections in the suprachiasmatic nucleus (SCN). Finally, we combine Brainbow and iDISCO tissue-clearing with immunohistochemistry to image large volumes of a mouse brain (1/4 mm^3), and again demonstrate successful application of BRIAN to trace individual axonal projections over large brain volumes.

Title: Whole brain imaging of neuronal projections using viral-mediated transfection and HaloTag bioorthogonal labeling

Authors: *M. N. BEDENBAUGH[1], J. R. LUCHSINGER[1], B. J. REISMAN[2], C. WANG[3], D. G. WINDER[4], R. B. SIMERLY[5];
[1]Mol. Physiol. and Biophysics, [2]Chem., [3]Vanderbilt Brain Inst., [5]Mol. Physiol. & Biophysics, [4]Vanderbilt Univ., Nashville, TN

Abstract: Axonal projections of specific neuronal populations define the anatomical and functional characteristics of a circuit. Typically, confocal microscopy of thin tissue sections has been used to visualize terminal fields. However, this approach only allows for a handful of selected tissue sections to be analyzed. Imaging axonal projections in whole brains using tissue clearing and light sheet microscopy would allow for better spatial and temporal resolution of intact neural circuits. The use of genetically encoded fluorescent proteins to label cell bodies in cleared brains exhibits bright labeling and excellent signal to noise ratios. However, capturing synaptic terminals is significantly more challenging. Using synthetic dyes that are brighter and more resistant to photobleaching compared to traditional fluorophores may offer a solution. Thus, we decided to use a bio-orthogonal approach to label regionally and genetically restricted synaptic terminals using click chemistry. To do this, HaloTag, a self-labeling protein, was tagged to synaptophysin and loaded into a viral construct (AAVDJ.hSyn.DIO.Synaptophysin:HaloTag). The bed nucleus of the stria terminalis (BST) was targeted in Corticotropin Releasing Factor (CRF)-Cre or Melanocortin 3 Receptor (MC3R)-Cre mice. The synthetic dyes, JF669-HTL or

JF635-HTL dye were dissolved in paraformaldehyde solution used for perfusion (669 and 635) or retro-orbitally injected (669) the day prior to tissue collection. These dyes readily labeled synaptophysin-HaloTag in specific brain regions via both delivery methods, and axonal projections were easily identified even at low magnification in whole brain tissue. As expected, prominent synaptic terminal labeling was observed in several distinct regions of the amygdala and hypothalamus that are known to be targeted by CRF and MC3R BST neuronal populations. Altogether, we demonstrate the utility of these tools and this approach to visualize axonal projections of relevant cell populations in an unbiased manner in intact, whole brain tissue.

Title: Modular organization of the Medial-Frontal Parietal Network in cognitively normal older adults and its relationship with episodic memory

Authors: *A. RIVERA-DOMPENCIEL[1], S. JAIN[1], C. OEHLER[1], V. MAGNOTTA[1], C. BASAK[3], H. LEE[4], M. VOSS[2];
[2]Dept. of Psychological and Brain Sci., [1]Univ. of Iowa, Iowa City, IA; [3]The Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX; [4]Posit Science, Inc., San Francisco, CA

Abstract: Normal aging entails highly variable cognitive, structural, and functional changes that could lead to pathological decline, such as that caused by Alzheimer's Disease. Episodic memory (EM), a cognitive function that critically depends on hippocampal-cortical interactions, is especially vulnerable to brain aging. The hippocampus is considered part of the Medial-Frontal Parietal Network (M-FPN, also known as the Default Mode Network), which is a functional brain network not only associated with EM processes, but also known to show functional connectivity (fc) alterations in normal and pathological aging as shown by resting state functional connectivity (rs-fc) magnetic resonance imaging. Leading neuroimaging frameworks for the M-FPN propose it to be comprised of three functionally distinct subnetworks. The *Schaefer parcellation* (Schaefer et al., 2018), further divides these three subnetworks into a set of

non-overlapping sections or parcels. However, because the M-FPN displays heterogeneous aging effects, whether the parcellations remain in the same functional groupings in cognitively normal older adults is not well characterized. The aim of this research is to understand the functional organization of the M-FPN in normal aging through modularity, a graph theory metric that can determine how regions or parcellations of a network are segregated into non-overlapping groups or modules. Specifically, we first developed data-driven modules (using the Schaefer parcels of the M-FPN) derived from rs-fc of cognitively normal older adults (OA; N=148, mean age=66.9±5.8) and used the normalized variation of information (VIn) as a metric of module dissimilarity. Results revealed a significant difference between the M-FPN modular organization of individuals from the OA sample and the Schaefer M-FPN parcellation (VIn mean=0.463±0.04, $t(147)=126$, $p<0.001$), suggesting normal aging influences the modular structure of the M-FPN. However, there were also significant differences between the M-FPN modular organization of individuals and that of the group average. Follow-up analyses will test the stability of the modular organization of the M-FPN in an independent OA group (N=71, mean age=71.5±4.7) and test whether individual differences in modular structure are related to EM performance. This project helps characterize the organization and stability of M-FPN subnetworks and their parcellations, as well as the relevance to EM, in cognitively normal older adults.

Title: A control-theoretical system for modulating hippocampal gamma oscillations using stimulation of the posterior cingulate cortex

Authors: *D. X. WANG[1], I. Y. MELIANE[2], M. RITZER[2], R. MORAN[3], C. E. DAVILA[1], B. C. LEGA[2];
[1]Electrical and Computer Engin., Southern Methodist Univ., Dallas, TX; [2]Neurosurg., UT Southwestern Med. Ctr., Dallas, TX; [3]Dept. of Neuroimaging, Inst. of Psychiatry, Psychology & Neuroscience, King's Col. London, London, United Kingdom

Abstract: Closed-loop stimulation for targeted modulation of brain signals has emerged as a promising strategy for episodic memory restoration. In parallel, closed-loop neuromodulation strategies have been applied to treat brain conditions including drug-resistant depression, Parkinson's Disease, and epilepsy. In this study, we seek to apply control theoretical principles to achieve closed loop modulation of hippocampal oscillatory activity. We focus on hippocampal gamma power, a signal with an established association for episodic memory processing, which may be a promising 'biomarker' for the modulation of memory performance. To develop a closed-loop stimulation paradigm that effectively modulates hippocampal gamma power, we use a novel data-set in which open-loop stimulation was applied to the posterior cingulate cortex and hippocampal gamma power was recorded during the encoding of episodic memories. The dataset was used to design and evaluate a linear quadratic integral (LQI) servo-controller in order to determine its viability for in-vivo use. In our testbed, we demonstrate that applying an LQI servo controller based on an autoregressive with exogenous input (ARX) plant model achieves effective control of hippocampal gamma power in 15 out of 18 experimental subjects who exhibited a gamma power increase related to stimulation. In contrast, we also implement a linear quadratic regulator (LQR) controller based on a linear state-space model (LSSM) which utilizes multi-channel gamma activities from the posterior cingulate cortex (PCC). We demonstrate that we are able to modulate gamma power using stimulation thresholds that are physiologically safe and on time scales that are reasonable for application in a clinical system, along with the ability to achieve temporal modulation of the control signal during item memory encoding. We outline further experimentation to test our proposed system and compare our findings to emerging closed-loop neuromodulation strategies.

Title: Machine learning approach to predict EEG sleep stages and transitions

Authors: *W. SHIH[1], A.-C. YANG[1,2,3];
[1]Inst. of Brain Sci., [2]Digital Med. Ctr., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan;
[3]Dept. of Med. Res., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Motivation: Conventional sleep staging is interpreted by sleep technologists with visual inspection, which is a time-consuming task. Therefore, experts have tried to develop a perfect automatic sleep staging system, but currently, none of them can meet the clinical use standards set by the American Academy of Sleep Medicine (AASM). The transition epoch is defined as a epoch of 30 seconds of EEG signal in which there are multiple sleep staging features such as arousing, which is more difficult to be staged accurately by machine learning in the past, and although the clinical sleep technologist can make judgments according to the relevant criteria set by AASM, different results may be obtained between sleep technologists, resulting in lower inter-rater reliability. Therefore, the goal of this research is to develop an automated Electroencephalography (EEG) sleep staging algorithm to improve the overall sleep staging and transition accuracy by using the anterior and posterior EEG signals to assist in judgment. **Methods:**This research used 8444 Polysomnography (PSG) data provided by the Sleep Heart Health Study, with a mean age of 66.2 years, including healthy subjects and Obstructive sleep apnea patients. We use C3 and C4 two EEG channels in the 10-20 system, with a sampling rate of 125 Hz. Since the EEG frequency is lower during sleep, we only use data with a frequency of 0.5~30 Hz. All data were preprocessed into sleep stages as defined by the AASM, and three 30-second EEG signals were grouped together as one set and Fourier transformed to calculate a total of 90 seconds of features. By using the first and last EEG signals, we can predict the sleep staging of the middle epoch more accurately during the training phase of the machine learning, and use the first two epochs of sleep staging prediction results to assist in determining the staging of the third epoch of the signal in a time-ordered manner. **Results:**Since N1 only accounts for 5.7% of the total sleep time, and the probability of continuous N1 after Markov chain analysis is only 51.53%, which is much lower than that of other stages, we use downsampling to achieve a balanced data. At present, the accuracy rate can reach 67.3% for one continuous set of the same stage. **Conclusion:**The current research has achieved good accuracy, which shows that the use of longer time data such as 90 seconds can effectively improve the model interpretation. Therefore, it would be a prospective research if more different preprocessing or other methods of extracting features could be done in the future.

Title: Estimating the degree of a driver's distraction based on functional connectivity analysis: An fNIRS study

Authors: *T. OGIHARA[1], T. HIROYASU[2], S. HIWA[2];
[1]Grad. Sch. of Life and Med. Sci., [2]Dept. of Biomed. Sci. and Informatics, Doshisha Univ., Kyotanabe-shi, Kyoto, Japan

Abstract: Objective
Distracted driving is a significant cause of traffic injuries. One cause of distracted driving is mind-wandering, shifting the driver’s thoughts away from what they should concentrate on. The objective of our study is to predict the degree of the driver's distraction based on brain activity. We measured the driver's brain activity during real-vehicle driving using functional near-infrared spectroscopy (fNIRS). Moreover, distracted driving behavior was predicted from preceding brain activity using connectome-based predictive modeling.
Participants and Materials
Twelve young male adults (aged 23.4 +/- 1.3 years) participated in this study. They were asked to drive a compact single-seat electric vehicle along an oval track course while preserving the vehicle speed to 20 km/h for 15 minutes. Beep tones were given randomly with intervals of 20-40 s. The participants were asked to respond to the beep tones immediately by stepping on the braking pedal until the vehicle speed was decreased to less than 10 km/h. fNIRS (NIRSport2, NIRx Medical Technologies, LLC.) with 16 sources x 14 detector probes and 16 short distance detector probes was used to measure OxyHb concentration changes during driving. Driving behavioral measures such as braking/accelerator pedal positions and vehicle speed were recorded and synchronized with fNIRS data using the Lab Streaming Layer library (https://labstreaminglayer.readthedocs.io).
Methods
The functional connectivity matrix was calculated using the OxyHb time series of a defined interval before presenting each beep tone. The brake reaction time (BRT) was calculated as the time between when the beep tone was presented until the driver started to step on the braking pedal, and used as the behavioral measure of distracted driving. We constructed a regression model where the BRT was used as an objective variable and a vectorized functional connectivity matrix was utilized as an explanatory variable. The model was built for each participant, and its accuracy was evaluated.
Results
We found positive correlations between predicted and actual BRTs for 6 out of 12 participants (p < 0.05). Discriminative connections were extracted for each model but no common connections could be identified for all the models. This result indicates that each participant had a different pattern of functional connectivity associated with his distracted state. These results suggest that distracted driving can be predicted from brain activity patterns for each individual.

Title: Precision Individualized Brain Models Directly Estimated From M/EEG

Authors: *M. SINGH[1], M. W. COLE[3], T. BRAVER[4], S. CHING[2];
[1]Washington Univ. In St. Louis, University City, MO; [2]Electrical and Systems Engin., Washington Univ. In St. Louis, Saint Louis, MO; [3]Rutgers The State Univ. of New Jersey, Newark, NJ; [4]Washington Univ. in St. Louis, St. Louis, MO

Abstract: Current efforts in large-scale neuroscience have led to the collection of sophisticated datasets measuring single-subject brains and behavior from multiple points of inquiry. However, integrating these facets into a concise description of individual brains has proven vexing. These efforts have been particularly stymied in two fronts: describing brain mechanisms across multiple spatial/temporal scales. Unifying these relationships in a formal modeling framework remains a key challenge for neuroscience and particularly human neuroimaging. Generating unified descriptions requires the development of brain models which can interrogate multiple scales of brain activity. However, such needs have not yet been met due to the challenges of high-dimensional optimization and the necessary tradeoffs between spatial (fMRI) and temporal (M/EEG) resolution for high-coverage methods. In the current work we present a new technique for estimating detailed brain (neural-mass) models using single-subject MEG data from the Human Connectome Project (HCP minimal pre-processing) and headmodels derived from MRI data. We estimated neural mass-style models directly from each subject's MEG sensor-level timeseries using a novel optimization algorithm: the Backpropagated Kalman Filter. This technique enables the parameterization of multiple neural populations (inhibitory and excitatory cells) and their connections across the cortical surface (100 parcels) directly from single-subject data. We demonstrate that these models are highly reliable in estimating both excitatory-to-excitatory and excitatory-to-inhibitory long-distance connections for each subject. Models accurately forecast future brain activity timeseries and predict long-term statistics such as correlation patterns and spectral power.

Title: Investigating the reliability of connectome-based predictive models across fMRI runs and datasets

Authors: *F. JOËSSEL[1], M. D. ROSENBERG[2], D. BAVELIER[1];
[1]Fac. of Psychology and Educ. Sci., Univ. de Geneve, Geneve, Switzerland; [2]Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: There is growing interest in building models that predict cognitive performance from functional connectivity (FC) data measured with fMRI. Although such connectome-based models can achieve high prediction accuracy and even generalize across independent participants and datasets [1-3], recent work reports that the reliability of feature weights is often low [4,5]. In addition, although large datasets of fMRI data are becoming increasingly common, constraints inherent to MRI data acquisition limit sample sizes for many experiments. We thus aimed to investigate how the number of participants and amount of data available per participant in single-lab samples impact the accuracy of connectome-based models and to characterize the feature-weight reliability of these models.
To this end, we analyzed data from four datasets (*N*s= 25, 62, 25, 49) collected at two scan sites. In each dataset, participants performed multiple runs of a sustained attention task, the gradual-onset continuous performance task (gradCPT). We built connectome-based predictive models (CPMs) [6] using leave-two-out cross-validation to predict participants' gradCPT performance from FC measured during the gradCPT. Specifically, in each dataset, we trained models using data from subsets of participants and task runs, and asked whether they generalized to predict gradCPT performance in novel participants and datasets. We also assessed the feature-weight similarity of models trained in the same and different datasets.
Our results show inconsistent accuracy of models trained on different datasets and different runs from the same dataset. For example, when models were trained on N=20, the mean correlation between predicted and observed behavioral scores was r=.78, 0.29, 0.01, and 0.11 in the four datasets, respectively . Looking at session-to-session variability in one dataset, the predictive accuracy for was r=.16 for one run and r=.4 for another. In addition, the correlation between the feature weights of models trained on different datasets does not exceed 0.3, even when models trained on one dataset successfully generalize to the other. The similarity of feature weights between CPMs trained on different runs in the same dataset range from .4-.7. These results suggest that CPMs can generalize across participants and datasets despite variable feature

weights, and compel further investigation into the relationships between sample size, amount of data per individual, prediction accuracy, and feature-weight reliability.

Title: Biophysically-detailed multiscale model of macaque auditory thalamocortical circuits

Authors: *E. GRIFFITH[1], S. DURA-BERNAL[2], A. BARCZAK[3], M. N. O'CONNELL[3], T. M. MCGINNIS[4], W. W. LYTTON[6], P. LAKATOS[5], S. A. NEYMOTIN[7];

For Psychiatric Res., Orangeburg, NY

Abstract: We used the NEURON simulator with NetPyNE to develop a biophysically-detailed model of the macaque auditory thalamocortical system, simulating a cortical column of 2000um depth and 200um diameter, with over 12k neurons and 30M synapses. Using this model, we reproduced oscillatory patterns observed in spontaneous electrophysiology data recorded from awake, nonhuman primate (NHP) primary auditory cortex (A1). Neuron classes, densities, biophysics, and connectivity were derived from experimental data. The A1 model included 6 cortical layers, 36 excitatory and inhibitory neuron populations (e.g. intratelencephalic cells in L2-6, neurogliaform cells in L1), and layer-specific reciprocal connectivity between A1 and medial geniculate body (MGB). The thalamic model included the MGB and the thalamic

reticular nucleus (TRN). The MGB contained locally-projecting thalamic interneurons, along with core and matrix populations of thalamocortical neurons, each with distinct projection patterns to different layers of A1. TRN included thalamic reticular neurons to inhibit MGB. Outputs from cochlear nerve and inferior colliculus (IC) were simulated using phenomenological models that captured the physiological transformations occurring in these structures in response to auditory stimuli. This allowed us to use any arbitrary sound as input to the model, including the stimuli presented experimentally to awake macaques, facilitating our ability to match model to primate.
We used evolutionary algorithms to tune several high-level network parameters (e.g. synaptic weight gains) in order to generate experimentally constrained firing rates in all 43 neuron populations. Each simulated second required approximately 15 minutes on 96 supercomputer cores. We ran 100 simultaneous simulations (9600 cores) for each generation of the evolutionary optimization.
We validated the model by comparing in vivo and in silico electrophysiology data using local field potential, current source density (CSD), and direct comparisons of individual cortical oscillation events. We found a similar distribution of oscillation events in different frequency bands and favorable comparisons between the shape of the individual oscillation event waveforms occurring within these frequency bands. Preliminary comparisons between model and NHP data in response to click and speech stimuli have also begun. Using CSD and network model manipulations, we will develop predictions regarding the mechanistic origins of these spatiotemporal oscillatory patterns, and test these predictions in vivo using deep brain electrical microstimulation and pharmacological manipulations.

Title: Towards Intuitive BCI - Feasibility Study of Decoding Visual Imagery EEG using Deep Learning

Authors: *S. LEE, S. JANG, S. C. JUN;
Sch. of Electrical Engin. and Computer Sci. (EECS), Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: In brain computer interface (BCI) systems, motor imagery (MI) has the advantage in that the user can control right or left movements (two degrees of freedom) actively. On the other hand, studies on decoding visual imaginary EEG data have been recently more attention due to the development of deep learning. The BCI through visual imagery has great potential in increasing the degree of freedom of manipulation. In this work, we analyzed the visual imagery EEG using the deep learning and explored the possibility that it can be useful for BCI. EEG data were acquired by 32-channel BioSemi Active 2. Twenty healthy male and female university students participated in the experiment. Each participant performed up to 10 sessions. Three categories (objects, digits, shapes) of visual images were presented for 2 seconds and participants were instructed to imagine the presented image for 4 seconds. One session consisted of 5 runs and each run consisted of 36 trials. A total of 180 visual imagery trials was collected in one session. EEG data were filtered using a 0.5-50Hz bandpass filter, and artifacts such as eye blinking were removed through the Independent Component Analysis (ICA) technique. Time frequency map for time window of 3 seconds long (1 second before onset and 2 seconds after imagery) was calculated within 0~30Hz, and then this time-frequency map was used as an input for deep learning. The pretrained MobileNet V2 model was used for classification, and the classification accuracy was calculated through 5-fold cross validation. GradCam, one of the explainable AI techniques, was used to extract features from each category. We found the location of major activations in each category by averaging over trials of each category. The averaged classification accuracy (three categories and 5-fold) was 57.2%. As a result of the GradCam, it was found that the activation was notably high at 10-20Hz between 0-1 seconds after the imagery onset. This trend was similar in all three categories, but some difference in activation among categories was observed in 10-13 Hz from 500 ms after onset. In particular, in the comparison of object and digit categories, there was relatively big difference in activation at low beta (about 20-25Hz) after 1 second of imagery onset. We performed visual imagery EEG experiments on three categories. Through deep learning, 57.2% of classification accuracy was obtained. In addition, activation in the alpha wave during imagery was observed as a notable feature through an explainable AI technique. From this work, we believe that visual imagery may have potential in BCI system, which is a more intuitive BCI paradigm.

Title: Effects of preprocessing on connectome fingerprinting in a sample of anxious and healthy youth

Authors: *G. RINGLEIN, A. WINKLER, D. PINE, A. ZUGMAN;
NIH, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Resting state fMRI connectivity has been found stable and sufficiently unique to identify subjects between sessions, a process known as connectome fingerprinting (CF). While simple ("full") correlation between regions is commonly used, partial correlations that take into account all other regions allow the study of direct connections. Motion correction is another area of ambiguity; there are many available methods, each with unknown effects on CF; regression of motion parameters ("6RP") and ICA-AROMA are popular approaches. Here we investigate how prediction accuracy is affected by type of correlation (full vs. partial) and motion correction (6RP vs. ICA-AROMA). Participants (n=84) were subjects with diagnosis of anxiety (n=56; F/M/unknown=33/22/1; age (mean±sd)=13.9±2.8) and controls (n=28; F/M=15/13; age =13.7±2.4). Each subject had two resting state fMRI scans (days between scans =126±42). Groups did not differ significantly in sex, age, or time between scans (p &gt 0.05). Functional connectivity was assessed between each pair of the regions from the Schaefer atlas (200 parcels) and 16 subcortical regions from FreeSurfer. We attempted to identify each individual by comparing their connectivity matrix at one time point with all individuals' matrices at the other time point. Thus, each preprocessing choice led to two accuracies: baseline to follow-up (b-f) and follow-up to baseline (f-b), for the 4 combinations of type of correlation and motion correction, producing 8 accuracies. For all analyses, accuracy was significantly better than chance.Results were as follows: partial correlation using motion regression (6RP) was the most accurate (b-f: 63 correct subjects, f-b: 64), followed by full correlation with ICA-AROMA (b-f: 55, f-b: 52), partial correlation with ICA-AROMA (b-f: 42, f-b: 46), and partial correlation with ICA-AROMA (b-f: 22, f-b: 23). In the full correlation analyses, there were significantly higher means of motion among the incorrect participants across both scans, except in f-b using 6RP motion regression. There was no significant association between motion when using partial correlations. We also computed the differential power (DP) of each edge, a measure of how much that edge contributes in identifying subjects. The edges with highest DP were inconsistent between the 4 analyses, with only 7 edges being in the top 5% for all analyses. These edges involve regions in the control network, default mode network, and temporal parietal network. The variability in accuracy and DP of edges between different kinds of analysis highlights the need for careful consideration of preprocessing steps before CF analysis.

Title: Functional hubs in the executive and attentional resting-state networks as revealed with causal discovery directed connectivity analysis

Authors: *E. RAWLS[1], E. KUMMERFELD[2], B. A. MUELLER[1], A. ZILVERSTAND[3]; [1]Psychiatry and Behavioral Sci., [2]Inst. for Hlth. Informatics, [3]Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Brain network analysis has paid particular attention to so-called "hubs", highly-connected brain regions that facilitate efficient information transfer. Previous evidence for functional and anatomical hubs of the brain has been restricted to undirected networks, despite increasing recognition that understanding causal interactions between brain regions is crucial to the development of targeted interventions for psychiatric populations. Here, we introduce a scalable method for calculating directed connectivity from fMRI: GANGO (Greedy Adjacencies and Non-Gaussian Orientations), and use this to investigate the causal hubs of the human cortex. Methods: Using a large resting-state dataset (Human Connectome Project, n = 442 unrelated subjects; 56% female), we generated sparse whole-cortex directed connectivity graphs on a per-subject basis using the GANGO method. GANGO initially defines directly connected brain regions using a scalable greedy search that maximizes model fit (Bayesian Information Criteria), then orients edges using non-Gaussianities in the BOLD signal distribution. To summarize the directed connectivity structure of the generated graphs, we characterized the hub structure of these graphs using analyses of inter-module connectivity (participation coefficient), centrality metrics (degree centrality, betweenness centrality), and virtual lesion analyses. Results: Across a variety of analyses, our directed connectivity networks revealed causal hub roles of frontoparietal, dorsal attention, and cingulo-opercular networks. Inter-network connectivity analyses clarified the functional roles of these networks: the dorsal attention network derived its high centrality from receiving information from sensory networks and sending information to cognitive networks, while the frontoparietal network derived its high centrality from facilitating communication between higher cognitive networks (cingulo-opercular, default mode, dorsal attention, ventral attention). Conclusion: Here, we present a method for generating a sparse "causal brain connectome" that highlights the roles of attentional and executive networks as critical causal hubs for brain network integration. In the future, this may guide the development of targeted brain-based interventions for psychiatric conditions directed at these causal hubs.

Title: Canonical Spectral Responses: Using large-scale group analysis of ECoG electrode spectral profiles to investigate the spectral organization of the brain.

Authors: *Z. FREUDENBURG[1], M. P. BRANCO[2], M. VANSTEENSEL[3], E. J. AARNOUTSE[4], N. F. RAMSEY[5];
[1]UMC Brain Center, Univ. Med. Center, Utrecht, Utrecht, Netherlands; [2]UMC Utrecht Brain Ctr., [3]UMC Brain Center, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [4]Neurol. and Neurosurg., [5]UMC Brain Center,University Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Neuroscience has generated varied maps of the human brain ranging from historic atlases based on cortical tissue composition [Brodmann 1909] to atlases that integrate structural and functional data, such as Human Connectome Project [Glasser et al. 2016]. Spectral features in human brain electrophysiology have been extensively studied and have been shown to be universal to human brain function to the extent that they are often used in clinical diagnostic practice and online closed-loop direct cognitive control of a computer. Yet, a spectral atlas of the brain has not been established. A spectral atlas can reveal brain region-specific fluctuations in power across frequencies, induced by changes in activity during task performance. Mu frequencies in motor cortex for instance (around 10 Hz), are known to selectively diminish in power during movement. Frequency-specific fluctuations as such indicate region-specific preferences for specific frequencies, possibly revealing neurophysiological mechanisms. , Scalp EEG recordings, the main modality used to study spectral features, are of limited use for spectral mapping due to limited sensitivity and spatial selectivity. Electrocorticography (ECoG), does allow for mapping of electrophysiological signals with high topographical precision, since each electrode measures only from cortical tissue in direct contact. ECoG has the added benefit of being sensitive to frequencies (50-300 Hz) closely linked to increased neuronal spiking and fMRI BOLD signal increases [Nir et al. 2007, Goense et al. 2008]. Due to the clinical setting in which ECoG data is collected, however, the cortical coverage in individual subjects is partial and varied. A spectral atlas thus requires data from a large number of patients, and techniques that can integrate results across subjects. In this work we leverage a large data set (57 subjects, 4418 total electrodes) and use clustering to group electrodes according to spectral profiles. ECoG was recorded with standard clinical grids during epileptic focus localization. Each electrode was

anatomically localized using MRI and CT scans [Branco et al. 2016], assigned a a spectral variance profile using irregular-resampling auto-spectral analysis [Wen and Liu 2016], and. then clustered using Affinity Propagation [Frey et al. 2007] into 9 groups of spectrally similar electrodes. While a recent paper [Wanga et al. 2021] used il-EEG to determine spectral peaks for anatomically defined regions, to our knowledge it is novel to uses spectral content to map cortical areas. This atlas can help to better interpret EEG recordings and be used to associate localized spectral information with other modalities.

Title: Identification and characterization of a simultaneous multi-slice (multiband) fMRI signal artifact in simultaneously acquired slices

Authors: *P. N. TUBIOLO[1,3], J. C. WILLIAMS[1,3], J. R. LUCENO[3], J. X. VAN SNELLENBERG[1,2,3];
[1]Biomed. Engin., [2]Psychology, Stony Brook Univ., Stony Brook, NY; [3]Psychiatry, Renaissance Sch. of Med. at Stony Brook Univ., Stony Brook, NY

Abstract: Multiband (MB) functional Magnetic Resonance Imaging (fMRI) achieves improved spatiotemporal resolution in clinical neuroimaging and cognitive neuroscience research, and is used in public datasets such as the Human Connectome Project (HCP). However, MB fMRI datasets may exhibit novel characteristics absent in legacy datasets. The aims of this study are to: (a) report the existence of a previously uncharacterized signal artifact across all MB fMRI datasets examined; (b) propose a regression-based technique to remove this artifact; and (c) provide a preliminary analysis of the isolated artifact. Unprocessed MB RS-fMRI data was utilized from a Siemens Prisma 3T scanner (n = 10, 4 runs/subject, MB acceleration factor (MBF) = 6, Repetition Time (TR) = 800 ms; one phantom run with TR = 1010 ms was analyzed separately), GE MR750 3T scanner (n = 10, 4 runs/subject, MBF= 6, TR = 850 ms), and the HCP 500 subjects release (n = 25, 4 runs/subject, Siemens Skyra 3T scanner, MBF= 8, TR = 720

ms). A shared artifact across simultaneously-acquired (SA+) slices was quantified as the difference in Pearson correlation between the average timeseries in each slice for SA+ and non-simultaneously acquired (SA-) slices, averaged over all slices in a volume. The isolated artifact time series was estimated separately for each slice as the residuals of a multiple linear regression modeling the average signal in each set of SA+ slices, but orthogonal to the global signal across SA- slices and estimated motion parameters. The original voxel-wise timeseries was then orthogonalized with respect to the estimated artifact signal for the corresponding slice to obtain corrected data. In addition, the estimated artifact timeseries was used to determine autocorrelation as a function of lag number. For each dataset, the power spectral density (PSD) was determined and colored noise characteristics were estimated using a linear regression of log-log transformed PSD with a lower bound of -2 log(Hz). Significantly elevated correlations between SA+ slices over SA- slices were observed in all datasets, indicating a shared signal source between SA+ slices (paired t-tests, all $p < 10^{-5}$). Correlations between SA+ slices were reduced after artifact removal in all datasets (paired t-tests, all $p < 10^{-5}$). Artifact signal was present in phantom data, suggesting a non-neural source. Power spectral analyses and autocorrelation calculations suggest that the artifact is largely composed of colored noise with a PSD proportional to frequency$^{-\alpha}$ where $1 \leq \alpha \leq 2$. We expect that removal of this artifact will improve neural activity estimates in MB fMRI studies.

Title: Detection of Gaussianity using envelopes

Authors: *V. M. HIDALGO[1], J. MPODOZIS[1], J. C. LETELIER[1], J. DIAZ[2];
[1]Biol. of Cognition Lab., Univ. of Chile, Santiago, Chile; [2]Intl. Inst. for Integrative Sleep Med., Univ. of Tsukuba, Tsukuba, Japan

Abstract: Assessing Gaussianity is a classic problem in the field of signal analysis, and a variety of methods have been devised to infer Gaussianity in time series. These methods span ideas both from the time and frequency domains. Time domain approaches rely on goodness-of-fit tests to assess experimental amplitude distributions, while frequency domain methods are spectral-based tests. In general, these two classes of methods present different drawbacks and in practice are

difficult to use to settle the question of Gaussianity in time series. Here we introduce a different solution by using the envelope of a signal. In effect, the envelope of zero-mean Gaussian noise is distributed according to the Rayleigh distribution, which has the special property that the ratio between its standard deviation (σ) and mean (μ), known as the coefficient of variation (CV=σ/μ), is constant and equal to $\sqrt{(4-\pi)/\pi} \approx 0.523$ (Diaz et al. 2007, DOI:10.1523/JNEUROSCI.4512-06.2007). Thus, when the envelope of a given signal is considered as a random variable, its CV (called the coefficient ofvariation of the envelope, CVE) can be used as a fingerprint of Gaussianity. Previously, we have used this tool to study the Gaussianity of a) the peripheral waves in the vertebrate olfactory epithelium (Diaz et al. 2007, DOI:10.1523/JNEUROSCI.4512-06.2007), b) the rat EEG during sleep (Diaz etal,DOI:10.1016/j.neuroimage.2018.01.063), and c) the human alpha rhythm (Hidalgo et al. 2021,DOI:10.1101/2021.03.31.437785). Here we summarize the mathematics and computer methods behind using the CVE as a fingerprint of Gaussianity. In particular, we present how to perform Gaussianity detection in a step-by-step fashion for experimental data, paying attention to the use of the Hilbert transform, and how this procedure can be employed to classify behavioral states. Furthermore, we use our method to assess the degree of coupling between coupled oscillators in the Kuramoto model. Additionally, through the use of the Fourier transform phase randomization, we reveal the interconnections among CVE, Gaussianity and signal amplitude modulation profiles. Moreover, the CVE method allows the similarities and differences between neural signals (M/EEG, LFP, and fMRI) and Gaussian noise to be studied within a solid mathematical framework that could also be used to study neural synchronization.

Title: Imaging Trigeminal Neuralgia Pain: Insights from Combining AI and Granger Causality

Authors: *Y. LIANG[1], Q. ZHAO[1], J. K. NEUBERT[2], M. DING[1];
[1]Biomed. Engin., [2]Orthodontics, Univ. of Florida, Gainesville, FL

Abstract: Trigeminal neuralgia (TN) is a severe and disabling chronic facial pain condition. It is considered one of the most severe pain conditions, often called the “suicide disease,” but presently available therapies for TN are mostly ineffective or inadequate. Both the unpredictable response to treatment and variability in long-term clinical outcomes in TN strongly suggest that a

range of peripheral and central mechanisms underlying TN pain remain to be understood. This study aims to achieve two objectives. Objective 1 is to identify the regions in the brain that underlie TN pain. Objective 2 is to characterize how these regions interact to produce TN pain perception. Functional MRI (fMRI) data were recorded from TN patients (N=57) while they rated their pain levels in real time using a tracking ball. Analytically, recognizing the limitations of traditional data analysis techniques (e.g., fMRI activation analysis), we turned to AI-inspired technology. In particular, a deep neural network (DNN) was designed and implemented, which was able to take fMRI data as input features to predict the moment-to-moment pain levels with high accuracy (75%). Importantly, from the DNN model, a set of brain regions, including the thalamus and the dorsal anterior cingulate cortex (dACC), were derived as signature centers of TN pain. Applying Granger causality analysis to fMRI data from the thalamus and dACC, we further showed that thalamus->dACC causal influence, but not dACC->thalamus causal influence, predicted daily experienced pain levels (R=0.55), consistent with the known physiology that the thalamus is a key brain structure in linking nociceptive sensory input to pain perception and dACC is a key brain structure for perceiving pain.

Title: Ecog high gamma is a band-limited signal

Authors: *J. A. LIVEZEY[1], A. HWANG[2], M. E. DOUGHERTY[3], K. E. BOUCHARD[4];
[1]E O Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]Mathematical, Computat. and Systems Biol., Univ. of California, Irvine, Irvine, CA; [3]Univ. of California, San Francisco, San Francisco, CA; [4]Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: A common problem in neuroscience is how to decompose noisy, multi-source signals measured in experiments (e.g., local field potentials, EEG) into biophysically interpretable components. Analysis of cortical surface electrical potentials (CSEPs) measured using ECoG arrays typifies this problem as CSEPs are believed to be composed of broadband and bandlimited signals with differing biophysical origins. The high frequency range (>70 Hz) has been shown to be a highly informative signal for encoding and decoding behaviors and stimuli. However, little work has been done to search for substructure in this range.
Here, in both rats and humans, we show that CSEPs are composed of band-limited high

frequency components. We first show evidence from rat microECoG that the high frequency band of cortical surface electrical potentials is composed of multiple distinct frequency components. In human CSEPs, it has previously been shown that at slow timescales, variations in the high gamma amplitude can be explained by a modulating power-law component. However, previous studies do not address whether variation in the high gamma amplitude can be explained by a modulating power-law component at fast behavioral timescales. Additionally, previous studies have not differentiated the structure of high gamma in electrodes which are engaged in the task from those which are not engaged. To answer these questions, we propose and use a robust regression model that can account for shoulders in the spectrum to show that at fast timescales and on single trials during speech production, the variation in high gamma amplitude cannot be explained by a modulating power-law component, i.e., it is band-limited. Furthermore, we show that the structure that cannot be explained by a power-law component contains a majority of the information that can be used for decoding produced speech. Together these results show that there are multiple, band-limited sources of high frequency power including the high gamma amplitude which may have different biophysical origins. Our work points to specific future modeling steps required to better understand the biophysical origin of different components of CSEPs.

Title: Dynamic reconfiguration of frequency-specific cortical coactivation patterns during psychedelic and anesthetized states induced by ketamine

Authors: *D. LI[1], G. A. MASHOUR[2];
[1]Ctr. for Consciousness Science; Dept. of Anesthesiol., [2]Ctr. for Consciousness Science; Dept. of Anesthesiology; Neurosci. Grad. Program; Dept. of Pharmacol, Univ. of Michigan, Ann Arbor, MI

Abstract: Ketamine is a unique drug that, depending on its dose, has psychedelic and anesthetic properties. We recently demonstrated the dose-dependent effect of ketamine on spatiotemporal

complexity as assessed by Lempel-Ziv complexity in spontaneous scalp EEG signals. Lempel-Ziv complexity reduces the spatiotemporal pattern to a unidimensional measure and assesses the local signal diversity on a short timescale of a few seconds, thus providing a simple and powerful way of indexing the ketamine-induced altered states of consciousness. However, how the different dosing of ketamine modulates the complex spatial dynamics over a longer time scale has not yet been explored. Furthermore, recent neuroimaging studies have demonstrated that spontaneous brain activity exhibits rich spatiotemporal structure that can be characterized as the exploration of a repertoire of spatially distributed patterns that recur over time, which may be a manifestation of covert cognitive information processing and reflect the information capacity of the brain that is thought to be central to consciousness. Here we investigated the dynamic organization of spontaneous cortical activity during wakefulness and during altered states of consciousness induced by different doses of ketamine. Through k-means cluster analysis on the envelope data of source-localized EEG signals, we identified a set of recurring states that represent frequency-specific cortical coactivation patterns, with the spectral and spatial properties resembling those derived from hidden Markov modeling analysis of spontaneous MEG signals at rest. Importantly, we found the effect of ketamine on individual brain states in terms of the fractional occupancy and transition probabilities, and ketamine anesthesia tends to shift the configuration toward states with low spatial complexity. Furthermore, we demonstrated a dose-dependent effect of ketamine on the richness of the dynamical repertoire by quantifying the temporal dynamics of the occurrence and transitions of brain states. We found that subanesthetic ketamine is associated with a richer repertoire, while anesthetic ketamine induces dynamic changes in the brain state organization, with the repertoire richness evolving from a reduced level to one comparable to that during normal wakefulness. These results provide a full description of ketamine's modulations of the dynamic repertoire of spontaneous cortical activity and advances understanding of the neurophysiological mechanism of ketamine in terms of the spatial, temporal, and spectral structures of the underlying whole-brain dynamics.

Abstract: Neural precursors (NPs) present in the hippocampus can be modulated by several neurogenic stimuli including environmental enrichment (EE), which acts through BDNF-TrkB signaling. We have recently identified NPs in meninges, however menigneal niche response to pro-neurogenic stimuli has never been investigated. To this aim, we analyzed the effects of 1 week EE treatment on NP distribution in mouse brain meninges. Following the neurogenic stimulus, although we did not detect modification of meningeal cell number and proliferation, we observed, in meninges, an increased number of β3-Tubulin+ immature neuronal cells. Lineage-tracing experiment confirmed that EE-induced β3-Tubulin+ immature neuronal cells present in meninges originated from GLAST+ radial glia cells. To investigate the molecular mechanism involved in this response, we studied the BDNF-TrkB interaction. Treatment with ANA-12, a TrkB non-competitive inhibitor, abolished the EE-induced increase of β3-Tubulin+ immature neuronal cells in meninges. Overall these data showed, for the first time, that the meningeal niche responded to neurogenic stimuli by increasing the immature neuronal population through TrkB-mediated signaling.This work opened new perspectives in the study of the neurogenic plasticity induced by EE.

Title: The long-term effects of prenatal methadone exposure on adult learning and memory and related hippocampal function

Authors: *M. E. GAMBLE, R. MARFATIA, M. R. DIAZ;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Prenatal opioid exposures lead to extensive cognitive and emotion-regulation problems in offspring, persisting at least through school-age. Surprisingly, this body of literature has only recently begun to track exposed children into adulthood. One opioid maintenance

treatment typically used for opioid use disorder is methadone, which has been approved for use in pregnant women for several decades. Importantly, however, the impacts of prenatal methadone exposure (PME), particularly on offspring as they progress into adulthood, has not been extensively examined. This is alarming, as methadone continues to be prescribed as a standard of care for use in pregnant women with opioid use disorder, without a complete understanding of the impacts on the exposed child. In recent years, animal models have shown several cognitive consequences as a result of PME, including evidence of hippocampal dysfunction and related behavioral deficits in exposed offspring. The present work aims to examine the persistent nature of these hippocampal and cognitive deficits resulting from PME. Pregnant Sprague Dawley rats received subcutaneous methadone or water injections twice daily from gestational days 3 -20. Following postnatal day 70, male and female offspring were behaviorally tested for several learning and memory tasks. Additionally, mRNA for markers of neurogenesis was quantified from the dorsal hippocampus and whole-cell patch-clamp electrophysiological recordings of dentate granule cells were performed. Results indicate that adult offspring show significant impairments in novel object recognition and preliminary data indicate some potential deficits in spatial learning and retention, particularly in females. Additionally, we observed a pattern of decreased mRNA expression in males for four markers associated with adult hippocampal neurogenesis, one mechanism that plays a major role in these learning and memory behaviors. Finally, preliminary electrophysiology data point toward decreased excitability of the dentate granule cells in both male and female adult exposed offspring. Overall, this work supports the continued investigation of the long-term effects of prenatal methadone exposure on adult male and female learning and memory, as well as promotes further exploration of adult hippocampal neurogenesis as a potential neural mechanism impacted by this exposure.

Title: Fear conditioning and new cells in the amydala in turtles.

Authors: *A. POWERS[1], C. LAU[2], Z. LEE[2], J. WELK[2], J. DENARO[2], C. GRANADOS[2], F. SERRAINO[2];
[2]Psychology, [1]Stony Brook Univ., Stony Brook, NY

Abstract: The amygdala in mammals is importantly involved in fear conditioning. We studied fear conditioning in turtles in order to understand the evolution of the amygdala and its role in fear. Turtles are closely related to the stem amniotes that gave rise to both mammals and reptiles. Although fear conditioning has been demonstrated in many different species, it had not been shown in turtles prior to this study. We developed a paradigm to study fear conditioning in painted turtles (*Chrysemys picta*), in order to study the brain changes that accompany such learning. For the experimental group (n=4), we gave 10 trials per day, pairing a 5-s red light conditioned stimulus with a 1.0 mA footshock (0.5 s, scrambled through a grid floor, overlapping with the end of the red light). The intertrial interval was variable, averaging 2 min. We compared the behavior of turtles in this paradigm to that of two control groups, one given unpaired presentations of light and shock, the other given light alone and no shock (n=4 in each group). Because we did not know what behavior would indicate learning, we measured movement, climbing, pulling in the limbs and/or head, and location in the chamber, comparing the behavior during the red light to the behavior in the 5 s before the red light came on. The only behavior that changed reliably was movement: turtles in the experimental group learned to stop moving when the light came on.After 9 days of training, we ran all groups on extinction (light alone for all groups) for 6 days. The experimental group showed a reversal of their freezing behavior during extinction.All animals were given 9 injections of BrdU (50 mg/kg) over a three-week period, starting one week before conditioning. Four weeks after beginning BrdU injections, all animals were euthanized, and immunohistochemistry for BrdU was done. We counted the number of new cells in the caudal half of the telencephalon, the region that contains the amygdala, because we expected that that region would be involved in fear learning. The experimental group had significantly more new cells in the caudal telencephalon than the two control groups, which did not differ from each other. The presence of new cells in the amygdalar areas when turtles learn conditioned fear suggests that this area is activated by such learning. In mammals, no or very few new cells are produced in the amygdala during fear learning. Nevertheless, these findings demonstrate the involvement of the amygdala in fear learning in turtles and suggest that the amygdala played a role in learning fear in the common ancestors of mammals and reptiles, the stem amniotes.

Title: A novel neurogenic compound, Ro6871135, improves pattern separation

Authors: *K. TEGANG[1], W.-L. CHANG[1], R. JAGASIA[2], J. WICHMANN[3], M. SAXE[4], R. HEN[1];
[1]Psychiatry, Columbia Univ/New York State Psychiatric Inst., New York, NY; [2]Neurosci. and Rare Dis. Discovery & Translational Area, [3]Therapeut. Modalities, Roche Innovation Ctr. Basel, Basel, Switzerland; [4]Biogen, Cambridge, MA

Abstract: Background: Prior work from our group has demonstrated that increasing adult hippocampal neurogenesis in mice was sufficient to improve pattern separation, a process in which the dentate gyrus transforms similar experiences or events into discrete, non-overlapping representations. In humans, individuals with panic disorder and posttraumatic stress disorder display poor performance in pattern separation tasks, and enhancing adult hippocampal neurogenesis is a potential therapeutic strategy for treating anxiety disorders. In this study, we determine the behavioral effects of the chronic administration of a novel pro-neurogenic compound, Ro6871135, on pattern separation in a contextual fear discrimination task.Methods: 8-week-old c57BL/6J male mice were administered 7.5 mg/kg of Ro6871135 compound by daily oral gavage. After 21 days of treatment with the vehicle or the compound, mice were behaviorally tested in a contextual fear discrimination task. On the days of behavioral testing, animals were subjected to gavage after cessation of behavioral testing for that day to avoid any possible acute effects of the drug treatment. Results: Using a two-way ANOVA, we found that vehicle and Ro6871135-treated mice showed elevated and indistinguishable levels of freezing in "Context A" 24 hours following training in the same context. Both groups displayed negligible levels of freezing behavior in a distinct "Context C" which differed in several features from Context A (and from Context B). The Ro6871135-treated mice successfully discriminated between Context A and Context B by the fifth day of exposure to both contexts while no significant interaction of Day and Context was found in vehicle-treated mice (n = 8 mice per group). Conclusion: We observed that chronic treatment with Ro6871135, a pro-neurogenic compound, improved performance on a contextual fear discrimination task without having a notable effect on baseline contextual fear conditioning. These results suggest that pharmacological stimulation of adult neurogenesis could be a promising direction for the development of novel therapeutics for disorders characterized by impaired pattern separation.

Title: A neurogenic microenvironment defined by excitatory-inhibitory neuronal circuits in adult dentate gyrus

Authors: M. UEMURA[1], S. BLANKVOORT[1], L. YUAN[2], L. F. COBAR ZELAYA[2], K. LIT[2], ***A. TASHIRO**[2,1];
[1]Kavli Inst. for Systems Neurosci., Norwegian Univ. of Sci. and Technol., Trondheim, Norway; [2]Nanyang Technological Univ., Singapore, Singapore

Abstract: Adult neurogenesis in the dentate gyrus plays a role in adaptive brain functions such as memory formation. Adding new neurons to a specific locus of a neural circuit with functional needs is an efficient way to achieve such an adaptive function. However, it is unknown whether neurogenesis is linked to local functional demands potentially specified by the activity of neuronal circuits. By examining the distribution of neurogenesis and different types of neuronal activity in the dentate gyrus of freely moving adult rats, we found that neurogenesis is positionally associated with active excitatory neurons, some of which show place-cell activity, but is positionally dissociated from a type of interneurons with high burst tendency. Our finding suggests that the behaviorally relevant activity of excitatory-inhibitory neuronal circuits can define a microenvironment stimulating/inhibiting neurogenesis. Such local regulation of neurogenesis may contribute to strategic recruitment of new neurons to modify functionally relevant neural circuits.

Title: A novel role for adult neurogenesis in a two-arm bandit reversal learning task

Authors: *K. B. HUNTZICKER[1,2], R.-M. KARLSSON[2], H. A. CAMERON[2];
[1]Neurosci., Brown Univ., Providence, RI; [2]Natl. Inst. of Mental Hlth. (NIMH), NIH, Bethesda, MD

Abstract: Neurogenesis in the mammalian hippocampus persists throughout adulthood, but the function of newly born hippocampal cells remains largely unknown. In this study, we employed a pharmacogenetic method of neurogenesis ablation to determine the effects of adult neurogenesis on decision-making behavior. Rats expressing herpes simplex thymidine kinase (HSV-TK) under control of the human glial fibrillary acidic protein (GFAP) promoter were fed an antiviral drug in adulthood to induce complete ablation of hippocampal neurogenesis. This method is highly specific, inhibiting neurogenesis only upon drug administration and affecting only neural progenitors. Treated transgenic (TK) rats do not exhibit deficits in many standard learning tasks. However, our lab has previously found that treated transgenic (TK) rats show differential responses to ambiguous threat cues when compared against wild-type controls. To test whether adult neurogenesis also underlies behavioral responses to uncertainty under non-threatening conditions, we trained rats on an operant probabilistic learning task. During this task, rats learn that one lever produces a food reward 80 percent of the time, and the other, 20 percent. This type of probabilistic learning – and subsequent reversal learning when lever outcomes are switched – provides rats with many instances of ambiguous feedback. For example, a previously lucrative lever failing to deliver a reward could represent either a reversal or the 20 percent chance that a correct lever does not produce a reward. By using outcome likelihoods that are probabilistic rather than deterministic, this paradigm is more translatable to human learning studies and more representative of situations in nature. We found that in one version of this task, male and female TK rats exhibited higher win-stay ratios and earned more rewards than wild-type controls, suggesting that TK rats may employ different strategies than WTs when seeking rewards under ambiguous conditions. Ongoing studies investigate whether these differences persist when reversal frequencies or reward probabilities are altered. Together, these findings suggest a role for adult neurogenesis in probabilistic decision-making and, more generally, in behavioral responses to situational uncertainty.

Title: Adult Hippocampal Neurogenesis Regulates Behavior in a Platform Mediated Avoidance Task

Authors: *A. SWIERCZ, H. MARTIN, R.-M. KARLSSON, H. A. CAMERON;
NIMH, NIH, Bethesda, MD

Abstract: Approach-avoidance conflicts occur when an animal is presented with stimuli associated with both positive and negative outcomes. These conflicts are resolved in part by the hippocampus, which acts to modulate the inhibition of prepotent behaviors. In the present study, we examined the role of neurogenesis in an approach-avoidance conflict, with the aim of determining whether adult-born neurons influence behavior when animals have the option to either avoid footshocks, obtain rewards, or attempt to do both. We examined the behavior of rats lacking adult hippocampal neurogenesis in a platform mediated avoidance (PMA) task (Bravo-Rivera et al., 2021). In the PMA task, animals can choose to avoid each footshock, but avoidance comes at the cost of being unable to lever-press for sucrose rewards. The simultaneous presentation of an auditory conditioned stimulus (CS) that reliably predicts a footshock, and a light cue signaling reward availability, creates an approach-avoidance conflict where the animal must balance threat avoidance with food-seeking behavior. Neurogenesis was eliminated by 8 weeks of treatment with valganciclovir in male transgenic Long Evans rats expressing the herpes simplex virus thymidine kinase (TK) under control of the glial fibrillary acidic protein (GFAP) promoter. Ablation of adult-born neurons was followed by three phases of behavioral training. During the avoidance training phase, animals learned to avoid CS-associated footshocks by stepping onto a small platform in the corner of the operant chamber. In reward training, sucrose pellets were dispensed each time a lever was pressed, but only when a light in the chamber was illuminated. During conflict training, auditory and light cues were presented simultaneously over the course of 16 days. The total time spent on the platform during CS presentation was similar between genotypes throughout avoidance training. Both groups also learned to increase lever pressing in response to the light during reward training. In the conflict phase, however, TK animals spent less time on the platform than wild-type controls. The TK group also pressed for rewards at a much higher rate and exhibited less freezing behavior in response to the cues. The loss of new neurons was associated with decreased avoidance and increased lever pressing during the presentation of conflicting stimuli, suggesting that neurogenesis plays an important role in regulating approach and avoidance behavior during high-conflict situations.

Title: The role of adult hippocampal neurogenesis in an approach-avoidance conflict task

Authors: *N. FREEDGOOD, R.-M. KARLSSON, H. A. CAMERON;
NIMH, Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: The hippocampus plays an essential role in behavioral inhibition and risk assessment. Previous studies using a non-spatial conditioned cue-based conflict task have shown that inactivation of the ventral hippocampus in rats suppresses avoidance and/or potentiates approach tendencies in a motivational conflict situation (Schumacher, Hippocampus 2015). Given these results, we sought to investigate whether animals lacking adult hippocampal neurogenesis also display impaired cue avoidance and/or approach in an approach-avoidance conflict test. Immature neurons were eliminated from the dentate gyrus of the hippocampus using transgenic rats that express herpes simplex virus thymidine kinase under the GFAP promoter and subsequent oral treatment with valganciclovir. The approach-avoidance conflict training and task utilized two or three arms of an 8 arm-radial arm maze. Bars of different colors and textures were placed along the lengths of each arm and served as cues for the unconditioned stimulus in each arm: appetitive (food reward), aversive (foot shock), and neutral (no stimulus). After all animals were trained to learn the association between the bars and the unconditioned stimuli, they were tested for arm preference to determine whether they had learned the bar cues associated with each stimulus. Both transgenic and wild-type control rats spent more time in the appetitive arm than the neutral arm, and more time in the neutral arm than the aversive arm, with no difference across genotypes, indicating learning of the cue associations was not impaired in the transgenic animals. The rats were then tested on an approach-avoidance conflict test, in which both appetitive and aversive bar cues were placed in one arm, while neutral cues remained in a second arm. Results of the conflict test show that the transgenic rats spent significantly more time in the conflict arm compared to wild-type rats. Overall, the transgenic rats spent more time in the conflict arm compared to the neutral arm, while the wild-type control rats spent more time in the neutral arm compared to the conflict arm. These results show that rats lacking adult hippocampal neurogenesis display suppressed avoidance and/or potentiated approach tendencies compared to controls in a conflict test, but not in the absence of conflict.

Title: Morpho-electric changes during the postnatal maturation of human supragranular pyramidal neurons

Authors: *M. B. VERHOOG[1], T. A. CHATIZA[1], R. M. HATTINGH[1], J. M. N. ENSLIN[2,3], R. L. MELVILL[4], A. A. FIGAJI[2,3], J. V. RAIMONDO[1];
[1]Human Biol., [2]Div. of Neurosurg., Univ. of Cape Town, Cape Town, South Africa; [3]Red Cross War Mem. Children's Hosp., Cape Town, South Africa; [4]Mediclinic Constantiaberg, Cape Town, South Africa

Abstract: Adult human pyramidal neurons possess unique morphological and physiological features which strongly impact their information processing capabilities, but little is known about what postnatal developmental stages these neurons go through to reach their mature form. Here, we make use of a rare opportunity to obtain live pediatric brain tissue resected during epilepsy surgery from patients in all stages of childhood. A pipeline involving multi-patch electrophysiological recordings, 3D dendritic reconstruction, high-resolution confocal imaging of dendritic spines, and computational modelling was used to systematically characterize human supragranular pyramidal neurons in temporal and frontal cortex from infancy to adulthood (n=25 patients, age range 0.8-40 yrs.). We find that, at 1.5 years of age, human pyramidal neurons are already ~70% of their adult size in terms of the extent of their apical and basal dendritic arborizations. Total dendritic length and number of branch points increase both as a function of depth from pia, as in adults, and as a function of age; these neurons appear to undergo a tightly correlated growth in size and complexity towards adulthood. Developmental changes were also observed in physiological properties, including resting membrane potential, input resistance, action potential kinetics and firing behavior. To explore the impact of these developmental changes on dendritic signal propagation, neural reconstructions of representative neurons for different age groups were used to build detailed compartmental models in the NEURON simulation environment, which were tuned to reproduce electrophysiological data recorded from the same neurons. Developmental changes in spine density were accounted for by adjusting the models' surface area using scale factors derived from dendritic spine imaging. Simulating synaptic activation of randomly distributed spines, we observe greater attenuation of synaptic potentials during passive propagation in pediatric neurons compared to adults, mainly as a result of increased spine density. Together, these findings show that human supragranular neurons undergo various morpho-electric changes during the protracted postnatal maturation of the human brain, which are likely to impact their function.

Title: Impact of human gut microbiota on dendritic complexity in neural circuits regulating anxiety and social behavior

Authors: *R. ROYCHOUDHURY[1], H. DUBEY[2], A. WHITE[2], S. LIU[2], R. C. KNICKMEYER[3];
[1]Col. of Osteo. Med., [3]Pediatrics, [2]Michigan State Univ., East Lansing, MI

Abstract: The ability of the gut microbiota to regulate brain development and behavior is increasinglyrecognized. For example, germ-free mice exhibit altered anxiety-like and social behaviors in avariety of paradigms as well as altered dendritic morphology in relevant brain regions such as theamygdala. However, the clinical relevance of these germ-free studies has been challenged as themajority of human development occurs in the presence of complex microbial communities. Toaddress this limitation and determine whether variation in human microbiomes influencesdevelopment of the neural circuits regulating anxiety and social behavior, we introducedmicrobiomes from typically developing infants into pregnant germ-free mice and evaluateddendritic morphology in the prefrontal cortex and amygdala of their adult offspring. We chose tofocus on infant microbiomes because infancy is a critical period in the establishment of the gutmicrobiome and in brain development. Furthermore, our team recently reported associationsbetween features of the human infant gut microbiome and amygdala and medial prefrontal cortexvolumes. One infant inoculum was characterized by high levels of *Bacteroides,* which is oftenconsidered anxiogenic, while the other was characterized by high levels of *Bifidobacterium,*which is often considered anxiolytic. Dendritic length and volume of pyramidal neurons weresignificantly greater in the prefrontal cortex of humanized *Bif* mice (N=4) compared tohumanized *Bac* mice (N=2), $p < 0.05$, suggesting that microbiomes with a high relativeabundance of *Bifidobacterium* may promote dendritogenesis of pyramidal neurons in this region.Specific-pathogen free mice (N=4) appeared more similar to the *Bac* mice, but did not differsignificantly from either group. No differences in dendritic length and volume were observed inaspiny inhibitory neurons in either the amygdala or nucleus accumbens. These findings suggestthat differences in the composition of the human gut microbiome influence development of theprefrontal cortex, which may influence social information processing and emotional regulation.However, results must be considered preliminary given the small sample size.

Title: High spatiotemporal-resolution imaging of dendritic refinement dynamics of barrel cortex layer 4 neurons in neonates

Authors: *L. WANG[1,2], S. NAKAZAWA[1,3], H. MIZUNO[4], T. IWASATO[1,2];
[1]Natl. Inst. of Genet., Mishima, Japan; [2]Dept. of Genet., The Grad. Univ. for Advanced Studies (SOKENDAI), Mishima, Japan; [3]Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland; [4]Intl. Res. Ctr. for Med. Sci. (IRCMS), Kumamoto Univ., Kumamoto, Japan

Abstract: The precise dendritic projection, which is an important component of cortical circuits, is established during early postnatal stages in an activity-dependent manner. The layer 4 (L4) spiny stellate (SS) neuron in the rodent barrel cortex is a good model to study dendritic refinement mechanisms. In adulthood, these neurons expand their basal dendrites predominantly in a single barrel and receive thalamic inputs specifically from thalamocortical axons (TCAs) transmitting tactile information from a single whisker. This characteristic dendritic projection pattern of SS neurons, which is critical for the proper sensory processing, is established during the first postnatal week under the strong influence of the thalamocortical inputs. We previously applied a two-photon time-lapse in vivo imaging approach to the analyses of dendritic refinement of SS neurons in neonatal mice (Mizuno et al., Neuron 2014; Nakazawa et al., Nature Commun. 2018). In the current study, to investigate the detailed dynamics of SS neuron dendritic refinement, we performed a shorter interval imaging. Barrel cortex L4 excitatory neurons were labeled sparsely using the in utero electroporation-based Supernova (Mizuno et al., 2014; Luo et al., Sci. Rep. 2016). TCA-GFP mice (Mizuno et al., 2014) were used to visualize the barrel map in vivo. We performed in vivo imaging of the same L4 neurons at postnatal day 4 with 1-hour interval for 8 hours. To visualize neuronal morphologies more clearly, we here used a membrane-bound RFP (mRFP) instead of a regular RFP. The regular RFP localizes primarily in the soma and often hampers the detailed analysis of dendritic morphologies. The usage of the mRFP dramatically improved the spatial resolution of the visualization of dendritic morphologies, particularly those of proximal dendrites. We found several interesting transient

morphological features in dendrites. We are currently quantifying the aspects of dendritic refinement dynamics of SS neurons as well as those of star pyramid (SP) neurons. L4 excitatory neurons are composed of SS and SP neurons, and SS neurons acquire specific dendritic orientation through dendritic refinement during development, while SP neurons do not. Thus, the comparison of dendritic dynamics between SS and SP neurons may reveal the dendritic refinement events that are critical for the formation of precise neuronal circuits. In particular, the dynamics of short dendritic trees, which are a key to dendritic refinement (Nakazawa et al., 2018), will be an important focus of our analyses. We will discuss more of our recent analysis in the presentation.

Title: Thioredoxin mediates neuronal differentiation in primary cultured mouse cerebral cortical neurons

Authors: M. LLANES-CUESTA, H. TAN, *J.-F. WANG;
Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Thioredoxin (Trx), as an oxidoreductase, can reverse protein cysteine thiol oxidative modifications, which plays a major role in cellular redox balance and defense against oxidative stress. Trx is maintained in a reduced state by Trx reductase (TrxR). Trx at a reduced state can bind to apoptosis signaling kinase 1 (ASK1) through its thiol group, which inhibits ASK1 and c-Jun N-terminal kinase (JNK)-mediated apoptosis. Recent evidence also showed that Trx overexpression increased the brain derived neurotrophic factor (BDNF) mRNA and protein levels. Because activation of ASK1 leads to neurodegeneration, while BDNF regulates neuronal differentiation, synapsis formation and survival through activation of transcription factor cAMP response element-binding protein (CREB), Trx may regulate neuronal differentiation and degeneration processes. The aim of the present study is to understand the role of Trx in neuronal differentiation, synapsis formation and survival. Primary cortical neurons were isolated from mouse fetus with 17-18 days gestation and cultured in neurobasal medium with N21 supplement from 1 to 32 days in vitro (DIV). Using western blot, we found that Trx, TrxR and phosphor-CREB protein levels increased during neuronal differentiation and maturation from 1 to 15 DIV.

Conversely, phosphor-ASK1 and phosphor-JNK protein levels are elevated during neurodegeneration after 22 DIV. Immunocytochemistry analysis showed that treatment with Trx inhibitor PX12 at 2 μM significantly reduced the number and length of primary dendrites and dendritic branches. Furthermore, treatment with 2 μM of PX12 reduced protein levels of synaptic proteins PSD95, syntaxin, SNAP25, vGlut1 and synaptophysin. Finally, treatment with 2 μM of PX12 reduced cell viability and phosphor-CREB levels while increasing phosphor-ASK1 and phosphor-JNK protein levels. Our findings suggest that Trx regulates neuronal differentiation and survival through activation of CREB and inhibition of ASK1-apoptotic pathway.

Title: Role of gamma-C4 Protocadherin in survival and self-avoidance in the mouse retina

Authors: *C. MCLEOD, G. R. NITSCHKE, A. M. GARRETT;
Pharmacol., Wayne State Univ., Detroit, MI

Abstract: Cell adhesion molecules (CAMs) are diverse cell surface molecules that are involved in an array of developmental functions, including neural circuit formation. One family of CAMs, the γ-Protocadherins, are a family of 22 protein isoforms hypothesized to play a role in defining neuronal identity. These proteins are capable of forming promiscuous multimers in cis, which then interact homophilically in trans resulting in thousands of potential recognition units between cell membranes. The specific cohort of γ-Pcdh isoforms expressed in each neuron varies at the single cell level and may endow the cell with a unique identity, thus mediating the process by which cells find their partners during neurodevelopment. The γ-Pcdhs regulate many essential processes during development of the CNS such as: neural cell survival, the formation of synapses, dendritic self-avoidance, and the formation of dendritic arbors. How exactly the γ-Pcdhs mediate these processes is not well understood. Recently one isoform, γC4, been identified as essential for postnatal viability and neuronal survival in mice, where mice lacking this isoform (C4KO) die soon after birth. This study seeks to understand the unique function and mechanism of the γC4 isoform in the processes of neuronal survival and self-avoidance in the mouse retina. We **hypothesize** that: 1) the γC4 isoform is the only necessary and sufficient isoform for promotion of neuronal survival in the retina due to its unique protein sequence. 2) γC4 alone cannot promote self-avoidance in starburst amacrine cells of the retina, also as a result of unique protein sequence. 3) γC4 has specific binding partners which promote neuronal survival. The **methods** used to investigate these hypotheses include the use of reduced diversity mouse lines

(γC4 knockout as well as γC4 only mice) to ask whether γC4's role in these two processes is truly unique among isoforms, and how that role is mediated. Preliminary **results** indicate loss of γC4 leads to decreased density of amacrine and retinal ganglion cell types, and that the presence of only γC4 in starburst amacrine cells results in disrupted self-avoidance. We **conclude** that by using the above outlined methods we will elucidate the function of and mechanism by which γC4 affects survival and self-avoidance in the retina.

Title: A hierarchical sequence dictates circuit formation during cochlear development.

Authors: *J. L. WEBBER[1], J. C. CLANCY[1], Y. ZHOU[1], N. YRAOLA[1], K. HOMMA[2], J. GARCIA-ANOVEROS[3];

Abstract: Hearing by the mammalian cochlea involves two types of sensory hair cells, each innervated by a distinct pair of afferent and efferent neuron types. Inner hair cells (IHCs), which transmit the bulk of sensory input to the brain, are innervated by type I afferents, which are in turn innervated axodendritically by lateral olivocochlear efferents (LOCs). Outer hair cells (OHCs), which fine-tune and amplify the auditory response, are directly (axosomatically) innervated by both type II afferents and medial olivocochlear efferents (MOCs). This simple arrangement of 2 sensory cells + 4 neuron types offers an ideal model system to explore neural circuit assembly during development.
In addition to differing innervation, IHCs and OHCs localize to distinct positions (inner and outer compartments) and are surrounded by different types of supporting cells. We used *Insm1* mouse mutants, in which IHCs appear amidst OHCs in the outer compartment (OC), to determine effects of cell type, environment and location on innervation. We find that type I afferents innervate IHCs regardless of position or environment, as long as they do not encounter a repelling OHC. Type II afferents can innervate both OHCs and IHCs, but only if they are not contacted by a type I afferent.

OCs of *Insm1* mutants, with OHCs and IHCs, were innervated by MOCs, not LOCs, indicating that terminal location, not HC type, determines the type of innervating efferent. However, whether the efferents terminate axodendritically (on afferents) or axosomatically (on HCs) was determined not by location nor type of HC, but by the type of innervating afferent. When OC-IHCs were innervated by type I afferents, these were contacted axodendritically by efferents; when OC-IHCs were innervated by type II afferents, they were also innervated axosomatically by efferents; and when type II afferent innervation was lost, efferent innervation disappeared. We deduce a sequential hierarchy for cochlear circuit formation. (1) IHCs attract, and OHCs repel, type I afferents; (2) type I afferents prevent innervation by type II afferents, so that these can only innervate the remaining HCs; (3) the type of afferent then instructs if and how efferents innervate: axodendritically on type I afferents, asxosomatically on HCs, or not at all.

Title: Temporal genetic program controls global wiring of post-mitotic neurons

Authors: *Y. LIN, S. JAIN, Y. Z. KURMANGALIYEV, S. A. LOCASCIO, P. MIRSHAHIDI, B. PARRINGTON, S. L. ZIPURSKY;
UCLA, Los Angeles, CA

Abstract: Brain development requires highly precise temporal regulation of gene expression. Though the temporal program of early neuron differentiation has been described in various contexts, how time is controlled in post-mitotic neurons remains unclear. In previous studies we demonstrated that developing neurons express many cell recognition molecules in neuron-type and temporal-specific ways. We speculate that these combinatorial patterns of cell surface gene expression play a central role in determining specific neural connections. Here we sought to identify the genetic programs regulating these expression patterns. We discovered that the ecdysone receptor induces a synchronous cascade of transcription factors in all differentiating neurons during synaptogenesis. Disruption of ecdysone signaling caused wiring defects in many

different neurons, including altering patterns of dendritic arborization and patterns of synaptic connections. Manipulation of different temporally expressed transcription factors in this cascade also yielded specific defects corresponding to the order of their expression during development. By performing single cell sequencing on genetically perturbed neurons, we identified downstream genes of this transcription factor cascade. The downstream genes include a common set of genes for general synapse formation and function, and a cell-type-dependent set for specific cell recognition during brain wiring. The divergence of cell-type-dependent targets of the global temporal program is regulated by cell-type-specific transcription factors. Taken together, this work identifies a synchronous temporal control of multiple aspects of wiring. We speculate that this global temporal program coordinates development across neurons to choreograph specific steps in circuits assembly.

Title: Characterization of potential growth factor-like proteins in the embryonic and adult cricket, Gryllus bimaculatus

Authors: A. L. BELL[1], W. BULHAN[2], T. N. AL MUSAWI[2], L. S. MIRANDA PORTILLO[2], A. W. RUBENSTEIN[2], F. WANG[2], L. L. LEDWIDGE[2], ***H. HORCH**[2];
[1]Bowdoin Col., Brunswick ME, ME; [2]Bowdoin Col., Brunswick, ME

Abstract: Although large scale structural plasticity in adult nervous systems is rare, some organisms maintain the ability to make compensatory structural changes into adulthood, offering the potential for insights into the mechanisms underlying structural plasticity in mature nervous systems. The cricket, *Gryllus bimaculatus*, exhibits unique and robust deafferentation-induced anatomical reorganization in the auditory system. In the cricket, two auditory organs on each forelimb send auditory afferents via nerve 5 to the prothoracic ganglion (PTG), where auditory afferents synapse onto mirror-image pairs of auditory neurons, notably Ascending Neurons 1 and 2 (AN1 and AN2). These cells receive auditory input only from the ipsilateral ear because

auditory system dendritic and axonal arbors are restricted by the midline. Upon unilateral loss of an ear, the deafferented ipsilateral AN1 and 2 dendrites sprout across the midline of the PTG, forming functional, frequency-specific synapses with contralateral auditory afferents. We have completed RNAseq experiments on control and deafferented PTGs. GO Term analysis of signalling pathways differentially expressed after deafferentation identified several growth factor-like candidates, including the Toll receptors and the Protein Yellows. Here we characterize several Toll receptors, their Späetzle ligands, and several Protein Yellow family members in the cricket. Generally, genes encoding these proteins are well-conserved in *Gryllus*, though there is an apparent loss of several genes, such as Späetzle-2, and Protein Yellow-c, -g, and -k. We also find evidence for duplication and divergence of Protein Yellows and Toll receptors. We are currently assessing the expression of several of these candidates in the nervous system of embryos and in the adult PTG and brain using *in situ* hybridization. Further characterization of splice variants and expression patterns will inform future experiments in which we explore the function of these growth factor-like proteins in the development, maintenance, and plasticity of the nervous system in the cricket.

Title: Reelin's regulation of translation during neuronal development

Authors: *G. LAGANI, U. BEFFERT, A. HO;
Boston Univ., Boston, MA

Abstract: Reelin is a large secreted glycoprotein with a broad spatiotemporal expression profile in the developing and adult mammalian brain. Reelin plays several important roles during brain development, including regulating neuronal migration, stimulating dendritogenesis, promoting dendritic spine maturation, and enhancing long-term potentiation (LTP) at mature hippocampal synapses. Canonically, Reelin binds to the receptors VLDLR and ApoER2, leading to phosphorylation of the Disabled 1 (Dab1) adaptor protein and stimulation of the PI3K/Akt/mTOR pathway. Since the mTOR pathway is a known regulator of protein translation, we hypothesize that Reelin stimulates specific translational dynamics during different phases of neuronal development. To address this, murine primary neuronal cultures were treated with Reelin or control conditioned media for 20 min at 3, 7, and 14 days *in vitro* (DIV). Neuronal

lysate was collected and subjected to SDS-PAGE and immunoblotted for total Akt, mTOR, and S6K1, as well as phosphorylated Akt-S473, mTOR-S2448, and S6K1-T389. Reelin treatment led to increased phosphorylation of both Akt-S473 and S6K1-T389 without changes in total Akt or S6K1 expression. Reelin-induced phosphorylation of Akt and S6K1 was most robust at DIV3 and DIV7 with an attenuated response at DIV14. In addition to immunoblotting, we immunostained DIV7 neuron cultures for Akt-S473 or S6K1-T389. Cultures were also immunostained with MAP2 or tau to visualize neuronal morphology. Total fluorescence intensity was used to measure the level of Akt-S473 and S6K1-T389 phosphorylation. To examine Reelin's role in stimulating translation, we used puromycin metabolic labeling. Primary neurons were treated with Reelin or control media followed by puromycin-labeling to tag nascent peptides. A puromycin specific antibody was used to visualize incorporation of newly translated peptides. Preliminary experiments show an increase in puromycin fluorescence intensity in response to Reelin, suggesting Reelin increases translational activity. Based on these results, we demonstrate Reelin to be a potent activator of the PI3K/Akt/mTOR pathway in early developmental time points and a positive regulator of translation.

Title: Successful functional recovery after peripheral nerve implantation to the targeted muscle in rats with nerve injury

Authors: *J. KWON[1,2], J. LEE[1,2], Y. YOON[3], J. KIM[2,4];
[1]Dept. of Rehabilitation, Col. of Hlth. Sci., [2]Transdisciplinary Major in Learning Hlth. Systems, Dept. of Healthcare Sci., Grad. School, Korea Univ., Seoul, Korea, Republic of; [3]Dept. of Physiology, Col. of Med., [4]Dept. of Physical Therapy, Col. of Hlth. Sci., Korea Univ., Seoul, Korea, Republic of

Abstract: In the prolonged pathologic status of peripheral nerve injury, formation of traumatic neuroma inhibits appropriate functional restoration and produces painful condition. Because they cannot make spontaneous recovery without surgical intervention, a variety of surgical attempts have been tried. Especially, targeted muscle reinnervation (TMR) known as a prominent microsurgery of transferring donor nerve to an alternate target muscle for preventing primary neuroma and providing environments for axon sprouts to proper direction. However, it has still limited clear improvement in functional recovery and versatile application because targeted muscle should be innervated by other nerves.In this study, we investigated if the implantation of injured peripheral nerve to adjacent muscle has effect on sensory and motor recovery even 12 days after targeted muscle had been denervated. For this, the tibial nerve was transected and transferred to the adjacent part of gastrocnemius muscle at the different time intervals after denervation (immediately or 12 days). Behavioral test for mechanical sensitivity was quantified by using paw withdrawal threshold (PWT) test and tibial nerve function index (TFI) was analyzed for confirming change of paw deformity. 8 months after nerve implantation, ventral part of spinal cord was analyzed for synaptic change by immunofluorescence with synaptophysin. To verify functional re-innervation of targeted muscle, morphological formation of neuromuscular junction (NMJ) was investigated by labeling acetylcholine receptor (AChR) and electromyography (EMG) was performed at the targeted muscle at 8~12 weeks after surgery. After nerve implantation, PWT was significantly increased and muscle atrophy was less progressed in all the nerve implantation group regardless of denervation time interval. Expression of synaptophysin showed no difference with nerve implantation and normal group while control group was decreased. The structure of pretzel-like AChR cluster was observed and the results of EMG implicate that targeted muscle have recovered function following re-innervation although not as much as normal muscle.The present results suggest that denervated muscle can be re-innervated by implanted nerve even after formation of traumatic neuroma. These sensory and functional outcomes may provide experimental foundation of clinical application to maximize the functional efficacy of surgical reconstruction for peripheral nerve regeneration and reinnervation.

Title: Knockout of the receptor tyrosine kinase Kit impairs feed-forward inhibition in the mouse cerebellum

Authors: T. ZAMAN, A. M. STAFFORD, Q. A. ALSABIA, D. VOGT, ***M. R. WILLIAMS**; Pediatrics & Human Develop., Michigan State Univ., Grand Rapids, MI

Abstract: The receptor tyrosine kinase Kit is enriched in discrete populations of neurons in the mouse and human brain. The endogenous activator of Kit, the sheddable transmembrane protein Kit Ligand, is enriched in populations of neurons known to synapse with those expressing Kit. This complementary pattern of expression has suggested that Kit Ligand-Kit interactions may mediate some essential aspects of synapse biology. Consistent with this idea, in mice and humans, mutation of Kit Ligand or Kit is associated with abnormalities of neuronal function or with neurodevelopmental disorders. We have therefor sought to use the mouse as a model organism to explicitly test the central hypothesis that Kit Ligand-Kit interactions influence synaptogenesis. Within mice and humans, Kit is highly enriched in GABAergic Molecular Layer Interneurons (MLIs) of the cerebellar cortex, while Kit Ligand is highly enriched in Purkinje Cells (PCs), which MLIs migrate to and synapse upon. We have recently reported that depletion of Kit Ligand from PCs decreases GABAergic events recorded in PCs, suggesting that the decreased activation of Kit in MLIs reduces their functional synaptogenesis upon PCs. To test this model, we generated a conditional knockout allele of Kit (having exon 4 floxed), and crossed these mice to Pax2-Cre mice, which enables early developmental ablation of Kit from MLIs (and other cell types). In Pax2-Cre mediated Kit KO animals, we observed a significant reduction in the frequency (but not the amplitude) of spontaneous GABAergic currents recorded in PCs, as compared to control littermates. This result is consistent with a reduction in the functional number of MLI-PC synapses. These results support the model that trans-synaptic activation of Kit by Kit Ligand may be a mechanism for the development or maintenance of central synapses.

Title: Nsg1 and nsg2 knockout mice display divergent behavioral phenotypes

Authors: A. J. ZIMMERMAN[1], P. CHANDER[2], R. AUSTIN[1], *J. WEICK[1];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Jefferson Unversity, Philadelphia, PA

Abstract: Members of the neuron-specific gene family (NSG1/NEEP21, NSG2/HMP19 and NSG3/Calcyon) are small endosomal proteins that have been implicated in the trafficking of multiple neuronal proteins including L1/NgCAM, β-APP, and neurotensin receptors. In addition, they are best characterized for their critical roles in the regulation of synaptic development and plasticity via modulation of AMPAR trafficking through endolysosomal pathways. NSG1 is principally thought to promote recycling of AMPARs to the plasma membrane during long-term potentiation, while NSG2 appears to promote heightened synaptic strength during basal activity. However, little is known about the functional requirement of NSG family members and whether they are involved in particular forms of motor, affective, and/or cognitive behavior. To test this, we performed a battery of behavioral assessments on adult mice with constitutive loss of NSG1 or NSG2. Interestingly, opposing phenotypes were found between NSG1 and NSG2 KOs on several behavioral modalities, with a general tendency for NSG1 KOs to perform slightly worse than wild-type controls and for NSG2 KOs to show improvement over wild-type animals. NSG1 KO mice displayed subtle motor deficits in gait as manifest by alterations in paw-surface contact. They also display heightened anxiety on elevated mazes, hyperactivity during subjective daytime, and no change in hippocampal-dependent cognition. In contrast, mice lacking NSG2 showed no motor impairments, demonstrated *reduced* activity during wake phases, and *enhanced* hippocampal-based learning and memory. These contrasting results between NSG1 and NSG2 KOs suggest that they have disparate roles in excitatory synaptic function, a conclusion supported by previous molecular studies. Additionally, they suggest that NSG1 and NSG2 function have different circuit-specific roles in synaptic maintenance of excitatory neurotransmission in adult animals. This occurs despite largely overlapping expression patterns during development and in adults as demonstrated by whole-mount immunohistochemical staining. However, the maintenance of greater amounts of NSG2 expression in adults likely contributes to stronger phenotypes in loss-of-function mutants.

Title: Role of Serotonin Signaling on Synaptic Plasticity in Tuberous Sclerosis Complex

Authors: R. SRINIVAS[1], R. KIRCHNER[2], W. FRANCESCONI[1], F. BERTON[1], ***A. YOSHII**[1]; [1]Dept. of Anat. and Cell Biol., Univ. of Illinois at Chicago, Col. of Med., Chicago, IL; [2]Biostatistics, Harvard Chan Sch. of Publ. Hlth., Boston, MA

Abstract: Tuberous sclerosis complex (TSC) is an autosomal dominant genetic disorder caused by mutations in *TSC1* or *TSC2*. While it is a multi-organ disease, neurological symptoms are prominent and include epilepsy, intellectual disabilities, and autistic behaviors. Dysregulated synapse formation and plasticity are likely to play a significant role in the pathophysiology of TSC. The TSC-1 and -2 proteins form a complex that downregulates the mammalian target of rapamycin (mTOR) pathway, and a gene mutation results in mTOR overactivation. mTOR is a critical regulator of protein synthesis, autophagy, cellular metabolism, and synaptic plasticity. Consequently, suppression of mTOR by rapamycin or its derivatives is one way to correct the pathophysiology of TSC. However, the mTOR pathway has multiple roles, and rapamycin neither specifically nor completely cures all neurological symptoms. A greater understanding of dysregulated synaptic function will enable identifying specific therapeutic targets for epilepsy and cognitive disabilities in TSC. To identify the cause of abnormal synaptic activities, we examined a pan-neuronal *Tsc1*$^{-/-}$ mouse. An unbiased analysis with RNA-seq revealed an excess of transcripts associated with the serotonin signaling pathway. The amount of protein was also higher, and its intracellular distribution was altered in pyramidal cells of the *TSC1*$^{-/-}$ cortex. We used calcium imaging and found that *Tsc1*$^{-/-}$ cultured cortical neurons had frequent Ca^{2+} bursts throughout the soma and dendrites that depended on the serotonin pathway, while wild-type neurons showed random and scattered transients mostly within dendritic spines. Furthermore, daily injection of the serotonin pathway antagonist rescued the premature death of the mutant pups. Remarkably, we also found that the developmental subunit switch of the NMDA-type glutamate receptor was aberrant in the pan-neuronal *Tsc1*$^{-/-}$ mouse cortex, and the serotonin pathway inhibition corrected perturbation of the GluN2B-to-2A subunit switch. Finally, *in vivo* calcium imaging using two-photon microscopy showed hypersynchrony of pyramidal cells in the *Tsc1*$^{-/-}$ mouse cortex. We will present the effect of the serotonin pathway antagonism. Our results indicate that intervening in the serotonergic pathway corrects synaptic dysregulations caused by excessive mTOR pathway activity and sets the stage for developing a new therapeutic approach.

Inst., Jan and Dan Duncan Neurolog. Res. Inst., Houston, TX

Abstract: While the contributions of some genes to neuropsychiatric disorders are clear, the downstream neuronal effects are poorly understood. Over-expression of *SHANK3*, which encodes a key synaptic protein, causes neuropsychiatric phenotypes in humans and manic-like behavior in mice providing an opportunity to interrogate the role of SHANK3 in a subset of neurons that might underlie the manic-like behavior. Herein, we describe Shank3's critical role in D2 dopamine receptor (D2dr) neurons and show that *Shank3* overexpression causes increased synaptic neurotransmission in D2dr, but not D1dr, expressing striatal medium spiny neurons. Either pharmacologic D2dr inhibition or genetic normalization of Shank3 abundance in D2-neurons ameliorates manic-like behaviors. Integrating bioinformatic analyses of Shank3's striatal interactome, D1 and D2 dopamine receptor binding proteins, and single-cell RNA-seq datasets, we demonstrate a functional relationship between Shank3 and the D2dr—but not the D1dr. Thus, while *Shank3* is over-expressed in both D1 and D2 dopamine receptor expressing striatal neurons, D2 neuronal dysfunction causes manic-like behaviors.

Title: Mechanism and function of glutamate/GABA cotransmission in entopeduncular nucleus projections to the lateral habenula

Authors: *S. KIM[1], M. L. WALLACE[2], M. EL-RIFAI[1], A. R. KNUDSEN[1], B. L. SABATINI[1];
[1]Harvard Med. Sch., Boston, MA; [2]Boston Univ. Sch. of Med., Boston, MA

Abstract: Many mammalian neurons release multiple neurotransmitters to activate diverse classes of ionotropic receptors on their postsynaptic targets. Previously, our lab has identified a subtype of entopeduncular (EP) nucleus neurons that project to the lateral habenula (LHb) releasing both excitatory and inhibitory neurotransmitters, glutamate and GABA, respectively. It remained unclear if these opposing neurotransmitters are packaged into the same or segregated pools of synaptic vesicles. Furthermore, function of glutamate/GABA cotransmission in behavior is not well understood.
First, we demonstrate a novel method combining electrophysiology, spatially-patterned optogenetics, and computational modeling designed to analyze the mechanism of glutamate/GABA corelease. We find that the properties of postsynaptic currents elicited in LHb neurons by optogenetic activation of EP terminals are only consistent with co-packaging of glutamate and GABA into individual vesicles.
Second, we perform fiber photometry to record bulk calcium signals from the glutamate/GABA coreleasing EP neurons during punishment-based learning. Our results describe response pattern of these neurons and have implications for how glutamate/GABA cotransmission may contribute towards aversive cue-outcome association.

Title: Aberrant visual responses in the SynGAP1+/- mouse model of autism spectrum disorder

Authors: *C. A. MARTIN[1], E. T. ANDERSON[2], K. F. K. EJENDAL[1], T. L. KINZER-URSEM[1], M. C. DADARLAT[1];
[1]Biomed. Engin., Purdue Univ., West Lafayette, IN; [2]IU Sch. of Med., Indianopolis, IN

Abstract: Autism spectrum disorder (ASD) is strongly associated with impairments in social function, including understanding complex and subtle social stimuli, which may arise in part from deficits in visual processing. Autism is a serious form of intellectual disability that can result from genetic mutations such as haploinsufficiency and loss of function mutations of the *SYNGAP1* gene. This gene codes for a synaptic GTPase-activating protein that is enriched in excitatory synapses and acts as part of a pathway regulating synaptic plasticity. Heterozygous *Syngap1*+/- mice, with reduced levels of SynGAP1 protein, exhibit an ASD-like behavioral phenotype with partial deficits in synaptic plasticity and an early-shifted developmental schedule, resulting in early closure of sensory critical periods and reduced experience-dependent plasticity that may interfere with normal development of the visual system. Furthermore, *Syngap1*+/- mice have decreased cortical gray matter brain volume throughout visual areas. However, hierarchical visual processing has not been previously well characterized in this mouse model. To address this gap, we used 64- and 128-channel microelectrode arrays to record neural activity in the primary visual cortex of four mice (140 neurons from 2 *Syngap1*+/- mice and 70 neurons from 2 wild-type littermate controls), ages between 2-6 months. Neural activity was recorded in response to visual stimuli to assess receptive field size, orientation tuning curves, and overall neural activity levels. *Syngap1*+/- mice had lower overall firing rates than WT controls (3.8 vs. 5.6 Hz, $p < 0.05$), but had significantly larger receptive fields (*Syngap1*+/- 450.5 visual degrees, wild-type 261.1 visual degrees, $p < 0.01$). For both genotypes, a fraction of neurons had no distinct receptive fields with 67.9% of *Syngap1*+/- and 25.7% of wild-type neurons demonstrating these properties. Furthermore, neurons from both groups showed clear orientation tuning curves in response to drifting oriented gratings. Overall *Syngap1*+/- mice had lower orientation selectivity values (0.29 (±0.19) vs. 0.40 (±0.32), $p < 0.01$), and similar circular variance (0.89 (±0.11) vs. 0.85 (±0.16), $p > 0.05$) – a parameter that estimates tuning width in a model-free manner. Our results support the hypothesis that the early maturation of excitatory synapses in *Syngap1*+/- mice impairs normal refinement of neural responses to visual stimuli during development, leading to deficits in normal visual processing in adult animals.

Title: Norbin regulates group I metabotropic glutamate receptor (mGluR) trafficking and fine-tunes mGluR-triggered AMPAR endocytosis through its interaction with protein kinase A (PKA) in mouse hippocampal neurons

Authors: *P. OJHA, S. PAL, S. BHATTACHARYYA;
Dept. of Biol. Sci. (DBS), INDIAN INSTITUTE OF SCIENCE EDUCATION AND RESEARCH, Mohali, India

Abstract: Synapses are dynamic formations within the neuronal architecture, they tend to strengthen and weaken depending on various neuronal responses. There are multiple proteins within the synaptic density for relaying information as well as for regulating "plasticity". One such group of proteins which are highly enriched in postsynaptic terminals and are essential for the regulation of synaptic plasticity are group I metabotropic glutamate receptors (mGluRs). Trafficking of mGluRs is known to modulate signaling and therefore synaptic plasticity by regulating the endocytosis of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs). Thus, it has to be tightly regulated by several postsynaptic density proteins in conjunction with other intracellular signalling molecules. In this study, we identify that Norbin is a scaffolding protein that regulates group I mGluR trafficking and mGluR-mediated synaptic plasticity. Using primary hippocampal neurons from P0 C57BL/6 mice of both sexes and differential antibody labelling of surface and internalized receptors to study receptor trafficking at single cell resolution, we report that Norbin is essential for the ligand-mediated internalization of group I mGluRs. We have used a "molecular replacement strategy" to knockdown endogenous Norbin and to study the effect of various heterologous constructs of Norbin within the same cell. We find that Norbin associates with protein kinase A (PKA) through its N-terminus and anchors mGluR5 through its C-terminus, both of which are necessary for ligand-mediated mGluR5 endocytosis. A point mutation (NorA687G) at the C-terminus of Norbin inhibits the binding of Norbin to mGluR5 and blocks mGluR5 endocytosis. We also identify a novel PKA-dependent modulation of the mGluR-AMPAR axis. Norbin acts as a central mediator for recruiting PKA to AMPARs upon the activation of group I mGluRs which is essential specifically for the mGluR-triggered AMPAR endocytosis, a cellular correlate of mGluR-mediated synaptic plasticity. Both knockdown of endogenous Norbin and deletion of the PKA-binding peptides from Norbin drastically inhibit the mGluR-mediated AMPAR endocytosis. Our findings confirm that Norbin has a dual role in the hippocampus,
(a) as a regulator of group I mGluRs and (b) as an A-kinase anchoring protein (AKAP) that recruits PKA and modulates mGluR-mediated AMPAR endocytosis. Thus, we have unraveled a previously uncharacterized role of Norbin in ligand-induced receptor endocytosis that can have clinical relevance in various neuropsychiatric disorders like schizophrenia, epilepsy etc., where Norbin and mGluR5 have together been implicated.

Title: Neurotrophic factor-α1 interaction with serotonin receptor 5HTR1E protects against neurotoxicity via β-arrestin/ERK-BCL2 signaling

Authors: V. K. SHARMA[1], X. YANG[1], S.-K. KIM[2], A. MAFI[2], D. S. SANCHEZ[3], L. XIAO[1], A. INOUE[4], W. A. GODDARD, III[2], ***Y. LOH**[1];

Abstract: Neurotrophic factor-α1/Carboxypeptidase E (NFα1/CPE) is secreted by neurons and endocrine cells where it acts as a prohormone processing enzyme intracellularly and as a neurotrophic factor, extracellularly. Previously we showed that extracellular treatment of hippocampal neurons with NFα1/CPE protected them from oxidative stress-induced cell death through ERK/BCL2 signaling. Based on these results, we hypothesized that NFα1/CPE activation of the ERk/BCL2 pathway to mediate neuroprotection should involve interaction with receptors at the cell membrane. To search for the receptor, we carried out high throughput screening of a library of 324 orphan GPCRs using NFα1/CPE as ligand. The screen identified 5-hydroxytryptamine receptor 1E (5HTR1E), a serotonin receptor, as a binding partner (or receptor), which was confirmed by co-immunoprecipitation and pull down experiments with NFα1/CPE. Radioligand binding studies in HEK293-5HTR1E overexpressing cells showed that recombinant ^{125}I NFα1/CPE bound to 5HTR1E with high affinity (Kd = 13.82 nM). Molecular modeling studies predicted that NFα1/CPE interacted with 5HTR1E, not at the serotonin binding pocket, but via the extracellular loop (ECL)2 of 5HTR1E, forming 3 stable salt bridges with specific amino acid residues in NFα1/CPE. To identify the mechanism underlying the 5HTR1E-NFα1/CPE mediated ERK phosphorylation, we used HEK293 cells stably expressing 5HTR1E. First we tested Gi and Gq protein inhibitors, but found no effect, suggesting that NFα1/CPE stimulated ERK activation was independent of G proteins. We then explored the involvement of β-arrestin, an alternative coupling mechanism with GPCRs for ERK activation. Studies in 5HTR1E expressing-HEK293-β-arrestin KO cells revealed that NFα1/CPE-5HTR1E complex was unable to induce ERK signaling in the absence of β-arrestin proteins. Furthermore, molecular docking studies revealed a very strong coupling of β-arrestin to intracellular loop (ICL) 2 and ICL3 of 5HTR1E. Using LDH cytotoxicity assay we then demonstrated that NF-α1/CPE was able to protect HEK-293-5HTR1E expressing cells against H_2O_2-induced cytotoxicity, *via* increasing pro-survival protein BCL2 expression; however, this protective effect of NFα1/CPE was diminished in the β-arrestin KO cells. Our findings have uncovered a novel mechanism involving NFα1/CPE-5HTR1E interaction to activate β-arrestin/ERK/BCL2 signaling pathway for protecting cells against oxidative stress induced cytoyoxicity.

Title: Norepinephrine triggers rapid nuclear PKA activity through activation of β1-adrenergic receptors localized to the inner nuclear membrane in astrocytes

Authors: *K. C. BENTON, D. S. WHEELER, M. B. ANSARI, B. KURTOGLU, J. G. MAGLASANG, S. KHURSHEED, S. HERGENROTHER, D. LOBNER, P. J. GASSER; Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: In the conventional model of adrenergic signaling norepinephrine activates G-protein-coupled receptors exclusively localized to plasma membranes. However, a growing body of evidence indicates norepinephrine can also initiate signaling intracellularly through activation of adrenergic receptors localized to endosomal, Golgi, and nuclear membranes. Norepinephrine is a cationic ligand, requiring carrier-mediated transport to activate intracellular-localized adrenergic receptors. We have previously demonstrated that a high-capacity transporter for norepinephrine, organic cation transporter 3 (OCT3), is localized to both plasma membranes and outer nuclear membranes in neurons and astrocytes, suggesting a potential role for nuclear adrenergic signaling in the central nervous system. We used immunocytochemistry and subcellular fractionation followed by western blot analysis to reveal that β1-adrenergic receptors are localized to inner nuclear membranes in primary cortical mouse astrocytes, and that key G_s-mediated signaling components are localized to the nuclear compartment. We identified the catecholamine transporters OCT3, OCT2, plasma membrane monoamine transporter (PMAT), dopamine transporter (DAT), and norepinephrine transporter (NET) localized to nuclear membranes in astrocytes. The present studies test the hypothesis that norepinephrine activation of nuclear adrenergic receptors is gated by catecholamine transporters. We expressed a nuclear-localized PKA activity sensor in primary astrocytes to observe real-time changes in PKA activity in the nuclear compartment. Treatment with norepinephrine induced both rapid and delayed increases in nuclear PKA activity. Pretreatment with a cocktail of inhibitors for OCTs, PMAT, NET, and DAT abolished the rapid, but not delayed, nuclear PKA response. These findings indicate that β1-adrenergic receptors are functionally coupled to key signaling components in the

nucleus of astrocytes, and that rapid nuclear PKA responses to norepinephrine require uptake by catecholamine transporters.

Title: Effects of oxytocin analogs on neurite outgrowth and cellular signaling in human-derived SH-SY5Y cell line

Authors: *M. PIERCE[1], N. VATTEM[2], A. GORE[2], A. LESCHINSKY[2], A. AZIZ[2], M. BUTT[2], J. ABURAS[1];
[1]Pharmacol., [2]Chicago Col. of Osteo. Med., Midwestern Univ., Downers Grove, IL

Abstract: Introduction Arginine vasopressin (AVP) and oxytocin (OT) are neuropeptides that bind to G-protein coupled receptors and influence social behaviors, and perturbations are associated with psychopathologies including autism spectrum disorder, schizophrenia, and depression. In mammals, consensus mammalian AVP and OT (Leu^8-OT) sequences are highly conserved. Six distinct OT ligand variants have been discovered in New World Monkeys, including two with in a proline in the 8th position of the peptide (Pro^8-OT; Val^3-Pro^8-OT) resulting in a polyproline helix. In addition to sequence homology between AVP and OT, structural homology between OT receptor (OTR) and vasopressin 1a receptor (V1aR) result in significant cross-reactivity between the ligands and receptors.
Methods The human-derived SH-SY5Y cell line exhibits morphological characteristics of neurons including neurites and endogenously expresses OTR, but not V1aR. Functional assays were performed using Fluo8-AM to measure ligand-induced calcium (Ca^{2+}) mobilization and FLIPR Membrane Potential (FMP) assays to assess ligand-induced hyperpolarization occurring as a consequence of stimulation of potassium (K^+) channel currents. To assess effects on neurite outgrowth, cells were treated with semi-logarithmic doses of OT analogs for 24 hours, fixed and stained with phalloidin and DAPI. The Nikon A1R confocal microscope was used to collect images to examine effects on neurite outgrowth using the Image J package FIJI with the NeuronJ plugin.
Results In SH-SY5Y cells, all three OT analogs were more potent than AVP at inducing Ca^{2+} mobilization. Specificity of the signaling at the OTR were confirmed using the V1aR antagonist SR49059 and the OTR antagonist L-371,257. Moreover, all three OT analogs displayed

equipotency at stimulating Ca^{2+}-mediated depolarization and K^{+}-mediated hyperpolarization. Finally, all OT analogs show a dose-dependent increase in neurite outgrowth.
Conclusions Together, these data suggest that OTR-mediated signaling pathways lead to neurite outgrowth in SH-SY5Y cells. Integrative studies of behavior, genetics and ligand-receptor interaction are crucial for translating signaling activation at the cellular level to effects of OT ligands on social behavior. Knowledge of how OT alters neuronal structure and function has the potential to both identify mechanisms that produce social dysfunction and to inform the development of therapeutic agents.

Title: Select second generation antipsychotics are arrestin-biased agonists at D3 dopamine receptors in prefrontal cortex

Authors: *S. SCHAMILOGLU[1], E. LEWIS[3], J. ATHILINGAM[2], K. J. BENDER[2], J. L. WHISTLER[3];
[1]Neurosciences Grad. Program, [2]Dept. of Neurol., UCSF, San Francisco, CA; [3]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Second generation antipsychotics (SGAs), including clozapine, quetiapine, and aripiprazole, are used to treat schizophrenia and bipolar disorder and show fewer extrapyramidal side effects than their earlier counterparts. SGAs bind with high affinity to G protein-coupled receptors (GPCRs), including D2 and D3 dopamine receptors (D2R, D3R). Their utility is thought to rely on blockade of dopamine-mediated G protein signaling. However, individual SGAs vary in their side effects, including seizures, depression, and metabolic dysfunction, suggesting that effectors other than G protein may be important for their function. SGA pharmacology is well-studied at D2R but less-characterized at D3R, which is expressed throughout brain regions implicated in psychiatric disorders, including prefrontal cortex (PFC). We have previously found that D3R agonist modulation of $Ca_V3.2$ calcium channels at the axon initial segment (AIS) requires noncanonical, G protein-independent signaling through arrestin-3. Here we demonstrate that select SGAs also engage arrestin-3 signaling at D3R, stimulating phosphorylation of ERK *in vitro* and modulating $Ca_V3.2$ at the AIS in D3R-expressing PFC

pyramidal cells. These results highlight a previously unrecognized difference in SGA signaling at D3R, that could inform the development of next-generation pharmaceuticals with improved effect/side-effect profiles.

Title: G α subunits selectively modulate mu opioid receptor pharmacology as observed with a BRET assay

Authors: M. E. BARNETT, B. I. KNAPP, ***J. M. BIDLACK**;
Univ. of Rochester Sch. of Med. and Dent., Rochester, NY

Abstract: The μ opioid receptor (MOR) is a G protein-coupled receptor that couples to the Gαi/o subunits. However, it is common to downplay the diversity within this class. Gαz is an often-overlooked member of this class, yet its prevalent expression in similar regions of the brain as opioid receptors suggests it may serve a distinct role in MOR signaling. Using a bioluminescence resonance energy transfer (BRET) sensor, we investigated the potential of Gαz and its regulator of G protein signaling counterpart, RGSZ, as a means to control both efficacy and potency of MOR agonists. Agonist binding to MOR resulted in an increase in BRET due to G-protein dissociation. The full agonists DAMGO, β-endorphin, endomorphin-1, methadone, etorphine, and fentanyl were more potent when MOR signaled through Gαz compared to other Gαi/o subunits. For example, the EC_{50} value of fentanyl increased 3-fold when the MOR signaled through Gαi1 compared to Gαz. Partial agonists, such as morphine, (-)pentazocine, metazocine, and ethylketocyclazocine, were more potent and more efficacious when the MOR signaled through Gαz compared to the other Gαi/o subunits. When RGSZ was present in the system, the concentration-response curves of DAMGO and morphine had a significant rightward shift. Increased activation and deactivation rates were correspondingly observed in the presence of RGSZ. Gαz has a slow rate of GTP hydroylsis in comparison to other Gαi/o proteins. To mimic the biochemical properties of Gαz, two different mutations were made in GαoA. GαoA G183S was RGS-insensitive and GαoA 41TSN43 had a slower intrinsic rate of GTP hydrolysis. Both mutants resulted in decreased rates of activation and deactivation for DAMGO and

morphine. When the MOR signaled through either mutant, the concentration-response curves of DAMGO and morphine both had a significant leftward shift. Taken together, signaling through mutant GαoA mimicked the ability of Gαz to enhance opioid potency and efficacy downstream of receptor binding. Enhanced potency and efficacy observed the MOR signaling through Gαz may be the result of slower GTP hydrolysis.

Title: Harnessing a light-sensitive, neuronal GPCR to study ciliary localization and signaling in vivo

Authors: *A. M. WINANS, D. FRIEDMANN, E. Y. ISACOFF;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Many differentiated cells in the body, including most neurons, produce a single, primary cilium. Mutations that affect primary cilia give rise to a host of diseases termed "ciliopathies" which often manifest neurodevelopmental and cognitive defects. Certain neuronal G-protein coupled receptors (GPCRs), such as serotonin and dopamine receptor subtypes, localize to the primary cilium. However, how ciliary localization modulates neuronal GPCR signaling and downstream behavior is still not well understood. Here, we compare ValopA, a ciliary non-visual opsin, and its homolog ValopB, a cell body-localized non-visual opsin, to interrogate potential effects of ciliary localization on behavior. ValopA expresses in the spinal cord of the embryonic zebrafish and inhibits spontaneous coiling when excited by blue green light. Photoinhibition of locomotion is followed by a post-excitatory phase lasting tens of minutes following cessation of the light. ValopB, when overexpressed in a ValopA knock-out animal, successfully rescues the inhibitory and excitatory phases but with markedly shorter kinetics. To probe the relationship between localization and signaling kinetics, we created a suite of ValopA/B chimeras with variable ciliary and cell body localization patterns, as well as a ValopB-Rab23 fusion protein that localizes to the cilium. Rescue experiments with these constructs show that increased ciliary localization coincides with increased photoinhibition length. Moreover, constructs with significant cell body expression will inhibit locomotion well upon repeated excitation whereas constructs with largely ciliary expression experience a decrease in inhibition efficiency and also take longer to reach full inhibition. Future experiments

will pinpoint the contribution of intrinsic signaling kinetics versus sub-cellular localization on the observed behavior.

Title: Non-visual opsin 3 functionally interacts with melanocortin receptors in hypothalamic neurons

Authors: *H. HADDAD, L. OLINSKI, C. CHUNG, E. OANCEA;
Brown Univ., Providence, RI

Abstract: Opsins are light-sensitive G-protein coupled receptors that convert external photons into intracellular signaling events. While most vertebrate opsins are well characterized, *the function and G-protein signaling of the extra-ocular opsin 3 (OPN3) in the central nervous system is unknown with untapped therapeutic potential*. Unlike other opsins mostly expressed in the retina, OPN3 is expressed in deep brain areas and peripheral tissue. In skin melanocytes, OPN3, via Gαi G-protein, inhibits the cAMP response triggered by activation of G-protein coupled receptor melanocortin 1 (MC1R), thus decreasing melanin levels in a light independent manner. Brain mapping of our OPN3-mCherry knock-in mouse model reveals high expression of OPN3 in brain areas that are associated with energy metabolism and food intake regulation, specifically the paraventricular nucleus of the hypothalamus. Neural melanocortin 4 receptor is highly expressed in this brain area and signals through cAMP to function in regulating energy balance and metabolism. More recently, MC4R was discovered to close inward rectifying potassium channel (Kir7.1) in a G-protein independent manner in response to α-melanocortin stimulating hormone (αMSH), an agonist of MC4R. This project explores the potential role of OPN3 in regulating MC4R-mediated signaling mechanisms. Through the monitoring of single-cell, real-time changes in intracellular cAMP, we found that in response to αMSH, OPN3 decreases cAMP accumulation compared to control conditions. This decrease in cAMP accumulation in OPN3 over-expressed cells was abolished after blocking Gαi activity using pertussis toxin. To examine potassium signaling, we used a thallium flux assay that measures flow of thallium through open potassium channels. By using live-cell imaging and OPN3 targeted shRNA to knock down OPN3, we discovered that knocking down OPN3 leads to a decreased thallium flux response compared to control condition when treated with αMSH. In an opposite manner, we also found that over-expressing OPN3 leads to an increased thallium flux response compared to αMSH treated control conditions. Blocking Kir7.1 channels with a

selective pore blocker (VU590) abolished the flux responses to αMSH. These findings suggest that OPN3 negatively regulates melanocortin receptor-activated cAMP signaling in a Gαi dependent manner. In terms of potassium signaling, our results indicate that OPN3 disinhibits the MC4R inhibition of Kir7.1 and leads to more channels opening upon MC4R activation. Our data reveal a novel signaling pathway with implications in energy regulation and therapies for metabolic diseases.

Title: Ciliary receptors in neurons: Competitive regulation and implications for excitability

Authors: *J. SHRESTHA[1], J. L. FUCHS[2];
[1]Biol. Sci., Univ. of North Texas, DENTON, TX; [2]Biol. Sci., Univ. of North Texas, Denton, TX

Abstract: Neurons commonly have a primary cilium, which is a non-motile organelle extending from the centrosome into the extracellular space. In most brain regions, cilia are highly enriched in either somatostatin type 3 receptors (SstR3) or melanin concentrating hormone type 1 receptors (MCHR1), or both. These GPCRs may affect neuronal excitability, as evidenced by heightened vulnerability to seizures in SstR3-/- mice and heightened resistance to seizures in MCHR1-/- mice. In the present study, we present evidence for competition between the two ciliary receptors. We have shown that in SstR3-/- mice, MCHR1(+) cilia are increase markedly in number and intensity. Here we also find the converse, that ciliary SstR3 was increased in MCHR1 knockouts. These striking comparisons suggest a competition between the two GPCRs. Further supporting this hypothesis is our analysis of the MCHR-/- hippocampus, in which the greatest increase in SstR3(+) cilia was in CA1, where MCHR1(+) cilia predominate in wildtypes; in contrast, little SstR3 upregulation occurred in CA3, where MCHR1(+) cilia are scarce in wildtypes. Moreover, in wildtype mice, SstR3 and MCHR1 levels were lower in cilia containing both receptor types than in cilia with only one. Receptor competition could occur at various levels, such as gene expression, access to transport systems, or space in the ciliary membrane. However, there is precedence for receptor competition at the transcriptional level: Olfactory neurons initially express multiple ciliary odorant receptors until one emerges as the sole victor, through transcriptional suppression of the alternatives. Receptor composition in neuronal primary cilia may also be governed by reciprocal competition, such that expression of

one gene entails suppression of the other(s). Accordingly, we are testing whether receptor colocalization is more common in early development, before dominance is established. Our findings have implications for understanding the functions of ciliary receptors. For example, SstR3 upregulation might contribute to seizure resistance in MCHR1-/- mice, and conversely, MCHR1 upregulation might contribute to seizure vulnerability in SstR3-/- mice. Thus, the role of any particular ciliary GPCR in normal or disease states is best understood in the context of alternative receptors. This insight will be important in designing approaches for modulating ciliary GPCRs in the treatment of epilepsy and other excitotoxic conditions.

Title: The design of a protean agonist to RFRP-1R that improves cardiac function through functional selectivity.

Authors: *R. NICHOLS, K. PITTALA, M. LEANDER, B. MAYNARD;
Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: The design of a protean agonist to RFRP-1R that improves cardiac function through functional selectivity.R. Nichols, K. Pittala, M. Leander, B. F. MaynardThe heart synthesizes peptides, which may play important roles in cardiovascular physiology,; yet much remains unknown about their signaling pathways. Delineating the structure-activity relationship (SAR) of a peptide is an established approach to identifying agonists and antagonists, molecular tools to dissect signaling and investigate function. In addition, peptides often act through G protein-coupled receptors (GPCRs), which may be druggable due to their defined binding pocket and ligand-receptor interactions. We discovered that the RFamide-related peptide -1 (RFRP-1; MPHSFANLPLRF-NH_2) acts through the GPCR RFRP-1R to decrease cardiac function [Nichols et al. 2010; Nichols et al. 2012]. In order to establish the RFRP-1 structure-activity relationship (SAR) for cardiac contractility, we assayed a series of single-substituted alanine and a set of N-terminal truncation analogs using isolated cardiomyocytes. From our SAR data, we identified the amidated C-terminal pentapeptide as the active core and designed a first-generation antagonist LPLAF-NH_2. We confirmed the alanyl-substituted pentapeptide competed out the effect of the active core in cardiomyocytes. We further Further, we complemented our SAR study with molecular docking software, analyzing the parent peptide, RFRP-1, active core, LPLRF-NH_2,

and antagonist, LPLAF-NH_2, to predict the binding pocket and ligand-receptor interactions involved in binding and receptor activation. A next step in our work was to design a proteolytically resistant antagonist, as peptides are susceptible to degradation by peptidases and thus limited in application. We took a two-prong approach to our design, we chose to substitute A9 with amino acid residues that would improve ligand-receptor to improve binding and also incorporated d-isomers to combat degradation and improve half-life. Next, we used molecular docking software to examine whether the analogs might interact with RFRP-1R. As we docked the series of analogs, we predicted the newly designed structures blocked RFRP-1 binding. In addition, based on their position in the binding pocket and ligand-receptor interactions, we predicted some structures may act as RFRP-1R protean agonists. Our subsequent work showed the putative protean agonist improved cardiac function in cardiomyocytes suggesting the ligand-directed RFRP-1R signaling may serve as a druggable GPCR in heart.

Title: Phosphorylation of Synaptotagmin by Protein Kinase C regulates vesicle fusion

Authors: *E. M. STROEVA[1], M. BERA[1], K. CHARI[2], K. WU[3], O. D. BELLO[1], J. COLEMAN[1], S. S. KRISHNAKUMAR[1], J. E. ROTHMAN[1];
[1]Cell Biol., [3]Mol. Biophysics and Biochem., [2]Yale Univ., New Haven, CT

Abstract: A family of Synaptotagmins (Syt) undergo several types of post-translational processing, which regulates neuronal growth and plasticity. Protein kinase C (PKC), which is highly expressed in the brain, has been previously shown to potentiate synaptic vesicle release via phosphorylation of the Syt1 isoform. However, the precise mechanism and functional effect of phosphorylation on Syt1 function remains unclear. In this work, we identified a new site of phosphorylation (T328/T329), located within polybasic patch of C2B domain which is functionally important for binding to PIP2 and other negative lipid headgroups. To study the effect of phosphorylation at this site, we introduced a phospho-mimetic amino acid substitution ($Syt1^{T328/329E}$). We used single-vesicle fusion assay to monitor the docking, clamping, fusion and release of a single vesicle. This fluorescence-based assay tracks individual v-SNARE containing vesicles (vSUVs) as they approach the physiologically relevant mimic of the target membrane.

vSUVs containing 24 copies of wild-type Syt1 ($Syt1^{WT}$) and 12 copies of VAMP2 remain stably docked and fuse after addition of 1 mM calcium ions. To the contrary, $Syt1^{T328/329E}$ containing vSUVs abolished clamping ability leading to spontaneous fusion. The role of phosphorylation of Syt1 by PKC was further corroborated by a γ-^{32}P radiography-based protocol for the *in vitro* phosphorylation of $Syt1^{WT}$-containing vSUVs. Phosphorylated vesicles recapitulated the loss-of-clamping behavior exhibited by the $Syt1^{T328/329E}$ -containing vesicles. Expectedly, phosphorylated Syt1 exhibited a dramatic reduction in its ability to bind negatively charged membrane in the basal (EDTA/Mg^{2+}) state and in the presence of physiologically relevant calcium concentrations. As PIP2 binding is crucial for Syt1 to oligomerize and clamp vesicle fusion, we posit that that phosphorylation of Syt1 at residue 328/329 abrogates clamping function, by disrupting Syt1 ability to oligomerize. Our findings suggest a novel mechanism of *in situ* regulation of Syt1 function by PKC.

Title: Synaptotagmin 7 is targeted to the axonal plasma membrane through γ-secretase processing to promote synaptic vesicle docking in mouse hippocampal neurons

Authors: *J. D. VEVEA[1], G. F. KUSICK[2], K. C. COURTNEY[1], E. CHEN[2], S. WATANABE[2], E. R. CHAPMAN[1];
[1]Neurosci., Howard Hughes Med. Inst., Madison, WI; [2]Dept. of Cell Biol., Johns Hopkins Univ., Baltimore, MD

Abstract: Synaptotagmin (SYT) 7 has emerged as a key regulator of presynaptic function, but its localization and precise role in the synaptic vesicle cycle remain the subject of debate. Here, we used iGluSnFR to optically interrogate glutamate release, at the single bouton level, in

SYT7KO dissociated mouse hippocampal neurons. We analyzed asynchronous release, paired pulse facilitation, and synaptic vesicle replenishment, and found that SYT7 contributes to each of these processes to different degrees. 'Zap-and-freeze' electron microscopy revealed that loss of SYT7 diminishes docking of synaptic vesicles after a stimulus and inhibits the recovery of depleted synaptic vesicles after a stimulus train. SYT7 supports these functions from the axonal plasma membrane, where its localization and stability require both γ-secretase-mediated cleavage and palmitoylation. In summary, SYT7 is a peripheral membrane protein that controls multiple modes of SV exocytosis and plasticity, in part, through enhancing activity-dependent docking of SVs.

Title: RNA editing of the synaptic vesicle fusion clamp Complexin alters synaptic transmission and synaptic development at Drosophila glutamatergic neuromuscular junctions

Authors: *E. BRIJA[1,2], S. K. JETTI[1,2], R. W. CHO[1,2], J. T. LITTLETON[1,2,3];
[1]The Picower Inst. for Learning and Memory, [2]Dept. of Brain and Cognitive Sci., [3]Dept. of Biol., MIT, Cambridge, MA

Abstract: Chemical synaptic transmission is a critical step in neuronal communication that is extensively regulated to generate plasticity and learning. Although most studies of synaptic plasticity have focused on changes occurring within the postsynaptic compartment, presynaptic modifications to the synaptic vesicle (SV) release machinery also contribute to alterations in synaptic output. The *Drosophila* neuromuscular junction (NMJ) has emerged as an excellent model synapse to study synaptic transmission, as well as activity-dependent structural and functional plasticity. Complexin (Cpx) regulates both spontaneous and evoked neurotransmitter release through its ability to bind assembling SNARE complexes and control SNARE zippering, providing an attractive point of modulation for altering presynaptic output. The *Drosophila cpx* locus undergoes alternative splicing to produce two isoforms that differ in the C-terminal ~15 amino acids of the protein. We previously observed that activity-dependent PKA phosphorylation of the C-terminus of the Cpx7B splice variant enhanced spontaneous

neurotransmitter release and synaptic growth. Unlike Cpx7B, the more abundant Cpx7A splice variant does not undergo PKA phosphorylation, but is subject to RNA editing by ADAR (adenosine deaminase acting on RNAs). *Cpx* transcript editing produces Cpx7A protein products with varying C-terminals, including changes to an asparagine residue (N130) near the PKA phosphorylation site in Cpx7B (S126). Editing of Cpx7A generates N130G, N130S and N130D variations that alter the ability of Cpx to clamp spontaneous SV fusion and properly regulate synaptic growth. Using single cell RNA sequencing and electrophysiology, we are characterizing the differential expression and function of Cpx7A RNA edited variants across several neuronal populations. These studies should provide new insight into how differential RNA editing contributes to neuronal activity and development, as well as how changes in Cpx function can alter neurotransmitter release and synaptic growth pathways.

Title: Synapsin domains mediating alpha-synuclein function

Authors: A. STAVSKY[1], S. TAL[1], L. A. PARRA[2], J. B. KAHN[1], S. ROY[2], ***D. GITLER**[1]; [1]Dept. of Physiol. and Cell Biol., Ben-Gurion Univ. of the Negev, Beer-Sheva, Israel; [2]Depts. of Pathology and Neurosci., UCSD, La Jolla, CA

Abstract: Despite extensive effort, the physiologic role of alpha-synuclein at the synapse is contentious and unclear. We and others have reported that modest over-expression of alpha-synuclein attenuates synaptic vesicle (SV) recycling in cultured hippocampal neurons suggesting that alpha-synuclein is a physiologic attenuator of neurotransmitter release. Exploring functional interactors of alpha-synuclein, we recently found that alpha-synuclein mediated synaptic attenuation was absent in neurons lacking all three synapsin genes (synapsin triple knockouts, TKO), suggesting that alpha-synuclein/synapsin interactions played a key role in alpha-synuclein function (Atias et al., PNAS 2019, 10.1073/pnas.1903054116). Though our experiments revealed a previously unknown role of synapsin in mediating alpha-synuclein function, the identity of the synapsin isoforms involved remained unknown. Alternate splicing of mammalian synapsins generate five major isoforms - synapsin Ia, Ib, IIa, IIb and IIIa - and each synapsin isoform is

composed of a specific combination of alternative domains (called “domains A-J”). To parse out the synapsin isoform responsible for mediating alpha-synuclein function, we individually reintroduced synapsins Ia, Ib, IIa, IIb and IIIa into synapsin TKO neurons that were also over-expressing alpha-synuclein. Interestingly, while reintroduction of synapsins Ia, IIa and IIIa restored the ability of alpha-synuclein to attenuate SV-recycling, synapsins Ib and IIb did not. The Ib/IIb isoforms also interacted poorly with alpha-synuclein in immunoprecipitation assays, suggesting that the synapsin “E domain” - common to synapsins Ia/IIa/IIIa but absent in Ib/IIb - is responsible for executing synaptic alpha-synuclein functions. We propose that the synapsin E domain plays an important role in regulating the functional co-dependency between synapsins and alpha-synuclein, perhaps by helping in organizing the SV clusters near the synaptic active zone.

Title: Metabolic adaptations of presynaptic function to glucose deprivation

Authors: *G. ASHRAFI[1], A. TIWARI[3], A. HASHEMIAGHDAM[2], M. LARAMIE[2]; [1]Washington Univ. Sch. of Med., Saint Louis, MO; [2]Washington Univ. Sch. of Med., St. Louis, MO; [3]Washington Univ. in St. Louis, St. Louis, MO

Abstract: The brain is the most energy-consuming organ of the body, but unlike other metabolically demanding tissues, it does not have significant energy stores. In the nervous system, neurons experience rapid energetic fluctuations particularly during intense circuit activity, fasting, or metabolic disorders. Neuronal bioenergetic plasticity is therefore essential to sustain cognitive function. Yet, the cellular pathways that enable neurons to achieve metabolic flexibility are largely unknown. A significant fraction of neuronal energy is consumed in nerve terminals during synaptic transmission. We have recently shown that nerve terminals can utilize either glucose or oxidative fuels through glycolysis or mitochondrial respiration, respectively. Neuronal access to fuels is not constant and can vary substantially. Thus, mitochondrial capacity for ATP synthesis is dynamically modulated to respond to physiological cues, such as, cellular energy demand or fuel supply. Here, we report a molecular pathway for metabolic adaptation of

neuronal mitochondria to nutrient deprivation. We performed RNA sequencing of cultured cortical neurons with differential access to glucose. We found that glucose deprivation activates a transcriptional program upregulating the expression of the mitochondrial master regulator *PGC-1α* and the mitochondrial NAD-dependent deacetylase *Sirtuin 3* (*Sirt3*), in a pathway that is dependent on the cellular energy sensor AMP kinase. Immunocytochemical analysis of cultured neurons and mouse hippocampal slices confirmed that Sirt3 localizes on axonal mitochondria of hippocampal neurons. We then examined the functional role of Sirt3 in presynaptic metabolism using quantitative optical assays. Presynaptic ATP measurements with the reporter Syn-ATP in Sirt3-deficient neurons showed that Sirt3 is required for maintaining baseline ATP levels in nerve terminals. Knockdown of Sirt3 did not affect Ca^{2+}-dependent upregulation of mitochondrial ATP production during electrical activity, further confirming its function in regulation of baseline, rather than activity-driven, mitochondrial metabolism. Sirt3 and its catalytic activity as a deacetylase are also essential for fast retrieval of synaptic vesicles after release in neurons supplied with oxidative fuels, indicating an essential role for Sirt3 in synaptic transmission. In summary, our findings suggest that the mitochondrial deacetylase Sirt3 modulates the metabolic fitness of nerve terminals and its transcriptional upregulation during energetic stress may facilitates neuronal bioenergetic plasticity.

Title: The serotonin transporter expressed in sympathoadrenal chromaffin cells controls the kinetics and amount of catecholamine released from individual secretory vesicles

Authors: R. L. BRINDLEY, ***K. P. M. CURRIE**;
Cooper Med. Sch. of Rowan Univ., Camden, NJ

Abstract: Adrenal chromaffin cells (ACCs) comprise the neuroendocrine arm of the sympathetic nervous system and are a powerful experimental model system to investigate neurotransmitter exocytosis. ACCs synthesize and secrete catecholamines (epinephrine, norepinephrine) which play important roles in the physiological response to stress. Even though mammalian ACCs do not synthesize serotonin (5-HT), they robustly express the antidepressant-sensitive serotonin transporter (SERT) which mediates the uptake and accumulation of 5-HT by the cells (5-HT

content of wild-type adrenal glands is <0.15% of the epinephrine content). The adrenal glands from global ($SERT^{-/-}$) or sympathoadrenal system-specific SERT knockout mice ($SERT^{\Delta TH}$) displayed reduced 5-HT but no change in catecholamine content. We isolated ACCs from the mouse adrenal glands and used carbon fiber amperometry to analyze transmitter secretion from individual secretory vesicles. The charge of individual amperometric spikes (i.e. quantal size / amount of transmitter released) was significantly smaller (~35%) in $SERT^{-/-}$ and $SERT^{\Delta TH}$ cells compared to matched controls. Spike half-width (duration), and the duration of the "prespike foot" which precedes some amperometric events, were significantly shorter in knockout cells. The decrease in quantal size (spike charge) was mimicked by treating wild-type cells for >24 hours with escitalopram (an SSRI antidepressant which blocks SERT), or by depleting extracellular 5-HT from the culture medium for >24 hours (use of dialyzed serum in the culture media). In contrast, acute (minutes) or short-term (<6-8 hrs) treatment with escitalopram or 5-HT depletion had no effect. ACCs do not synthesize 5-HT because they lack the rate limiting biosynthetic enzyme tryptophan hydroxylase. However, if the product of this enzyme (5-hydroxytryptophan; 5-HTP) is provided to bypass the lack of tryptophan hydroxylase, then it can be converted into 5-HT by aromatic L-amino acid decarboxylase (AADC), which is endogenously expressed and also participates in catecholamine biosynthesis. Treating cells with 5-HTP for 1-3 hrs had no effect but 24 hr treatment fully rescued the reduced spike charge seen in SERT knockout cells. Together, our data suggest that SERT-mediated 5-HT uptake by ACCs modulates the kinetics and thus fraction of secretory vesicle contents released during a fusion event. Ongoing work will further dissect this and other potential mechanisms by which adrenal SERT regulates catecholamine secretion and hence the sympathoadrenal stress response.

Title: Genetic deletion of the membrane transporter mGAT1 in dopamine neurons selectively abolishes GABA co-release

Authors: *R. MELANI, N. X. TRITSCH;
New York Univ. Neurosci. & Physiol., New York, NY

Abstract: Midbrain dopaminergic (DA) neurons in the Substantia Nigra pars compacta (SNc) have been shown to inhibit dorsal striatum by synaptic co-release of GABA. We previously suggested that in these cells GABA release does not depend on cell-autonomous synthesis, but on axonal uptake by the membrane transporter mGAT1 (Slc6a1). However, the mechanism

responsible for this GABA co-release is still unclear. To better define the role of mGAT1, we generated conditional knocked out (cKO) mice in which Slc6a1 is ablated exclusively in DA neurons. Optogenetically stimulating DA axons in dorsal striatum, we find that dopaminergic GABA release in mGAT1cKO mice is selectively and entirely abolished. Our results show that cell-specific deletion of Slc6a1 does not impair vesicular exocytosis or cell survival, confirm that GABA co-release from DA neurons requires mGAT1 transporter function, and pave the way for future studies investigating the contribution of this transmission in modulating striatal function and behavior.

Title: Presynaptic Rac1 is a key regulator of synaptic strength at a mammalian central synapse

Authors: *M. AL-YAARI[1], C. KEINE[1], P. VALINO RAMOS[1], D. GUERRO-GIVEN[3], N. KAMASAWA[3], S. M. YOUNG, Jr.[1,2];
[1]Anat. and Cell Biology, Iowa Neurosci. Inst., [2]Dept. of Otolaryngology, Iowa Neurosci. Institute, Aging Mind Brain Initiative, Univ. of Iowa, Iowa city, IA; [3]Max Planck Florida Electron Microscopy Core, Max Plank Florida Inst. for Neurosci., Jupiter, FL

Abstract: Sound information encoding within the initial auditory processing stations requires reliable and precise synaptic transmission in response to rapid and large fluctuations in action potential (AP) firing rates. However, the number of synaptic vesicles (SVs) available for AP-evoked release is limited. Actin cytoskeleton is an important regulator of synaptic transmission. Rac1 is a core protein of the actin cytoskeleton cascades and it is implicated in several

neurodevelopmental diseases. Moreover, it plays a fundamental role in regulating synaptic transmission. Although Rac1 has been well-studied in the postsynaptic compartment, currently, the role of Rac1 in the presynaptic regulation of synaptic transmission is poorly understood. The calyx of Held is a large glutamatergic presynaptic terminal in the auditory brainstem and relies on high-fidelity transmission at frequencies of up to 1 kHz. It conveys the temporal information of sound precisely, which requires very fast and continuous synaptic transmission at high rates. Thus, it is an ideal model to determine how presynaptic Rac1 regulates synaptic transmission. We utilized a Rac1 conditional knock out (CKO) mouse in conjunction with viral vector mediate approaches to delete Rac1 in the presynaptic compartment at the matured synapse (after hearing onset) to bypass the potential roles of Rac1 in developmental stages. Our data show that Rac1 regulates synaptic transmission and plasticity, suggesting a critical role of presynaptic Rac1. Our results and their implications will be discussed.

Title: Presynaptic $\alpha_2\delta$-3 plays a critical role in synaptic transmission at the calyx of Held

Authors: *W. MILANICK[1], T. RADULOVIC[2], S. M. YOUNG[2];
[1]Interdisiplinary Grad. Program in Neurosci., [2]Dept. of Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA

Abstract: The $\alpha_2\delta$ family of proteins are critical regulators of pre- and postsynaptic functions, including voltage-gated Ca^{2+} (Ca_V) channel trafficking, Ca_V Ca^{2+} currents, synapse morphogenesis, axon regeneration, and action potential waveform. Previous research has shown that global knockout (KO) of $\alpha_2\delta$-3 can impair synapse morphogenesis and synaptic transmission and cause auditory dysfunction. However, global KO models complicate conclusions on whether functions are pre- or postsynaptic and cannot rule out developmental causes. Therefore, it is difficult to define the presynaptic roles of $\alpha_2\delta$-3 with traditional models. To study the presynaptic roles of $\alpha_2\delta$-3 we developed a novel $\alpha_2\delta$-3 conditional KO mouse model. We used the calyx of

Held/medial nucleus of the trapezoid body (MNTB) synapse as our model. The calyx is a large glutamatergic presynaptic terminal that plays critical roles in the auditory system. It is the sole driver of action potentials in the MNTB, making it a powerful model to examine the molecular mechanisms of synaptic function. Globular bushy cells give rise to the calyx and are located in the cochlear nucleus - where $\alpha_2\delta$-3 is expressed. To assess the presynaptic roles of $\alpha_2\delta$-3 we performed afferent fiber stimulation at different frequencies. We collected data from mice at postnatal 18-23, when the calyx of Held/MNTB synapse is in its mature state. Recordings were done in physiological Ca^{2+} (1.2mM), and at physiological temperature 37°C. Results will be discussed.

Title: Cell type-specific nonlinear interactions of top-down and bottom-up synaptic input to posterior parietal cortex

Authors: *D. RINDNER, A. PRODDUTUR, G. LUR;
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Cognitive functions including attention, memory, and prediction rely on interactions between top-down and bottom-up information streams. Nonetheless little is known about the integration of top-down and bottom-up inputs at the cellular level, partially due to the technical difficulty of simultaneously manipulating two distinct afferent populations. We overcome this limitation using a dual-color optogenetic strategy to determine spatiotemporal features of multi-modal synaptic integration in the mouse posterior parietal cortex (PPC). We expressed Chrimson, a red light-sensitive channelrhodopsin variant, in the primary auditory cortex (A1) and ChR2, a blue light-sensitive opsin, in the anterior cingulate cortex (ACC), a frontal region commonly associated with attention and working memory. This opsin combination allowed independent control of bottom-up sensory and top-down frontal inputs to the PPC. Using whole-cell patch clamp recordings in acute brain slices we show that the PPC receives direct, monosynaptic inputs from both A1 and ACC. We found that two classes of pyramidal neurons, intrinsically bursting and regular spiking, have distinct patterns of frontal-sensory synaptic

integration. Intrinsically bursting cells displayed a robust supralinear enhancement of coincident input from A1 and ACC, an effect that diminished with increasing delays between inputs. Conversely, regular spiking cells showed linear integration of coincident input, and maximal enhancement when afferents were activated with delay. Both bursting cell coincident and regular spiking delayed enhancement were reduced by bath application of either the low-threshold calcium channel or NMDA receptor antagonists mibefradil and AP5, respectively. Notably, only bursting cell coincident enhancement was reduced when sodium channels were blocked with TTX. These results suggest that sodium channels provide a mechanism for temporally specific detection of coincident frontal-sensory inputs. Our data demonstrate that frontal-sensory synaptic interactions have cell type-specificity in the PPC and offers a novel mechanistic description of top-down and bottom-up integration.

Title: Synaptic cooperativity controls somatic spike precision via noise-induced stochastic gating

Authors: *S. XIAO, S. YADAV, K. JAYANT;
Purdue Univ., West Lafayette, IN

Abstract: Clustered and distributed synaptic co-operativity is a fundamental property of cortical pyramidal neurons and has been implicated in maintaining coincidence detection, feature binding and dendritic branch specific plasticity. However, the exact biophysical mechanisms by which synaptic cooperativity controls and modulates somatic output are still unclear. In basal dendrites, co-activated spines in close proximity to one another give rise to a N-methyl-D-Aspartate (NMDA) spike accompanied with both an increase in local Ca^{2+} concentration as well as sodium dependent dendritic spikes. However, how these non-linearities and distributed synapses across the vast expanse of the dendritic tree as well as multiple dendritic trees control, interact, and cooperate to modulate somatic output remains unknown. Our limited understanding of both intra- and inter-branch synaptic cooperativity stems partly from technical barriers in manipulating spine properties with high-resolution and monitoring the effects of these manipulations across different depths (as not all dendrites are at the same depth). Here, we

performed simultaneous electrophysiology, calcium imaging, and two-photon glutamate uncaging on basal dendrites of cortical pyramidal neurons in acute brain slices using a spatial light modulator (SLM) with custom built pulse compression. The SLM allows simultaneous activation up to 12 spines (~15mW per spine) with up to 24 spines within 5 ms (time for phase mask change) distributed in 3D (across 30 um) with near-diffraction-limited resolution. We found that co-activation of clustered spines on some but not all basal dendritic branches gives rise to a complex EPSP waveform, characterized with a Na^+ spikelet followed by a NMDA plateau. Compared to NMDA spikes without a Na spikelet, these complex dendritic spikes increase the temporal precision of somatic action potentials, especially when the resting potential is close to threshold. We find that temporal precision is made possible by a combination of the persistent sodium current (as it influences both the non-linear interaction and the increased input resistance) and stochastic ion-channel gating. Together, this suggests that Na^+ spikelets are a source of noise that can help bind temporally precise input patterns. More importantly, our results suggest that dendritic noise as a function of clustered inputs could serve as a way of multiplexing diverse inputs via unique somatic spike time/frequency signatures, even within the same dendritic tree. We discuss the above results through both modeling and experiments along with detailed optical characterization.

Title: Differences in ionic conductance and microcircuit architecture underlie distinct frontal-sensory integration in cortical neuron subclasses

Authors: *A. PRODDUTUR[1], D. J. RINDNER[1], G. LUR[2];
[1]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: The posterior parietal cortex (PPC) is a multimodal cortical area involved in higher-order perceptual and executive processes. Critical for these functions is a convergence of bottom-up (sensory) and top-down (frontal) afferent innervation. Pyramidal neurons with complex dendritic structures perform nonlinear integration; a synaptic interaction thought to be underpinned by active and passive mechanisms. However, the precise mechanisms of how sensory and top-down synapses interact in single neurons are unknown. In the PPC, L5

pyramidal cells characterized by either regular spiking (RS) or intrinsic burst spiking (IB) perform nonlinear integration of inputs from auditory (A1) and anterior cingulate cortex (ACC). Specifically, coincident activation of A1-ACC inputs leads to supralinear integration in IB cells, whereas only delayed activation (50ms) of these inputs leads to supralinear synaptic enhancement in RS cells. Using a compartmental model, we evaluated the role of sodium (Na^+), and T-type calcium (T-Ca^{2+}) channels, and NMDA receptor kinetics in nonlinear integration of A1-ACC inputs. We found that high Na^+ conductance and faster NMDAR decay kinetics recapitulate all experimentally observed integration characteristics in IB cells.Conversely, in RS cells, higher T-Ca^{2+} conductance and slower NMDAR decay kinetics lead to supralinear integration during delayed activation. However, across the entire parameter space, our model predicted supralinear integration of coincident inputs in RS cells as well. This finding was in contrast with electrophysiology data and suggested that the mechanisms driving synaptic integration in RS cells might not be exclusively cell-autonomous. For example, dendrite targeting inhibition is known to modulate synaptic integration in pyramidal neurons. Thus, we tested the effect of disynaptic, feedforward GABAergic input on sensory-frontal integration in RS cells. We found that $GABA_A$ receptor-driven inhibition suppresses the supralinear integration in the coincident condition without affecting integration under the delayed condition. *In vitro* testing of the model's predictions revealed that RS, but not IB cells receive significant feedforward inhibition. Together, our modeling and *in vitro* data offer insights into synaptic integration in a cell-type-specific manner controlled at two levels: cell-autonomous differences in channel expression and kinetics, complemented by distinct microcircuit architecture.

Title: Simulation analysis of subthreshold voltage signaling along hippocampal mossy fibers

Authors: *H. KAMIYA;
Dept. of Neurobio., Hokkaido Univ. Grad. Sch. of Med., Sapporo, Japan

Abstract: Axons are classically thought of as electrically well isolated from other parts of the neuron. Recent studies, however, revealed that subthreshold somatodendritic depolarization distributes for a substantial distance along the axons. To further explore the functional significance of subthreshold voltage propagation to the axons, the model of propagation of

excitatory presynaptic potential (EPreSP) suggested by Alle & Geiger was reconstructed and was incorporated the model of axonal sodium, potassium & leak channels by Engel & Jonas and the model of presynaptic calcium channels composed of P/Q-, N-, and R-type channels at mossy fiber boutons by Li, Bischofberger & Jonas. Preceding subthreshold EPreSPs slightly reduced the action potential-evoked presynaptic calcium currents by a decrease in the amplitude of action potentials due to the slow depolarization. EPreSPs by themselves elicited small calcium currents during subthreshold depolarization through these high-voltage activated calcium channels. Since the previous study by simultaneous pre and postsynaptic recordings demonstrated that EPreSPs enhanced action potential-evoked transmitter release from the mossy fiber terminals, it has been suggested that different mechanisms from the enhancement of action potential-evoked presynaptic calcium entry may involve enhanced transmitter release by EPreSP. Small calcium entry by subthreshold EPreSPs may enhance transmitter release from the mossy fiber terminals by high-affinity calcium sensors for enhancing transmitter release.

Title: Molecular and functional NMDA receptor diversity enables selective tuning of corticothalamic circuit function.

Authors: Y. CHEN[1,2], M. LADISLAV[1], S. SWANGER[1,3,4];
[1]Fralin Biomed. Res. Inst. at VTC, Virginia Tech,, roanoke, VA; [2]Translational Biology, Medicine, and Hlth. Grad. Program, Roanoke, VA; [3]VA-MD Col. of Vet. Med., Blacksburg, VA; [4]Virginia Tech. Carilion Sch. of Med., Roanoke, VA

Abstract: The somatosensory corticothalamic (CT) circuit processes ascending sensory signals and selects the appropriate information for our conscious brain to receive. Disruption to the balance of excitation and inhibition within CT circuitry leads to absence seizures, sleep disorders, and attention deficits. In this circuit, glutamatergic CT projections gate somatosensory information flow through the thalamus by innervating glutamatergic thalamocortical neurons in the ventral posteromedial thalamus (VPM) and GABAergic reticular thalamus neurons (nRT),

which provide robust feed-forward inhibition to the VPM. Our goal is to identify strategies for selectively modulating CT-nRT and CT-VPM synapses to correct disease-associated excitation-inhibition imbalances. N-methyl-D-aspartate (NMDA) receptors mediate glutamatergic CT synaptic transmission, but CT-nRT and CT-VPM excitatory postsynaptic currents have distinct NMDA receptor amplitudes, decay kinetics, and voltage-dependences. VPM and nRT neurons express four NMDA receptor subtypes, GluN2A-GluN2D, which have distinct functional properties. In this study, we sought to determine: 1) how GluN2 subunit diversity contributes to NMDA receptor function in nRT and VPM neurons and 2) whether NMDA receptor modulation has cell-type-specific effects on spike firing in response to corticothalamic input. Single-molecule multiplex fluorescent in situ hybridization revealed greater NMDA receptor mRNA levels in VPM neurons compared to nRT, and the relative abundance of GluN2A-GluN2D mRNAs differed between the two cell-types. Utilizing brain slice electrophysiology, we demonstrated GluN2-specific roles in regulating tonic inhibition as well as cell-type-specific NMDA receptor contributions to synaptic transmission and spike firing in response to CT input. Notably, NMDA receptor inhibition reduced VPM spike firing significantly more than nRT spike firing in response to high frequency stimulation. Furthermore, NMDA receptor inhibition reduced VPM spike firing in response to high frequency CT input significantly more than during low frequency CT input. These data suggest that NMDA receptor contributions to thalamic spike firing are cell-type-specific and frequency-dependent. Given the differential regulation of inhibitory and excitatory neuron function, we hypothesize that NMDA receptor modulation could be useful for context-dependent tuning of thalamic excitability based on which synaptic inputs are dysregulated or how excitation and inhibition are imbalanced in neurological disease.

Title: Mouse cortical nerve endings release exosomes in a Ca^{2+}-dependent fashion: new insights into synaptic transmission.

Authors: G. OLIVERO[1], A. ROGGERI[1], G. VALLARINO[1], *D. DI PAOLO[2], D. MARIMPIETRI[3], M. GAGLIANI[4], M. PODESTÀ[3], K. CORTESE[4], ***A. Therapies in Oncology, [3]Stem Cell Lab. and Cell Therapy Ctr., IRCCS Giannina Gaslini Hosp., Genova, Italy; [4]Dept. of Exptl. Medicine, DIMES, Univ. of Genova, Genova, Italy

Abstract: Whether exosomes can be actively released from presynaptic nerve terminals is matter of debate. To address the point, mouse cortical synaptosomes were incubated in basal and depolarizing (25 mM KCl enriched medium) conditions and extracellular vesicles were isolated from the synaptosomal supernatants to be characterized by dynamic light scattering, transmission electron microscopy, western blot and flow cytometry analyses. The structural and biochemical analysis unveiled that supernatants contain vesicles having the size and the shape of exosomes, that were immunopositive for the exosomal markers TSG101, flotillin-1, CD63 and CD9. The markers content increased upon the exposure of nerve terminals to the high-KCl stimulus, consistent with an active release of the exosomes from the depolarized synaptosomes. High KCl-induced depolarization elicits the Ca^{2+}-dependent exocytosis of glutamate. Interestingly, also the depolarization-evoked release of exosomes from cortical synaptosomes occurred in a Ca^{2+}-dependent fashion, since TSG101, CD63 and CD9 contents in the exosomal fraction isolated from supernatants of depolarized synaptosomes were significantly reduced when omitting external Ca^{2+}ions.. However, (±)-baclofen (10 μM), which significantly reduced the glutamate exocytosis, didn't affect the release of exosomes, suggesting that the $GABA_B$-mediated mechanism of control is inactive on this event. Our findings suggest that the exposure of synaptosomes to a depolarizing stimulus elicits a presynaptic release of exosomes that occurs in Ca^{2+}-dependent fashion. The insensitivity to the presynaptic $GABA_B$ receptors, however, leaves open the question on whether the release of exosomes could be a druggable target for new therapeutic intervention for the cure of synaptopathies.

Title: Revealing the link between spiking cross-correlation patterns and the underlying subthreshold dynamics: oscillations and resonances

Authors: R. F. O. PENA, ***H. G. ROTSTEIN**;
Federated Dept. of Biol. Sci., NJIT, Newark, NJ

Abstract: A sharp peak near zero in cross-correlation functions (CCFs) indicates the presence of a putative monosynaptic connection between the pre- and post-synaptic neurons (Toyama et al.,

1981; English et al., 2017; Platkiewicz et al., 2021). However, CCFs are complex and contain significantly more information about the spiking pattern relationships and the mechanisms controlling the interactions between the participating neurons, in particular in the presence of intrinsic oscillations and resonances. Some of this information is apparent from the spiking patterns themselves, but spiking patterns are controlled by the subthreshold (membrane potential) dynamics whose effects often remain hidden in CCFs. Whether and how the subthreshold dynamic information of post-synaptic neurons can be extracted from the CCFs remains an open question. This is not a straightforward task since in vivo neuronal interactions occur in the presence of background noise, synaptic dynamics, oscillatory activity and resonances. Similar patterns may be generated by different mechanisms and this degeneracy might be difficult to resolve. We address this issue by combining biophysical modeling, numerical simulations and dynamical systems tools (phase-space analysis). We systematically focus on a wide number of representative scenarios and identify the presence of additional peaks in the CCFs, lower than the characteristic sharp peak, and link these lower peaks to the type of nonlinearities and time scales that operate at the subthreshold level and ultimately reflect the neuronal biophysical properties. Under certain conditions, the combination of these dynamic components cause a subset of trajectories in the phase-space diagrams to remain at subthreshold levels for a longer time than others before producing a spike. The presence and variability of this spike-time delay is due to a combination of noise and neuronal intrinsic dynamics. Lower peaks also emerge in the presence of other factors, such as background oscillations or ripples, but these come from a second wave of spikes. We analyze the differences between these two types of lower peaks. Our results have implications for the inference of synaptic interactions between neurons in the presence of oscillatory activity, synaptic dynamics and unidentified background patterns, and for the understanding of the biophysical and dynamics mechanisms controlling synaptic interactions between neurons in a network.

Abstract: Commissures form the largest axonal tracts that wire the two brain hemispheres, yet the commissural organization and function remain largely unknown. We discovered that commissural inputs, in contrast to local parasubicular inputs, synapsed preferentially on distal dendrites of stellate cells in the mouse medial entorhinal cortex. Subsequent optogenetic experiments verified the functionally distinct anatomical inputs. Preliminary investigation showed that commissural inputs were essential for grid-like firing in behaving mice. Analysis combining octuple patch-clamp recordings, optogenetic activation, and functional Ca^{2+} and Na^{+} imaging revealed that commissural inputs interacted with local perisomatic parasubicular inputs via axosomatodendritic channels, which amplified coincident and theta rhythmic commissural synaptic events selectively in entorhinal stellate cells, but not pyramidal neurons and interneurons. Pilot neuronal simulation validated this salience selection mechanism. These data reconstruct essential neuronal constituents with their synaptic connections that encompass an excitatory commissural circuit involved in spatial coding.

Title: Voltage compartmentalization by dendritic spines in vivo

Authors: *V. CORNEJO, N. OFER, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Dendritic spines mediate most excitatory neurotransmission in the nervous system, so their function is likely critical for brain function. While it has been demonstrated that spines are

biochemical compartments, their electrical role is still unclear. Using a genetically-encoded voltage indicator and two-photon microscopy, we measured membrane potential in spines and dendrites from pyramidal neurons of somatosensory cortex in mice during spontaneous activity and sensory stimulation. We found different regimes for dendrite and spine voltage dynamics during supra- and sub-threshold potentials. Spine depolarizations are similar to dendritic ones when the neuron fires action potentials, but during subthreshold synaptic potentials spines often experience different voltages than parent dendrites, even activating independently. Confirming these two types of spine voltage regimes, after two-photon optogenetic activation of the parent dendrites, spine potentials are similar to dendritic potentials, but they remain compartmentalized during optogenetic activation of spine heads. Our results demonstrate that spines are voltage compartments, acting as electrical diodes, with little or no dendrite-to-spine attenuation of dendritic potentials but significant spine-to-dendrite attenuation of synaptic potentials. The regulation of the electrical behavior of spines could be important for synaptic function, plasticity and dendritic integration.

Abstract: Activity-dependent hippocampal synaptic plasticity is a leading candidate for the cellular mechanism underlying learning and memory. Extensive research has uncovered diverse forms of synaptic plasticity and a wide array of molecular signaling mechanisms that act as positive or negative regulators. Specifically, cAMP-dependent signaling pathways have been crucially implicated in persistent forms of synaptic plasticity. In this study, we examine the role of Popeye Domain-containing Protein POPDC1 (or BVES, Blood Vessel Epicardial Substance), a cAMP effector protein expressed in brain, in modulating hippocampal synaptic plasticity. Unlike other cAMP effectors, such as PKA and EPAC, POPDC1 is membrane-bound and the sequence of the cAMP-binding cassette differs from canonical cAMP-binding domains. These properties suggest that POPDC1 may have a unique role in cAMP-mediated signaling underlying synaptic plasticity. Our results show that POPDC1 is enriched in hippocampal synaptoneurosomes. Acute hippocampal slices from *Popdc1* knockout (KO) mice show enhanced long-term potentiation (LTP) induced by a variety of stimulation paradigms, particularly in response to weak stimulation paradigms that in slices from wildtype mice induce only transient LTP. Furthermore, *Popdc1* KO mice did not display any further enhancement in forskolin-induced LTP observed following inhibition of phosphodiesterases (PDEs), suggesting a possible modulation of cAMP-PDE signaling by POPDC1. Taken together, these data reveal POPDC1 as a novel player in the regulation of hippocampal synaptic plasticity and as a potential target for cognitive enhancement strategies.

Title: Non-canonical and canonical AKT pathways can coexist and intersect upon E-LTP expression and memory formation

Authors: *D. GOROBETS[1], A. SHEININ[2], A. PINHASOV[3], I. MICHAELEVSKI[4];
[1]Ariel Univ. Ctr., Ariel, Israel; [2]Tel Aviv Univ., Tel Aviv, Israel; [4]Integrative Brain Sci. Ctr. - Ariel, Mol. Biol., [3]Ariel Univ., Ariel, Israel

Abstract: AKT is a serine/threonine kinase involved in the broad spectrum of processes in the nervous system as neurons growth, survival and development, growth and maturation of the neuronal spines and long-term synaptic plasticity and memory. Novel results obtained in our lab emphasize that AKT activity is obligatory for expression of early phase long-term potentiation (E-LTP). Furthermore, classical downstream pathway of AKT demonstrated its redundance for

the expression of E-LTP. We hypothesized that AKT mediates E-LTP expression via previously unknown non-canonical downstream pathway. Here we report about the interplay of E-LTP expression and AKT, its non-canonical pathway, and mTORC1/GSK3β-dependent signaling pathways. We found that: a) separate or concomitant pharmacological activation of mTORC1 as well as inhibition of GSK3β fail to alter E-LTP expression; b) concomitant inhibition of GSK3β by TWS119 and AKT by AKT inhibitor VIII (A6730) rescued E-LTP expression attenuation evoked by reduction of AKT activity; c) similarly AKT inhibition on E-LTP was partially rescued by TWS119-induced inhibition of GSK3β; d) concomitant activation of mTORC1 by dorsomorphin and inhibition of AKT restored E-LTP expression as well as activation of the mTORC1 followed AKT inhibition prevents the effect of the latter; e) overexpression of the AKT1 in the CA1 region of hippocampus leading to the diminishing of the effect of its pharmacological inhibition on E-LTP; f) overexpression or knock-down of AKT1 in the hippocampus enhance short- and long-term types of both spatial and non-spatial memory. Summarizing, we suggest that AKT non-canonical and canonical pathways may serve as compensatory mechanisms for E-LTP expression, AKT isoforms may mutually compensate each other upon downregulation and maintain expression of E-LTP.

Title: Pkcζ And pkcι, are not required for hippocampal synaptic plasticity

Authors: *Q. ZHU[1], M. TIAN[2], R. C. JOHNSON[4], L. J. VOLK[5], R. L. HUGANIR[3]; [1]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Neurosci., [3]Dept. Neurosci., Johns Hopkins Univ. Dept. of Neurosci., Baltimore, MD; [4]Johns Hopkins Univ., BALTIMORE, MD; [5]Neurosci., Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: We previously showed using constitutive and conditional knockout (cKO) techniques that the atypical PKCζ was not required for hippocampal synaptic plasticity, learning and memory. However, subsequent studies from Todd Sacktor's laboratory have suggested that our findings were due to a compensation of the loss of PKCζ by increases in the activity of a related atypical PKC, PKCι. To investigate this further we generated conditional cKOs of both atypical PKCs. These mice are constitutive KOs of PKMζ and conditional KOs of PKCι/λ using

CaMKIIpro-CRE mice. We obtained efficient KO/KD of both isoforms of PKC, with no detectable PKMζ and ~13% of PKCι/λ in the hippocampi lysates of the double cKOs. By comparing the littermates of the atypical PKCs double KOs and the PKMζ single KOs, we found that the expression and maintenance of LTP in double KOs was not affected. Combined with the previous result that the PKMζ single KO had no effect on LTP maintenance, our data indicated both atypical PKCs are not required for LTP. Moreover, we observed that LTP maintenance in the double cKO mice was still inhibited by the well-known PKCζ inhibitor zeta inhibitory peptide (ZIP) indicating PKCι/λ and PKMζ are not the relevant targets of ZIP. These results provide compelling evidence that PKCζ is not required for LTP expression and maintenance and supports the idea that the ZIP peptide is a nonspecific inhibitor.

Title: Post-hypoxic long-term potentiation in mice lacking glutamate antiporter, system x_c-

Authors: *B. HEIT[1], A. CHU[2], J. E. RICHMOND[2], D. E. FEATHERSTONE[2], A. MCRAY[2], J. R. LARSON[2];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Ischemic stroke remains the leading cause of adult disability in the world. Efforts to reduce stroke severity, however, have been plagued by translational failure due to gaps in our understanding of cellular and molecular mechanisms leading to brain damage after metabolic insult. Loss of blood supply to brain tissue depletes neurons of energy, which induces a sequela of events within the neuronal network. The glial-bound cystine/glutamate antiporter, system x_c-, with specific subunit xCT, supplies 60-80% of ambient extracellular glutamate in the brain**.** Using slice electrophysiology, we have previously shown that xCT-mediated glutamate release influences both the rapidity and synchrony of depolarizing events after total oxygen deprivation (anoxia). Both genetic deletion and pharmacological antagonism of system x_c- provided ischemic neuroprotection by increasing latency to anoxic depolarization (AD), attenuating AD wave amplitudes, and extending AD wave durations. The sudden onset and rapid regenerative nature of AD, however, may obscure subtle, but important, antecedent differences. Partial hypoxia, or reduced regional blood flow *in vivo*, is an ischemic condition that alters synaptic signaling, but is

not noxious enough to induce glutamate excitotoxicity or de-stabilize transmembrane ion gradients. Mild hypoxia elicits a suppression of synaptic transmission proportional to the degree of oxygen deprivation, ATP breakdown, and accumulation of extracellular adenosine. The present study employed mild hypoxia to better understand ischemia-induced alterations in neuronal responsiveness from WT and xCT KO ($xCT^{-/-}$) mice. Hippocampal slices from both genotypes were prepared, incubated, subjected to 30 minutes hypoxia (25% O_2/75% N_2), and fully re-oxygenated. Although WT and $xCT^{-/-}$ slices did not differ in hypoxia-induced synaptic suppression, mutant slices exhibited accelerated rate of recovery and post-hypoxic potentiation, which resembled LTP. Experiments using CPX, an A_1 adenosine antagonist, showed that this differential effect was not due to enhanced adenosine release in the $xCT^{-/-}$. Contrarily, further experimentation revealed that post-hypoxic potentiation in $xCT^{-/-}$ mice is driven by activation of NMDARs and enhanced calcium influx. Thus, post-hypoxic changes in mutant mice are propagated by mechanisms similar to those involved in LTP. This latter finding was remarkable as $xCT^{-/-}$ mice showed no differences in electrically-induced LTP compared to WT. Taken together, these data confirm system x_c- as a salient regulator of neuronal responses during ischemia and a therapeutic target ripe for exploration.

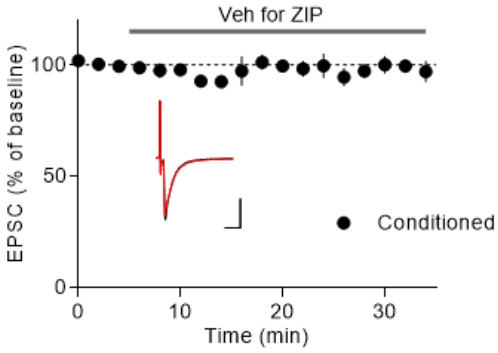
Title: Gsk-3β Activation is required for zip-induced disruption of learned fear



Authors: *S. SONG[1], J. KIM[2], K. PARK[3], K. PARK[3], J. LEE[4], S. PARK[4], S. LEE[1], J. KIM[1], I. HONG[5], B. SONG[6], S. CHOI[4];

Abstract: As an peptide inhibitor for protein kinase C/Mζ (PKCζ/PKMζ), the myristoylated zeta inhibitory peptide (ZIP) is developed, and it is known to produce retrograde amnesia in various systems. However, recent findings shows ZIP induces memory loss even in the absence of PKMζ. Therefore, the mechanism of action of ZIP, remains elusive. Through a kinome-wide screen, we found that glycogen synthase kinase 3 beta (GSK-3β) was robustly activated by ZIP in vitro. While ZIP induced depotentiation (a cellular substrate of memory erasure) of fear conditioning-induced potentiation at LA synapses, it was prevented by a GSK-3β inhibitor, 6-bromoindirubin-3-acetoxime (BIO-acetoxime). Also, GSK-3β inhibition by BIO-acetoxime infusion or LA-specific GSK-3β knockdown by GSK-3β shRNA attenuated ZIP-induced disruption of learned fear. Furthermore, conditioned fear was weakened by an afterward expression of a constitutively active form of GSK-3β in the LA. Our findings suggest that GSK-3β activation leads to a disruption of memory and it is a critical step for ZIP-induced amnesic effects.

Title: Febrile-induced seizures during infancy promotes synaptic instability in dorsal hippocampus in adulthood

Authors: *T. RODRIGUEZ[1,2], M. L. KLOC[3], G. GUZMAN[2], S. DILAWARI[2], G. L. HOLMES[3], J. BARRY[3], P. A. SERRANO[1,2];
[1]Biochem., The Grad. Center, CUNY, New York, NY; [2]Psychology, Hunter College, CUNY, New York, NY; [3]Dept. of Neurolog. Sci., Univ. of Vermont Col. of Med., Burlington, VT

Abstract: Febrile status epilepticus (FSE) in early childhood is associated with enduring cognitive impairments and temporal lobe epilepsy. However, the underlying neural mechanisms for these deficits are unknown. We used a hyperthermia-induced experimental Febrile status epilepticus (eFSE) model in infant rats and investigated the α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor, the N-methyl-D-aspartate (NMDA) receptor, and the post-synaptic density 95 (PSD95) protein levels in these rats during adulthood. AMPA receptor subunit dynamics are known to be necessary for cognition by regulating neural excitability via alteration of the c-terminal phosphorylation site for GluA1 and GluA2 subunits and their overall level of expression. The NMDA subunit NR1 plays an essential role in the calcium channel function of the receptor. The s295 phosphorylation site on PSD95 is essential for synapse stability and maturation. We performed Western blot analysis on the dorsal hippocampal tissue from Febrile status and control rats (maternal separation without seizure). In the dorsal hippocampus we show a significant decrease in GluA2, the calcium impermeable subunit important for anchoring the AMPA receptor to the synaptic membrane; a significant decrease in GluA3, the calcium permeable subunit which plays a role in synaptic strengthening; and no change in GluA1. The NR1 subunit was significantly downregulated and may contribute to a decrease in calcium influx at the post synaptic membrane. We also report a significant decrease in PSD95 and in the s295 phosphorylation site, which is important for synaptic stabilization. These results indicate that Febrile status during infancy weakens synaptic strength, destabilizes post-synaptic AMPA receptor subunits and reduces functioning of NMDA receptors in the adult dorsal hippocampus. Future work will study how these changes contribute to FSE associated memory deficits as a consequence of putative cellular hyperexcitability in different hippocampal subfields and changes to entorhinal-hippocampal synaptic efficacy.

Title: Synaptic and intrinsic potentiation in oriens lacunosum moleculare interneurons induced by theta frequency stimulations

Authors: *M. SAMMARI, Y. INGLEBERT, M. RUSSIER, N. ANKRI, S. INCONTRO, D. DEBANNE;
UNIS 1072, Aix-Marseille Univ., Marseille, France

Abstract: Functional plasticity in cortical neurons generally includes two complementary sides, i.e. synaptic modifications and plasticity of intrinsic neuronal excitability. In inhibitory interneurons, synaptic plasticity has been mostly investigated and except for a few rare cases, intrinsic plasticity in GABAergic interneurons is largely overlooked. Oriens lacunosum moleculare (OLM) interneurons display anti Hebbian long term synaptic potentiation (LTP) conferred by calcium permeable AMPA receptors (CP AMPAR) that preferentially open under hyperpolarization of the postsynaptic membrane. So far, LTP in OLM cells has been induced with induction protocols that are not physiologically realistic. We report here induction of both synaptic and intrinsic potentiation in OLM interneurons following stimulation of afferent glutamatergic inputs in the theta frequency range (5 Hz). LTP is induced by synaptic activation of CP AMPAR whereas long term potentiation of intrinsic excitability (LTP IE) results from the group I metabotropic glutamate receptor (mGluR1) dependent down regulation of Kv7 and hyperpolarization activated cyclic nucleotide gated (HCN) channels. We also investigate the signal transduction pathway involved in these down regulations, more specifically the role of phosphatidylinositol 4,5 bisphosphate (PiP2), phospholipase C (PLC) and protein kinase C (PKC). We conclude that theta frequency stimulations induce intrinsic plasticity and synaptic potentiation in OLM interneurons through two separated pathways.

Title: Permissive environment of perisynaptic astroglia in hippocampal dentate gyrus during LTP

Authors: *A. J. NAM[1], M. KUWAJIMA[2], J. M. MENDENHALL[2], D. D. HUBBARD[2], D. C. HANKA[2], P. H. PARKER[2], W. C. ABRAHAM[3], K. M. HARRIS[2];

Abstract: Perisynaptic astroglial processes (PAPs) play a major role in modulating synapse formation and synaptic transmission. Both *in vivo* and *in vitro* experiments have demonstrated the motile nature of these processes, which can affect the degree that PAPs influence synapses. Long-term potentiation (LTP), a widely studied cellular mechanism of learning and memory, is associated with increased informational content at hippocampal dentate gyrus synapses. Given the intertwined nature of astrocyte-neuron interactions, it is important to examine the role that PAPs play in LTP. While previous work has focused primarily on area CA1 of the hippocampus, we explored PAP structure during control stimulation and with plasticity following the induction of LTP in the dentate gyrus. LTP was induced in adult rats *in vivo* via delta burst stimulation administered through electrodes implanted in the medial perforant pathway. The contralateral hemisphere of each animal served as the control, and received only baseline stimulation. Serial section transmission electron microscopy was used to capture high resolution images of the dentate gyrus neuropil. Three-dimensional reconstructions were then generated from the electron micrographs and used to compare PAP structural changes in the LTP versus control conditions. The results demonstrated the highly interdigitating nature of PAPs. Approximately 80% of the synapses for both conditions exhibited PAP apposition at the axon-spine interface (ASI). This is compared to around 60% of synapses with PAP ASI apposition for area CA1. All synapses had at least some glia present at one or more of the following locations: ASI, presynaptic axon only, postsynaptic dendritic spine only, or pre- and postsynaptic structures but not at the ASI. Those synapses with PAP ASI apposition had a wider range of postsynaptic density areas compared to the synapses with no PAPs at the ASI. Interestingly, there was no significant difference in the percent of the ASI surrounded by PAPs 2 hours after LTP induction versus control. These preliminary results suggest the increased information content for synapses occurs in close proximity to astrocytic processes. Moreover, additional variables beyond the degree of ASI apposition, such as subcellular resource distribution or surface-to-volume ratio, may be the important determinants of the effects that PAPs exert at dentate gyrus synapses.

Title: Adgrb1 (Bai1) deletion leads to social deficits, increased seizure susceptibility, and altered brain development

Authors: *F. SHIU[1], J. C. WONG[1], R. H. PURCELL[2], T. LALA[3], S. OWINO[4], D. ZHU[5], E. G. VAN MEIR[6], R. A. HALL[7], A. ESCAYG[1];

Abstract: The adhesion G protein-coupled receptor BAI1/ADGRB1 plays an important role in suppressing angiogenesis, mediating phagocytosis, and acting as a tumor suppressor. Previous research demonstrated in vitro and in vivo knockdown of BAI1 leads to immature dendrite formation while overexpression leads to dendrite retraction. BAI1 also functionally interacts with autism-relevant proteins such as Neuroligin 1 and IRSp53. However, little is known about the relationship between altered BAI1 function and clinically relevant neurological phenotypes. Therefore, we evaluated the effect of reduced Bai1 expression on behavior, seizure susceptibility, and brain morphology in Adgrb1 mutant mice. We compared adult homozygous (*Adgrb1*$^{-/-}$), heterozygous (*Adgrb1*$^{+/-}$), and wild-type (WT) littermates using a battery of tests to assess social behavior, anxiety, repetitive behavior, locomotor function, and seizure susceptibility. We found that *Adgrb1*$^{-/-}$ mice showed deficits in cognition and social behavior, and increased vulnerability to induced seizures. *Adgrb1*$^{-/-}$ mice also weighed significantly less than littermates beginning at P15 for males and P9 for females, but body weights were comparable between same-sex littermates by P37. We also compared brain weights between Adgrb1 mutants and WT littermates. While no significant differences were observed in P1 mice, average brain weights were lower in *Adgrb1*$^{-/-}$ mice compared to *Adgrb1*$^{+/-}$ and WT littermates at 3 weeks and 2-3 months after birth. Reduced neuron density was observed in 2-3 months old *Adgrb1*$^{-/-}$ mice, while levels of astrogliosis and microgliosis were comparable to WT littermates. Finally, higher levels of apoptosis were observed in the hippocampus and cortex of *Adgrb1*$^{-/-}$ mice at P1, but not at later timepoints (3 weeks and 2-3 months). These results suggest that Bai1 dysfunction might be associated with a broader range of clinically relevant neurological phenotypes than previously reported.

Title: Setting a new platform for antiseizure drug testing: a mouse model with impaired mitochondrial oxidative phosphorylation recapitulates the human drug-resistant epilepsy.

Authors: *S. KUMAR[1], A. A. LAGUNIN[2], R. K. GOEL[1];
[1]Dept. of Pharmaceut. Sci. & Drug Res., Punjabi Univ., Patiala, India; [2]Dept. of Bioinformatics, Inst. of Biomed. Chemistary, Moscow, Russian Federation

Abstract: Epilepsy is characterized by recurrent disabling seizures. Every third patient with epilepsy remains resistant to drug therapy with devastating consequences on the quality and expectancy of the patient's life. The mechanisms governing drug-resistant epilepsy are diverse and imperfectly known therefore, recreating drug-resistant epilepsy in laboratory animals continues to be a challenge in epilepsy research. We propose to select a clinically relevant drug-resistance mechanism, using system biology and network pharmacology approach, to produce a new animal model with high face, construct, and translational validity. Several databases have been searched to gather information on 42-licensed antiseizure drugs (Drugs@FDA Database), 175-molecular drug targets (DrugBank and DrugCentral), and 601-epilepsy-gene associations (DisGeNET, and Disease-Connect). Collected information has been transformed into two datasets (Venn analysis) i.e. Disease-drug targets (n=58) and Disease non-drug targets (n=543). The most suitable mechanism of drug-resistance i.e. Mitochondrial oxidative phosphorylation has been extracted from 543 disease non-drug targets (using DAVID web-service and DIAMOnD algorithm) and manually verified from clinical reports. For in-vivo modeling, a commercially available specific inhibitor of mitochondrial complex-I was injected into the adult mice via an intraperitoneal route (2.5mg/kg rotenone). Rotenone pre-treated mice were daily exposed to electric shock (20V, 15 mA, 6Hz) twice a day for ~15 days or injected with chemoconvulsant (35mg/kg pentylenetetrazole, i.p) for ~35 days. Drug resistance epilepsy was characterized by licensed antiseizure drugs applied as described by International League Against Epilepsy. According to our observations, the rotenone kindling model shows significant resistance ($P<0.05$) to Lamotrigine (15mg/kg), Levetiracetam (40mg/kg), Carbamazepine (40mg/kg), Zonisamide (100mg/kg), Gabapentin (224mg/kg), Pregabalin (30mg/kg), Phenytoin (35mg/kg), Topiramate (300mg/kg), Valproate (200mg/kg), and two drug combinations (lamotrigine + aforementioned drugs), with less than 10% mortality. Pre-clinical drug testing through the rotenone-kindling model may uncover more effective drug therapies for the management of drug-resistant epilepsy because the rotenone-kindling model shows resistance to third-generation antiseizure drugs as well as their two-drug combinations.

Title: Comparison of soman-induced epileptogenesis and neuropathology in juvenile and adult male rats treated with midazolam

Authors: D. A. NGUYEN[1], B. MARRERO-ROSADO[1], C. R. SCHULTZ[1], M. F. STONE[1], M. DE ARAUJO FURTADO[2], *L. A. LUMLEY[1];
[1]US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD; [2]BioSEad, LLC, Rockville, MD

Abstract: Organophosphorus nerve agents (OPNAs) are acetylcholinesterase inhibitors that lead to pharmacoresistant *status epilepticus* when treatment with benzodiazepines is delayed. In adult male rodents, exposure to the OPNA soman leads to extensive loss of neurons, epileptogenesis and functional impairment when seizure is unmitigated. While the majority of research on OPNA exposure has evaluated its short-term effects in adult male rodents, much less is known about the detrimental responses in younger animals. Our laboratory previously reported that young rats (postnatal day [PND] 7 and 14) are highly susceptible to the lethal effects of OPNAs, while juvenile (PND42) rats are less susceptible compared to adults. This current study evaluated age differences in the development of epileptogenesis, neurodegeneration and neuroinflammatory responses following soman exposure. **Methods.** Juvenile and adult male and female rats implanted with telemetry transmitters for electroencephalographic recordings were exposed subcutaneously (SC) to an equitoxic 1.2 x median lethal dose of soman (PND42: female, 159.6 μg/kg; male 224.4 μg/kg; PND70: female, 88.8 μg/kg; male: 118.1 μg/kg) and treated intramuscularly (IM) with atropine sulfate (2 mg/kg) and HI-6 dimethanesulfonate salt (DMS; 118.5 mg/kg) 1 min after exposure, and with midazolam (3 mg/kg; IM) 40 min after seizure onset. Rats were euthanized at 3, 14 or 30 days after exposure for evaluation of neuronal degeneration and microglial activation. **Results.** Delayed midazolam treatment did not prevent epileptogenesis, neurodegeneration or neuroinflammation following soman exposure. Fewer juvenile rats exposed to soman tended to develop spontaneous recurrent seizure compared to adult rats. By 2 weeks after soman exposure, more extensive neuronal loss and greater microglial activation were observed in adult rats compared to juvenile rats in the thalamus, amygdala and piriform cortex. **Conclusions**. This study further demonstrates that delayed treatment with

midazolam is not fully protective against soman-induced epileptogenesis and neuropathology, exemplifying the need for adjunct anti-seizure treatment. Also, juvenile rats had better outcomes compared to adult rats treated with delayed midazolam, despite receiving a greater dose of soman. The views expressed are solely those of the authors and do not necessarily represent the official views of the CCRP, NIAID, NIH, HHS, USAMRICD or DoD

Abstract: Autoimmune encephalitis associated with auto-antibodies directed against the Leucin rich, glioma inactivated 1 protein (anti-LGI1 AIE) is responsible for pathognomonic tonic-dystonic seizures (TDS). Several anti-LGI1 antibodies-related changes in neuronal activity and excitability, notably associated with dysfunctions in voltage-dependent potassium channels and AMPA receptors, have been previously reported. However, their relation to seizures remains unknown. We developed a new *in vivo* experimental model to test the hypothesis that a focal cortical inhibition of voltage-dependent potassium channels could recapitulate the human TDS. Comparing electro-clinical features of TDS in the model with those recorded in a cohort of anti-LGI1 AIE patients revealed striking similarities between human and rodent seizures, including a similar frequency of recurrence and motor semiology, and their systematic precession by a large-amplitude slow EEG wave. By combining multi-site extracellular and intracellular recordings of cortical pyramidal neurons in sedated rats, we demonstrated that a sequence of changes in

neuronal excitability and synaptic activity concurs to initiate the massive membrane depolarization, and associated high-frequency firing, underlying the paroxysmal EEG activity. This new *in vivo* animal model could serve future investigations for further delineation of the ictogenesis mechanisms in this frequent auto-immune encephalitis.

Title: Enhanced GABA-mediated calcium activity regulates aberrant neurogenesis in a mouse model of epilepsy.

Authors: *Z. LYBRAND[1], S. GOSWAMI[2], J. ZHU[3], V. JARZABEK[2], N. MERLOCK[2], M. AKTAR[4], C. SMITH[2], L. ZHANG[3], P. VARMA[2], K. CHO[5], S. GE[6], J. HSIEH[2];

Abstract: Aberrant neurogenesis is the generation of pro-epileptic adult-born granule cells (abGC) in the mouse hippocampus that is characterized by abnormalities abGC migration, dendritic development, intrinsic excitability, synaptic connectivity, and is associated with spontaneous recurrent seizures (SRS). In this study, we identified enhanced intracellular calcium events associated with early stages of aberrant neurogenesis in a pilocarpine mouse model of epilepsy. Using chemogenetic tools to prevent this increased calcium activity selectively in abGC at different stages of maturation, we identify a critical window that promotes the aberrant maturation of abGCs. Suppressing this calcium activity during this critical window of aberrant neurogenesis prevents the abnormal development of abGCs and reduces SRS. Using mono-

synaptic pseudotyped rabies tracing, we further demonstrated that chemogenetic modulation of calcium activity in aberrant abGCs decreased recurrent CA3 back-projections and restored proper entorhinal connections typically lost in pilocarpine models of epilepsy. Furthermore, we demonstrate that this enhance calcium activity that promotes aberrant neurogenesis is mediated by early GABA A receptor activity. These results illustrate the pathological potential of adult-born granule cells in the hippocampus. Despite their limited number, abGCs have an unlimited capacity to disrupt the hippocampus circuitry.

Title: Memory disruption and alterations of the PI3K/AKT/mTOR signaling pathway following single kainate induced seizure

Authors: *G. SULLENS, K. BLANDIN, D. NARVAIZ, P. D. WOMBLE, D. SANTANA COELHO, J. N. LUGO, JR;
Psychology and Neurosci., Baylor Univ., Waco, TX

Abstract: Individuals with epilepsy report memory deficits and disturbances as a major quality of life concern. Most studies have focused on the long-term effects of kainate (KA) induced status epilepticus (continuous seizures) on learning and memory. We examined the acute effects of a single KA induced seizure on learning and memory following a single seizure episode. Male and female C57BL/6J mice underwent Delay Fear Conditioning one or six hours after cessation of seizures following 10mg/kg i.p injection of kainic acid. Mice were tested for contextual and cued memory either 24 hours or one week after seizure induction. KA induced seizures resulted in a contextual fear memory deficit 24 hours later for both one- and six-hour training cohorts. Mice that received KA seizures had a deficit in contextual fear memory when trained one hour later ($p < .05$), but there was no effect of KA nor training time for cued fear memory 24 hours after seizure induction. One week after seizure induction, only mice that seized one hour prior to training showed a cued fear memory deficit compared to saline controls trained at the same time and both KA and saline controls trained six hours after recovery, $p < .05$. Levels of AKT, pAKT, S6, and pS6 were measured by western blotting as indicators of alterations in the mTOR

signaling pathway in the hippocampus. Twenty-four hours after seizure induction there was an overall decrease in total AKT for KA mice compared to controls, $p < 0.01$. This decrease was not present one week later. No alterations in total S6 were observed at either time point. KA increased levels of pS6/S6 and pAKT/AKT 24 hours after seizure induction compared to controls, $p < 0.01$, but not one week later. We also measured changes in the levels of microglia and astrocytes in the hippocampus. We found Iba1 was significantly increased after seizures compared to controls 24 hours and one week after seizure induction, $p < .05$. This study adds to the growing literature which indicates time dependent learning and memory deficits after a single seizure. Additionally, this study indicates there are transient alterations in the mTOR signaling pathway and persistent inflammatory responses within the hippocampus which may play a role in the memory disturbances observed.

Title: Responses to Obstructive Sleep Apnea and Chemoreflex Stimulation in Rats with Epilepsy Induced by Pilocarpine

Authors: C. QUINTINO[1], P. P. GHAZALE[2], P. P. BRAGA[1], K. P. GOMES[1], C. E. G. OLIVEIRA[1], D. H. MATTA[1], G. H. SCHOORLEMMER[2], T. S. MOREIRA[3], E. P. MENDES[1], C. H. CASTRO[1], D. B. COLUGNATI[1], ***A. P. PANSANI**[1];
[1]Federal Univ. of Goiás, Goiânia, Brazil; [2]Federal Univ. of São Paulo, São Paulo, Brazil; [3]Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Obstructive sleep apnea (OSA) and chemoreflex alterations are common in patients with epilepsy and may contribute to sudden unexpected death in epilepsy (SUDEP). The aim of our study was to characterize in rats with chronic epilepsy 1) the latency to awake from obstructive apneas made in sleep, 2) changes in heart rate and respiratory effort during obstructive apnea in sleep, and 3) peripheral chemoreflex sensitivity. Epilepsy was induced with pilocarpine (350 mg/kg, i.p.) in 6 male Wistar rats. Six control rats received a saline injection. Sixty days after the first spontaneous seizure, we implanted a tracheal balloon to induce

obstructive apnea, EEG and EMG electrodes to detect sleep phases, ECG electrodes to measure heart rate, and a thoracic balloon to record respiratory effort (thoracic pressure variation). For 8 hours during the light period, we induced apneas (up to 1 apnea/min) during sleep. Each apnea ended as soon as the rat awoke (triggered by increased muscle tone). Subsequently, cannulas were implanted in the femoral artery and vein. The next day, the peripheral chemoreflex was triggered by i.v. injection of 40 µg/kg potassium cyanide (KCN). The apnea duration showed interaction between group and sleep phase in the median quartile. Both control and epileptic rats woke up after about 6.4 s when apneas were made during NREM. However, when apneas were made during REM, the latency to awake was lower in rats with epilepsy than in controls (median: 7.3 vs. 8.2 s, linear regression model and t-test, $p < 0.01$). To analyze the effect of epilepsy on respiratory effort and heart rate during apnea, we selected apneas with a duration of 10 s, and compared the mean curves of response against time by functional ANOVA. Respiratory effort increased, and heart rate fell during apneas made in REM and NREM sleep, but the mean curves in epileptic rats were not different from those in controls (functional ANOVA and Cuevas Heteroscedastic - CS test, $p > 0.05$). KCN injection induced transient bradycardia, respiratory effort, and hypertension in both groups. In epileptic subjects, but not in controls, the pressor response was followed a transient hypotension (functional ANOVA and CS test, $p<0.05$). In conclusion, our study demonstrated that rats with epilepsy had a reduced latency to awake from apnea in REM, but not in NREM, which could be possible related with alteration on cholinergic system. The changed arterial pressure response after chemoreflex stimulation in rats with epilepsy suggests changes in sympathetic control. Further studies should be performed to understand if and how these alterations affect SUDEP risk.

Title: Impact of raptor or rictor deletion on hippocampal dentate granule cell morphology during epileptogenesis

Authors: *C. M. GODALE[1], N. MAYER[2], E. PARKINS[1], K. KRAUS[1], C. GROSS[3], S. C. DANZER[3];

[1]Univ. of Cincinnati, Cincinnati, OH; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: The mechanistic target of rapamycin (mTOR) signaling pathway is hyperactivated during epileptogenesis. The central regulators of this pathway are mTOR complexes, mTORC1 and mTORC2, which are controlled by the regulatory-associated protein of mTOR (Raptor) and the rapamycin-insensitive companion of mTOR (Rictor), respectively. It is known that hippocampal dentate granule cells are a target of mTOR hyperactivation in temporal lobe epilepsy (TLE). However, the exact roles played by mTORC1 and mTORC2 in regulating pathologies found in TLE are unknown. Granule cell pathology has been hypothesized to mediate the development of TLE; therefore, understanding how mTOR regulates granule cell dysmorphogenesis may have therapeutic benefits. We developed a viral cre-recombinase driven strategy to produce sparse deletions of Raptor or Rictor from hippocampal dentate granule cells in mice during epileptogenesis. Sparse deletions were titrated to produce knockout (KO) cells in each mouse without impacting epileptogenesis. One week after pilocarpine-induced status epilepticus (SE), Raptor$^{fl/fl}$, tdTomato$^{+/-}$ or Rictor$^{fl/fl}$, tdTomato$^{+/-}$ mice received hippocampal injections of AAV9.CamKII.HI.eGFP and AAV9.CamKII.Cre, producing a mixture of eGFP+ wildtype and tdTomato+ Raptor or Rictor knockout cells in each mouse. Animals were video monitored for seizures during week seven, and brains were collected at the end of the eighth week for histology. Soma area measurements revealed Raptor KO cells had consistently smaller soma areas than adjacent wildtype cells, while Rictor KO cells were statistically identical to wildtype cells. Studies are ongoing to reveal the roles of mTORC1 and mTORC2 signaling during epileptogenesis in granule cell TLE pathologies.

Title: Cell-type specific expression and function of NRSF in the developing dentate gyrus: lessons from epilepsy

Authors: *Y. CHEN, N. KAMEI, J. DAGLIAN, K. CHEN, A. L. PHAM, T. Z. BARAM; Univ. of California Irvine, Irvine, CA

Abstract: Background: Neuron-restrictive silencing factor (NRSF) is a transcriptional repressor of many activity-dependent neuronal genes that carry NRSF-response elements (NRSE). NRSF is upregulated by seizures and insults, which promotes epileptogenesis by regulating a group of genes that critically influence hippocampal neuronal function. We have reported that experimental febrile status epilepticus (eFSE) leads to epileptogenesis and disruption of spatial memory network development yet blocking the activity of hippocampal NRSF after FSE ameliorates spatial memory defects and selectively rescues dendritic structure of dentate gyrus (DG) granule cells. The granule cell layer contains cells at different developmental stages and cells of different ages contribute differently to the formation of an aberrant neuronal circuit. Notably, the expression and function of NRSF varies by cell type and age and some granule cells may not express NRSF after eFSE. To determine the contribution of NRSF to eFSE-induced DG network disruption at the required resolution in time and space, we investigate the cell-type specific expression of NRSF in the developing DG and the developmental stage of granule cells expressing NRSF after eFSE. **Methods:** eFSE were generated as described, by increasing core and brain temperatures of P10-11 rats to >38.5°C for 30 min, which generates limbic FSE-like seizures. NRSF expression was detected via single cell resolution in situ hybridization, validated by NRSF ICC, then coupled with ICC of several cellular markers. The age of NRSF-expressing cells was determined using Edu birth-dating. **Results:** Within 48-72h, eFSE upregulated the expression of NRSF in selective subpopulations of DG cells. These were neurons, apparent from NeuN expression and absence of the microglial marker Iba1. NRSF-expressing cells in the GC layer co-expressed Prox1 indicating that they are granule cells. In the subgranular zone (SGZ) of eFSE rats, NRSF cells co-expressed GFAP, suggesting their immaturity. Studies of overt NRSF expression in newborn, infant, or mature GCs are ongoing.

Title: Genetic compensation at the AIS: Scn8a, Kcna1 and Kcnq2.

Authors: *S. HILL[1], P. JAFAR-NEJAD[2], F. RIGO[3], M. H. MEISLER[4];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Neurosci. drug discovery, [3]Ionis Pharmaceuticals, Carlsbad, CA; [4]Dept Human Genet., Univ. Michigan, Ann Arbor, MI

Abstract: The neuronal voltage-gated sodium channel $Na_v1.6$ is concentrated at the axon initial segment (AIS), where it plays a key role in initiation of action potentials. Gain-of-function mutations in *SCN8A* are a cause of developmental and epileptic encephalopathy (DEE). Administration of an antisense oligonucleotide (ASO) that reduces expression of *Scn8a* results in delayed seizure onset in a mouse model of *Scn8a* DEE, and this ASO also rescues survival of Dravet mice with mutation of *Scn1a* (*Lenk et al, Ann. Neurol. 87:339-346, 2020*). We asked whether reduction of *Scn8a* expression could ameliorate the seizure phenotypes of mice with mutations in two genes encoding potassium channels that are also localized at the AIS: *Kcnq2* and *Kcna1*. Mice with homozygous mutations of *Kcna1* (*Smart et al Neuron 1998*), *Kcnq2* (*Soh et al, J. Neurosci. 34:5311-5321, 2014*) and *Lgi1* (*Chambrol et al, Brain 133:2749-2762*) were treated on postnatal day 2 by intracerebroventricular injection of the ASO that reduces the level of *Scn8a* transcript by 50%. Surviving mice were given repeated doses of the ASO at four-week intervals. The number of convulsive seizures and length of survival were monitored. In both the *Kcna1* and *Kcnq2* mutant mice, treatment with the *Scn8a* ASO significantly increased the length of survival, demonstrating functional interaction between ion channels at the AIS. We also examined the effect of *Scn8a* reduction on mice with mutation of the synaptic protein LGI1, which resulted in an increase in survival from 3 weeks to 4 weeks. The data demonstrate amelioration of genetic epilepsies by modulation of AIS-localized ion channel expression. An *SCN8A* ASO may have therapeutic relevance for a range of genetic epilepsies.

Title: Kcc2 expression in dentate gyrus of rat fed ketogenic diet with seizures induced by amygdala kindling

Authors: *T. E. JUÁREZ ZEPEDA[1], C. RUBIO[2], V. CUSTODIO[2], L. E. BAENHA ALVAREZ[1], L. HERNÁNDEZ LÓPEZ[2], K. JERÓNIMO CRUZ[1], J. G. MARTÍNEZ-GALINDO[2], M. TAPIA RODRÍGUEZ[3], E. COBALLASE URRUTIA[1], L. CARMONA APARICIO[1], A. VANOYE CARLO[1], C. PAZ TRES[2], L. GRANADOS ROJAS[1];

Abstract: Ketogenic diet (KD), is a high fat, low carbohydrate and adequate protein regimen, which has been used as a non-pharmacological treatment of refractory epilepsy. However, their mechanism of action is unknown. In patients with refractory epilepsy and in rat epilepsy models, KCC2 expression cation-chloride cotransporter is down-regulated. KCC2 transports chloride out of neurons, contributing thus the intracellular concentration of this ion, which determines the strength and polarity of the gamma-aminobutyric acid (GABA)-mediated neurotransmission. Alterations in homeostasis of KCC2 could explain the hyperexcitability observed in epilepsy. Therefore, the aim of this study was to analyze the effect of the KD on cotransporter KCC2 expression in the three layers of the dentate gyrus, in rats with seizures induced by amygdala kindling. Groups of intact animals and with kindling fed on normal or ketogenic diet were evaluated. 50 μm thick cuts of the brain were obtained and processed with immunodetection techniques for the KCC2 cotransporter. Subsequently, the optical density of the immunohistochemical staining of the KCC2 cotransporter was obtained to evaluate its expression. The results indicated that animals fed a ketogenic diet increase the concentration of glucose and decrease the concentration of β-hydroxybutarate. Kindling animals fed a ketogenic diet reduced their body weight. The optical density of the KCC2 cotransporter in the three layers of the dentate gyrus was reduced in kindling animals. The ketogenic diet reversed the reduction of the KCC2 cotransporter produced by kindling in all three layers of the dentate gyrus. Also, ketogenic diet per se increased the expression of the KCC2 cotransporter. It is likely that the mechanism of action of the ketogenic diet to control seizures is through the modulation of the expression of the KCC2 cotransporter.

Title: Cannabidiol administration significantly improves social behavior and increases seizure resistance in an Scn8a mouse model

Authors: *J. C. WONG, L. SHAPIRO, A. ESCAYG;
Emory Univ., Atlanta, GA

Abstract: An increasing number of *de novo SCN8A* mutations have been identified in patients with catastrophic, treatment-resistant childhood epilepsy. *De novo SCN8A* mutations have also been found in patients with autism, intellectual disability and developmental delay but with less severe epilepsy. Since *SCN8A*-associated epilepsy mutations have only recently been identified, it is unclear which treatments are the most efficacious for these patients. Furthermore, attempts at seizure control are not always effective at improving behavioral outcomes and can sometimes exacerbate behavioral abnormalities. Recent clinical trials demonstrate that cannabidiol (CBD) significantly reduces seizure frequency in patients with Dravet syndrome and Lennox-Gastuat syndrome. It is hypothesized that the antiepileptic effects of CBD may be mediated, in part, by reducing resurgent sodium currents. In HEK293T cells, CBD was shown to reduce resurgent current in both wild-type (WT) $Na_v1.6$ and mutant $Na_v1.6$ channels, suggesting that CBD may be beneficial in *SCN8A*-associated disease.

Using CRISPR/Cas9, we knocked in the human *SCN8A* R1620L mutation into the corresponding position in the mouse *Scn8a* gene. We previously showed that heterozygous mutants (RL/+) exhibit increased seizure susceptibility and a range of behavioral abnormalities, including hyperactivity and social behavior deficits. To evaluate whether CBD could protect against induced seizures, RL/+ mutants and WT littermates were administered 200-360 mg/kg CBD and seizures were induced using the 6 Hz paradigm and pentylenetetrazole (PTZ). We found that 320 mg/kg CBD was the minimum dose required to observe a statistically significant increase in protection against 6 Hz seizures in the RL/+ mutants (N = 10-12/dose). CBD (200 mg/kg) was able to increase resistance to PTZ-induced seizures in WT littermates; however, a higher dose of CBD (360 mg/kg) was required to significantly increase resistance in the RL/+ mutants (N = 9/group).

To determine whether CBD could also improve behavior, RL/+ mutants and WT mice were administered 10-100 mg/kg CBD two hours prior to behavioral testing. The mice were subjected to a battery of behavioral assessments to evaluate locomotor activity, motor coordination, and social behavior. CBD was able to reduce locomotor activity and restore normal social behavior in the RL/+ mutants at doses of 100 mg/kg and 10 mg/kg, respectively (N = 12-13/group). Our results demonstrate that CBD can significantly increase seizure resistance and improve social behavior in an *Scn8a* mouse model. These findings suggest that CBD may be therapeutic in patients with *SCN8A*-associated disease.

Title: Novel synthetic cannabidiol enantiomer modulates delta and beta wavelength EEG activity

Authors: *A. CONTRERAS[1], W. A. MAIO[2], D. J. HINES[1], R. M. HINES[1];
[1]Psychological and Brain Sci., Univ. of Nevada, Las Vegas, Las Vegas, NV; [2]New Mexico State Univ., Las Cruces, NM

Abstract: Novel synthetic cannabidiol enantiomer modulates δ and β wavelength EEG activity April Contreras[1], William A. Maio[2], Dustin J. Hines[1], and Rochelle M. Hines[11]Interdisciplinary Neuroscience PhD Program, Department of Psychological and Brain Sciences,University of Nevada, Las Vegas[2]Department of Chemistry, New Mexico State University
Cannabidiol (CBD) is the major non-psychotropic cannabinoid (CB) of *Cannabis* with therapeutic potential as an anticonvulsant and anxiolytic. Compared to other constituents of *Cannabis*, CBD has a low affinity for CB1 and CB2 receptors. Novel synthetic CBD derivatives have been designed to improve affinity for CB receptors and receptor activation, however little is known about the behavioral and electroencephalographic (EEG) effects of novel CBD congeners. In the present study, we examine the effects of caraway derived CBD congeners in mice to further our understanding of these compounds, with the larger goal of developing novel therapeutics for childhood epilepsy syndromes and anxiety disorders. A series of (+)-*enantiomer*-CBD congeners ((+)-*ent*-CBD) with elongated alkyl chains were synthesized using an innovative 4-step method using conversion of (+)-carvone into isopiperitenol. (+)-*ent*-CBD congeners with elongated alkyl chains were administered to mice via oral gavage following one hour of EEG baseline recording. Three of the (+)-*ent*-CBD congeners elicited a significant change in the beta (β) frequency of the EEG compared to baseline. Of these, the congener with the longest alkyl chain ((+)-*ent*-CBD-**8**) had particularly potent effects on both the β and delta (δ) frequency bands. This suggests that variations in alkyl chain length of synthetic congeners may subtly modulate central nervous system activity. Our findings contribute to the understanding of novel synthetic CBD derivatives on neuronal signaling, with major implications for the development of novel anticonvulsant and anxiolytic therapies which target CB1 and CB2 receptors with differential specificity.

Title: Comparative potencies of cannabidiol (CBD), cannabigerol (CBG) and cannabichromene oil (CBC oil) in the mouse maximal electroshock test

Authors: *A. DHIR[1], S. FERBER[2], M. MASCAL[3], N. SHEVCHENKO[3], M. A. ROGAWSKI[1]; [1]Dept. of Neurology, Sch. of Med., Univ. of California, Davis, Sacramento, CA; [2]Flawless Creations, Los Angeles, CA; [3]Dept. of Chem., Univ. of California, Davis, CA

Abstract: Cannabidiol (CBD), a biologically active constituent of the cannabis (hemp) plant, has been approved for the treatment of seizures associated with Lennox-Gastaut syndrome, Dravet syndrome, and tuberous sclerosis complex. CBD protects against tonic hindlimb extension (THLE) in the mouse maximal electroshock (MES) test, a standard model used in the identification of antiseizure agents. Although CBD has been extensively studied, many other plant cannabinoids have not been assessed for potential utility in epilepsy therapy. The current study determined the effectiveness and potencies of cannabigerol (CBG) and cannabichromene (CBC) in the mouse MES test. Samples of CBD, both from decarboxylation of cannabidiolic acid (CBDA) and a commercial source, were tested in parallel as a comparator. Samples of CBD and CBG were prepared by decarboxylating their respective active precursors CBDA and cannabigerolic acid (CBGA; 95+% pure) by heating at 102°C for 60 min. The precursor compounds were isolated from hemp. For comparison, the antiseizure activity of pure, commercial, hemp-derived CBD and chemically synthesized CBG in crystalline form was also determined in the MES test. We also investigated whether CBDA and CBGA have antiseizure potential at the highest dose tested (150 mg/kg) in this model. Male CF1 mice were used in the current study. Sixty min after IP injection of the cannabinoids, the animals were subjected to a 0.2-s, 60-Hz, 50-mA electrical stimulus delivered with corneal electrodes (5 mm diameter stainless steel balls) wetted with 0.9% saline. Animals failing to show THLE were scored as protected. CBD obtained from CBDA isolates protected animals from THLE at doses between 25-150 mg/kg with an ED50 value of 62.7 ± 5.6 mg/kg. CBG obtained from CBGA was also protective in a similar range of doses 65-200 mg/kg with an ED50 value of 99.03 ± 7.01 mg/kg. A commercial sample of crystalline, hemp-derived CBD and crystalline, synthetic CBG had similar efficacies and potencies. The ED50 value of commercial CBD was 83.7 ± 5.7 mg/kg. Pure crystalline CBG protected 62.5%, 75% and 62.5% of animals at 100 mg/kg, 150 mg/kg and 200 mg/kg. In contrast, CBC oil was less potent than CBD and CBG. At doses of 50, 100, 150 and 250 mg/kg, the fraction of animals protected was 11.1%, 12.5%, 12.5% and 25%, respectively. CBDA had no antiseizure activity at the highest dose tested whereas CBGA protected 25% of animals tested. The rank order of potencies of the cannabinoids was CBD > CBG > CBC. CBG is sufficiently effective and potent that it may have clinical utility.

Title: Adverse Effects of Transcranial Focused Ultrasound in Treating Epilepsy

Authors: *M. KOO[1], T. CHOI[2], J. JOO[3], Y.-M. SHON[3,4,5], J. PARK[1,2];
[1]Biomed. Engin. - Intelligent Precision Healthcare Convergence, [2]Dept. of Intelligent Precision Healthcare Convergence, Sungkyunkwan Univ., Suwon, Korea, Republic of; [3]Samsung Med. Ctr., [4]Biomed. Engin. Res. Center, Samsung Med. Center, Sch. of Med., [5]Samsung Advanced Inst. for Hlth. Sci. & Technol., Sungkyunkwan Univ., Seoul, Korea, Republic of

Abstract: Transcranial focused ultrasound stimulation (tFUS) has demonstrated its effectiveness in alleviating the pathological hyperexcitability of small animal epilepsy models. However, no studies have reported the functional adverse effects of tFUS in treating epilepsy. With chemical and electrical stimuli, paradoxical responses of post-inhibitory rebound (PIR) which triggers excitatory responses following a brief activation of inhibitory GABAergic neurons were previously demonstrated. Thus, tFUS for treating epilepsy could also adversely trigger proconvulsive responses. This study aims to explore tFUS stimulus sequences which could generate adverse effects of amplifying the epileptiform activities. The experiment was conducted via pentylenetetrazol-injected acute epilepsy rat model (Male Sprague-Dawley rat, 8wk, n=26) where tFUS was applied for six times at the thalamic region under urethane anesthesia. While the acoustic pressure was fixed to 0.25 MPa, the burst length (10s, 20s, 40s) and interval (50s, 40s, 40s) of the acoustic transmissions were varied. Brain electrical activities were evaluated via electroencephalograph. Immunohistochemistry analysis was performed with c-Fos and GAD65 antibodies to figure out the excitatory and inhibitory cell responses, respectively. The ratio of the number of epileptic discharges after tFUS to the baseline decreased from 2.56 (SEM=0.35) to 1.20 (SEM=0.26) as the stimulation length was elongated from 10s to 40s. After the brief suppressive responses identified as the reduced number of peak ratio during the 10s stimulation, the significant increased ratio (p=0.0001) compared to the non-stimulated group (2.31; SEM=0.47) was presented in the post-stimulus period. The c-Fos-positive cell ratio analysis at

the dentate gyrus (DG) granular layer showed higher proportions of c-Fos labeled cells in 10s stimuli group (80.72%; SEM=2.00%) than the non-stimulated group (71.73%; SEM=5.81%). However, the expression ratio was dramatically reduced in the 40s stimuli group (24.22%; SEM=14.134%). In the GAD65-positive cell density analysis at the DG, 10s stimuli group (6.41 cells/mm^2; SEM=1.06) showed higher expression than the non-stimulated group (2.33 cells/mm^2; SEM=0.49), while 40s stimuli (13.58 cells/mm^2; SEM=1.58) showed the highest value. Although an anti-seizure effect was remarkably provoked by the longer period of ultrasonic stimuli, the shorter transmission (10s) of tFUS may trigger excitatory responses following brief inhibitory responses. Thus, adverse effects caused by PIR excitatory responses need to be considered when tFUS sequence is scheduled to provide for neuro-therapeutics.

Abstract: Excessive glutamate release from synapses during seizures leads to neural excitotoxic injury in vulnerable forebrain neurons and subsequent epileptic disease in the kainic acid animal model of temporal lobe epilepsy. Here, we have further characterized neuron-specific, calcium and neural activity regulated, high-affinity methylaminoisobutryic acid (MeAIB) / glutamine transport activity in mature hippocampal neuronal cultures that is inhibited by **riluzole**, a benzothiazole anti-convulsant and known neuroprotective agent against glutamate-induced excitotoxicity. We have sequentially screened two libraries of riluzole derivatives to identify compounds that inhibit spontaneous neural activity-regulated, high affinity MeAIB transport potently like riluzole and have synthesized new chemical thiazole derivatives of riluzole that are more selective for the high-affinity MeAIB transport system over neuronal sodium channel blockade than riluzole *in vitro*. One of the most potent transport inhibitors in our *in vitro* screens,

SKA-378, is orally active, brain penetrant and prevents kainic acid-induced hippocampal neural injury in all hippocampal pyramidal neuron CA subfields when given before or after kainic acid-induced status epilepticus when injury is evaluated after 3d. SKA-378 also protected neurons in other established interconnected limbic regions including the subiculum and the entorhinal and pyriform cortex, and in mid-line amygdalar and select thalamic neurons. These results indicate that our novel riluzole aminothiazole derivatives may be useful agents to explore mechanisms involved in the development, prevention, and management of chronic temporal lobe epilepsy.

Title: Investigating the degree of chronic reactive astrocyte heterogeneity during Toxoplasma gondii infection

Authors: *Z. FIGUEROA[1], W. AGNEW-SVOBODA[1], E. VIZCARRA[2], M. RICCOMAGNO[3], T. A. FIACCO[3], E. WILSON[4];

Abstract: Neuroinflammation is common to neurodegenerative diseases and brain injuries, resulting in immune responses characterized by changes in astrocytes. Astrocytes ordinarily provide critical support for neurons but become reactive in response to brain disease, injury, or infection. Reactive astrocytes (RAs) are defined by their increased proliferation, enlarged cell bodies and processes, and change in function. A longstanding and unresolved issue is whether RAs contribute to or help alleviate disease progression, but overall, RAs have been discovered to be an important contributor to several neurological diseases. *Toxoplasma gondii* infects a third of the world's population and is asymptomatic except during times of immunocompromise when infection leads to severe neurological damage. *Toxoplasma* is a highly successful neurotropic parasite that causes persistent subclinical neuroinflammation due to cyst formation in neurons lasting for the lifetime of the host, making this a key resource for our studies. During chronic *Toxoplasma* infection, astrocytes demonstrate a neuroprotective function by inhibiting parasite replication via STAT1-mediated mechanisms, while simultaneously demonstrating detrimental

effects by downregulating GLT-1, suggesting heterogeneity exists among RAs. Utilizing flow cytometry, we have characterized surface integrin subsets found during chronic *Toxoplasma* infection. Experiments demonstrate that during infection potential chronic reactive astrocyte subsets are present and may be contributing directly to known functions present during infection. However, variability exists within these heterogeneous astrocytic naïve and infected subsets. To further determine if astrocytes define a chronic inflammatory state, single cell RNA sequencing experiments on astrocytes at various stages of infection were conducted to determine if similar populations are expressed during acute compared to chronic infection. In addition, to investigate RA function we have created a transgenic reporter mouse, $Lcn2^{CreERT2}$; $Rosa26^{lsl\text{-}tdTomato}$, that will allow for isolation of RA populations during infection for the first time, providing a novel tool for future use.

Title: Reactive Astrocytes Prevent Maladaptive Plasticity after Ischemic Stroke

Authors: M. ASWENDT[1], U. WILHELMSSOM[2], A. STOKOWSKA[2], Y. DE PABLO[2], M. HOEHN[1], M. PEKNA[2], ***M. PEKNY**[2];

Abstract: Restoration of functional connectivity is a major contributor to functional recovery after stroke. We investigated the role of reactive astrocytes in functional connectivity and recovery after photothrombotic stroke in mice with attenuated reactive gliosis ($GFAP^{-/-}Vim^{-/-}$). Infarct volume and longitudinal functional connectivity changes were determined by *in vivo* T2-weighted magnetic resonance imaging (MRI) and resting-state functional MRI. Sensorimotor function was assessed with behavioral tests, and glial and neural plasticity responses were

quantified in the peri-infarct region. Four weeks after stroke, *GFAP*$^{-/-}$*Vim*$^{-/-}$ mice showed impaired recovery of sensorimotor function and aberrant restoration of global neuronal connectivity. These mice also exhibited maladaptive plasticity responses, shown by higher number of lost and newly formed functional connections between primary and secondary targets of cortical stroke regions and increased peri-infarct expression of the axonal plasticity marker Gap43. We conclude that reactive astrocytes are required for optimal recovery-promoting plasticity responses after ischemic stroke.

Title: The role of Orai1 in astrocyte-mediated neuroinflammation

Authors: *M. NOVAKOVIC, M. PRAKRIYA;
Northwestern Univ., Chicago, IL

Abstract: Rationale: Neuroinflammation mediated by astrocytes and other glia are implicated in a growing list of neurological pathologies from depression and stroke to dementia. In these disease states, astrocytes become reactive, releasing cytokines and inflammatory factors which affect neuronal survival, synaptic transmission, and cognitive functions. However, the cellular checkpoints and signaling that control the transformation of astrocytes from their resting state to the reactive state and how these checkpoints contribute to neuronal dysfunction are poorly resolved. This study is designed to understand how astrocytic calcium signaling through store-operated Orai1 channels mediates reactive astrogliosis and neuroinflammation. Methods: All cellular experiments were performed on astrocytes cultured from neonatal C57BL/6 mice. Orai1 knockout (KO) and wild-type (WT) astrocytes were obtained using the cre/loxp system: WT (Orai1 fl/fl) and Orai1 KO (Orai1 fl/fl; nestin-cre+) astrocytes from littermates were used for the in vitro experiments. Behavioral studies were performed on both male and female astrocyte-specific Orai1 KO mice obtained using the inducible cre line Ald1h1-Cre. Tamoxifen-injected cre-negative mice served as littermate controls for the Orai1 KO mice. Results: Orai1 mediates the production of multiple pro-inflammatory cytokines through regulation of transcription factors, NFAT and NFκB. The global effect of astrocytic Orai1 signaling was assessed in a behavioral model where neuroinflammation triggered by lipopolysaccharide (LPS) injection

induces depressive-like behaviors in mice. In this paradigm, astrocyte-specific Orai1 knockout mice are partially protected from the neuroinflammation-induced depression, and differences between male and female behavioral patterns were observed. Together, these studies implicate Orai1 signaling in astrocytes as a vital component of the neuroinflammatory response, and provide insight into the role of astrocytes in neuroinflammatory disease.

Title: Deletion of Bergmann glial glutamate transporters causes progressive motor deficits and astrogliosis without Purkinje cell degeneration

Authors: *H. BI[1], Y. HIRAOKA[1], Y. OKUBO[3], V. T. NGUYEN-MINH[2], T. WANG[2], I. SUGIHARA[2], K. SAKIMURA[4], K. TANAKA[1];

Abstract: Glutamate transporters play critical roles in the maintenance of glutamatergic homeostasis. In the cerebellum, the glia glutamate transporters, GLAST and GLT1 are co-localized in the processes of Bergmann glia (BG), specialized astrocytes that enwrap excitatory synapses on Purkinje cells (PC). Various studies have suggested loss of GLAST and/or GLT1 is involved in the pathogenesis of neurological disorders. However, the contributions of GLAST and GLT1 to the pathophysiology of neurological disorders are poorly understood. To investigate the role of GLAST/GLT1 in cerebellar dysfunction, we generate conditional double knockouts (cDKOs) to ablate GLAST and GLT1 selectively in BG. We crossed mice expressing the Cre-recombinase under the BG-specific Septin 4-promoter (Sept4-iCre) with floxed-GLAST and floxed-GLT1 mice. GLAST/GLT1 expression was completely lost in BG at around 6 weeks in cDKOs. We investigated the motor behavior of cDKOs using rotarod and an elevated balance beam test. cDKO mice showed motor discoordination starting from 6-week-old. In addition, cDKOs exhibited episodes of motor attacks including ataxia, tremor and dystonia when exposed to physical or emotional stress. Motor deficits in male and female cDKOs are progressive. Patch clamp recordings of EPSCs of PCs in acute slice preparations revealed that the decay time

constants of CF-EPSCs and PF-EPSCs are significantly prolonged in cDKOs. Histological analysis revealed normal development of the cerebellum in cDKOs. Immunohistochemistry showed that deletion of GLAST/GLT1 did not affect the density and morphology of PC. In contrast, the density of BG in PC layer is increased in 9-month-old cDKOs. Furthermore, the unique cellular architecture of BG was disrupted in cDKOs, such as the retraction of BG fine processes, abnormal translocation of BG into the molecular layer and transformation into stellate-shaped cells by 9-month-old. We also found intracellular Ca^{2+} concentration of BG is increased in cDKO mice compared to controls after PF stimulation by Ca^{2+}imaging. These results suggest loss of glia glutamate transporters in BG causes motor deficits with alternation in morphology, number and Ca^{2+} homeostasis of BG without PC loss. Our finding may provide novel insights into the mechanism of how motor diseases arise without neurodegeneration.

Title: Differential dysregulation of glutamate transporter expression contributes to relative susceptibility to methylmercury of wild type, and Nrf2-knockout derived spinal astrocytes.

Authors: *D. WIWATRATANA[1], W. D. ATCHISON[2];
[1]Neurosci. Ctr. for Res. and Innovation, Learning Institute, KMUTT, Bangkok, Thailand;
[2]Pharmacol. and Toxicology and Neurosci. Program, Michigan State Univ., East Lansing, MI

Abstract: Dysregulation of redox and glutamate homeostasis is involved in methylmercury (MeHg)- induced neuronal and astrocytic degeneration. MeHg disrupts not only the expression of Nrf2, a master regulator of the antioxidant pathway, but also glutamate transporter expression and its concentration. To characterize the role of Nrf2 in MeHg- induced spinal astrocyte degeneration, spinal cord astrocytes (SCAs) viability, and antioxidant genes from Nrf2 knockout derived SCAs (Nrf2-KO SCA) were compared to the wild-type derived SCA (WT-SCAs). The results showed that Nrf2-KO SCAs were more susceptible to MeHg compared to WT-SCAs. A one-hour exposure to 5 µM MeHg significantly reduced the viability of Nrf2-KO SCAs by 60% compared to WT-SCAs. The viability of Nrf2-KO SCAs further decreased and was considerably lower than the WT-SCA with prolonged exposure to MeHg. While antioxidant genes such as *Gclc*, *GPx1*, and *GPx4* involved in glutathione synthesis were significantly reduced in both WT-

and Nrf2-KO SCAs during MeHg exposure, the cystine/glutamate antiporter (or system Xc-) gene (*Slc7a11*) increased in WT-SCA (5-fold induction) and appeared to reduce in Nrf2-KO SCAs. The excitatory amino acid transporter 2 (EAAT2) gene, *Slc1a2* was significantly reduced following MeHg exposure for 18h in both WT- and Nrf2-KO SCAs compared to their same genotype treated with the vehicle. The EAAT1 gene, *Slc1a3* was significantly reduced only in Nrf2-KO derived SCAs, but only slightly affected in the WT SCAs. There was a differential expression of *Slc1a3* and *Slca1a2* in Nrf2 KO SCAs in which the *Slc1a3* expression was significantly higher than WT-SCAs (4-fold higher), and *Slc1a2* expression was about 2-fold higher than WT SCAs. The perturbation of Nrf2 in MeHg-induced SCA toxicity involved the reduction of GSH synthesis genes. Differential susceptibility between Nrf2-KO SCA and WT-SCA through the differential glutamate transporter expressions suggests a genetic background also plays a role in differential susceptibility to MeHg.

Title: Glial-specific knockdown of a group of evolutionarily conserved genes rescues hypoxia-induced lethality in Drosophila melanogaster

Authors: *D. ZHOU[1], J. XUE[1], C. MARSH[1], T. STOBDAN[1], G. G. HADDAD[1,2,3]; [1]Pediatrics, [2]Neurosciences, UCSD, La Jolla, CA; [3]The Rady Children's Hospital, San Diego, San Diego, CA

Abstract: Hypoxia, lack of oxygen supply to the tissues/cells, is one of the critical pathological elements in many human diseases, including ischemic stroke, myocardial infarction and solid tumors. Understanding the mechanisms regulating hypoxia tolerance or susceptibility is essential for developing effective strategies for medical therapy. In this regard, we have generated *Drosophila melanogaster* populations that tolerate severe hypoxia through laboratory-directed evolution, sequenced and analyzed their genomes. In parallel, we took advantage of the natural evolution of humans in high-altitude regions and sequenced/analyzed the whole genomes of Ethiopian and Andean highlanders. Through a comparative genomic approach, we obtained a group of evolutionarily conserved genes (28 human/23 *Drosophila* genes) that are potentially involved in regulating hypoxia tolerance in both human highlanders and the hypoxia-tolerant flies. Indeed, we confirmed so far that ubiquitous knocking down of the *grn/GATA3*, *inv/EN1*,

Mkk4/MAP2K4, Pxt/DUOX1/DUOX2, pyd/TJP1, RapGAP1/RAP1GAP2, Shal/KCN and *shep/RBMS3* dramatically enhanced hypoxia tolerance *in vivo* in *Drosophila*. In addition, we found that glial-specific knocking down of *Egfr, grn, pyd* and *Shal* rescued hypoxia-induced lethality. Some of them (i.e., *bnl, croc,* and *Mkk4* and *shep*) mediate Notch activation-conferred survival in hypoxic environment, and the others (i.e., *Egfr, grn, pyd* and *Shal*) regulate hypoxia tolerance through Notch-independent mechanisms. We believe that these evolutionarily conserved mechanisms are novel targets that have a strong potential to be translated into therapeutic strategies to treat hypoxia-related diseases.

Title: Macrophage-derived amphiregulin modulates astrocyte network reactivity

Authors: *M. L. COOPER[1], M. SELLÉS[1], S. A. LIDDELOW[2], M. V. CHAO[1];
[1]Skirball Inst. of Biomolecular Med., [2]Neurosci. Inst., New York Univ. Langone Med. Ctr., New York, NY

Abstract: Early in neurodegenerative disease, astrocytes can expand their gap junctional networks to redistribute resources and maintain neuronal function. How is this beneficial form of astrocyte reactivity induced? To answer this, we looked at similar mechanisms in other organs and applied them to the nervous system. In the heart, cardiac macrophages induce gap-junctional network expansion in myocytes during arrhythmia. There, macrophage-derived amphiregulin (AREG) signals upon epidermal growth factor receptor (EGFR) to induce phosphorylation of connexin 43 (cx43), recruiting it to the cell membrane to form additional gap junctions and rescue the tissue. Here, we test this mechanism in the resident macrophages of the brain (microglia) and the resident cx43 network mediators (astrocytes). Like cardiac macrophages, cultured primary microglia (n = 2 isolations) release AREG in response to stress (LPS, 1ug/ml; $p < 0.001$ vs baseline). Cultured primary astrocytes (mRNA n = 3 isolations; protein n = 5 isolations) respond to AREG (100ng/mL) like cardiac myocytes: they phosphorylate cx43, with a 3-fold increase 9 minutes after AREG ($p < 0.001$). Phosphorylation returns to baseline within 90 minutes. Three minutes after AREG administration, cx43 mRNA increases 2-fold; protein levels

increase 2-fold by 11 minutes (mRNA $p = 0.007$; protein $p \leq 0.01$). Although astrocytes constitutively express little dimerized EGFR, AREG administration increases EGFR dimerization 2-fold within a minute ($p = 0.006$) and 3-fold in 7 minutes ($p < 0.001$). To measure the change in functional gap-junction network size induced by AREG, astrocytes were cut-loaded with biotin (244Da, traverses gap junctions) and dextran (10kDa, marks initially loaded astrocytes). We found a 3-fold increase in astrocyte connectivity in as little as 10 min after AREG ($p < 0.001$). Intriguingly, higher levels of AREG (1000 ng/mL) have the opposite effect – cx43 mRNA is reduced 2-fold in 3 minutes ($p = 0.02$), and cx43 protein declines 2-fold within 30 minutes ($p = 0.01$; $n = 3$ isolations). This is likely due to differential dimeric conformations of the EGFR extracellular region. Weakened dimerization through lower concentrations of partial agonists such as AREG elicits more sustained EGFR signaling, inducing cellular expansion and process outgrowth pathways. In contrast, strong dimerization through high concentrations of partial agonists or full agonists, such as EGF or TGFα, activates rapid proliferation and inflammation pathways. This differential response to EGFR activation may dictate whether astrocytes enlarge or contract their network to respond to a stressor through beneficial or harmful forms of reactivity.

Title: Hiv-1 induces region-specific astrocyte dysfunction in the hiv^+ human brains

Authors: *A. DONNER[1], L. CHEN[2], M. ASH[3], J. SCHNEIDER[3], L. AL-HARTHI[4], X.-T. HU[2];
[1]Rush Univ., Chicago, IL; [2]Microbial Pathogens and Immunity, [4]Dept. Immunology/Microbiology, [3]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Combined antiretroviral therapy (cART) has improved life expectancy for people living with HIV/AIDS (PLWH); but that is association with HIV-1 associated neurocognitive

disorders (HAND). The mechanism underlying HAND is unknown; but it is likely related to HIV-induced interactive neuron/astrocyte dysfunction in the brain regions that regulate neurocognition. HIV induces neurotoxicity, causing dysregulation, injury, and in severe cases, death of neurons in such brain regions, which could be worsened by astrocyte dysfunction. Among astrocytes, HIV not only dysregulates cytokines/chemokines, but also disturbs K^+ buffering (mediated by inwardly rectifying $K_{ir}4.1$ channels), glutamate uptake (mediated by excitatory amino acid transporters, GluT-1), and cell-to-cell communication (mediated by gap-junction protein connexin, Cx43); all could promote/induce neurotoxicity. However, previous studies focusing on assessing HIV-induced astrocyte dysfunction mainly use animal or cell culture models. Very little is known if, how and to what extent HIV actually alters astrocyte function in human brains, for instance, by disrupting $K_{ir}4.1$ channel, GluT-1, and Cx43 function; and that has not been studied. Here we assessed HIV-induced changes in the protein/mRNA levels of $K_{ir}4.1$ channels, GluT-1s and Cx43 in the prefrontal cortex (PFC), caudate nucleus (CN; two key regulators of neurocognition), and cerebellum (a non-regulator of cognition) from post-mortem HIV^+ human brains (at age of 44~97; HIV^+ n=6 vs. HIV^- n=4 HIV^+). We found that the protein levels of $K_{ir}4.1$ channels and GluT-1s were significantly decreased ($p<0.01$ and $p<0.05$, respectively); while $K_{ir}4.1$ channel mRNA levels were significantly increased ($p<0.05$), along with a trend of increase in GluT-1 and decrease in Cx43 mRNA (likely compensatory responses to the reduced protein levels), in HIV^+ human PFC compared to HIV^- controls. We also found that, differing from that seen in PFC, the protein levels of $K_{ir}4.1$ channels and GluT-1 ($p<0.05$) were significantly increased in HIV^+ human CN compared to HIV^- controls; and there was no significant change in their mRNA levels. In contrast, there was no significant change in the expression of such proteins/mRNAs in HIV^+ human cerebellum. Collectively, our novel findings demonstrate that HIV induces astrocyte dysfunction in the human brain by altering the expression/function of $K_{ir}4.1$ channels, GluT-1s, and Cx43. Importantly, such astrocyte dysfunction is region-specific, occurring specifically in the key brain regions that regulate neurocognition. Further studies are needed to determine if such dysfunction contribute to the mechanism underlying HAND.

Title: Spatial transcriptomics and single nuclei RNA sequencing identify spatially resolved overlapping prefrontal cortex cell-type specific mechanisms between alcohol dependence and immune activation mouse models.

Authors: *N. A. SALEM[1], O. PONOMAREVA[1], L. MANZANO[2], G. R. TIWARI[1], A. J. ROBERTS[3], M. ROBERTO[4], R. MAYFIELD[1];
[1]Waggoner Ctr. for Alcohol and Addiction Res., [2]The Univ. of Texas at Austin, Austin, TX; [3]Animal Models Core, The Scripps Res. Inst., La Jolla, CA; [4]Scripps Res. Inst., La Jolla, CA

Abstract: Alcohol use disorders (AUDs) affected 8.6% of men and 1.7% of women globally and attributed to 5.3% of all global deaths in 2016. We aim to identify novel molecular mechanisms implicated in the escalation of alcohol consumption, which will provide the potential for therapeutics development to prevent or reverse this escalation. We utilized chronic intermittent exposure treatment paradigm (CIE), an alcohol dependence model that produces escalated drinking in mice, and neurobiological and behavioral adaptations in mice that mimic those found in humans with AUD. We have previously shown that immune genes in brain glial cells are important regulators of alcohol drinking behavior. TLR7, key player in neuroimmune activation, is differentially expressed in mice following CIE exposure. Chronic treatment with R848, a TLR7 activator, increases alcohol consumption in mice. We performed single nuclei RNA sequencing (snRNA-seq) on micro-punches obtained from pre-frontal cortex (PFC) of CIE and control mice, to determine cell-type-specific alcohol-induced gene expression changes. Analyses pipelines resulted in the identification of 24 clusters, the expression levels of canonical markers of each cell type were used to determine the clusters' cellular identity. We identified differentially expressed (DE) genes and their enriched pathways in each cluster. Astrocytic and microglial DE genes were enriched in inflammation-related pathways (Il-2, CXCR4, IL-17, and chemokine signaling). To understand the spatial context of overlapping mechanisms between CIE and immune activation model, we generated 10x Genomics Visium Spatial transcriptomics data from coronal PFC sections (10 µm) from C57BL/6J mice treated by a single injection of the R848 (50 µg, i.p.) or saline. We utilized an 'anchor'-based integration workflow introduced in Seurat on snRNA-seq data obtained from PFC micro-punches (reference) and the spatial RNA sequencing data (query), this pipeline outputs, for each spatial capture spot, a prediction score for each of the snRNA-seq derived cell types. Our analysis showed increased microglial prediction scores in layers 2/3 and astrocytic prediction scores in layers 5/6, indicating location-specific cell-type specific response to R848 treatment.Additionally, we identified 19 DE genes in R848 brain slices overlapping with CIE astrocytes and microglia DE genes. Gene ontology analyses show association of those genes to response to stress/stimuli. Integration of the two datasets aims to identify spatially resolved transcriptomic changes induced by immune activation in the PFC mediating the escalation of alcohol consumption.

Title: Palmitic acid reduces cell viability and alters VEGF-A and VEGFR2 expression in Müller glial cells.

Authors: *A. E. MEDINA ARELLANO[1], L. D. OCHOA DE LA PAZ[2];
[1]Biochem., Univ. Nacional Autónoma De México, Mexico city, Mexico; [2]BIOCHEMISTRY, UNIVERSIDAD NACIONAL AUTÓNOMA DE MÉXICO, Mexico city, Mayotte

Abstract: Lipids perform a diversity of functions in biological processes. Recent studies have established a relationship between dyslipidemia and the progress of diabetic retinopathy (DR), the most common microvascular disease associated with diabetes. In this pathology, palmitic acid (PA), a saturated fatty acid, increase levels in plasma of DR patients. In the retina, Müller glial cells (MGC) regulate a plethora of homeostatic functions, such as potassium ion buffering, neurotransmitter recycling, and angiogenic factors regulation. This study aimed to investigate the role of PA in MGC viability, morphology, and expression of angiogenic molecules such VEGF. We also explore the effect of PA on $GABA_A$ receptors. MGC primary cultures from CD1 mice were exposed to 250 μM PA and vehicle (0.008% DMSO) during 24, 48, 72, or 96 hours. Cell viability was measured by trypan blue and CCK-8 assays. Cell morphology was evaluated by immunofluorescence (IF) against CRALBP, and VEGF protein expression was confirmed by IF. VEGFR2 and HIF-1α transcripts were also determined by RT-PCR. We find that PA reduces cell viability in MGC cultures after 72 hours of exposition (92.07 ± 1.05 vs 48.52 ± 4.55, $p<0.001$). The vehicle was unable to mimic these effects (92.07 ± 1.05 vs 91.33 ± 3, ns). PA also induced morphological changes in this retinal cells, altering cellular and nuclear area (1440μm^2 ± 104.5 vs 860.0 ± 102.1, $p<0.01$ and 168.6 ± 5.11 vs 97.8 ± 8.72, $p<0.001$, respectively). By immunofluorescence assays, we detect a significant increase of VEGF-A in MGC cultures exposed to PA (13321 ± 2519 vs 43590 ± 4979 a.u., $p<0.001$). Transcriptional expression of molecules related to VEGF signaling was also studied. VEGFR2 mRNA expression decreased in MGC cultures during PA treatments (0.3210 ± 0.0050 vs 0.2787 ± 0.0071, $p<0.05$), but HIF-1α not change during this exposition (0.4611 ± 0.0208 vs 0.4520 ± 0.0152, ns). Interestingly, PA downregulate $GABA_AR$ alfa 1 subunit mRNA (0.2326 ± 0.1137 vs 0.093 ± 0.0154, $p<0.01$), but not beta2 (0.2046 ± 0.0126 vs 0.1699 ± 0.0606, ns). These results together suggest that MGC plays a pivotal role in the VEGF synthesis, possibly through HIF-1α activation and modulating VEGFR2 expression, in response to increment in the PA levels, an event associated with DR pathology. Also, the AP ability to regulate $GABA_AR$ subunit expression suggests a homeostatic

disruption related to the synaptic process during DR. This observation makes imperative to explore the mechanism involved in this process.

Title: L-kynurenine prevents oxidative damage induced by pro-oxidants in rat brain homogenates and primary astrocytes culture: an independent effect of kynurenic acid

Authors: *T. BLANCO-AYALA[1,2], P. UGALDE-MUÑIZ[4], R. LUGO-HUITRÓN[5], D. RAMÍREZ-ORTEGA[3], B. PINEDA[3], D. F. GONZÁLEZ-ESQUIVEL[3], J. PEDRAZA-CHAVERRÍ[6], L. A. RAMOS-CHÁVEZ[7], G. I. VÁZQUEZ-CERVANTES[3], A. JIMÉNEZ-ANGUIANO[1], V. PÉREZ DE LA CRUZ[3];

Nacional de Psiquiatría, Mexico City, Mexico

Abstract: L-kynurenine (L-KYN) is an endogenous metabolite from the tryptophan ctabolism which can be metabolized further metabolized to 3-hydroxykynurenine, kynurenic acid (KYNA) or anthranilic acid. L-KYN has been used as a neuroprotective strategy in some experimental models; however, its protective effects have been attributed to KYNA production. Recently, L-KYN has also shown to be susceptible toward oxidation, suggesting that can exert redox effects. The aim of this study was to describe the scavenger and antioxidant properties of L-KYN both and evaluate whether this effect is independent to KYNA production. First, we investigated whether L-KYN itself can act as a scavenger for superoxide anion ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), hydroxyl radical (●OH) and peroxynitrite ($ONOO^-$). Our data show that L-KYN can scavenge OH● and $ONOO^-$, but not $O_2^{\bullet -}$ or H_2O_2 in chemical combinatory assays. L-KYN prevents the DNA and protein degradation induced by ●OH in a concentration dependent-manner. Therefore, ROS production was evaluated in brain homogenates exposed to $FeSO_4$ (5 µM), 3-NP (5 mM) and $ONOO^-$ (25 µM) in presence or absence of L-KYN (0 - 5 µM). ROS production increased in a time dependent-manner with all the pro-oxidants used, whereas the co-

incubation with L-KYN decreased ROS levels. Lipid peroxidation (LP) increased and MTT reduction decreased with the oxidants, and these effects were abolished in presence of L-KYN. Furthermore, in order to clarify if the KYN effect involves KYNA scavenger activity, two different strategies were employed: 1) primary astrocytes cultures obtained from kynurenine aminotransferase II - main enzyme involved in KYNA production - knock-out mice (KAT-II KO), exposed to different pro-oxidants and 2) using a polyclonal KYNA antibody that recognize KYNA, which is produced by the of L-KYN - ROS interaction in a synthetic system of combinatory chemistry. ROS production was increased in astrocytes exposed to 3-NP and $ONOO^-$ and was attenuated in presence of L-KYN. The peroxynitrite scavenger effect of L-KYN in combinatory chemical assays was maintained even when the KYNA antibody was used in combination with L-KYN. Additionally we evaluated Nrf2 levels in brain tissues from rats treated with a daily injection of L-KYN (75 mg/kg, i.p., 5 days) to further characterize L-KYN antioxidant profile. Altogether, these findings strongly suggest that L-KYN can be considered as a potential endogenous antioxidant, regardless of its ability to produce KYNA.

Title: The Behavioral and Pathological Effects of Tamiflu in an Alzheimer's Disease Mouse Model

Authors: *C. FASTENAU, L. SOLANO, J. L. WICKLINE, S. SMITH, K. ODFALK, K. F. BIENIEK, S. C. HOPP;
UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Many patients with viral symptoms are treated with the widely-used antiviral agent Tamiflu (oseltamivir phosphate), which is highly efficacious against influenza. However, observational studies have reported acute and delayed adverse neuropsychiatric side effects in patients with age-related neurodegenerative diseases such as Alzheimer’s Disease (AD). Here, we test the hypothesis that an interaction between Tamiflu and AD pathology may contribute to abnormal behavioral side effects. Specifically, we hypothesize that Tamiflu’s mechanism as a neuraminidase inhibitor blocks the removal of sialic acid residues and leads to an increase in sialylation levels in extracellular proteins, including the pathognomonic feature of AD amyloid-

beta (Aβ) plaques. We have observed enhanced α2–6 sialic acid bonds surrounding Aβ plaques in the 5XFAD mouse model of AD and in human AD cases which we hypothesized could increase following Tamiflu treatment leading to exacerbation of behavioral deficits. To test this hypothesis, we investigated the effects of Tamiflu (or vehicle) treatment on aged 5XFAD mice and wild-type (WT) littermates. After initial treatment (daily for five days), the mice were tested with the Open Field (OF) Behavior for anxiety-like behaviors. Following drug administration, a second OF test was performed followed by a two-day Novel Object Recognition (NOR) test. Analyses of behavioral data demonstrated no overall drug effect in this cohort; however, 5XFAD mice exhibited greater velocity in a 2-Way ANOVA compared to WT mice for OF (5.249 cm/s vs 4.403 cm/s, p=0.01) and NOR (4.361 cm/s vs 3.1 cm/s, p=0.002) possibly indicative of hyperactivity. Following behavioral testing, the mice were euthanized and their brains were fixed in 10% neutral buffered formalin (24 hours) and processed to generate paraffin-embedded tissue blocks. Preliminary lectin staining of aged 5XFAD and WT brains suggest that plaque-associated microglia are sialylated at the α2–6 and α2–3 bonds while there is minimal α2–6 and α2–3 sialic acid labeling present in WT mice. Taken together, these observations suggest that disease associated microglia are heavily sialylated in AD. Qualitative analysis of the experimental 5XFAD mice suggests different structures are sialylated at the α2–6 and α2–3 bonds between treatment groups. The α2–6 specific lectin appears to be staining plaque associated microglia while the α2–3 specific lectin is staining a variety of extracellular features. Further analysis is required to define the sialic acid interactions within treatment groups. Thus, this study aims to untangle the complex role sialylation may play in disease pathogenesis and aging.

Title: Membralin deficiency in astrocytes disrupted ER homeostasis and induced reactive status of astrocytes

Authors: *L.-L. JIANG, X. LI, S. MYERS, T. HUANG, R. J. KAUFMAN;
Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: The endoplasmic reticulum (ER) is the primary organelle for synthesizing membrane proteins, secretory proteins, and lipids. Disturbance of ER homeostasis in peripheral immune

cells induces inflammatory responses. Glial cells, including astrocytes and microglia, are the immune cells in the brains, becoming reactive/gliosis during the progression of Alzheimer's disease (AD) and many other neurodegenerative disorders. However, whether glial protein homeostasis mediates the reactive status of glial cells is yet to be investigated. Previously, we identified an ER-associated degradation protein, membralin, as an important mediator in neurodegeneration. Loss of membralin impaired the turnover of nicastrin protein, which increased γ-secretase complex formation and activity. Moreover, deletion of membralin in astrocytes decreased excitatory amino acid transporter 2 (EAAT2) expression and induced excitotoxicity. Using adeno-associated viral (AAV) vectors to elevate membralin levels in *SOD1* ^{G93A} ALS mouse model can significantly extend the lifespan of the animals. Here, we show that membralin is critical in mediating the reactive status of astrocytes. Astroglial membralin knockout animals developed strong neuroinflammation phenotypes through pathological analysis and transcriptomic analysis. Loss of membralin in astrocytes disrupted ER homeostasis and nuclear envelop and induced the production of pro-inflammatory cytokines. In contrast, the elevation of membralin in astrocytes can alleviate the induction of C3+ astrocytes. Further, elevating membralin levels in *5XFAD* mouse model can significantly reduce the AD pathologies. Therefore, modulation of atroglial membralin levels can be a promising target to regulate neuroinflammation for AD therapy.

Title: Loss of circulating memory CD8 T cells that induce AD-like pathology in mice correspond to decreased CSF Abeta42 and increased CSF total Tau and pTau181 in human patients

Authors: *C. WHEELER[1,2,3], D. VAN DAM[4,6], Y. VERMEIREN[4,6], H. DE REU[5], P. DE DEYN[4,6], V. YAMAMOTO[7], K. TRUJILLO[1];

Hematology, Univ. of Antwerp, Antwerp, Belgium; [6]Neurol., Univ. of Groningen, Groningen, Netherlands; [7]Head and Neck Cancer, USC, Los Angeles, CA

Abstract: Objective: We assessed the relationship between Amyloid Precursor Protein (APP)-peptide-specific, KLRG1^{+} CD8 T cell levels in blood and CSF Aβ1-42, total Tau, and pTau181

in Alzheimer's (AD), mild cognitively impaired (MCI), and normal aging patients.
Rationale: We previously engineered mice to accumulate age-related, antigen-specific memory CD8 T cells as in aging humans. These mice spontaneously develop all major hallmarks of AD with aging. Analogous T cells reactive to an APP epitope were found in aging humans, accumulated in AD brain, and decreased in AD blood where their levels tracked the disease with high accuracy. The relationship of these cells to established AD biomarkers could suggest the mechanism(s) by which they impact pathology and define the limits of their ability to track the AD continuum.
Methods: Antigen-specific CD8 T cells in blood were quantified by flow cytometry after staining with anti-CD8, anti-KLRG1 and APP peptide-HLA-A2 multimers in confirmed late-onset AD patient, MCI with or without CSF biomarkers of AD, and normal aging cohorts (n = 50). Aβ1-42, total Tau, and pTau181 were quantified in CSF, and cognitive performance assessed by MMSE.
Results: Percentage of APP-specific memory CD8 T cells was significantly decreased with dementia (0.68 + 0.29% for MMSE <25; 1.63 + 0.32% for MMSE >24), reaching minimal levels in AD. Although this precluded meaningful correlations of APP-specific T cells within AD alone, decreases in the larger parental ($KLRG1^{+}$) memory CD8 T cell population correlated with decreased CSF Aβ1-42 in AD (r = 0.511; *P* = 0.003; n = 31). Decreasing APP-specific CD8 T cells in blood also correlated with lower CSF Aβ1-42 in normal aging patients (r = 0.518; *P* = 0.028; n = 18). In addition, patients with the highest third of APP-specific CD8 T cells in blood had significantly elevated total Tau and pTau181 in CSF (482$\pm$39 vs. 370$\pm$47 total Tau, *P* = 0.011; 70$\pm$4 vs. 60$\pm$6 pTau181, *P* = 0.027).
Conclusion: Our results reveal that age-related memory CD8 T cells in blood decrease with dementia, and in proportion to established CSF biomarkers for AD, especially Aβ1-42. Given that decreased CSF Aβ1-42 is among the earliest biomarkers for AD, this supports the notion that antigen-specific memory CD8 T cells are associated with the earliest detectable pathologic changes in AD, and as such may represent novel candidates to predict and track the disease.

Title: N-as-triggered spms are direct regulators of microglia in a model of alzheimer’s disease

Authors: B. CHOI[1], K. PARK[2], J.-S. BAE[2], *H. JIN[1];
[1]Col. of Vet. Medicine, Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Sch. of Medicine, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Sphingosine kinase1 (SphK1) is an acetyl-CoA dependent acetyltransferase which acts on cyclooxygenase2 (COX2) in neurons in a model of Alzheimer’s disease (AD). However, the mechanism underlying this activity was unexplored. Here we show that N-acetyl sphingosine (N-AS) is first generated by acetyl-CoA and sphingosine through SphK1. N-AS then acetylates serine 565 (S565) of COX2, and the N-AS-acetylated COX2 induces the production of specialized pro-resolving mediators (SPMs). In a mouse model of AD, microglia show a reduction in N-AS generation, leading to decreased acetyl-S565 COX2 and SPM production. Treatment with N-AS increases acetylated COX2 and N-AS-triggered SPMs in microglia of AD mice, leading to resolution of neuroinflammation, an increase in microglial phagocytosis, and improved memory. Taken together, these results identify a role of N-AS in the dysfunction of microglia in AD.

Title: Reprogramming Transcriptional Activation State in Plaque-associated Microglia in 5xFAD Mice with Increased Gene-dosage of Wildtype TREM2 but not TREM2-R47H Variant

Authors: *C. LEE[1], **A. J. DE LA ROCHA**[1], X. GU[1], A. DAGGETT[1], K. INOUYE[1], P. LANGFELDER[1], N. WANG[1], X. W. YANG[1,2];
[1]Semel Inst. for Neurosci. and Human Behavior, [2]Brain Res. Inst., UCLA, Los Angeles, CA

Abstract: In late onset Alzheimer’s disease (AD), the rare variant of Triggering Receptor Expressed on Myeloid Cells 2 (TREM2), TREM2-R47H, is associated with about two-fold higher disease risk. TREM2 expression is highly enriched in the microglia, the resident innate immune cells in the brain. In AD brains, TREM2 is proposed to mediate the formation of a microglial neuroprotective barrier surrounding amyloid-β plaques, as well as the activation of a

disease-associated transcriptomic signature. Recently, our lab showed that elevated TREM2 gene-dosage in BAC transgenic mice is beneficial in amyloid AD mouse models resulting in reduced plaque loads, reprogramming of microglial transcriptomic activation state, altered plaque-associated microglial morphology, and rescued behavioral deficits. However, 5xFAD mice with a BAC transgene overexpressing the human TREM2-R47H variant, unlike those overexpressing wild-type human TREM2, showed a significant reduction in the beneficial effects of TREM2 gene-dosage increase. Additionally, cortical RNA-sequencing studies showed that the microglial transcriptomic signature of TREM2-mediated microglial reprogramming is abolished in the 5xFAD/TREM2-R47H mice. We next applied RNAscope, a multiplexing *in situ* hybridization method, to examine the transcriptional activation states of plaque-associated microglia. Our results reveal that elevated wild-type TREM2 gene-dosage induces an alternative transcriptional activation state in plaque-associated microglia, where the expression of a subset of TREM2 dosage-dependent (TD) genes decreased while another subset of TD genes increased. Importantly, this TREM2 gene-dosage dependent activation state for plaque-associated microglia was absent in 5xFAD/TREM2-R47H mice. Together, our study demonstrates that TREM2 gene-dosage confers an alternative activation state in plaque-associated microglia, and this i*n vivo* function of human TREM2 in the BAC model is abolished with TREM2-R47H, the AD-risk variant.

Title: Cd4+ effector t cells accelerate alzheimer's disease in mice

Authors: *J. MACHHI[1], P. YEAPURI[2], Y. LU[2], R. MOSLEY[3], H. E. GENDELMAN[4]; [2]Pharmacol. and Exptl. Neurosci., [3]Dept Pharmacol. and Exp Neurosci., [4]Prof & Chair Dept Pharmacol, [1]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Background: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by cognitive impairments linked to pathological deposition of misfolded self-protein amyloid beta (Aβ) which in kind facilitates tau aggregation and neurodegeneration. Neuroinflammation is accepted as key disease driver caused by innate microglia activation. Recently, adaptive immune alterations have been uncovered beginning early and extending throughout the disease. How these occurs and whether they can be harnessed to affect disease progress is unclear. We propose that self-antigens would induct autoreactive effector T cells (Teff) serving to drive pro-inflammatory and neurodestructive immunity. Here, we investigated the role of effector immunity could affect cellular level disease pathobiology in an AD animal model. **Methods:** In this report, we developed and characterized amyloid beta (Aβ) reactive type 1 T helper (Th1) and type 17 Th (Th17) cloned lines and studied their role in AD pathogenesis. The cellular phenotype and antigen-specify of Aβ-specific Th1 and Th17 clones were confirmed using flow cytometry, immunoblot staining and Aβ T cell epitope loaded haplotype-matched major histocompatibility complex II IA^b (MHCII-IA^b-KLVFFAEDVGSNKGA) tetramer binding. Aβ-Th1 and Aβ-Th17 clones were adoptively transferred into the APP/PS1 double transgenic mice expressing a chimeric mouse/human amyloid precursor protein and a mutant human presenilin 1 and mice were assessed for memory impairments. Finally, mice were sacrificed and blood, spleen, lymph nodes and brain were harvested for immunological, biochemical, and histological analysis. **Results:** The propagated Aβ-Th1 and Aβ-Th17 cells were confirmed stable and long-lived. Treatment of APP/PS1 mice with Aβ reactive effector T cells (Teffs) accelerated memory impairment and systemic inflammation, increased amyloid burden, elevated microglia activation, and exacerbated neuroinflammation. Both Th1 and Th17 Aβ reactive Teffs progressed AD pathology by downregulating anti-inflammatory and immunosuppressive regulatory T cells (Treg) as recorded in the periphery and within the central nervous system. **Conclusions:** These results underscore an important pathological role for CD4+ Teffs in AD progression. We posit that aberrant disease-associated effector immune responses can be controlled by the induction of Aβ reactive Tregs.

Title: Influence of intestinal bacteria on colitis-induced exacerbation of Alzheimer's disease

Authors: *L. JOHNSON[1], B. SAHU[2], M. SOHRABI[2], C. K. COMBS[2];
[2]Biomed. Sci., [1]Univ. of North Dakota, Grand Forks, ND

Abstract: Alzheimer's disease (AD) is characterized by progressive cognitive decline and is a leading cause of death in the United States. Neuroinflammation has been implicated in the progression of AD and several recent studies suggest that peripheral immune dysfunction is also an aspect of disease. Continuing evidence indicates that intestinal dysbiosis is an attribute of AD and inflammatory bowel disease (IBD) has been shown to aggravate cognitive impairment. Previously, we demonstrated that an IBD-like condition exacerbates, and a probiotic intervention attenuates, AD-related changes in the brains of AppNL-G-F mice. In this study, we investigated whether dietary intervention with a probiotic, VSL#3, could attenuate IBD-potentiated changes in the brains of these mice. Age matched 6-10-month-old male C57BL/6 wild type (WT) and AppNL-G-F mice were randomly divided into 4 groups: Vehicle control, oral VSL#3, dextran sulfate sodium (2% DSS dissolved in drinking water), and DSS given with VSL#3. Mice were sacrificed at the end of the experiment and colons and brains were collected for biochemical and immunohistochemical analyses. Colons were used to quantify lipocalin levels via ELISA as a measure of inflammatory change. Fixed brain sections were used for performing immunohistochemistry for amyloid beta (Aβ). Aβ ELISAs and cytokine arrays were performed on hippocampal and cortical lysates, respectively. As anticipated, VSL#3 treatment attenuated the DSS-induced colitis disease activity index and weight loss in WT and AppNL-G-F mice. Although VSL#3 significantly attenuated the DSS-mediated increase in WT colonic lipocalin levels, it was less protective in the AppNL-G-F DSS treated group. In spite of apparent intestinal benefit, VSL#3 treatment did not attenuate DSS-dependent increases in plaque load or Aβ levels in the AppNL-G-F brains. Corresponding with this lack of efficacy, VSL#3 treatment did not alter many of the DSS-induced increases in brain cytokines in AppNL-G-F mice and even potentiated levels of some including IFN-γ and IL-6. Altogether, our data indicates that dietary probiotic intervention with VSL#3, while sufficient to provide some protection against the colitis-like condition, may exacerbate communication of IBD-associated inflammation to the brain.

Title: Conditional genetic deletion of CSF1 receptor in microglia ameliorates the physiopathology of Alzheimer's disease

Authors: *V. PONS[1], S. RIVEST[2];
[1]Mol. Med., [2]Mol. medicine, Ctr. de recherche Univ. Laval, Quebec, QC, Canada

Abstract: Background: Alzheimer's disease (AD) is a progressive neurodegenerative disorder and the most common form of dementia in the world. Microglia are the innate immune cells of CNS, their proliferation, activation and survival in pathologic and healthy brain have previously been shown to be highly dependent on CSF1R. **Methods:** Here we investigate the impact of such receptor on AD etiology and microglia. We deleted CSF1R using Cre/Lox system, the knockout (KO) is restricted to microglia in the APP/PS1 mouse model. We induced the knockout at 3-month-old, before plaque formation and evaluated both 6 and 8-month-old groups of mice. **Results:** Our findings demonstrated that CSF1R KO did not impair microglial survival and proliferation at 6 and 8 months of age in APP cKO compared to their littermate-control groups $APP_{Swe/PS1}$. We have also shown that cognitive decline is delayed in CSF1R-deleted mice. Ameliorations of AD etiology is associated with a decrease in plaque volume in cortex and hippocampus area. A compensating system seems to take place following the knockout, since TREM2/β-Catenin and IL-34 expression are significantly increased. Such a compensatory mechanism may promote microglial survival and phagocytosis of Aβ in the brain. **Conclusions:** Our results provide new insights on the role of CSF1R in microglia and how it interacts with the TREM2/β-Catenin and IL-34 system to clear Aβ and ameliorates the physiopathology of AD.

Title: Behavioural and anti-inflammatory outcomes of EP2 antagonist treatment in a two-hit mouse model of Alzheimer's disease

Authors: *A. BANIK, R. AMARADHI, M. SAU, R. J. DINGLEDINE, T. GANESH;
Pharmacol. and Chem. Biol., Emory Univ., Atlanta, GA

Abstract: Alzheimer's disease (AD) is one of the leading causes of dementia. Approximately 50 million people are living with AD and related forms of dementia globally while adequate disease modifying treatment for AD is still not available. Neuroinflammation is widely evident in AD brains and thought to contribute and exacerbate the AD-pathology and ensuing cognitive and behavioral deficits in patients. Prostaglandin-E_2 (PGE_2) receptor EP2, which is activated downstream of cyclooxygenase-2 (COX-2) signaling, emerged as a neuroinflammatory target in several neurodegenerative diseases including AD, and treatment with a selective small molecule antagonist of EP2 mitigates the neuroinflammation in acute brain injury models. Therefore, we investigated the effect of a selective EP2 antagonist on behavioral deficits in 5xFAD transgenic mice subjected to mild, systemic inflammation by lipopolysaccharide (LPS). We have exposed a cohort of 5xFAD mice in B6SJL background with once-a-week intraperitoneal injection of LPS (1 mg/kg), and treated with either vehicle or EP2 antagonist TG11-77. HCl (100 mg/kg/day) for 12 weeks in drinking water. Complete blood count (CBC) analysis was performed to demonstrate that LPS induced an anemia of inflammation, and induction of inflammatory gene expression (mRNA) in these mice brains is being measured. Further, we aim to determine the effect of EP2 antagonist treatment on these inflammatory markers and behavioral parameters such as working memory and spatial memory (Y-maze and Morris Water Maze). The outcome of this study will indicate whether EP2 antagonism is a prudent therapeutic strategy in reducing brain inflammation and behavioral deficits in this two-hit model of AD (transgenic line with LPS).

Title: The Effects of Chronic Voluntary Alcohol Consumption in a Mouse Model of Alzheimer's Disease

Authors: *S. C. GIRONDA[1], S. M. DAY[2], S. L. MACAULEY[3], J. L. WEINER[2];
[1]Neurosci., [2]Integrative Physiol. and Pharmacol., [3]Gerontology and Geriatric Med., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The majority of Alzheimer's disease (AD) cases are sporadic with unknown causes. Many dietary factors, including alcohol intake, have been reported to increase the risk to develop AD. The effect of alcohol on cognitive function and AD pathogenesis remains elusive. Nearly 6% of Americans, or 15 million people are currently diagnosed with alcohol use disorder (AUD). Seeing the concordance between AUD and AD, we sought to identify the effects of chronic voluntary alcohol consumption on affective behavior, cognitive performance, metabolism, amyloid plaque deposition, and immune activation in a mouse model of dementia. 17 male APP/PS1 transgenic mice and 17 male wild-type control mice at four months of age were singly housed and randomly assigned to one of two conditions. The first provided access to 20% alcohol and water (12 hrs/4 days week during the dark phase) and the second provided access to only water in their home cages. Prior to alcohol exposure, mice were run through a battery of behavioral tests to assess baseline affective state and cognitive performance. At 4 months of age, mice were provided access to alcohol for 10 weeks. Throughout the drinking exposure, food consumption and weights were monitored and recorded. There were no genotype effects on alcohol intake or preference however alcohol intake selectively decreased food consumption in APP/PS1 mice. During the last five weeks of drinking, the baseline behavioral battery was repeated on non-alcohol-drinking days. While there were no significant differences between the groups prior to alcohol exposure, alcohol consumption elicited changes in several measures of affective state including the open field test, marble burying, and nest building in the alcohol-exposed APP/PS1 mice. We did not find any differences in performance on cognitive tests such as novel object recognition. In addition, alcohol significantly increased small amyloid plaque deposition. These findings are consistent with research in the clinical literature suggesting that alterations in affective state are a precursor to changes in cognitive performance and influenced by chronic alcohol consumption in AD. This model may prove useful to elucidate the neural mechanisms through which alcohol consumption exacerbates behavioral and neurobiological AD phenotypes.

Dept., Claremont McKenna Col., Claremont, CA; [6]La Salle High Sch., Pasadena, CA; [7]Oak Park High Sch., Oak Park, CA; [8]Neurol., Univ. of California Irvine Dept. of Neurol., Irvine, CA

Abstract: Alzheimer’s disease (AD) is a chronic neurodegenerative disease with limited treatments. Erythropoietin(EPO), a neurotrophin, is a potential therapeutic for AD but has limited blood-brain barrier (BBB)permeability. A fusion protein of EPO and the transferrin receptor monoclonal antibody (cTfRMAb) actsas a molecular trojan horse by shuttling the EPO into the brain via the transvascular route. We previouslyshowed that this BBB-penetrating cTfRMAb-EPO is protective in a mouse model of amyloidosis, but theprotective effects of this BBB-penetrating EPO on tauopathy are unknown (Yang et al, PMID: 32579360,2020). We engineered an aglycosylated cTfRMAb-EPO fusion protein, designated TfRMAb-N292G-EPO, by removing the Fc N-linked glycosylation site at position 292, to reduce TfRMAb Fc-effectorfunction related adverse effects. This study aimed to investigate the effects of cTfRMAb-N292G-EPO inthe PS19 mouse model of tauopathy. Male and female hemizygous Tg(Prnp-MAPT*P301S)PS19Vle(PS19) 6-month-old mice were injected intraperitoneally with saline (n=9) or cTfRMAb-N292G-EPO (10mg/kg, n=10), two to three days a week for 8 weeks. Age-matched wildtype littermates were injectedintraperitoneally with saline (n=12). Locomotion, hyperactivity, and anxiety were assessed by the open-field test. Sagittal mouse brain sections were analyzed by blinded readers for phospho-tau (ser202,thr205) and microgliosis (iba1) by immunofluorescence in the cerebral cortex, hippocampus, amygdala,and entorhinal cortex. The cTfRMAb-N292G-EPO significantly reduced the phospho-tau-positive area inall regions analyzed ($p<0.01$) and microglia-positive area in the entorhinal cortex and amygdala ($p<0.05$).This trend was seen in both sexes. The locomotion hyperactivity and reduced anxiety observed in thePS19 mice were significantly ($p<0.05$) depreciated by the cTfRMAb-N292G-EPO compared to thesaline-treated PS19 mice. Overall, this study demonstrated the therapeutic effects of the BBB-penetratingerythropoietin in a PS19 mouse model of tauopathy.

Title: The relationship between sleep disruption and tau pathology in the progression and treatment of Alzheimer's Disease

Authors: *S. MARTIN[1], M. YE[1], J. LORD[1], L. SHAREK[1], G. H. DIERING[2];
[1]Cell Biol. and Physiol., Univ. of North Carolina Chapel Hill, Chapel Hill, NC; [2]Cell Biol. and Physiol., Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Sleep is an essential physiological behavior that supports brain health and cognitive function. In Alzheimer’s disease (AD), a devastating neurodegenerative disorder, patients experience accelerated sleep loss which can be correlated with AD onset and contribute to AD progression. Tau is an axonal microtubule stabilizing protein that forms aggregates in AD and contributes to cognitive decline, synapse loss and neuronal death. Tau mislocalization and aggregation at synapses may impair sleep and restorative sleep-dependent homeostatic plasticity. I hypothesize that sleep disruption occurs early in AD progression and subsequently drives further tau mislocalization and aggregation, and cognitive decline. Preliminary data using P301S (PS19) transgenic mice shows that differences in sleep behavior arise as early as 3 months in females and 6 months in males. Accumulation of tau becomes apparent between 6-9months. These results highlight sex differences in the onset of sleep disruption and support sleep disruption as an early-stage symptom. Endocannabinoids provide an intriguing avenue for therapeutic intervention because of their role in promoting sleep and anti-inflammatory signaling. Preliminary work shows that sleep disruption in PS19 mice can be acutely reversed by increasing the endocannabinoid anandamide. Therefore, the objectives of this work are to test the link between sleep loss and tau aggregation through correlation and causation and to identify the therapeutic window targeting endocannabinoid signaling during sleep in advance of tau pathology and cognitive decline. These studies will provide a deeper understanding of the behavioral and molecular changes that occur during abnormal sleep in AD and highlight endocannabinoids as a suitable signaling pathway for enhancing the restorative benefits of sleep.

Title: Investigating isoform-specific functions of Tau under healthy and pathological conditions using Tau-deficient hiPSC derived cortical neurons

Authors: *S. BACHMANN, M. BELL, M. AL KABBANI, J. KLIMEK, H. ZEMPEL;
Inst. of Human Genet., Univ. Hosp. Cologne, Cologne, Germany

Abstract: One hallmark of many neurodegenerative diseases, such as Alzheimer's disease (AD), is the formation of neurofibrillary tangles by hyperphosphorylated Tau in the brain, resulting in neuronal death and cognitive decline. In the adult human brain, six Tau isoforms are expressed, originating from alternative splicing of exons 2, 3, and 10 of the *MAPT* gene. The isoforms differ in the number of N-terminal inserts (0, 1, or 2N) and the C-terminal repeat number (3 or 4R). Normally, 3R and 4R isoforms are expressed in equal ratios throughout the brain however, mutations in the *MAPT* gene affecting splicing can alter the Tau isoform ratio and ultimately cause neurodegenerative diseases. Recent results from murine primary neurons and human neuroblastoma cells highlight that the six human-specific isoforms are differentially localized within neurons and influence microtubule dynamics in an isoform-specific manner. To further investigate the Tau isoforms in a human neuronal context, we generated three Tau KO iPSC cell lines derived from Ngn2-WTC11 cells using CRISPR/Cas9. Basic characterization of the Tau KO cell lines showed no difference in the morphology or pluripotency of iPSCs, the capability of Ngn2-induced neuronal differentiation or neuronal morphology compared to WT iPSCs and induced neurons. In addition, live-cell calcium imaging revealed no difference between WT and Tau KO neurons in spontaneous activity. Initial results from re-expressed Tau isoforms in Tau KO human neurons support the differential localization of the isoforms observed previously in rodent neurons. Further experiments will investigate the isoform-specific role of Tau regarding microtubule dynamics, axonal branching, and synapse formation under basal and pathological conditions. Expected results will provide a major understanding of basic biological functions of Tau and help to identify potential therapeutic targets for the treatment of AD and related neurodegenerative diseases.

Title: Expression of pathological tau in hippocampal interneurons

Authors: *E. LEGGETT, A. R. MCQUISTON;
Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Alzheimer's Disease (AD), a progressive disease of cognitive decline, is the sixth leading cause of death in the United States. No medications exist to stop disease progression. One pathological hallmark at early stages of AD is the accumulation of hyperphosphorylated and oligomeric forms of microtubule-associated tau protein (tau) in the entorhinal cortex and one of its downstream targets, the CA1 region of the hippocampus. Mouse models expressing mutant forms of human tau, which cause pathological tau variant formation in familial frontotemporal lobe dementia (FTLD) patients, display dementia-like symptoms in mice. We used a similar strategy to express hybrid FTLD human tau mutants (hTau-P301L or hTau-P301L-S320F) (Koller et al 2019, Strang et al 2018) in the medial entorhinal cortex (MEC) or hippocampal CA1 of genetically-modified mouse lines via intracranial injection of Cre-recombinase-dependent adeno-associated viruses. Expression of hTau-P301L in layer 3 pyramidal cells of the MEC of pOXR1-Cre mice resulted in the trans-synaptic spread of hTau-P301L into both pyramidal cells and select inhibitory interneurons in hippocampal CA1. One subclass of interneuron in hippocampal CA1 vulnerable to trans-synaptic spread was the calretinin-positive interneuron-selective interneurons. Calretinin and calbindin were co-expressed with hTau-P301L, but parvalbumin, another calcium-binding protein, was not. To further examine pathological tau expression in calretinin interneurons, a Cre-recombinase-dependent AAV carrying the coding sequence of hTau-P301L-S320F was injected into ventral hippocampal CA1 of Calb2-Cre mice. The presence of hyperphosphorylated or misfolded tau was examined using the antibodies AT8, PHF1, and MC1. In separate experiments using the same tissue, thioflavin-S staining was used to detect the presence of neurofibrillary tangles. Images were analyzed for the presence of tau forms at different timepoints following injection to examine the progression of pathological tau variant formation in the hippocampus. These results identified the vulnerability of select subtypes of hippocampal interneurons to the trans-synaptic spread of tau. Using these data, we can target neuronal subtypes of hippocampal CA1 that are vulnerable to the trans-synaptic spread of tau for future functional experiments.

Title: Rev-erb-alpha Regulates tau accumulation via modulating microglia phagocytosis in a sex-dependent manner

Authors: *J. LEE, J. M. DIMITRY, E. S. MUSIEK;
Washington Univ. in St. Louis, Saint Louis, MO

Abstract: REV-ERBα is a nuclear receptor and circadian clock component that has been implicated in the regulation of microglial activation. Disrupted REV-ERBα (*Nr1d1*) expression abrogates endogenous circadian machinery in microglia and increases their phagocytic activity. Microglia exhibit sex-dependent responses to disease-associate stimuli, but is incompletely understood how this is regulated. Here, we show that microglial REV-ERBα influences Tau pathology in a sex-dependent manner and investigate sex-specific transcriptome changes of REV-ERBα deficient microglia. Microglial-specific REV-ERBα deletion in female Tau P301L-expressing mice resulted in less accumulation of phosphorylated Tau, but slightly increase tau in male mice. We verify that the absence of REV-ERBα in microglia accelerates the clearance of injected FITC-conjugated Tau monomer protein in the hippocampus, particularly in female mice. These data implicate that understanding the sex-dependent effects of REV-ERBα on tauopathy will inform future therapeutic efforts targeting REV-ERBs, and shed light on the mechanisms underlying the increased risk of AD in women.

Title: The role of ovarian hormones in mediating the neuroprotective effects of irisin in tauopathy model mice

Authors: *S. J. TERRILL, K. A. BRETLAND, L. LIN, G. LEONE, S. M. FLEMING, C. M. DENGLER-CRISH;
Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Tauopathies, including Alzheimer's disease (AD), progressive supranuclear palsy, corticobasal syndrome, and chronic traumatic encephalopathy, are progressive neurodegenerative disorders that are pathologically defined by neurofibrillary tangle formation, a result of pathological aggregation of misfolded and abnormally phosphorylated tau protein. These progressive and fatal brain disorders gradually destroy an individual's memory, ability to learn, reason, and communicate. Despite substantial scientific effort over the last few decades, there are currently no established therapies that modify disease progression of tauopathies. Recently, the novel exercise-induced hormone irisin has emerged as a potential therapeutic agent for the treatment of neurodegenerative diseases. New evidence suggests this hormone can protect the brain against neuronal degeneration, yet the biological mechanisms mediating the neuroprotective effects of irisin remain poorly understood. Recently, we have demonstrated that peripherally administered recombinant human irisin reduces hippocampal tau hyperphosphorylation and neuroinflammation in female but not male htau mice, a transgenic mouse model that develops tauopathy similar to AD and frontotemporal dementia. Here we directly assessed whether endogenous female sex hormones are necessary for the expression of neuroprotective factors following irisin treatment in female htau mice. Following bilateral ovariectomy (OVX) or sham surgical procedure, female htau and control mice received weekly injections of recombinant irisin (i.p.). Following 4 weeks of injections, brain tissue was processed for changes in key proteins associated with inflammation and pathology after vehicle or irisin treatment. Our results demonstrate that ovarian hormones may mediate irisin efficacy in reducing early accumulation of hyperphosphorylated tau in the hippocampus of female htau mice. However, our results also suggest that irisin's ability to reduce neuroinflammation (TNFα) does not require intact ovarian cycling. Collectively, these preliminary findings suggest that female sex hormones may facilitate the neuroprotective effect of irisin in female htau mice. Ongoing analyses will further elucidate neurobiological mechanisms through which irisin and estrogens modulate brain pathology in htau mice.

Title: The effects of high-fat diet administration on cognitive and non-cognitive behaviors in a tau mouse model of Alzheimer's disease

Authors: *S. L. P. LIPPI[1], B. A. COLLINS[1], A. E. HOWARD[1], M. N. RODRIGUEZ[1], G. L. PARRISH[1], J. A. OLIVAREZ[2], A. PORRAS[1];

Abstract: Alzheimer's disease (AD) is a neurodegenerative condition that leads to deficits in memory, alterations in behavior, and changes in activities of daily living. While poor dietary choices, in the form of high-fat diet (HFD) administration, have been shown to impair spatial memory and exacerbate AD pathology in APP mice, few studies have assessed the effects of HFD on mice modeling solely neurofibrillary tangle (NFT) pathology. We examined the effects of HFD on both cognitive and noncognitive behaviors in rTg4510 (P301L) mice. Preliminary analysis reveals that HFD does lead to significant weight gain ($p < 0.05$) and while genotype effects were strong in the Morris Water Maze (MWM) spatial memory task, with tau mice performing worse than wildtype (WT) mice ($p < 0.01$), HFD had no effect on spatial memory measures. Tau mice spent significantly less time in the open arms of the elevated zero maze (EZM) than WT mice ($p < 0.05$) and took longer to enter into the open arms ($p < 0.05$). No differences in distance (cm) or time spent in the center of the open field test were seen. While HFD did not have any effects on anxiety or spatial memory, it did have an effect on nesting behavior (non-cognitive behavior). Tau mice built significantly poorer nests than WT mice ($p < 0.001$) and HFD significantly affected nest building; however, it was dependent on genotype. In WT mice, HFD impaired nest building ($p = 0.002$) while in tau mice HFD improved nesting score ($p < 0.001$) compared to the control diet (CD) counterparts. Results from other studies show that HFD impairs spatial memory while the current preliminary data suggest otherwise. Upcoming analyses on brain tissue examining inflammatory markers, phosphorylated tau, and neurotrophins (BDNF) aim to explore the effects of HFD on NFT pathology and brain health in this tau mouse model.

Abstract: Down syndrome (DS) is caused by the triplication of chromosome 21. By early middle-age, individuals with DS develop Alzheimer's disease (AD) neuropathology including amyloid-β plaques, neurofibrillary tangles, and loss of cholinergic neurons in the basal forebrain. The trisomic Ts65Dn mouse recapitulates key aspects of DS/AD pathology, including deficits in hippocampal dependent learning and memory, dysregulation of the endosomal-lysosomal (EL) system, and degeneration of basal forebrain cholinergic neurons (BFCNs). We previously showed maternal choline supplementation (MCS), a well-tolerated treatment modality, was able to attenuate overexpression of EL regulatory genes and rescue early endosomal defects within BFCNs of 10-12 month old (MO) Ts65Dn mice. To explore whether amelioration of endosomal pathology within the septohippocampal circuit affects neuronal atrophy, we performed morphometric analyses of vulnerable neuronal populations in the medial septum and vertical limb of the diagonal band (MS/VDB) of the basal forebrain. Utilizing novel, custom-designed stereology tools in ImageJ (COANSI), choline acetyltransferase (ChAT)-immunoreactive BFCNs were compared in Ts65Dn mice and normal disomic (2N) littermates at two timepoints: 3-4 MO (pre-BFCN degeneration) and 10-12 MO (post-BFCN degeneration). Quantitative analysis of fluorescent z-stacks revealed 10-12 MO Ts65Dn mice receiving perinatal MCS had significantly increased numbers of ChAT-positive BFCNs in the MS/VDB compared to age-matched trisomic mice from dams on a normal choline diet. Significant increases in neuronal density and area of the MS/VDB occupied by neuropil were also observed. MCS treated 3-4 MO Ts65Dn and 2N offspring also had increases in BFCN number and regional area, suggesting early life choline delivery has organizational effects on neurodevelopment of BFCNs independent of genotype. To assess the efficacy of MCS treatment on non-cholinergic populations, we investigated GABAergic neurons within the MS/VDB of 10-12 MO mice. Preliminary data suggests aged Ts65Dn mice experience a loss of parvalbumin-positive GABAergic neurons compared to 2N littermates, and that MCS rescues this population from degeneration. Taken together, these data suggest perinatal MCS has long-lasting neuroprotective benefits on diverse neuronal populations within the septohippocampal circuit and possibly throughout the CNS. Behavioral improvements in MCS treated Ts65Dn mice may reflect an ability to shield vulnerable basal forebrain neurons from progressive neurodegenerative processes.

Title: The Effect of Melatonin on spatial learning and Aβ load in an Alzheimer's Disease Mouse Model

Authors: *A. G. RILEY-DIPAOLO[1], E. MILIOTOU[2], **A. J. STAVNEZER**[3];
[1]Dept. of Neurol., Univ. of Florida, Gainesville, FL; [2]Neurol. Dept., UCLA, Los Angeles, CA; [3]Col. of Wooster, Wooster, OH

Abstract: The neurohormone melatonin is released fromform the pineal gland and is an endogenous antioxidant and free radical scavenger that regulates sleep/wake cycle and circadian rhythm. Decline of nocturnal melatonin secretion with severe sleep disturbance has been consistently reported in Alzheimer's Disease (AD), a neurodegenerative disease characterized by cognitive deficits and neuronal loss. However, exogenous melatonin supplementation has been repeatedly found tocan reduce Aβ neurotoxicity and formation while improving cognitive performance and sleep quality. In this study, the long-term influence of melatonin on behavioral and neuropathological changes were evaluated in the 5xFAD mouse model, when treatment was started in adolescence. The 5xFAD mouse is a transgenic model of AD that mimics the accumulation of senile plaques, neuronal apoptosis and memory deficits. After ~204 weeks of orally administered melatonin (10 mg/kg), open field and Morris water maze behaviour were was assessed in 54 mice, followed by quantification in hippocampal tissue. Overall, transgenic mice showed decreased anxiety, impaired learning, and a significant increase in plaque load, replicating previous results with this strain. Melatonin marginally improved learning in transgenic mice by decreasing distance travelled in the Morris water maze and slightly decreasing concentration in the hippocampus of 5xFAD mice compared with untreated 5xFAD. These results support the hypothesis that long-term melatonin supplementation may be beneficial at early stages of the disease process and should be explored more fully. Abnormal accumulation of neurotoxic forms of Aβ occur in brain regions involved in the regulation of sleep in AD patients and the disturbed regulation of sleep that occurs early in the disease may contribute to cognitive decline by decreasing Aβ clearance. Early melatonin interventions may be one of the most promising strategies in the development of methods to retard or prevent Aβ and memory deficits during this stage of the disease. In sharp contrast to conventional antioxidants, melatonin

crosses the blood-brain barrier, is relatively devoid of toxicity, and constitutes a straight-forward potential therapeutic candidate in AD treatment, perhaps due to improving sleep quality and clearing Aβ plaques.

Abstract: The cholinergic forebrain or nucleus basalis of Meynert (NBM) provides acetylcholine to the entire cortical mantle and degenerates sooner than other brain regions during Alzheimer's disease (AD). The current frontline AD therapy of cholinesterase inhibitors improves cognition for about half of a year until becoming ineffective. Our previous research demonstrated that intermittent, instead of continuous, electrical stimulation of the NBM improves working memory in a young adult primate model. Here we implanted bilateral electrodes into the cholinergic forebrain of wild-type and 5xFAD mouse models at 4 months old. Mice received daily NBM intermittent stimulation for 1 hour at 100uA until the age of 9 months. Both stimulated mouse groups outperformed unstimulated groups during learning of the Morris Water Maze task. However, only 5xFAD treated mice significantly outperformed their control group during the probe test. In both groups, treatment increased expression of nerve growth factor's receptor TrkA while reducing expression of the amyloidogenic enzyme beta-site APP cleaving enzyme 1 (BACE1), as well as displaying reduction in Aβ(1-42) concentration. To determine the necessity of cholinergic receptor subtypes and their roles in eliciting these expression changes, we then bilaterally implanted NBM electrodes into 4 month-old mice and unilaterally stimulated one hemisphere for 2 weeks while simultaneously antagonizing different cholinergic receptor subtypes. Comparing the hemispheric differences of expression of

neurotrophic and beta-amyloidogenic markers between receptor subtype groups identifies which subtypes elicit the observed treatment response.

Abstract: Background: Although the pathogenesis of Alzheimer's Disease (AD) is not completely understood, most researchers agree that the symptoms of AD result from the accumulation of aggregated tau and amyloid beta, both intra- and extracellularly. The 3D6 monoclonal antibody (mAb) has previously been shown to clear amyloid plaques when repeatedly delivered passively in mouse models of AD and a humanized version of the antibody (bapineuzimab) progressed to Ph3 clinical trials at which time development was halted because of lack of efficacy in the tolerable dose range. We reasoned that vectored delivery might enable efficient clearance of amyloid with only a single injection, and might even mitigate vascular toxicities, depending on the route of administration. **Methodology & Results:** In partnership with UPenn, we tested AAV-vectored antibody therapeutics for AD. After delivery of AAV vector-encoded 3D6 (1e11 genome copies, single injection), we show target engagement in the brains of three different mouse models of Alzheimer's disease by measuring the Aβ plaque-binding. Further, using both histological readouts in APP-KI mice and binding measurements in rat interstitial fluid, we show that there is limited spread of this secreted transgene product after neuronal transduction in the parenchyma. Finally, we used aged amyloid transgenic mice (PDAPP) that overexpress human amyloid precursor protein (APP) to compare efficacy of AAV vector-encoded 3D6 (1e11 genome copies, single injection) versus passive delivery of 3D6 (3

mg/kg/week). Animals receiving AAV had equivalent amyloid clearance when compared to those receiving 3D6 passively. Unfortunately, vascular toxicities occurred after both delivery methods. **Conclusion:** Our collaborative efforts demonstrate that a one-time AAV injection is an effective vehicle for antibody delivery in neurodegenerative disorders. In these rodent models, intramuscular delivery of a vectored antibody allowed for widespread target engagement in the brain. Further, CNS-directed gene therapy can concentrate therapeutic molecules in the brain to ameliorate pathologies associated with neurodegenerative disorders.

Title: In vivo testing of a CRISPR based gene therapy for Alzheimer's disease

Authors: *B. AULSTON[1], J. SUN[2], K. BRANES[1], N. CHECKA[1], S. ROY[1];
[1]Univ. of California San Diego, La jolla, CA; [2]Southern Univ. of Sci. & Technol., Shenzhen People's Hosp., Guangdong, China

Abstract: To date there is no therapeutic agent that can slow down the relentless course of Alzheimer’s disease (AD). Surprisingly, very few therapeutic strategies target amyloid precursor

protein (APP) - a gene that plays an unequivocal role in AD pathogenesis. Key evidence includes APP-duplications that lead to familial disease and an APP “Icelandic” mutation is protective for sporadic AD. Our lab has developed a novel CRISPR-based APP-editing approach that favorably modulates APP-cleavage - attenuating pathologic ß-cleavage, while upregulating neuroprotective a-cleavage. Importantly, the vast majority of the APP molecule - including the elaborate N-terminus and membrane-spanning domain - remains intact in this setting, ensuring that physiological processes continue unabated. Our strategy uses gene editing to effectively delete the YENPTY endocytic domain at the extreme C-terminus of APP, a pentapeptide motif facilitating ß-cleavage and Aß production. In this submission, we present in vivo evidence that our APP-editing strategy is both safe and efficacious. First, in order to analyze our strategy in “an ideal setting” we created two novel mouse lines in which the C-terminus of APP was genomically edited using APP CRISPRs. To generate mice, APP gRNA-Cas9 ribonucleoproteins were injected into APP knockin ($APP^{NL/G/F}$) and Wt, C57 zygotes. Two types of indels were identified at the APP C-terminus editing site in P0 mice: a thymine insertion (InsT) and 5 bp deletion (Del5) both of which shift the reading frame of APP and disrupt the Y188 motif. APP KI and C57 “ΔC-term” term mice were then bred to homozygosity for experiments. Homozygous APP KI ΔC-term showed attenuated amyloid pathology and neuroinflammation compared to APP KI controls and no gross histological defects were observed in C57 ΔC-term mice. In a second set of experiments we introduced APP CRISPRs into $APP^{NL/G/F}$ mice using AAV vectors. Control (scrambled sequence) and APP targeting gRNA constructs were packaged into AAV-PHP.eB vectors and viruses were retro-orbitally injected into 6week-old APP KI, Cas9 expressing mice. Mice were maintained for 2.5 weeks post-injection then sacrificed for tissues analysis. IHC and WB analysis of brain tissue revealed robust editing of the APP C-terminus in APP CRISPR treated mice which was associated with a dramatic reduction of amyloid plaques. In total, these data demonstrate the in vivo feasibility of APP C-terminus CRISPR editing as a treatment strategy for AD.

Abstract: Amnesia is a major clinical problem among elderly. Alzheimer disease is one of Neuro-degenerative disease which is associated with memory loss during old age and no reliable treatment is available despite of many clinical trials. In this study we aimed to determine the efficacy of Lin-ve stem cells (SC) derived from Umbilical cord blood (UCB) of Yoga practitioner mothers during pregnancy in reversal of Amyloid beta (Aβ) induced memory loss and simultaneously the pathways involved with this reversal. The efficacy of the UCB has already been studied in enhancing memory in such memory loss models. We want to see whether the UCB from Yoga practitioner mothers has more stemness and effects in memory reversal or not. This study included both human population (Pregnant women aged b/w 18 to 35 , n=13) and animal model (Swiss albino,6-8 weeks old, 6 groups) of brain injury, which was created via administration of Aβ in hippocampal region of mice brain. Participants were given Yoga intervention from 16th-18th week onward till delivery (4 months). UCB was collected, Lin+ve and Lin-ve population were separated and stemness of Lin-ve SC was assessed through flow cytometery for markers such as CD34 and CD117. Aβ was injected in hippocampus stereotactically to create memory loss and after 21 days of Aβ administration, Lin-ve SCs were injected through same path at the same location. Neurobehavioral tests (Morris Water Maze & Passive avoidance), Immunohistochemistry (IHC), and qPCR techniques were used in this study to examine memory loss, memory reversal and then various molecules involved in the pathway. Neuro-behavioral analysis after 10 days of transplantation
showed improved memory. Yoga can be adopted as a lifestyle during pregnancy for improved outcomes and Lin-ve SCs derived from these practitioners can be considered a good source of memory reversal in amnesia and dementia patients however, more studies are warranted in the arena.

Title: Reduction of beta-amyloid pathology and improvement of cognitive functions in an Alzheimer's disease mouse model by targeting acid sphingomyelinase in blood with a novel anti-ASM monoclonal antibody

Authors: M. PARK[1], **S.-B. HONG**[2], B. CHOI[3], K. PARK[1], M. HONG[2], B. SHIN[2], J.-I. CHO[2], W. KIM[4], J. LEE[4], M. SO[4], H. JIN[3], *J.-S. BAE[1];

Abstract: Elevated activities of acid sphingomyelinase (ASM) in the blood of Alzheimer's disease (AD) patients and normal aged persons are implicated in the AD pathology, and age-related blood-brain barrier dysfunction and subsequent neurodegeneration. Here we sought to determine whether secreted ASM in blood is pivotal in AD pathogenesis and can be a therapeutic target by inhibiting ASM activity with a novel anti-ASM monoclonal antibody in a mouse model of AD. A high affinity monoclonal anti-ASM scFv (clone#: 9104), cross-reactive to both human and mouse ASM was identified by screening a synthetic human scFv phage library. A chimeric anti-ASM antibody (9104-mIgG1; human Fab with mouse IgG1 Fc) was generated for animal studies. Although the anti-ASM antibody did not inhibit purified recombinant ASM, it inhibited ASM activity present in the plasma membrane and thus reduced the levels of ceramide, a catabolized product of sphingomyelin, in the plasma membrane. As previously demonstrated, ASM activity was significantly elevated in the plasma of AD model mice (APP/PS1) compared to wildtype littermates (wildtype: 0.145±0.04 nmol/mg/h; APP/PS1: 0.251±0.05 nmol/mg/h). Upon repeated intraperitoneal injection of the anti-ASM antibody (50 mg/kg, Q2W for 8 weeks), ASM activity was reduced by 64% in the plasma (APP/PS1-9104-mIgG1: 0.090±0.10 nmol/mg/h). On the contrary, ASM activities in the brain (cortex and hippocampus) were not affected possibly due to blood-brain-barrier that limits penetration of the antibody. Cognitive functions were significantly improved as demonstrated by Morris' water maze and fear conditioning tests. Amyloid plaques and soluble amyloid beta peptides (Aβ40 and Aβ42) were significantly reduced in both cortex and hippocampus. GFAP (astrocyte marker) expression was also significantly reduced in both cortex and hippocampus, while phospho-Tau and Iba-1 (microglia marker) expression was lower but not to the level of significance. The presented results indicate that elevated ASM in blood is a potential therapeutic target for AD and a monoclonal anti-ASM antibody would be an applicable therapy that indirectly reduces amyloid-beta pathology.

Radiology, [7]Dept Neurol., Duke Univ. Med. Ctr., Durham, NC

Abstract: Alzheimer's disease (AD) is a complex, age-dependent condition influenced by genetic and environmental factors, and there is increasing evidence to support the role of physical exercise in slowing AD progression. This study aimed to examine the relationship between AD behavioral impairments, types of chronic exercise and cerebral blood flow (CBF). Female, 52 wk old, CVN-AD mice (APPSwDI/mNos2-/- which have mutated APP and a lowered expression of NOS2) were exercised, from 28 to 52 weeks of age (WOA) on one of two exercise regimens: Voluntary (VOL) - wheel running 6-8 hrs/day, 5 days/wk or voluntary plus enforced (ENF) - wheel running plus 45 min treadmill training 2 days/wk. Sedentary (SED) CVN-AD mice were controls. Daily wheel running distance was greater in ENF mice than VOL mice and body wts of all mice decreased with increased cardiovascular effort. Because symptoms of AD include both memory loss and anhedonia, mice were trained after 8 and 24 wks of exercise on a novel object recognition task and a sucrose preference test. At both timepoints, SED mice showed no memory for the familiar object and no consistent preference for sweetened water. While VOL mice also showed no memory for the familiar object after 8 wks of running, they did show novel object preference after 24 wks. Like the SED mice they did not show consistent sucrose preference. In contrast, ENF mice showed novel object preference at both

time points and consistent sucrose preference after 24 wks of training, demonstrating that the combined exercise regimen was best at improving memory and reducing anhedonia. In vivo MRI used a 7.1T Bruker imaging system with 20 cm bore and 440 mT/m gradient set, with a 72 mm volume excitation coil, and a 4 channels surface receive coil. We used pseudo continuous Arterial Spin Labeling for estimation of CBF. To quantify CBF, T1 maps were acquired at the same resolution using an inversion recovery sequence, and spin labeling efficiency was measured in the brain feeding arteries using an FcFLASH protocol in one single slice, for each mouse. In vivo perfusion imaging of whole brain of AD-mice revealed CBF was the most variable in SED mice, followed by ENF mice. ANOVA revealed that perfusion values differed with exercise ($F(2,24)=3.7$, $p=0.04$). Post hoc tests revealed that CBF values were higher in VOL relative to SED mice ($p=0.04$), suggesting that CBF increases with chronic voluntary exercise, but added treadmill training prevents this increase, perhaps due to chronic stress from enforced exercise. Interestingly, higher CBF did not correlate with more exercise, improved memory, or lower anhedonia. Regional blood flow analysis in targeted brain regions may better explain these data.

Title: Novel bi-level gene regulation underlies Tip60 HAT mediated neuroprotection in Alzheimer’s disease

Authors: *A. BHATNAGAR, B. C. KARISETTY, F. ELEFANT;
Biol., Drexel Univ., Philadelphia, PA

Abstract: Epigenetic mechanisms, such as histone acetylation modifications, play a crucial role in Alzheimer’s disease (AD) pathogenesis. Accordingly, our lab has shown that downregulation of Tip60 histone acetyltransferase (HAT) in the human AD hippocampus and the *Drosophila* AD

brain results in reduced chromatin acetylation and concomitant epigenetic repression of critical synaptic genes. Remarkably, these phenotypes are prevented by Tip60 overexpression in the *Drosophila* AD brain, supporting a neuroprotective role for Tip60 in AD. Although Tip60's role in chromatin dynamics has been well established, alternative Tip60 cellular mechanisms remain unexplored. Here, we show a novel RNA binding function for Tip60 HAT *in vivo* in the *Drosophila* brain. Using genome-wide sequencing of the RNA molecules bound with Tip60, Tip60's RNA binding function was found to be highly specific, selective and reproducible with its RNA targets being enriched for critical neuronal processes and AD. Remarkably, 77% of Tip60's RNA targets overlap with its gene targets, suggesting Tip60 orchestrates a bi-level gene regulation at the chromatin and the RNA levels that is unprecedented for any other HAT. Further, Tip60's RNA binding function in *Drosophila* is conserved in human hippocampal tissue and appeared compromised in AD patients, demonstrating mammalian conservation of Tip60-RNA interactions while further underscoring human AD relavance. Preliminary data suggests a role for Tip60 in alternative splicing and loss of Tip60 in AD could negatively affect splicing of its RNA synaptic gene targets, therefore contributing towards AD pathogenesis. We are first to uncover an RNA binding function for Tip60 HAT and propose a novel bi-level gene regulation that may underly Tip60's neuroprotection in AD-linked neurodegeneration.

Title: Intranasal administration of CSF-derived extracellular vesicles from patients with Parkinson's Disease induce Parkinson-like symptoms and pathology

Authors: *S. HERMAN[1,2], R. DJALDETTI[3], B. MOLLENHAUER[4,5], D. OFFEN[1,2];
[1]Tel Aviv Univ., Tel aviv, Israel; [3]Dept. of Neurol., [2]Felsenstein Med. Res. Ctr., Petah Tikva, Israel; [4]Dept. of Neurol. and Dept. of Clin. Neurophysiol., Paracelsus-Elena-Klinik, Kassel, Germany; [5]Georg-August Univ. Goettingen, Goettingen, Germany

Abstract: Parkinson's disease (PD) is characterized by the gradual appearance of intraneuronal lewy aggregates (Lewy bodies), which are primarily composed of misfolded α-synuclein (α-syn), resulting in cytotoxicity and neural death. Recent *in-vitro* and *in-vivo* studies support the idea of transcellular spread of misfolded α-syn in a prion-like transmission via extracellular vesicles (EVs) secretion and induce pathological aggregates in healthy neurons. EVs derived from brain

lysates and cerebrospinal fluid (CSF) of PD patients have been shown to propagate α-syn aggregation in healthy cells. Braak et al. hypothesized the olfactory bulb as a primary propagation site for the initiation of the disease. To examine whether pathological α-syn can actively spread from the nasal cavity to the brain via EVs and initiate pathological aggregate in the brain, we isolated CSF-derived EVs from PD patients or from non-synucleinopathies patients (non-PD). Healthy 2-months old C57/Bl mice were given EVs isolated from patient's CSF (PD or non-PD) by internasal administration. 3 months after treatment mice were subjected to behavior testing and examined for PD-related brain pathology. Intranasal delivery of CSF-derived EVs from PD patients to healthy mice induced PD-like symptoms and pathology; PD-treated mice had impairments in motor behavior, hyposmia and elevated anxiety compared to non-PD treated and healthy untreated mice. Striatums of PD-EVs treated mice revealed increased phosphorylated ser129 α-syn aggregation, decreased tyrosine hydroxylase expression, astrogliosis and impaired autophagy compared to non-PD treated and healthy treated mice. Together, these data suggest that EVs from PD patients are sufficient for propagating α-syn aggregation *in-vivo* and initiating PD-like symptoms and pathology in healthy mice when delivered by intranasal routes.

Title: Mao-b inhibition facilitates α-synuclein secretion via an abc transporter-mediated pathway and delays its aggregation

Authors: *Y. NAKAMURA[1], H. SATO[2], K. TAKAHATA[3], H. TSUNEKAWA[3], T. SHIGEKIYO[1], T. KATO[2], S. ARAWAKA[1];
[1]Neurol., Osaka Med. and Pharmaceut. Univ., Osaka, Japan; [2]Neurol., Yamagata Univ., Yamagata, Japan; [3]Scientific Res., FP Pharmaceut. Corp., Osaka, Japan

Abstract: α-Synuclein (α-syn) is secreted under physiological conditions in mouse primary neurons and brain interstitial fluids, showing that extracellular α-syn may play a key role in cell-to-cell transmission of its pathology in Parkinson’s disease (PD). However, the mechanisms that regulate extracellular α-syn secretion are not fully elucidated. In this study, we investigated effects of monoamine oxidase-B (MAO-B) inhibition on α-syn secretion in cultured cells (n=3~6 per group) and its aggregation in recombinant adeno-associated virus (rAAV)-based rat models (male Sprague-Dawley rat, n=3~8 per group). In SH-SY5Y cell line stably expressing wild-type α-syn, both inhibition of MAO-B activity by selegiline or rasagiline and siRNA-mediated

knockdown of MAO-B facilitated α-syn secretion. Conversely, TVP-1022, the 1,000 times less active S-isomer of rasagiline, did not alter α-syn secretion. This MAO-B inhibition-induced increase in α-syn secretion was not blocked by brefeldin A, which inhibits endoplasmic reticulum/Golgi classical transport, while it was blocked by probenecid and glyburide, which inhibit ATP-binding cassette (ABC) transporter function. MAO-B inhibition preferentially facilitated the secretion of detergent-insoluble α-syn protein and reduced its intracellular accumulation under chloroquine-induced lysosomal dysfunction. Also, in mouse primary cortical neurons, α-syn secretion was facilitated by MAO-B inhibition and blocked by ABC transporter inhibition. Moreover, in a rat model injected rAAV-A53T α-syn into the substantia nigra, administration of selegiline delayed the striatal formation of Ser129-phosphorylated α-syn aggregates and loss of nigrostriatal dopaminergic neurons. Selegiline delayed α-syn aggregation and dopaminergic neuronal loss in a cell-to-cell transmission rat model generated by injecting rAAV-wild-type α-syn and externally inoculating α-syn fibrils into the striatum. These findings suggest that MAO-B inhibition modulates the intracellular clearance of detergent-insoluble α-syn via the ABC transporter-mediated non-classical secretion pathway in vitro, and temporarily delays the formation and transmission of α-syn aggregates in rat models. We propose a new function of MAO-B inhibition that modulates α-syn secretion and aggregation in PD treatment.

Title: Loss of tau expression attenuates neurodegeneration associated alpha synuclein pathology in vivo

Authors: *S. C. VERMILYEA[1], A. CHRISTENSEN[1], B. SINGH[1], R. KARIM[1], J. MEINTS[1], M. K. LEE[1,2];
[1]Neurosci., [2]Inst. for Translational Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Parkinson's Disease (PD) is a progressive neurodegenerative disease characterized by the loss of several neuronal populations, including dopaminergic neurons of the substantia nigra pars compacta. Another hallmark of the disease is the identification of intracellular proteinaceous inclusions called Lewy bodies (LBs) and Lewy neurites (LNs). The small presynaptic protein α-

synuclein (αS) is the major component of LBs and LNs in PD and highly related LB Dementia (LBD). Neuronal dysfunction and degeneration linked to α-synuclein (αS) pathology is thought to be responsible for the neurodegeneration in PD and LBD. However, studies indicate bidirectional pathological relationships between αS pathology and microtubule associated protein tau abnormalities. For example, we showed that A53T mutant human αS (HuαS) can cause tau dependent post-synaptic and cognitive deficits. Therefore, we examined whether tau is involved in the onset and progression of overt α-synucleinopathy. We induced α-synucleinopathy by intramuscular (IM) injections of HuαS preformed fibrils (PFF) in A53T mutant transgenic mice (TgA53T), in $mTau^{-/-}$ or wildtype background. IM inoculation of TgA53T mice leads to motor dysfunction onset by ~70 days post inoculation (dpi) and end stage paralysis by ~100 dpi. Therefore, motor behavior at 70 dpi and disease progression were evaluated as well as biochemical and histological analysis at 40dpi, 70dpi, and end stage.Significantly, $TgA53T/mTau^{-/-}$ mice exhibit reduced motor deficits at 70 dpi measured by rotarod performance as well as a significant delay of disease onset, progression, and time to reach end stage criteria. Analysis of neuropathology shows that end stage TgA53T mice and $TgA53T/mTau^{-/-}$ mice show comparable pathology. However, at 70 dpi, $TgA53T/mTau^{-/-}$ mice had modest yet significant reductions of α-synucleinopathy, as well as inflammatory markers Iba1 and GFAP. In addition, tau removal delayed ventral horn motor neuron degeneration at 70 dpi. Interestingly, no differences were observed at 40 dpi. Similarly, *in vitro* application of PFF to primary hippocampal neurons demonstrated no change of PFF uptake and processing, nor pS129αS aggregation as a function of tau expression. However, PFF-induced neurotoxic indicators including morphology and postsynaptic density deficits in wildtype neurons were prevented with tau removal. We conclude that while tau expression does not impact onset and progression of αS aggregation, loss of tau expression protects neurons from downstream toxic effects of αS aggregation. Therefore, tau reduction and the pathways activated may represent novel therapeutic targets for α-synucleinopathy.

Title: Differential metabolism of α-Syn pre-formed fibril (PFFs) in neuronal and non-neuronal cells

Authors: *M. KARIM[1], E. GASPARINI[2], H. MARTINEZ[2], M. RASHID[2], B. BALVINDAR SINGH[2], M. K. LEE[2];

Abstract: Parkinson's disease (PD) and other α-synucleinopathies are characterized by the accumulation of α-synuclein (αS) aggregates. Studies indicate that αS pathology can spread via the cell-to-cell transmission of αS pathology. To better understand how various brain cells contribute to the spreading of αS pathology, we examined the metabolism of αS pre-formed fibril (PFFs) by neurons and glial cells (microglia, astrocytes, and oligodendrocytes). Our results show that microglia and astrocytes rapidly metabolize αS PFF where the half live of αS PFF in these glial cells are ~5 hours. In neurons, while the full-length αS rapidly disappears following αS PFF uptake, truncated αS accumulates with the half-life of over 48 hours. Epitope mapping and fractionation studies indicate that in αS PFF is truncated at C-terminal region and remains insoluble/aggregated. The differential processing of αS can be recapitulated in cell lines as differentiated CLU neuronal cell lines show stable accumulation of truncated αS while undifferentiated cells rapidly metabolize αS. Immunolocalization and subcellular fractionation studies show that αS PFF is initially localized to endosomes followed by lysosomes. Inhibition of lysosomal function leads to stabilization of full-length and truncated αS in all cell types. Our data show that lysosomal degradation system is involved in the metabolism of extracellular αS aggregates taken up by various cell types. Further, our studies indicate that glial cells protect neurons αS aggregates by rapid clearance of αS aggregates while αS aggregates taken up by neurons are metabolized to aggregation prone C-terminally truncated αS.

Title: Brain region-specific characteristics of alpha-synuclein propagation in synucleinopathy models

Authors: *J.-C. ROCHET[1], S. DUTTA[1], J. A. HENSEL[1], A. SALAZAR-CHAPARRO[1], U. K. ARYAL[1], C. R. FERREIRA[1], S. MIN[1], L. A. VOLPICELLI-DALEY[2], D. J. TRADER[1]; [1]Purdue Univ., West Lafayette, IN; [2]Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: In Parkinson's disease (PD) and other synucleinopathy disorders, aggregated forms of the presynaptic protein alpha-synuclein (aSyn) can spread throughout the brain via anatomically connected neuronal pathways. Data collected over the past 10 years have revealed that the propagation mechanism involves the internalization of pathogenic aSyn aggregates by neurons via an endocytic mechanism, after which the internalized protein stimulates the conversion of endogenous cytosolic aSyn to the fibrillar form via a seeding mechanism. Despite these insights, factors that determine brain region-specific differences in propagation efficiency and propagation-related toxicity are poorly understood. To address this knowledge gap, we characterized aSyn preformed fibrils (PFFs) in terms of their brain region-specific spreading efficiencies and molecular perturbations in cellular and *in vivo* propagation models. We observed that neurons prepared from the hippocampal and cortical regions (but not the midbrain region) of embryonic rat brain showed evidence of aSyn inclusions. This selectivity was found to reflect differences in levels of aSyn expression and PFF-mediated proteasomal dysfunction, but not the efficiency of PFF uptake, in different types of neurons. Current efforts are focused on characterizing brain region-specific proteomic and lipidomic perturbations in rats injected with aSyn PFFs in the frontal cortex, amygdala, and substantia nigra. Data from an initial proteomics study revealed that elongation factor-2 was selectively down-regulated in the amygdala of PFF-treated animals. Moreover, a pilot lipidomics analysis revealed an apparent increase in lipids in the PC/SM, PE, DAG, and ceramide families in the amygdala and/or cortex (but not the SN) of PFF-injected rats. Collectively, these findings suggest that seeded aSyn aggregation occurs more readily in certain types of neurons and elicits brain region-specific proteomic and lipidomic changes. Ultimately, the results of these studies will deepen our understanding of the molecular underpinnings of the spread of pathology in synucleinopathy disorders, laying the groundwork for developing well-tailored intervention strategies in the brains of patients.

Abstract: Lewy bodies (LBs) are intracellular aggregates of misfolded alpha-synuclein observed in dopaminergic neurons of the substantia nigra pars compacta (SNpc) in Parkinson's disease (PD), representing the main pathological hallmark of this neurodegenerative disorder. Available experimental evidence supported that misfolded alpha-synuclein can spread in a prion-like fashion trans-synaptically, i.e. between interconnected neurons. In this regard, it has been postulated that synucleinopathy propagates from the enteric system to the dorsal motor nucleus of the vagus, then spreading rostrally until reaching the SNpc and finally the cerebral cortex (the so-called "Braak hypothesis"). To what extent this spread drives the clinical course of PD still is a matter of debate, in particular when evaluating both the functional and clinical relevance for this alpha-synuclein propagation. Surprisingly, first evidence for this spread came from PD patients transplanted with embryonic dopaminergic cells, where postmortem evaluation showed LB pathology in grafted cells. Although at the experimental level there is conclusive evidence for a prion-like dissemination of preformed alpha-synuclein fibrils through interconnected brain areas, interactions between exogenous fibrils and endogenous alpha-synuclein remained unclear. In other words, evidence showing transneuronal spread of endogenous alpha-synuclein is still lacking. Here we took advantage of a viral vector coding for human tyrosinase for driving a time-dependent neuromelanin (NMel) accumulation in dopaminergic cells of *Macaca fascicularis*. Furthermore, accumulation of NMel induced synucleinopathy (Lewy and Marinesco bodies) in SNpc neurons. Most importantly, LB-pathology was observed in pyramidal neurons located in cerebral cortical regions receiving dopaminergic afferents, such as the dorsal frontal gyrus and the precentral gyrus. In other words, here we provide the first evidence showing spread of endogenous alpha-synuclein in the macaque brain, thus providing a straightforward demonstration of the transneuronal propagation of endogenous alpha-synuclein.

Title: Neurexin 1alpha Mediates Export of Pathologic alpha-Synuclein

Authors: *X. YIN[1], X. MAO[1], S. LIU[2], S. S. KARUPPAGOUNDER[1], H. WANG[1], J. SONG[2], V. L. DAWSON[1], T. M. DAWSON[1];

Abstract: Cell-to-cell transmission and accumulation of misfolded pathologic α-synuclein (α-syn) underlies Parkinson's disease (PD). What drives the export of pathologic α-syn out of cells is unknown. Here we show that Neurexin 1α (Nrxn1α) binding to α-syn preformed fibrils (α-syn PFF) initiates the exosome-associated exocytosis of pathologic α-syn. Disruption of Nrxn1α in cultured neurons blocks α-syn PFF propagation, which leads to accelerated pathologic α-syn accumulation, enhanced phospho-Ser129 α-syn phosphorylation and neurotoxicity. In vivo, the lack of Nrxn1α prevents the spread of α-syn PFF from the striatum to neighboring brain regions, resulting in a reduction in α-syn pathology throughout the brain. The reduction in the spread of pathologic α-syn leads to less DA neuron loss and neurophysiological and behavioral deficits. These results support an essential role for Nrxn1α in the pathogenesis of PD through facilitation of pathologic α-syn exosome-based release and identifies new opportunities to develop effective approaches to halt the progression of PD.

AbstractChronic ultra-mild stress (CUMS) has been reported to induce an anhedonic-like state in mice that resembles some of the symptoms of human depression. Many individuals with depression have prevalent pathology of α-synuclein (αsyn) and tau in the brain whereas molecular chaperones protect neurons from the deleterious effects of αsyn and tau misfolding. In the present study, utilizing CUMS animal model of depression, we report the role of cereblon (CRBN, the substrate receptor of the CUL4A/B-Roc1-RBX1 E3-ubiquitin ligase) in regulating the activities of chaperones DNAJA1 (DJ2) and DNAJB1 (DJ1) which in turn modulate the pathological effects of tau and αsyn, respectively. Pathological phosphorylation of tau and αsyn was significantly low in the neuronal tissues of *Crbn*$^{-/-}$ mice model of CUMS. Moreover, *Crbn*$^{-/-}$ mice showed resilient behavioral responsiveness as compared to *Crbn*$^{+/+}$ mice. LC-MS/MS analysis showed an enriched metabolic and antioxidant status in the brains of *Crbn*$^{-/-}$ subjects as compared to *Crbn*$^{+/+}$ ones. Certain antioxidant proteins were elevated in the neuronal tissues of *Crbn*$^{-/-}$ mice; for instance, quinone oxidoreductase, superoxide dismutase (Sod1), glutathione S-transferase (Gstm1), peroxiredoxin-2 and biliverdin reductase A. Similarly, certain isoforms of molecular chaperones and co-chaperones were higher in the brains of *Crbn*$^{-/-}$ mice; for example, Hspa8 heat shock cognate 71, Hspd1 isoform 1 of 60 kDa heat shock protein, DJ1, and DJ2. The present study highlights the roles of CRBN in regulating the typical core behaviors, reshaping metabolic status and the fate of aggregation-prone proteins in the brains of mice exposed to CUMS. A better understanding of the molecular mechanism of depression and neurodegeneration will improve the development of better and novel treatments.

Abstract: PPARβ/δ, the most PPAR abundant isoform in the central nervous system, is expressed in its major cell types, and is involved in the modulation of microglial homeostasis and energetic metabolism. Several studies demonstrated that people suffering from type 2 diabetes mellitus (T2DM) develop cognitive decline turning insulin resistance one of the best predictors of this disturbance. Although numerous investigations have studied the role of PPARβ/δ in metabolism, its role in neuronal and cognitive function has been underexplored. Therefore, the aim of the study is to determine the role of PPARβ/δ in the neuropathological pathways involved in the development of cognitive decline and as to whether a risk factor involved in cognitive loss such as obesity modulates neuropathological markers. In the present work, 6-month-old male PPARβ/δ-null (PPARβ/$\delta^{-/-}$) and wild type (WT) littermates with the same genetic background (C57BL/6X129/SV) were used. After the weaning (at 21 days old), animals were fed either with conventional chow (CT) or with a palmitic acid-enriched diet containing 45% of fat mainly from hydrogenated coconut oil (HFD). Thus, four groups were defined: WT CT, WT HFD, PPARβ/$\delta^{-/-}$ CT and PPARβ/$\delta^{-/-}$ HFD. Since it has been described that behavior alterations could be observed

among hybrids/strains, open field test was performed to compare C57BL/6X129/SV and C57BL/6 mice to assess anxiety levels. Our results confirmed that C57BL/6X129/SV showed significantly increased levels of anxiety compared to C57BL/6. Therefore, in order to evaluate cognitive decline, behavioral tests were dismissed, and dendritic spine quantification and other biochemical biomarkers were performed. In this line, PPARβ/$\delta^{-/-}$ mice exhibited a decrease in dendritic spine density and synaptic markers, such as PSD95 and BDNF, suggesting an alteration in cognitive function and synaptic plasticity. Likewise, our study demonstrated that the lack of PPARβ/δ receptor enhances the gliosis in the hippocampus, contributing to astrocyte and microglial activation and also, induced an increase in neuroinflammatory biomarkers such as TLR4 and PTP1B. Additionally, alterations in the hippocampal insulin receptor pathway were found. A fact to note is that HFD intake did not enhance the effects observed in the PPARβ/$\delta^{-/-}$ mice at the hippocampal level the studied mechanism. Taken together, these findings suggest that the loss of PPARβ/$\delta^{-/-}$ affects neuronal and synaptic structure, contributing to cognitive dysfunction and, they also present this receptor as a possible new target for the treatment of cognitive decline.

Title: Demyelination and interferon signaling in axons cause retrograde upregulation of neuronal ISGylation pathway genes

Authors: *B. D. S. CLARKSON, C. L. HOWE;
Neurol., Mayo Clin., Rochester, MN

Abstract: Cognitive impairment in MS is associated with diffuse gray matter injury, which remains poorly understood. Given that axons span both white and gray matter regions, it's possible that signals within these axons contribute to the spread of diffuse injury in the brain. We show that retrograde IFNg signaling in axons (in vitro human and murine) and demyelination (murine in vivo) cause transcriptional / translational changes in neuronal cell bodies. Chief among the candidate signaling pathways identified is ISGylation, a process whereby a multitude

of cellular proteins are modified by the attachment of one or more ISG15 molecules. Using custom adeno-associated viral vectors we tested how altering ISGylation in neurons affects neuronal synaptic function and how it affects neuronal responsiveness to specific inflammatory factors in cell cultures. We also measured ISGylation in MS brain tissues to see if neuronal ISGylation correlates with gray matter injury in MS. We report early evidence that increased neuron ISGylation alters the composition of neuron-derived extracellular vesicles. Microglia treated with extracellular vesicles from neurons overexpressing ISGylation pathway genes exhibited morphology consistent with increased phagocytic activity and increased mRNA expression of inflammatory cytokines including: CCL2, IL1b, TNFa, iNOS, CXCL10, CCL5, and IL6. At this point, it is still unclear how these changes are related to gray matter pathology. However, it is possible that microglial activation by these vesicles is involved with driving synapse loss as activated microglia are known to be capable of stripping neuronal synapses.

Title: Phagocytic glia drive prion-like spreading of mutant huntingtin aggregates in Drosophila brains

Authors: *M. PANNING PEARCE, K. M. DONNELLY, A. ZAYA, G. DAVIS, O. DELORENZO, W. THU, G. PISANO;
Univ. of the Sci., Philadelphia, PA

Abstract: A key pathological and diagnostic feature of most neurodegenerative diseases is appearance of insoluble aggregates as a result of protein misfolding in the central nervous system (CNS). Accumulation of toxic protein aggregates in the brain is partially offset by a number of clearance mechanisms, such as the ubiquitin-proteasome pathway, autophagy, and engulfment by phagocytic glial cells; however, these mechanisms fail or become overwhelmed over time. A growing body of evidence supports the hypothesis that pathogenic aggregates associated with many neurodegenerative diseases behave similarly to infectious prions--they spread from cell-to-cell and nucleate the aggregation of natively-folded versions of the same protein, events which are thought to propagate aggregate-induced neurotoxicity along synaptic tracts the brain. We have recently reported that mutant huntingtin (mHTT) aggregates associated with the inherited

neurodegenerative disorder Huntington's disease spread in a "prion-like" manner between synaptically-connected neurons and glial cells in the *Drosophila* CNS. mHTT aggregates formed in presynaptic olfactory receptor neuron (ORN) axons directly nucleate the aggregation of soluble wild-type HTT (wtHTT) proteins expressed in the cytoplasm of post-synaptic partner projection neurons (PNs) or nearby glial cells. ORN-to-PN and ORN-to-glia transfer of mHTT aggregates is enhanced when ORNs are genetically silenced, slowed when caspase-dependent apoptosis in ORNs is blocked, and remarkably, require expression of the conserved glial scavenger receptor Draper/MEGF10. Further, mHTT aggregate transmission between synaptically-connected ORNs and PNs requires a transient visit to the glial cytoplasm, indicating that phagocytic glia can directly mediate aggregate transfer between neurons in vivo. Preliminary data from our lab indicate that entry of phagocytosed neuronal mHTT aggregates into the glial cytoplasm involves certain Rab GTPases with proposed roles in intracellular vesicle membrane fusion, suggesting that inefficient or stalled phagosome maturation and/or phago-lysosome fusion events can generate a reservoir of seeding-competent mHTT aggregate species in the glial cytoplasm. In support of this, expression of mHTT in ORNs accelerates age-related decline in phagocytic capacity of nearby glial cells. Together, our findings add to a growing understanding of phagocytic glia as double-edged players in neurodegeneration—these cells can clear neurotoxic aggregates, but age- and/or disease-related defects in this process can paradoxically promote aggregate propagation through in the brain.

Title: Alcohol-induced alternative splicing in drosophila memory circuits

Authors: *T. M. BROWN[1], E. PETRUCCELLI[3], S. J. GRATZ[2], A. G. WATERMAN[1], K. M. NUÑEZ[2], K. M. O'CONNOR-GILES[1], K. R. KAUN[2];
[1]Neurosci., [2]Brown Univ., PROVIDENCE, RI; [3]Biol. Sci., Southern Illinois University, Edwardsville, Edwardsville, IL

Abstract: Repeated alcohol experiences produce long-lasting memories for sensory cues associated with intoxication. These memories can problematically trigger relapse in individuals recovering from alcohol use disorder (AUD). The molecular mechanisms by which ethanol changes memories to become long-lasting and inflexible remain unclear. We recently demonstrated that formation of these memories results in expression of alternative transcript isoforms in memory-encoding neurons in *Drosophila melanogaster*. *Drosophila* rely on mushroom body (MB) neurons to make associative memories, including memories of ethanol-associated sensory cues. Decreasing expression of genes that play a role in splicing in adult MB neurons reduces formation of these memories, demonstrating the necessity of RNA processing in ethanol memory formation. Moreover, decreasing expression of alternatively spliced targets like *Dop2R* and *Stat92E* in adult MB neurons reduces ethanol memory formation. This suggests that the splicing changes in these transcripts has functional implications for maladaptive behaviors like addiction. To test this, we engineered mutant *Drosophila* lines with forced expression of the naïve or ethanol memory-associated isoform of *Dop2R* and *Stat92E*. We assessed mutant preference for an odor previously associated with ethanol following Pavlovian conditioning in a novel three-choice assay. We hypothesized that naïve or ethanol memory associated isoforms would reduce or enhance ethanol cue preference, respectively. Our results suggest that single target-specific splicing within memory-encoding neurons has functional consequences. These findings highlight the functional role of dynamic splicing in the nervous system and demonstrate a role for alternative splicing in the development of AUD.

Title: Selective phosphorylation of serine 345 on p47-phox serves as a priming signal of ROS-mediated axonal degeneration

Authors: *T. ARAKI, S. WAKATSUKI;
Dept PNS Res., Natl. Inst. Neurosci, NCNP, Tokyo, Japan

Abstract: Axonal degeneration is observed as a major component in many neurodegenerative diseases. We previously reported that the E3 ubiquitin ligase ZNRF1 promotes axonal degeneration by degrading AKT. We showed that, in response to reactive oxygen species (ROS) generated by NADPH oxidases, the EGFR-dependent phosphorylation of ZNRF1 at the 103rd tyrosine residue (pY103) induces its ubiquitin ligase activity in transected neurites. Here, we show that a NADPH oxidase subunit p47-phox/neutrophil cytosolic factor 1 regulates ZNRF1 activity. Interestingly, transection-induced phosphorylation of p47-phox at the 345th serine residue by p38 MAPK serves as an initiating signal to activate ZNRF1. The phosphorylated p47 (pS345) or a phospho-mimetic mutant p47-phox binds directly to ZNRF1 whereas a phosphorylation-resistant mutant p47-phox cannot bind to ZNRF1 and its overexpression in neurites significantly suppresses pY103 of ZNRF1, AKT ubiquitination, and degeneration after transection, suggesting that pS345 might enhance the EGFR-mediated phosphorylation-dependent activation of ZNRF1. Collectively, our findings suggest that pS345 might represent an important checkpoint to initiate the ZNRF1-mediated neurite degeneration and could serve as a novel target for neurite protection.

Abstract: The long length of axons creates distinct metabolic and cellular challenges to synaptic terminals and axons that are physically distant from their cell bodies. Axonal function requires support from glial cells as well as physical transport of proteins and organelles from the cell body. When transport is acutely interrupted by injury to the axon, the distal axon undergoes Wallerian degeneration, a cell autonomous breakdown process triggered by the activation of the NADase enzyme Sarm1 (Sterile Alpha And TIR Motif Containing 1). The regulation and function of Sarm1 is closely linked with the synthesis and breakdown of NAD+, an essential co-enzyme and metabolite. It is thought that activated Sarm1 promotes axonal degeneration through metabolic catastrophe. We were therefore surprised to find that multiple genetic manipulations

that are expected to impair energy homeostasis in neurons counterintuitively lead to a delay in Wallerian degeneration of injured axons. These manipulations include knockdown of a key glycolytic enzyme pyruvate kinase (PyK), and ATP synthase subunit G (ATPsynG) which is essential for ATP generation by oxidative phosphorylation. Mutations that impair mitochondrial localization in axons (for example in the mitochondrial rho GTPase miro), and, strikingly, ectopic expression of a constitutively active NADase enzyme (via a self-dimerizable TIR domain from Sarm1) leads to a delay in the degeneration of injured axons compared to control axons. We hypothesize that energy impairments in axons trigger a stress response pathway that alters the kinetics of axonal degeneration, and note that activation of nuclear markers of JNK signaling is a shared feature of the manipulations that impair Wallerian degeneration. Overexpression of Dicer 2 (Dcr2) is required to see the delay in injury-induced degeneration following NADase activation, which may indicate a role for Dcr2 in regulating this process. We are currently implementing ATP reporters in live Drosophila axons to probe the relationship between axonal energetics and the Wallerian degeneration pathway.

Title: Metabolomic and transcriptional profiling reveals bioenergetic stress and neuroinflammation in vivo after neuronal deletional of NAMPT

Authors: *S. LUNDT, N. ZHANG, Z. ZHANG, L. ZHANG, S. DING;
Univ. of Missouri, Columbia, MO

Abstract: Nicotinamide phosphoribosyltransferase (NAMPT) is the rate-limiting enzyme in the NAD^+ salvage pathway. Our previous study demonstrated that deletion of NAMPT gene in projection neurons using Thy1-$NAMPT^{-/-}$ conditional knockout (cKO) mice causes neuronal degeneration, muscle atrophy, neuromuscular junction abnormalities, paralysis and eventually death. Here we conducted a combined metabolomic and transcriptional profiling study *in vivo* in an attempt to further investigate the mechanism of neuronal degeneration at metabolite and mRNA levels after NAMPT deletion. Here using steady-state metabolomics, we demonstrate

that deletion of NAMPT causes a significant decrease of NAD^+ metabolome and bioenergetics, a buildup of metabolic intermediates upstream of glyceraldehyde 3-phosphate dehydrogenase (GAPDH) in glycolysis, and an increase of oxidative stress. RNA-seq shows that NAMPT deletion leads to the increase of mRNA levels of enzymes in NAD metabolism, in particular PARP family of NAD^+ consumption enzymes, as well as glycolytic genes Glut1, Hk2 and PFBFK3 before GAPDH. GO, KEGG and GSEA analyses show the activations of apoptosis, inflammation and immune responsive pathways and the inhibition of neuronal/synaptic function in the cKO mice. The current study suggests that increased oxidative stress, apoptosis and neuroinflammation contribute to neurodegeneration and mouse death as a direct consequence of bioenergetic stress after NAMPT deletion.

Title: Identification of a novel disease mechanism and a potential treatment for newly discovered neurodevelopmental disease “NEDAMSS”

Authors: *S. SINHA RAY[1], D. DUTTA[3], C. N. DENNYS[5], F. ROUSSEL[1], S. POWERS[2], X. ZHANG[1], P. BISWAS[1], J. CAROLE[1], N. WEIN[1], H. J. BELLEN[6], S. LIKHITE[1], P. C. MARCOGLIESE[4], K. C. MEYER[7];

Inst. at Nationwide Children's Ho, Columbus, OH; [6]Dept Molec & Human Genet., Howard Hughes Med. Inst., Houston, TX; [7]Ctr. for Gene Therapy, Res. Inst. Nationwide Childrens Hosp., Columbus, OH

Abstract: NEDAMSS is a recently discovered neurodevelopmental disorder with growth regression, abnormal movements, loss of speech and seizures. The disease is caused by heterozygous mutations in the Interferon Regulatory Factor 2 Binding Protein-Like (IRF2BPL) gene. IRF2BPL is a ubiquitously expressed intron-less transcriptional regulator. The function of the protein is currently unknown, but the observed disease phenotype in patients indicates a role in development and maintenance of the nervous system. To study the disease mechanism, we used patient skin-derived fibroblasts with nonsense variants in the gene and utilizing an *in vitro*

modelling system we directly reprogrammed them into induced neuronal progenitor cells (iNPCs). The iNPCs were then differentiated into astrocytes, the most numerous cell type within the central nervous system. Additionally, we also used a direct conversion method to generate neurons directly from the skin fibroblasts to observe any morphological defects. Using these methods and performing molecular and functional analysis on the astrocytes, we identified a novel disease mechanism not previously described. While IRF2BPL is localized in the nucleus in healthy individuals, we found that several patient cell lines displayed mis-localization of the full-length protein in the cytoplasm both *in vitro* and *in vivo* within a fly model, caused by the dimerization with truncated mutant proteins. Moreover, the patient astrocytes also showed caused neuronal death in co-culture assays and abnormal mitochondrial ATP-linked respiration levels. Based on these observations, we treated our cell lines with CuATSM, a small molecule, neuroprotective drug currently in clinical trials for ALS. We found that CuATSM successfully rescued neuronal survival and reduced ATP-linked respiration to normal levels in NEDAMSS astrocytes. In summary, we identified a novel disease mechanism involved in NEDAMSS disease and found a promising treatment that might be able to slow or halt the progression of the disease.

Title: The bacterial microbiome controls neurodegenerative death in Drosophila

Authors: *A. K. SHUKLA, K. R. JOHNSON, E. GINIGER;
NIH/ NINDS, Bethesda, MD

Abstract: There has been a growing recognition that the microbiome plays a pivotal role in aging and neurodegenerative disease (ND), but the complexity of the interaction between microbe and host has made it difficult to dissect. To better understand how host-microbe interactions affect NDs, we used a *Drosophila melanogaster* model of neurodegeneration, activation of the endogenous tau kinase, Cdk5, by overexpression of its activating subunit, Dp35.

Under conventional, microbe-rich conditions, overexpressing Dp35 reduces lifespan by ~40%. To our surprise, however, we found that lifespan is ***completely*** rescued in flies overexpressing Dp35 if they are raised without bacteria (axenic hereafter) (Median survival 39.5±7.7 days in conventional and 69.5±3.5 days in axenic). To uncover the underlying molecular basis for the pathological interaction between the microbiome, aging, and ND we performed gene expression profiling on axenic and conventionally raised flies at various ages. Gene ontology (GO) analyses of these data demonstrate that the microbiome-driven effect on lifespan in the ND condition is associated with profound changes in chromatin structure and genome integrity, mediated specifically via altered regulation of histone genes and transposons. Given the profound effect of the microbiome on lifespan in the ND condition, we next investigated how the microbial population changes with host age. In male flies, the total bacterial load does not change much over the lifespan, but 16S ribosomal rDNA sequencing revealed that the diversity of the microbiome undergoes drastic simplification over the course of the fly's lifespan. Remarkably, the drop in bacterial species diversity is greatly accelerated in OE Dp35. Moreover, the species that remain at older ages are altered by overexpression of Dp35 in the host. We are currently working to understand why bacterial diversity changes with age, why it depends on Cdk5/Dp35, and whether the particular species that remain are significant. We are also investigating how chromatin modification is associated with the microbiome-dependent neurodegenerative death of the organism. Overall, this work highlights the importance of host-microbe interactions as a fundamental regulatory system in modulating neurodegenerative death.

Title: Neurological deficit appeared 3 weeks post heat exposure by cerebellar dysfunction in the rodent model of heatstroke.

Authors: K. MIYAMOTO[1], H. OHTAKI[3], *A. YOSHIKAWA[4], H. YAMAGA[1], M. NAKAMURA[1], K. SUZUKI[1], K. HONDA[2], K. DOHI[1];

Abstract: Introduction: Brain is extremely sensitive to hyperthermia. Disorientation, confusion, delirium and seizures are often seen in human heatstroke. Such consciousness disturbance improves once the core body temperature falls below the critical level in acute phase. However, there are cases that neurological sequelae remain after heatstroke that interrupts the patients getting the back to social life. Among them, cerebellar structures are vulnerable to heat, therefore cerebellar ataxia is often appeared. Interestingly, there are several interesting reports cerebellar ataxia appearing not immediately after heatstroke but after several weeks have passed. Thought, the pathomechanism of this delayed cerebellar ataxia after heatstroke is not well understood. Therefore, we focused on the delayed cerebellar ataxia after heatstroke using the rodent heatstroke model.**Methods:** Male C57BL6J mice were subjected to heat exposure (HE), 41℃, RH>95% for 60 min as a heatstroke group (HS). The animals which were not exposed to heat were prepared as a control (Ct). Behavioral test (Rota-rod) was performed 1, 3, 5, 7 and 9 weeks post heat exposure and running time was compared between Ct and HS group. Then, another two group (Ct, HS) were prepared and brains were removed 1, 3 and 9 weeks post heat exposure. Kluver-Barrera (KB) staining was performed to evaluate the demyelination at cerebellum and corpus callosum. Immunostaining of Calbindin was performed to semi-quantify of the Purkinje cells. Moreover, we performed immunostaining of Synaptophysin and Postsynaptic density-95 (PSD-95) to evaluate the pre and post synapses around Purkinje cells post heat exposure. **Results:** Motor coordination disorder in HS group significantly appeared 3 weeks post heat exposure and gradually improved to some extent over time. Demyelination was detected 1, 3 weeks and the number of Purkinje cell significantly decreased 1,3 and 9 weeks post heat exposure. The expression of Synaptophysine and PSD-95 around Purkinje cells were weakest in 3 weeks post heat exposure and improved over the time.**Conclusion:** Delayed cerebellar ataxia in heatstroke appeared from 3 week and recovered to some extent over time. Our results suggested that permanent Purkinje cells loss, transient demyelination and synaptic impairment at cerebellum might correlated with delayed cerebellar ataxia of heatstroke.

Title: Prenatal activation of the maternal immune system alters prefrontal cortex neuroanatomy in adult offspring

Authors: *V. R. RIESGO[1], E. P. SELLINGER[2], J. M. JURASKA[2], J. WILLING[1];
[1]Bowling Green State Univ., Bowling Green, OH; [2]Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: In light of the COVID-19 pandemic, it is vitally important to further our understanding of how the maternal immune system can affect brain development in offspring. During the prenatal period, the developing brain is especially sensitive to exogenous and endogenous factors that can disrupt vital developmental processes, including the optimization of regional neuron number. Maternal infection has been shown to affect certain cells of the prefrontal cortex (PFC) and PFC-mediated behaviors. However, little is known about the long-term effects of maternal infection on neuron number and volume of the medial prefrontal cortex (mPFC), a region critical for executive functions and behavior inhibition. The present study assesses the effects of prenatal lipopolysaccharide (LPS), which activates the maternal immune system, on mPFC anatomy in young adult offspring. 100 µg/kg LPS was administered intraperitoneally to pregnant rats on embryonic days 15 and 16, and brain tissue was collected from offspring on postnatal day (P) P60. Maternal LPS treatment reduced the number of successful pregnancies and reduced litter size compared to controls. Additionally, stereological analysis of young adult male and female offspring showed that LPS reduced mPFC neuron number, mPFC volume and white matter volume under the PFC (n=10-11 males and females per group). These results indicate that maternal infection can permanently alter the structure of this region and may further implicate a role for maternal infection in psychiatric illnesses characterized by PFC dysfunction.

Title: Generation of a Glia-Midbrain Neuron Co-Culture System Derived From Human Pluripotent Stem Cells

Authors: N. LEBLANC[1], J. WANG[1], J. CHAN[1], A. C. EAVES[1,2], S. A. LOUIS[1], *E. KNOCK[1];
[1]STEMCELL Technologies Inc., Vancouver, BC, Canada; [2]Terry Fox Laboratory, BC Cancer, Vancouver, BC, Canada

Abstract: Astrogliosis is a hallmark of Alzheimer’s and Parkinson’s diseases, and astrocytes and microglia play key roles in both neurodevelopment and neuroinflammation. To allow

investigation of neuron-glia interactions in the context of disease modeling, we developed STEMdiff™ Midbrain Neuron and STEMdiff™ Astrocyte Differentiation and Maturation Kits to efficiently generate functional hPSC-derived midbrain neurons and astrocytes. hPSC-derived neural progenitor cells (NPCs) generated using the STEMdiff™ Neural Induction kit monolayer protocol were either plated into STEMdiff™ Astrocyte Differentiation Medium or STEMdiff™ Midbrain Neuron Differentiation Medium. Astrocytes were passaged every week using the recommended protocol. On the third passage, the medium was replaced with STEMdiff™ Astrocyte Maturation Medium and similarly maintained for an additional two weeks. Midbrain neurons were passaged after one week into STEMdiff™ Midbrain Maturation Medium and cultured for an additional two weeks. Cell identity was confirmed using immunocytochemistry for S100β, GFAP, and DCX (astrocytes), or BIIITUB and TH (midbrain neurons). We then co-cultured the astrocytes and neurons for one week. Our data show that using STEMdiff™ Astrocyte Differentiation and Maturation Kits can result in a highly pure population of astrocytes (S100β: 72.0% ± 20.4%; GFAP: 33.8% ± 30.0%; DCX: 0.8% ± 1.5%; n = 6). Our STEMdiff™ Midbrain Neuron Differentiation and Maturation Kits produce a subpopulation of BIIITUB+ neurons expressing tyrosine hydroxylase (TH), the enzyme implicated in dopamine biosynthesis (BIIITUB: 93.46% ± 6.93; TH: 16.57% ± 10.67; n = 13). Functional data using MEA show electrical activity up to 6 months in culture (up to 0.85 ± 0.33 Hz mean firing rate). Interestingly, after one week of co-culture, the number of BIIITUB-positive and TH-positive neurons was higher in the astrocyte co-culture group than in the neuron-only control (BIIITUB: 2.76 ± 1.50-fold higher, P = 0.0003; TH: 2.63 ± 0.99-fold higher, P=0.01; n = 6, unpaired t-test), which indicates co-culture with astrocytes could lead to better survival and maturation of neurons in vitro. These data show that STEMdiff™ Midbrain Neuron Differentiation and Maturation Kits can generate functional hPSC-derived dopaminergic-midbrain neurons, which, used alongside STEMdiff™ Astrocyte Differentiation and Maturation Kits, create co-culture models suited for in vitro studies of neurodegeneration.

Title: Muscarinic acetylcholine type 1 receptor antagonists augment mitochondrial function through AMPK in human neuroblastoma cells

Authors: *F. NAZNIN, P. FERNYHOUGH;
Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Introduction Impairments in mitochondrial physiology play a vital role in the progression of multiple degenerative conditions in diabetes, such as diabetic peripheral neuropathy, and activation of muscarinic acetylcholine type 1 receptor (M1R) has been linked with mitochondrial dysfunction. In rodent models of diabetes, inhibition of M1R in sensory neurons induced AMP-activated protein kinase (AMPK) activity and nerve regeneration. We *hypothesized* that specific (muscarinic toxin 7; MT7) and selective (pirenzepine; PZ) antagonists of M1R, would enhance AMPK activity and contribute to augmentation of mitochondrial function in human neuroblastoma SH-SY5Y cells. This comprehensive study aimed at evaluating mitochondrial parameters including oxygen consumption rate (OCR), mitochondrial membrane potential (MMP) and expression of component proteins of the mitochondrial complexes (OXPHOS).
Methods SH-SY5Y cells expressing M1R were treated with different doses of M1R antagonists (PZ and MT7) at different time points in the presence or absence of inhibitors or siRNAs of AMPK. Cellular bioenergetic status was assessed using a Seahorse Biosciences XF-24 Analyzer. The intracellular MMP was evaluated by using a fluorescent dye (JC-1) and the fluorescence intensity was measured by microplate reader. Expression analysis of AMPK and OXPHOS proteins was done by Western blot. Data are reported as the mean ± SEM, and one-way ANOVA with Tukey's or Dunnett's multiple comparison post-hoc tests were applied. A value of $p<0.05$ was considered statistically significant.
Results Both PZ and MT7 treatment in SH-SY5Y cell culture significantly increased AMPK phosphorylation in a dose-dependent manner at different time points. Mitochondrial protein expression (OXPHOS) and OCR (including parameters for maximal respiration and spare respiratory capacity), ATP production. MMP were also augmented in PZ and MT7 treated cells. Exposure to PZ for 6-h increased the MMP with earlier time points without effect. Compound C or AMPK (α1 and α2)-specific siRNA suppressed the PZ or MT7 induced elevation of mitochondrial function and MMP.
Conclusion. PZ and MT7 treatment in SH-SY5Y cells improved mitochondrial function through a M1R-modulated pathway involving activation of AMPK and may represent a potential therapeutic target to regulate mitochondrial function and nerve regeneration in diabetic neuropathy.

Title: Chronic alcohol exposure following TLR3 agonist changes neuroimmune genes expression in the insular cortex and nucleus accumbens of female rat brains

Authors: *W. LIU[1], K. J. VAN VOORHIES[1], J. LIU[1], J. BESHEER[2];
[1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Psychiatry; Bowles Ctr. for Alcohol Studies, Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Chronic alcohol consumption can result in permanent damage to brain, and promote changes in the expression of neuroimmune genes. Toll-like receptors (TLRs) are key components of neuroimmune activation. Our previous study showed that treatment with poly(I:C), a TLR3 agonist, escalated alcohol self-administration. The goal of the present study was to examine the effects of chronic alcohol treatment on neuroimmune signaling triggered by TLR3. Female Long Evans rats were randomly assigned to two groups. Alcohol group was administered ethanol (5 g/kg, i.g.) once daily for 14 days, control group with water. General locomotor activity was assessed following the 13th day of alcohol exposure in the open field test. Chronic alcohol exposure decreased both the percentage of center time and total activity in the open field relative to the water group. Rats were allowed to withdraw for 24 hours after last alcohol exposure. Both control and alcohol groups were subdivided into two groups matched on body weight. One group was injected with poly(I:C) (3 mg/kg, i.p.), and another with saline. All rats were sacrificed 24 hours after poly(I:C). To investigate the effect of poly(I:C) following chronic alcohol exposure on neuroimmune gene expression, TLR3, TLR7, IRF3, IRF7, IL1β, IL6, TNFα, CD11b and GLT-1 were examined in the anterior insular cortex (IC) and nucleus accumbens core (AcbC) using RT-qPCR. Our studies found that poly(I:C) increased TLR3 and TLR7 gene expression in both IC and AcbC. Alcohol-poly(I:C) significantly potentiated alcohol-induced increase in TLR3 and TLR7 in the IC. Chronic alcohol exposure and poly(I:C) upregulated TNFα gene expression, and chronic alcohol exposure potentiated TLR3 activation-induced increase in both IC and AcbC. Poly(I:C) significantly increased IRF7 gene expression in the IC and AcbC, chronic alcohol exposure potentiated IRF7 expression in the IC, but not in AcbC. IL1β, IL6 and IRF3 gene expression were not changed in the IC or AcbC. CD11b, a myeloid cell integrin receptor which are expressed by both macrophages and microglia, were increased by chronic alcohol and poly(I:C) in the IC and AcbC. TLR3 activation enhanced alcohol-induced CD11b gene expression in the IC, but not in AcbC. Upregulation of the astroglial glutamate transporter GLT-1 was observed in the IC following chronic alcohol exposure, and the increase in GLT-1 gene expression was blunted by TLR3 activation in the IC,

and not changed in the AcbC. These findings indicate that TLR3 activation can potentiate chronic alcohol-induced changes in neuroimmune gene expression, which varies in the IC and AcbC, two regions known to be involved in modulating alcohol drinking.

Abstract: Approximately 10% of patients who are treated for Lyme Disease (LD) continue to have persistent symptoms, known as Post-Treatment Lyme Disease (PTLD). Patients with PTLD often report lingering cognitive difficulties, such as poor memory and “brain fog”. Few neuroimaging studies have been conducted with PTLD patients, however, to understand the underlying mechanisms of these cognitive symptoms. The hippocampus is a brain region that has been associated with learning and memory and is a major component of cognition. Therefore, this study used voxel-based morphometry (VBM) to assess whether gray matter (GM) changes in the hippocampus were associated with cognitive performance in PTLD. Twelve human participants’ structural brain images were obtained via magnetic resonance imaging, including 7 men and 5 women, with an average age of approximately 45 years, and education level of approximately 16 years. Their mean duration of illness was 2.6 years. They were administered standard neuropsychiatric tests related to verbal recall, working memory, and processing speed. An exploratory VBM analysis of GM volume in the hippocampus was conducted using hippocampal masks to delineate CA1, CA2, CA3, dentate gyrus, entorhinal cortex, and subiculum sub-regions. GM within these sub-regions were compared to cognitive performance. Results revealed negative associations between hippocampal gray matter and delayed verbal memory recall, digit span, and processing speed. These associations were strongest in the subiculum. These results suggest that hippocampal GM increases were associated with lower cognitive function. Further research is needed to understand these underlying mechanisms, and how interventions can aid the treatment of cognitive difficulties in PTLD.

Title: Oxidative stressors induced glycan modifications of extracellular vesicles derived from HT22 murine hippocampal cells

Authors: *T. SATO[1], A. SHIMODA[2], N. MIYANISHI[3], T. NEDACHI[2];
[2]Grad. Sch. of Life Sci., [3]Grad. Sch. of Food and Nutritional Sci., [1]Toyo Univ., Gunma, Japan

Abstract: It is widely accepted that oxidative stress has been implicated in the progression of neurodegenerative diseases. We have previously revealed that the protein/RNA contents of extracellular vesicles (EVs) released from HT22 murine hippocampal cells was significantly altered by oxidative stress. On the other hands, although glycan modification of EVs is crucial for their internalization into the target cells, the impact of oxidative stress on glycan modification of EVs has not been well understood. In this study, we established a new method for analyze surface glycosylation of EVs released from HT22 cells and investigated the impact of oxidative stress on the glycosylation. HT22 cells were cultured with or without 250 μM H_2O_2 for 48 hours and the released EVs were purified by using the ultracentrifugation methods. The purity of EVs was then routinely confirmed by western blotting, transmission electron microscopes, and nano particle analysis. In order to analyze surface glycans of EVs, we used the permethylation method to replace all reactive glycan hydrogens into methyl groups, and the permethylated glycans were analyzed by using MALDI/TOFMS analysis. This method was suitable for robust analysis of small amounts of glycan samples, such as purified EVs. The results indicated that both the N-linked glycan and O-linked glycans in EVs contained sialic acids, and the proportion of sialylated glycan in EVs was significantly increased by oxidative stress. To elucidate physiological roles of this glycan modification of EVs, we measured the uptake of control EVs or EVs rich in sialic acids, into HT22 cells. In brief, HT22 cells were treated with PKH26-labeled EVs for 24 hours, and the uptake of EVs into HT22 cells was monitored by fluorescence microscopy. Control EVs were effectively incorporated into HT22 cells, whereas little amounts of EVs rich in sialic acids were uptaken by the cells. Overall, these suggested that the glycosylation of EVs released from HT22 cells were tightly engaged to oxidative states of the cells, and the modification of EVs possibly regulated their incorporation into the target cells. Given that the release and incorporation of EVs in central nervous systems were important for

the progression of several neurodegenerative diseases, the glycan modification of EVs may be an attractive therapeutic target as wells as an useful biomarker for neurodegenerative diseases.

Abstract: Inflammation is a critical component for the return to homeostasis post insult or injury; however, inflammation in the central nervous system (CNS) can lead to irreparable damage. The balance between pro- and anti-inflammation in the CNS rapidly shifts towards a neurotoxic proinflammatory state during neurodegenerative diseases such as Alzheimer's Disease (AD) or Multiple Sclerosis (MS). These dramatic inflammatory responses are also coupled with extensive blood brain barrier (BBB) leakage and breakdown. This BBB breakdown enables the entry of leukocytes, including neutrophils, which mediate early inflammatory responses and modulate pathogenesis of both AD and MS. We propose a unique mechanism by which circadian regulation of CXCL5 in astrocytes allows for tight temporal and spatial control over these mechanisms. CXCL5 is a potent chemokine that both induces BBB breakdown and neutrophil chemotaxis - two immune responses critical during neurodegeneration. Our preliminary data shows clear circadian rhythms in *Cxcl5* expression in astrocytes, and that deletion of the circadian transcription factor *Bmal1* in astrocytes causes a striking increase in CXCL5 expression, an effect that is exacerbated in an AD mouse model. We will use both an astrocyte specific *Bmal1* knock-out (KO) and CXCL5 overexpression to address the role of astrocytic CXCL5 in different models of neuroinflammation. Ultimately, we hope to better understand if circadian regulation of astrocytic CXCL5 levels mediates daily rhythms in neutrophil recruitment into the brain, and how disrupting this influences CNS immune responses and BBB integrity in mouse models of AD and multiple sclerosis.

Title: Characterizing the Role of IFNβ in Neuronal Injury Induced by HIV-1

Authors: *H. SINGH, J. KOURY, R. MAUNG, M. KAUL;
Univ. of California, Riverside, Riverside, CA

Abstract: The HIV-1 virus can enter the central nervous system (CNS) early in infection and continues to cause HIV-associated neurocognitive disorders (HAND). This is of global concern as 38 million people worldwide are diagnosed with HIV, and an estimated 50% of people living with HIV develop HAND. The pathogenic mechanism of HAND and HIV-associated dementia (HAD), the most severe neurological complication of HIV/AIDS, remains incompletely understood, and there is no specific treatment available. One model that shares key features of neuropathology, differential gene expression, and impaired learning and memory with people living with HIV and HAND/HAD and encephalitis (HIVE) is a transgenic (tg) mouse expressing the HIV envelope glycoprotein gp120 (HIVgp120) in the CNS under the control of the glial fibrillary acidic protein (GFAP) promoter in astrocytes. Interferons (IFNs) play a major role as the first line of host defense against HIV in the brain. Our microarray study revealed that brains of HIVgp120tg mice share a significant fraction of differentially regulated genes with HIV and HIVHIVE patients with neurocognitive impairment, including transient expression of genes induced by interferon-β (IFNβ). We have demonstrated that intranasal treatment with IFNβ prevents in vivo neuronal damage triggered by HIVgp120, and our in vitro experiments showed that neuroprotection depended on IFNAR1 and CCL4. However, in the absence of protective amounts of IFNβ, IFNAR1 (the receptor for type I IFNs) can contribute to neuronal injury in the presence of HIVgp120. To characterize the role of endogenous IFNβ, we cross-bred HIVgp120tg with IFNβ knockout (IFNβKO). The brains of these mice were analyzed for hallmarks of HIV-induced neuropathology and gene expression. While the IFNβKO did not overall worsen the neuropathology, it was critical for the upregulation of IRF7, -9, and RIG-I, but not IRF3, in

HIVgp120tg brains. Thus, endogenous IFNβ contributes to the innate immune response of the brain but is insufficient to prevent neuronal injury in the long-term.

Title: Nimodipine inhibition of spreading depolarization: metabolic dependency in brain slices

Authors: *M. BENNETT[1], J. WEISEND[1], A. CARLSON[2], C. SHUTTLEWORTH[1];
[1]Neurosci., [2]Neurosurg., Univ. of New Mexico, Albuquerque, NM

Abstract: Introduction: Spreading depolarizations (SD)s have recently been identified as key contributors to progression of acute brain injuries, but specific mechanisms of neuronal injury after SD remain incompletely explained. Prior work showed that L-type calcium channel antagonists (including nimodipine) can reduce the initiation and propagation of SD, due to block of neuronal Zn^{2+} accumulation. However that prior work could not address neuronal injury as, under control conditions with adequate substrate supply, neurons recovered fully after each SD. The goal of the present study was to explore L-type channel involvement in conditions that model the vulnerable ischemic penumbra. **Methods:** SD was induced in the hippocampal CA1 region of murine brain slices, and SD progression and swelling monitored with intrinsic optical imaging, extracellular recordings of DC potential shifts and field excitatory postsynaptic potentials (fEPSPs). Responses in control conditions were compared with metabolically compromised conditions, using flow restriction as previously described (Exp Neurol 305 (2018) 121-128). **Results:** As previously reported, reduction in metabolic substrate availability conferred vulnerability to neuronal damage after SD. Thus, in control conditions, SD caused a brief period of synaptic silencing followed by full recovery, whereas metabolically compromised slices did not recover after a single SD. In vulnerable slices, SD led to persistent inhibition of fEPSPs and a marked decrease in IOS signal that is attributed to structural disruption. Nimodipine pre-exposure (10μM) prevented deleterious effects of SD in compromised slices. fEPSPs recovered, and IOS decreases were prevented (27.5% decrease vs 10.97% increase at 10 min post-SD, $P<0.02$, n=6-8). Nimodipine also reduced the second phase of SD-induced DC shift to near control levels ($P=0.0049$; n=6-8) as well as reduced overall duration of DC shift ($P=0.0464$; n=6-8). Like nimodipine, zinc chelation via TPEN (50μM) also resulted in slice

recoverability following SD in vulnerable slices. Conclusions: These results suggest that L-type channels can be involved in damaging effects of SD in metabolically compromised tissue. Zn^{2+} is released at high levels during SD, and prevention of neuronal Zn^{2+} and Ca^{2+} overload following SD, while avoiding hypotensive or other deleterious effects, could provide a useful additional approach to limit damaging effects of SD in stroke and other injuries. Title: Basal Excitability and CaMKII mediate SD induced Potentiation

Authors: *J. WEISEND[1], A. CARLSON[2], C. W. SHUTTLEWORTH[1];
[1]Neurosciences, [2]Neurosurg., Univ. of New Mexico, Albuquerque, NM

Abstract: Spreading depolarizations (SDs) are transient recurring waves of extended depolarization associated with stroke. SD can generate long lasting synaptic potentiation, but mechanisms and pathophysiological relevance are unestablished. We examined mechanisms of synaptic potentiation in conditions modeling either vulnerable tissue contributing to infarct expansion or healthy peri-infarct tissue. Focal microinjection of KCl initiated SDs in the hippocampal CA1 subregion of murine brain slices. Intrinsic optical signals (iOS) were recorded to monitor SD propagation and tissue swelling. Field excitatory postsynaptic potentials (fEPSPs) were fully recoverable after SD in control recording conditions, but persistent synaptic depression and iOS depression (both signaling tissue injury) was seen in recording conditions where metabolic substrate supply was reduced by flow restriction (Exp Neuro 305 (2018) 121-128). In control conditions, a single SD produced the well-described transient abolition of fEPSP (~10 min), and was followed by recovery to a potentiated level (125.4% ± 17.5 at 30 min post-SD, n=18). Studies of repetitive SDs showed that synaptic potentiation was saturated after a single SD. Tissue swelling, a potential confound, was resolved ~12 min after SD, and neither peak swelling nor recovery rates correlated with the degree of sustained potentiation. Adenosine accumulation after SD delays fEPSPs recovery and may mask the degree of potentiation.

However adenosine accumulation typically resolves in ~10min, and pre-exposure with the adenosine A1 receptor antagonist DPCPX (300nM), did not unmask additional potentiation (n=6). Potentiation was unaffected by an inhibitor of protein kinase C activity (K252a, 200nM), but was significantly reduced by an inhibitor of Ca^{2+}/calmodulin-dependent protein kinase II (Arcyriaflavin A, 250nM, n=6, $p<0.05$). In metabolically compromised tissues SD is followed by persistent suppression of fEPSPs. This is partly due to persistent adenosine accumulation, as DPCPX recovered fEPSP amplitude towards baseline values, but did not unmask persistent potentiation. These data suggest a single SD saturates long-term plasticity and that this could involve CaMKII-dependent signaling, as described previously for experimentally-evoked LTP in this preparation. SD induced synaptic strengthening is evident in control conditions that model peri-infarct tissue destined to survive following stroke, but absent in conditions that model expansion of an infarct core. These findings provide a basis for future studies of whether SD-induced plasticity may contribute to adaptation and recovery around stroke lesions.

Title: Identification of neuronal injury and survival pathways after spreading depolarization using transcriptome sequencing

Authors: *M. DELL'ORCO[1], J. WEISEND[1], N. PERRONE-BIZZOZERO[1], R. A. MORTON[1], A. CARLSON[2], C. W. SHUTTLEWORTH[1];
[1]Neurosciences, [2]Neurosurg., Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Spreading depolarization (SD) is a slowly propagating wave of profound depolarization that sweeps through cortical tissue. SD is not harmful to healthy brain tissue, but can cause irrecoverable injury to metabolically compromised tissue, exacerbating acute brain injuries. SDs occur in stroke brain, usually originating near ischemic foci and propagating throughout peri-infarct and surrounding tissue leading to tissue loss. Previous studies have shown changes in expression levels of genes known to regulate synaptic plasticity and neurogenesis following SD. This study aimed to perform an extensive, unbiased analysis to identify a more complete range of biological pathways modified by SD using RNAseq. SDs were induced repetitively (4 SDs in 2 hours every 30 min) in healthy, female mice and confirmed with

Intrinsic Optical Signal imaging. SD induction was with either focal application of KCl (NaCl for sham controls, n=6) in C57Bl/6 mice or with optogenetic stimulation (2 mW for 20 sec) in Thy1-ChR2-YFP mice (n=6). Two hours after onset of the initial SD, total cortical RNA was extracted and subjected to Illumina paired-end RNAseq to identify differentially expressed (DE) genes (fold change >1.25, p value <0.05). We identified 122 significantly upregulated genes after KCl-induced SDs and 169 after optogenetic induction; of these 63 genes (27.6%) where in common. Consistent with previous studies, top DE genes include the neurotrophic factor BDNF and VGF, as well as intermediate early genes ARC, FOS, JUN and EGR. Among other DE genes with significantly increased levels include HOMER1, COX2, ADRB1, NR4A1 nuclear receptor, COX2, DUSP gene family, GABRB3 GABA receptor, and KCNJ2 potassium channel. Through pathway analysis we found significant increases in the expression of genes associated with axogenesis, branching of axons, neuritogenesis, dendritic growth, and regeneration of neurites. Upstream analysis also showed significant activation of MAPKs signaling. Interestingly, we also found a significant decrease in the expression in genes associated with cell death, apoptosis and neuronal degeneration. These results indicate that SD in healthy tissues causes relatively rapid upregulation of pathways that could potentially be involved in plasticity or circuit modification. Additionally, downregulation of pathways involved in neuronal injury could contribute to previous reports of ischemic preconditioning by SD. These results also identify a range of novel targets that could be used to test whether clusters of SD may enhance plasticity or recovery in surviving peri-infarct tissue, in addition to the well-established role of SD in expansion of the infarct core.

Title: A hemolysis assay to detect release of a molecular activator of spreading depolarization

Authors: C. LOWRY[1], B. M. BENNETT[1], R. D. ANDREW[2];
[1]Queens Univ., Kingston, ON, Canada; [2]Queen's Univ., Kingston, ON, Canada

Abstract: The channel that opens to drive spreading depolarization (SD) may not be a conventional channel under normal physiological conditions, one reason why it has eluded identification for +30 years. The Na^+/K^+-ATPase (the pump) is a transporter that normally shuttles cations across the neuronal plasma membrane. But when brain tissue loses blood flow, we hypothesize that a chemical activator is released which binds to the pump, converting it into an open channel that then drives SD. To test this concept of a released SD *activator* (SD*a*), we collected samples (containing putatively released SD*a*) from live brain slices undergoing SD evoked by simulated ischemia (O_2/glucose deprivation, OGD). After slices were removed, the artificial cerebrospinal fluid (aCSF) that bathed the slices was superfused over a healthy slice. SD was evoked in ~64% of these naïve slices, and this was not a result of elevated K^+ released by the slices. While this is a crude bioassay for SD*a* release, a higher throughput assay would be useful to help isolate and identify the SD*a*. Palytoxin (PLTX) is a marine poison. Its potency converting the Na^+/K^+-ATPase into an open channel can be measured using an hemolysis assay (Habermann et al. 1981). That is, pump molecules on the red blood cell (RBC) are converted to an open channel by PLTX binding. The RBCs swell and burst, releasing hemoglobin which is then colorimetrically assayed. If our SD*a* acts like PLTX, then SD*a* samples should induce RBC hemolysis. First, we replicated the Habermann RBC bioassay, generating a concentration-response curve for log [PLTX] vs % hemolysis ranging from [PLTX] = 0.01 to 1 nM. Hemolysis by 0.03 nM PLTX was increasingly inhibited by 100 to 500 μM ouabain which competes with PLTX binding at the Na^+/K^+-ATPase. Next, we tested the hemolytic activity of our SD*a* fractions. Hemolysis significantly increased in tubes containing aCSF which had bathed slices that generated SD (`post-SD` aCSF) as compared to pre-SD aCSF (n=4; $p<0.0001$).The latter evoked half the hemolysis of post-SD aCSF. This was repeated and replicated using slices in aCSF where SD was induced with brief hyperthermia (44°C). These data indicate a PLTX-like hemolytic effect by a compound released from those brain slices undergoing SD. Interestingly, the hemolytic efficacy of the putative SD*a* required a small priming amount of PLTX (.01 nM) which itself evoked only minimal hemolysis. These data support our previous electrophysiological work implicating the release of a molecule from metabolically stressed gray matter that promotes SD by converting the Na^+/K^+-ATPase from transporter to open channel in a PLTX-like fashion.

Title: Tissue-scale computer modeling of spreading depolarization, ischemia and cytotoxic edema

Authors: *C. KELLEY[1], A. J. H. NEWTON[2], M. L. HINES[3], R. A. MCDOUGAL[4], W. W. LYTTON[5];
[1]Biomed. Engin., SUNY Downstate Hlth. Sci. Univ., Brooklyn, NY; [2]Dept. of Pathology, Yale Sch. of Med., New Haven, CT; [3]Neurosci., [4]Ctr. for Med. Informatics, Yale Univ., New Haven, CT; [5]Dept. of Physiol. & Pharmacol., SUNY Downstate, Brooklyn, NY

Abstract: Spreading depolarization (SD) is characterized by a breakdown in the homeostatic maintenance of intracellular and extracellular ion concentrations, leading to a wave of depolarization spreading slowly through a neuronal population at 2-7 mm/min with a period of neuronal silence lasting minutes following in its wake. SD at the cellular level produces the spreading depression seen in extracellular field potentials. Using the NEURON simulator and its reaction-diffusion module, we developed tissue-scale models 0.125 - 1.0 mm^3 in size that include neurons with dynamic volumes in realistic densities, extracellular diffusion of ions and O_2, and glial buffering of extracellular K^+. We modeled SD for *in vitro* (O_2 diffuses into tissue from bath solution) and *in vivo* (O_2 replenished throughout tissue) environments, normoxic (0.04 mM O_2, extracellular volume fraction (α) 0.2, extracellular tortuosity (λ) 1.6) and ischemic (0.01 mM O_2, α= 0.07, λ= 1.8) conditions, and in presence of cytotoxic edema (cell swelling). SD was initiated by elevating extracellular K^+ (20-40 mM; 200 μm diameter) in a central core. Realistic neuronal surface:volume ratio (S:V) greater than 1 μm^{-1} was essential for producing SD with observed speeds, and SD wave speed increased roughly linearly with S:V. In the ischemic *in vitro* condition (neuronal volume fraction 0.24), SD could not be initiated with S:V= 0.02 μm^{-1}. The SD wave traveled at 1.2 mm/min with S:V= 1.0 μm^{-1}, 2.4 mm/min with S:V= 2.0 μm^{-1}, 4.8 mm/min with S:V= 3.0 μm^{-1} which is typical of cortex, and 6.0 mm/min with S:V= 4.0 μm^{-1}. SD wave speed is also dependent on tissue oxygenation, traveling at 2 mm/min in the normoxic state and 4.8 mm/min in the anoxic state when SA:V= 3 μm^{-1}. In the *in vivo* environment, the thresholds of required core size and elevated extracellular K^+ were higher in the normoxic condition than in ischemic conditions. Furthermore, when there was an ischemic core with cytotoxic edema but no initially elevated extracellular K^+, SD initiated spontaneously within 4 seconds then traveled at a speed of 1.8 mm/min. Our model demonstrated how imbalances in extracellular K^+ concentration, alterations to the extracellular space from edema, and impaired tissue oxygenation during ischemia produce SD. Using this approach to study SD, we can bridge the gap between empirical findings from SD elicited in experimental settings and SD associated with neurological conditions like ischemic stroke, traumatic brain injury, and migraine aura.

Title: Probing the mechanism of rapid guanosine release during ischemia

Authors: *M. E. WEESE, A. E. ROSS;
Chem., Univ. of Cincinnati, Cincinnati, OH

Abstract: Guanosine is a purinergic signaling molecule implicated in a range of neuroprotective functions, including ischemia. While adenosine's role in neuroprotection has been investigated, guanosine's role remains largely unknown. Guanosine is released rapidly following injury to reduce damage and prevent glutamate excitotoxicity. Similarly, guanosine minimizes reperfusion injury and greatly decreases the amount of infarct tissue following ischemic attack. Our lab recently discovered spontaneous transient guanosine release in the CA1 of the hippocampus, which increases significantly in concentration during ischemia. Despite this work, the mechanism of rapid release and the extent to which release is impacted during ischemia remains unknown. Here, we investigate guanosine's rapid release mechanism in both normoxic and ischemic conditions *ex vivo* using fast-scan cyclic voltammetry (FSCV). Mechanistic information was determined by evaluating the impact of Ca^{2+} chelation, voltage-gated Na^{+} channel blockage, inhibition of GTP hydrolysis, and adenosine A_1R antagonism on transient guanosine release. On average, guanosine transients are 222 ± 59 nM per event, last approximately 0.93 ± 0.05s, and occur approximately every 37 ± 7.3 s. Calcium chelation significantly decreased the frequency of guanosine events during normoxia and the events that remained were longer in duration (n = 16, $p < 0.0001$). These results indicate vesicular release drives the primary release mechanism. Preliminary work from the competitive inhibition of extracellular GTP hydrolases suggests both direct guanosine and GTP release. Understanding the mechanism of rapid guanosine release under both healthy and ischemic conditions will provide insight into guanosine's neuroprotective properties and open pathways for understanding its role during ischemia.

Title: Spontaneous release of hippocampal guanosine during normoxia and ischemia

Authors: *M. T. CRYAN, A. E. ROSS;
Dept. of Chem., Univ. of Cincinnati, Cincinnati, OH

Abstract: Guanosine is an important neuromodulator that is believed to protect the central nervous system during chemical injuries like stroke and ischemia. Previous reports have supported slow release of guanosine in response to chemical injury over the course of hours to days using liquid chromatography and microdialysis; however, it is not currently known if guanosine signals on a more rapid timescale in immediate response to these kinds of injuries. In this study, we used fast-scan cyclic voltammetry (FSCV) to electrochemically detect and characterize subsecond release of guanosine in the hippocampal CA1 region of the *ex vivo* rat brain. Guanosine transient release was quantitated under normal conditions and during a period of global ischemia. Transient event concentration and duration were significantly increased during the ischemic period. Guanosine was also shown to be released in a more burst-like, clustered fashion during ischemia compared to normoxic conditions. These changes in release behavior during ischemic stress gave rise to an overall increase in total guanosine concentration in response to tissue injury. POM1, an NTPDase inhibitor which blocks the breakdown of purine triphosphates to their ribonucleoside form, was used to support the observed transients as purinergic in nature and explore direct release of guanosine. The number of transient events was reduced during administration of POM1 compared to the predrug control. Total guanosine concentration was also lowered, implying that most transient guanosine is a result of breakdown from GTP. We report the first measurements of rapid guanosine release during normal conditions and during episodes of ischemic stress characterized with FSCV.

Title: Refinement of cortico-rubro tract activity during long-term skilled motor learning and post-stroke rehabilitation

Authors: *H. GHUMAN, F. APARICIO, S. BARATI, K. GANGULY;
Univ. of California, San Francisco, San Francisco, CA

Abstract: Motor impairments after a stroke has been linked to the structural and functional integrity of the pathways that connect motor cortex and spinal cord. Besides the pyramidal tract (PT) in humans, alternate motor fibers (AMFs) have been suggested to play a key role in modulating recovery after stroke. In rodents, AMFs consist of the cortico-rubro-spinal and cortico-reticulo-spinal tracts. Lesioning of PT in rodents have shown to induce axonal sprouting of the cortico-rubro tract (CRT) neurons, but the precise role of CRT in skilled motor learning and execution remains poorly understood. Using retrograde labeling and head-mounted miniscope imaging, we first investigated the timing of when the CRT in primary motor cortex (M1) is recruited during learning a skilled reach-to-grasp task in free-behaving mice. We trained the mice for 10-12 weeks (250 trials/day, 5 days/week) to examine the stability of the CRT during long term motor learning and execution. We then induced a stroke in the secondary motor cortex (M2) of skilled mice using photothrombosis and investigated the interaction between CRT activity in M1 and functional recovery during post-stroke rehabilitation. In vivo calcium imaging of CRT neurons during motor task revealed a sequential activation of task-modulated neurons that remained task-engaged during long term learning. Improvements in task performance during early learning paralleled with the recruitment and activation of task-modulated CRT neurons. During the early (< 2 weeks) post-stroke rehabilitation, the motor performance of the skilled mice was severely impaired due to variable reach trajectories and unsuccessful grasps. The activity of the M1 CRT neurons during this period was significantly reduced and showed high inter-trial variability. During 8 weeks of post-stroke rehabilitation, task-modulated M1 CRT neurons again emerged that correlated to the functional recovery of the forelimb. These findings suggest that CRT plays a key role in modulating long term motor performance and recovery after a stroke.

Title: Change over time feature of recruitment of motor unit of the paretic muscle of hemispheric stroke during the recovery phase

Authors: *M. YOSHIDA[1,2], T. ITO[1], H. FUNAKOSHI[1], T. MASUDA[3], T. KOKUBUN[4];
[1]Grad. school of Saitama Prefectural Univ., Koshigaya, Japan; [2]Rehabil. Amakusa Hosp.,

Koshigaya, Japan; [3]Fukushima Univ., Fukushima, Japan; [4]Physical Therapy, Saitama Prefectural Univ., Koshigaya, Japan

Abstract: The paralysis after the stroke induces the abnormality of the motor unit (MU) recruitment pattern. Generally, normal MU is recruited according to the size principle and regulates a firing rate. However, chronic hemiparetic stroke recruits small MU selectively, and it has been reported that it regulates a firing rate. From these reports, we thought that we might clarify the recruitment process of MU of the paralysis if we tracked a change of MU after the stroke. This pilot study aims to investigate the features of the motor unit recruitment of the paretic muscle in the recovery period of hemispheric stroke. One stroke patient participated in this study. This study was approved by the ethics review committee. We measured the muscle activity of the biceps brachii using surface electromyography (Delsys. Inc) with six-time points at the recovery period after stroke. We also measured elbow flexure torque using a handheld dynamometer (HHD) simultaneously. The raw EMG data were decomposed into motor unit action potential (MUAP). Then mean firing rate (MFR) and peak amplitude of MUAP were calculated by decomposed MUAP. Additionally, coefficients and intercepts of the regression line were calculated by MFR and MUAP's peak amplitude. The coefficient of the linear regression line was adopted as the outcome to evaluate a range of the recruited MU size, and the intercept of the linear regression line was adopted as the outcome to evaluate the change of the mean firing rate of MU recruited early. The elbow joint maximum flexure torque was calculated by maximum torque and the forearm length. The standard deviation of the root means square (RMS) of the biceps brachii was calculated by EMG data before the decomposition. The change over time of each time point was evaluated by the changing of three elements; MU data (regression, coefficient, and intercept), elbow joint maximum flexure torque, and the standard deviation of RMS of the biceps brachii. The coefficient and intercept of the regression line, elbow joint flexure torque, and the standard deviation of RMS the biceps brachii showed the tendencies to increase over time. The time-dependent increase of the regression coefficient showed a restrictive MU recruitment pattern. In addition, the time-dependent change of the intercept of the regression line showed that the early recruited MU firing rate increased. This pilot study clarified the MU properties of change over time in the paretic muscle of hemispheric stroke. The features to recruit a small MU over time and to increase firing rates were observed. The MU recruitment pattern in the paralysis muscle of the patient with convalescence stroke changes over time and small MU is selectively recruited.

Title: Investigation of acute hyperglycemia on immune responses and stroke outcome after ischemic stroke

Authors: *H. CHEN[1], T. C. CHIANG[2], A. KIM[1], T. BLISS[3], M. Y. CHENG[2], G. K. STEINBERG[4];
[1]Stanford Univ., Palo Alto, CA; [2]Neurosurg., [3]Dept of Neurosurg, [4]Stanford Univ., Stanford, CA

Abstract: Background: Hyperglycemia occurs in over 40% of ischemic stroke patients, and exacerbates hemorrhagic transformation (HT) and worsens stroke outcomes. Previous rodent studies reported deleterious effects of hyperglycemia on stroke outcome during acute stroke (within hours to days), however, the impact of hyperglycemia during the subacute stroke period (days to weeks) remains unclear. Moreover, the mechanism of hyperglycemia worsening stroke outcome remains elusive. In this study, we investigated the effects of acute hyperglycemia on stroke outcome and its effect on the peripheral and central immune responses, in both the acute and subacute phase of ischemic stroke.Method: C57BL6 male mice were subjected to ischemic stroke by intraluminal middle cerebral artery occlusion (MCAO) for 30 min followed by reperfusion. Glucose was injected intraperitoneally 10 min before MCAO to induce hyperglycemia (HG). One cohort was sacrificed at 24hr (acute stroke phase), and brain infarct, hemorrhagic transformation and brain edema were quantified. Another cohort was allowed to survive for two weeks post-stroke (subacute stroke phase). Neurological deficits were assessed by neurological scores on post-stroke days (PD) 1, 3 and 7. Horizontal rotating beam tests were performed to evaluate motor-sensory functions on pre-stroke for baseline and PD 4, 7, 11 and 14. Peripheral and brain immune cells were analyzed by flow cytometry.Result: In the acute phase (24hr), hyperglycemia did not alter brain infarct volume but significantly induced brain edema and HT, indicating that hyperglycemia-enhanced brain edema and HT are independent of the brain infarct. In the subacute phase, hyperglycemia stroke mice exhibited greater body weight loss ($p<0.0001$) and significant increase in mortality: 100% of hyperglycemic mice died by PD 8 compared to 25% mortality for euglycemic mice ($p=0.0008$). Post-mortem results show that 100% of hyperglycemia mice had macro-visible HT. Hyperglycemia stroke mice also had worsened neurological deficit at PD 1, 3, and 7 ($p<0.001$), and significantly impaired performance on the rotating beam test compared to the euglycemia group. Our pilot data suggests that hyperglycemia increased myeloid cell infiltration into ischemic brains, including neutrophils and monocytic cells.Conclusion: Hyperglycemia adversely impacts stroke outcomes, with higher mortality and worsened functional deficit. Modulation of the post-stroke immune response may contribute to these detrimental effects of hyperglycemia. Understanding the mechanisms by which hyperglycemia exacerbates stroke injury will be important to improve clinical outcomes.

Title: Altered motor drive to the lower limbs in individuals with bilateral cerebral palsy during a step-up task: a pilot study

Authors: *V. GOYAL[1,2], T. SUKAL-MOULTON[2,3];
[1]Biomed. Engin., [2]Physical Therapy and Human Movement Sci., [3]Pediatrics, Northwestern Univ., Chicago, IL

Abstract: Individuals with bilateral cerebral palsy (CP) often experience a loss of selective voluntary motor control (SVMC) in the lower limbs, such as abnormal coupling between the hip adductors and sagittal plane extensors. Reduced SVMC ability is postulated to be a peripheral biomarker for damage to corticospinal tracts and upregulation of corticobulbospinal tracts in humans. Individuals with bilateral CP spend the majority of the inclined gait cycle in the stance phase, yet investigation into the loss of SVMC during this phase has been limited. The stance requirements of stair climbing include a high degree of coordination between the hip abductors and sagittal plane extensors, making this activity of daily living an ideal task to investigate abnormal extensor coupling. Progressive weighting of the limbs is a technique that has previously been used to test the limits of SVMC ability in cerebral palsy. Thus, we combined a step-up task with load modulation to investigate abnormal extensor coupling in individuals with bilateral CP.
We included 5 participants with typical development (one male aged 18 years, four females aged 6, 11, 14, and 19 years) and 1 participant with bilateral CP (male aged 15 years) in our pilot study. Participants were outfitted with reflective markers for motion tracking and instructed to step-up repeatedly onto a 4-inch platform mounted on force plates. Body weight was modulated from -20% to +15% in 5% increments using a weighted vest and the Zero-G. Data analysis focused on two stance phases: the push-off phase of stance, where the trailing leg is pushing the body up onto the platform, and the pull-up phase of stance, where the leading leg is pulling the body up onto the platform. To quantify a stereotypical adductor/extensor coupling, peak support moments (the sum of hip, knee, and ankle sagittal plane moments) and hip abduction moments at the time of peak support moments were identified for each stance phase. All joint moments were normalized to body weight and the zero-load condition for comparison.
Participants with typical development showed increases in peak support moment and concurrent hip abduction moment with increased load in both stance phases. However, the participant with bilateral CP showed an increase in peak support moment and a decrease in concurrent hip abduction moment with increased load in the push-off phase of stance. These early results

indicate that abnormal extensor coupling, possibly from use of extrapyramidal motor tracts, may challenge strategies during dynamic activities of daily living. We suggest that the experimental paradigm is useful to explore the limits of SVMC in a practical and functional context.

Title: Within-subject comparison of the neural activity patterns in premotor and somatosensory cortex pre- and post-ischemic injury to primary motor cortex in the rat.

Authors: *F. BARBAN[1,2], H. M. HUDSON[3], R. J. NUDO[3,4], M. CHIAPPALONE[1,2], D. J. GUGGENMOS[3];
[1]Italian Inst. of Technol., Genova, Italy; [2]Dept. of Informatics, Bioengineering, Robotics and Systems Engin., Univ. of Genoa, Genova, Italy; [3]Dept. of Rehabil. Med., [4]Landon Ctr. on Aging, Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Acquired brain injuries, such as stroke, are a leading contributor of long-term disability worldwide. When an injury occurs within primary motor cortex (M1) there is a loss of descending output information to the spinal cord, a disruption in the integration of somatosensory and motor planning inputs (from primary somatosensory cortex (S1) and premotor cortex (PM), respectively) and ultimately global changes in functional connectivity and activity between spared, interconnected regions throughout the brain. While the loss of integrative and descending information contributes to the severity of observed motor deficits, some motor recovery can and does occur in spite of the permanent loss of M1 inputs and outputs. It is likely that the neuroplastic changes and their evolution that occur in the previously connected, spared brain regions are critical for the recovery process. While these changes have been demonstrated through anatomical and motor representational analyses, it is unclear what changes in neural activity occur following an ischemic injury to M1 and how this activity contributes to motor impairment and recovery. To further elucidate this effect, we designed a within-subject experiment in which Long-Evans rats were trained to perform a skilled reaching task. Following task acquisition, each rat was chronically implanted with fixed, 32-channel intracortical microwires arrays in PM and S1. Two, 1-hour long behavioral sessions were taken while full-bandwidth neural activity was recorded from all electrode sites and synchronized to video feeds box sensors. Following these baseline sessions, an ischemic injury was induced in

M1 unilateral to the cortical implants through endothelin-1 injections. Two additional behavioral sessions were acquired at Day 4 and Day 7 post-injury. Neural activity was processed using custom tools to analyze both Local Field Potential and multi-unit activity within and between S1 and PM and synchronized with the reaching behavior. Preliminary results in the week immediately following ischemic injury suggest there is a global reduction in LFP power and variance a cross all bands. A disruption in the connectivity structure, estimated using power envelope correlation and phase coherence, was also revealed between the arrays implanted in PM and S1 after the lesion. These results offer direct evidence of the disruption in firing patterns within and between PM and S1 following M1 injury. Ultimately, this study will help us better understand the neural mechanisms underlying stroke recovery and possibly provide spatiotemporal stimulation targets for electroceutical rehabilitation therapies.

Title: Bihemispheric motor cortex connectivity to the jaw and tongue muscles after unilateral stroke in young and aged rats

Authors: M. J. CULLINS, N. P. CONNOR;
Dept. of Surgery, Univ. of Wisconsin, Madison, WI

Abstract: Introduction: Oral motor deficits, including dysphagia, commonly occur after stroke, yet the mechanisms of corticobulbar plasticity after stroke are not well understood. Due to the bihemispheric control of swallowing, it has been suggested that plasticity of the contralesional (intact) cortex drives recovery of swallowing. Age may be an important factor in that stroke most commonly occurs in aged individuals, age is an independent predictor of dysphagia after stroke, and neuroplasticity may be reduced with age. We sought to determine the impact of unilateral stroke and age on oromotor cortical plasticity by examining the volume of the sensorimotor cortex that activates the jaw and tongue muscles in both hemispheres. **Methods**: Using the middle cerebral artery occlusion rat stroke model, intracortical microstimulation (ICMS) was

used to map regions of sensorimotor cortex that activate tongue and jaw muscles in both hemispheres. Larger cortical maps suggest greater functional connectivity. Young adult (7 mo) and aged (30 mo) F344xBN rats underwent either a stroke via left middle cerebral artery occlusion or a control sham surgery, followed by ICMS mapping 8 weeks later. N = 11 aged stroke, 8 aged sham, 13 young stroke, 13 young sham. **Results**: The volume of sensorimotor cortex that activates the tongue in the ipsilesional (damaged) hemisphere was reduced with stroke in the aged group (aged sham = 4.73 mm^3, aged stroke = 0.85 mm^3, $p < 0.001$), but failed to reach significance in the young group (young sham = 4.36 mm^3, young stroke = 3.04 mm^3, $p = 0.124$). Previous studies found that swallowing bolus area was reduced with stroke. In this study, within the aged stroke group, bolus area was correlated with the volume of cortex activating the tongue in the ipsilesional hemisphere (Pearson's $r = 0.74$, $p = 0.008$). Stroke in the aged group was also associated with an increased jaw representation in the contralesional hemisphere ($p = 0.009$). Both age groups exhibited increased stimulation thresholds in the ipsilateral hemisphere (young $p = 0.007$; aged $p = 0.007$). No significant differences in motor map size with age were found within the sham group. **Conclusion**: Unilateral MCA stroke is associated with a significant loss of functional connectivity between the sensorimotor cortex and the tongue muscles, which is greater with age. This reduced cortical input is likely to represent reduced volitional control of the lingual musculature. An increase in the jaw representation in the intact hemisphere is in agreement with studies that have suggested a role for contralesional cortical plasticity in the recovery of oral motor function after stroke.

Title: Comparison of stroke induction procedures on olfactory discrimination and performance in mice

Authors: T. O. COTHREN, J. T. HOLSTEN, K. B. PRESCOTT, T. C. PETERSON, *D. A. MACQUEEN, III;
Psychology, Univ. of North Carolina Wilmington, Wilmington, NC

Abstract: Stroke is a leading cause of disability in the United States. A stroke can cause both physical and cognitive deficits. Levels of impairment on physical and cognitive functioning depend on the brain structures affected by the stroke. The current study compared the behavioral effects produced by two different stroke induction procedures on an automated Odor Discrimination Task (ODT). Twelve C57BL/6J mice were trained to stability on the ODT, which

consists of five odors assigned as target stimuli and one odor assigned as a non-target. Across a series of trials, mice are required to lick in response to target-odors to receive a sucrose reward, and to inhibit licking in response to the non-target odor. Measures derived from the ODT allow for the evaluation of both sensorimotor and cognitive effects. Following training, subjects were counterbalanced into groups based upon performance. Each subject received either a sham operation (n = 4), a photothrombotic stroke (P stroke; n = 4), or a distal middle cerebral artery occlusion (dMCAO; n = 4). The dMCAO models the most common type of ischemic stroke observed in humans. The photothrombotic stroke surgery utilized administration of a light-sensitive dye (Rose Bengal) and a high intensity light stereotactically placed above the primary motor cortex to create microcoagulation. Measures derived from the ODT include sensitivity index, responsivity index, trials completed, short samples (trials terminated prematurely), lick density, hit rate, and correct rejection rate. A 2-way ANOVA of time by condition was used to analyze data for each response parameter. There was a significant time X condition interaction for trials completed (p = 0.008), hit rate (p = 0.007), and lick density during the initial odor exposure period ($p < 0.001$). Only P stroke led to significantly greater lick density (during the odor release period) compared with baseline; observable on post-surgery day 1 and points up to 2-weeks following surgery. All groups exhibited significant decreases from baseline in trials completed at various points within the post-surgery period. No group evidenced significant differences from baseline with regard to hit rate. Though photothrombotic stroke procedures induced a transitory impact on lick density, performance was similar across conditions by the conclusion of the study (28 days). The lick monitoring procedures of the ODT can be used to detect differential motoric effects of stroke induction procedures.

Title: Large Vessel Stroke as a Presenting Neurological Manifestation after Covid Vaccination in a Young Adult

Authors: K. AFFRAM[1], **L. AYARI**[3], M. JOHN[3], *B. KIRMANI[2,1];
[1]TEXAS A & M Coll of Med/ CHI St. Joseph Hlth., College station, TX; [2]TEXAS A & M Coll of Med/ CHI St. Joseph Hlth., COLLEGE STATION, TX; [3]TEXAS A & M Coll of Med., College station, TX

Abstract: Adenovirus-based COVID 19 vaccines from AstraZeneca and Johnson & Johnson have been associated with a syndrome of thrombosis, mainly involving the venous system, as well as thrombocytopenia akin to heparin-induced thrombocytopenia. Most of the cases were in women. Arterial thrombosis associated with these vaccines is relatively rare; however, a few cases have been reported with the AstraZeneca vaccine but not Johnson and Johnson. Here we report a case of a 24-year-old African American with a history of PTSD was brought to the ED, a week after his COVID vaccination, on account of mental status alteration, dysarthria with a right facial droop. Besides testing positive for cannabinoids in his urine, his laboratory results including platelets were within normal limits. CT angiogram showed an infarct in the distribution of the left middle cerebral artery with a relatively small infarct area with a large penumbra. The lesion was confirmed with brain MRI . . Neurosurgery was consulted; however, he did not meet the criteria for thrombectomy. and also did not receive TPA as he did not meet the criteria giving the extent of his lesion. An echocardiogram revealed no intramural thrombosis and no arrhythmia on telemetry. A thrombophilia workup did not reveal any predisposition to clot formation. Interestingly, his symptoms completely resolved within two days of admission and he was successfully discharged to follow up as an out-patient. Given the rarity of a stroke at his age and his apparent lack of risk factors, it is quite likely that his stroke was due to increased coagulation due to the vaccine. The fact that he did not have thrombocytopenia and HIT-like features or a thrombogenic risk presents the possibility of alternative mechanisms to thrombosis due to the vaccine. His quick recovery could be attributed to his youth and the possible reversibility of the pathogenic process. However, more data is required for a clearer picture of the incidence, distribution, and pathogenesis of stroke in young people after JnJ vaccination so that appropriate recommendations and interventions can be put in place for optimal management.

Title: Neuroprotectin D1 analogue modulates spinal cord synaptic transmission in a mouse model of chronic itch

Authors: *K. FURUTANI[1], O. CHEN[1], R.-R. JI[2];
[2]Pain Res. Division, Anesthesiol., [1]Duke Univ. Med. Ctr., Durham, NC

Abstract: Patients with cutaneous T cell lymphomas (CTCL) frequently have severe chronic itching. Our lab established an animal model of CTCL in nude mice, showing robust lymphoma growth and chronic itch on the back of mice (Han et al., Neuron, 2018). Specialized pro-

resolving mediators (SPMs), such as resolvins, protectins, and maresins, have demonstrated potent anti-inflammation, pro-resolution, and antinociception actions in different animal models of inflammation (Xu et al., Nat Med, 2010). Recently, we reported that a stable analogue of neuroprotection D1 (NPD1), 3-oxa-PD1n-3 DPA (Oxa), produced potent inhibition in itching behaviors (scratching) in CTCL mice following intrathecal injection (Nesman et al., 2021). However, the mechanism by which Oxa suppresses chronic itch is unknown. Here, we show that Oxa can rapidly modulate excitatory and inhibitory neurotransmission in the cervical spinal dorsal horn (SDH) neurons. We used whole-cell patch clamp recordings from SDH neurons of naïve and CTCL mice. Baseline frequency of spontaneous excitatory postsynaptic current (sEPSC) was significantly higher in CTCL mice compared with that of naïve mice ($P = 0.0075$). Perfusion of spinal cord slices with Oxa (10 ng/ml) rapidly (< 3 min) decreased the sEPSC frequency in SDH neurons from CTCL mice but had no effects in SDH neurons of naïve mice. There were no significant effects of Oxa on the amplitude of sEPSC in both groups of mice. Next, we recorded spontaneous inhibitory postsynaptic current (sIPSC). The baseline frequency and amplitude of sIPSC were not different between CTCL mice and naïve mice. Notably, perfusion of Oxa (10 ng/ml) increased the frequency of sIPSC in the CTCL mice. These results indicate that a stable analogue of NPD1, 3-oxa-PD1 can potently inhibit the release of excitatory neurotransmitters and enhance the release of inhibitory neurotransmitters from presynaptic nerve terminals in the spinal cord in chronic itch conditions. Our results provide a new mechanism by which SPM relieves chronic itch.

Title: Molecular determinants of central sensitization in chronic itch - computational modeling studies

Authors: *R. D. GRAHAM[1], H. LEE[2], B. DUAN[2], S. F. LEMPKA[1];
[1]Dept. of Biomed. Engin., [2]Dept. of Molecular, Cell. and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Chronic itch is a debilitating condition that can be symptomatic of many clinical disorders (e.g., chronic kidney disease, depression). Recent work has found that spinal interneurons that express urocortin 3 (Ucn3+) are sensitized in chronic itch conditions. Furthermore, Ucn3+ neurons receive inhibitory synaptic inputs from interneurons that express neuropeptide Y (NPY+), and this inhibition is reduced in chronic itch conditions. However, we do not understand the molecular constituents governing the development of chronic itch phenotypes. Uncovering these mechanisms may assist in developing novel treatments for chronic itch. To study chronic itch pathogenesis, we developed multi-compartment models of Ucn3+ and NPY+ spinal interneurons. We represented both model types using a ball-and-stick morphology described in previous studies of spinal interneurons. We simulated the active membrane properties of each neuron using Hodgkin-Huxley-style dynamics. Experimental data showed that the expression levels of several ion channels ($Na_v1.6$, SK, $Ca_v2.3$, BK) are significantly affected in a calcipotriol-treated mouse model of atopic dermatitis. We used a Markov Chain Monte Carlo method to generated and test thousands of combinations of ion channel conductances, which produced hundreds of biophysically plausible Ucn3+ and NPY+ neuron models in control and chronic itch conditions. We validated these model populations on their ability to reproduce experimentally measured excitability metrics (e.g., rheobase, spike interval). The model populations reproduced many of the distributions of experimentally measured excitability metrics. To determine which ion channels contribute to chronic itch pathogenesis, we systematically increased or decreased the conductance of each channel type in each cell model to mimic the changes in channel expression observed experimentally. We found that increasing $Na_v1.6$ conductance in model Ucn3+ neurons produced a modest increase in Ucn3+ excitability, whereas decreasing $Na_v1.6$ conductance in model NPY+ neurons produced a considerable decrease in excitability typical of chronic itch conditions. Furthermore, decreasing $Na_v1.6$ conductance in NPY+ neurons increased the likelihood that Ucn3+ neurons would generated action potentials in response to afferent inputs. Therefore, decreased $Na_v1.6$ expression in NPY+ neurons may be a key mechanism of chronic itch pathogenesis. Preliminary data suggest that electrical stimulation of Abeta axons in the dorsal roots may decrease the output of Ucn3+ neurons. Going forward, we will further explore the use of electrical stimulation therapies in treating chronic itch.

Abstract: Nociceptive and pruriceptive neurons in the dorsal root ganglia (DRG) convey sensations of pain and itch to the spinal cord, respectively. One subtype of mature DRG neurons, comprising about 5% of neurons in the ganglia, is responsible for sensing mediators of acute itch and atopic dermatitis, including the cytokine IL-31. How itch-sensitive (pruriceptive) neurons are specified is unclear. Here we show that *Tmem184b*, a gene with roles in axon degeneration and nerve terminal maintenance, is required for the expression of a large cohort of itch receptors, including those for IL-31, Leukotriene C4, and Histamine. Male and female mice lacking *Tmem184b* show reduced responses to IL-31, but maintain normal responses to pain and mechanical force, indicating a specific behavioral defect in pruriception. Calcium imaging experiments indicate that a reduction in IL-31 induced calcium entry is a likely contributor to this phenotype. We identify an early failure of proper Wnt-dependent transcriptional signatures and signaling components in Tmem184b mutant mice that may explain the improper DRG neuronal subtype specification. Accordingly, lentiviral re-expression of Tmem184b in mutant embryonic neurons restores Wnt signatures. Together, these data demonstrate that Tmem184b promotes adult somatosensation through developmental Wnt signaling and promotion of proper pruriceptive gene expression. Our data illuminate a new key regulatory step in the processes controlling the establishment of diversity in the somatosensory system

Title: Npy2r^{+} neurons play distinct roles in itch and pain in the amygdala

Authors: *D. PAVLENKO[1], K. SANDERS[1], R. VERPILE[1], A. MARKAN[2], H. ISHIDA[1], T. AKIYAMA[1];
[1]Dermatol., [2]Univ. of Miami, Miami, FL

Abstract: Title: NPY2R^{+} neurons play distinct roles in itch and pain in the amygdala The amygdala plays an important role in the neural pathways of itch and pain. Recent studies have demonstrated that stimulating itch-responsive neurons in the amygdala increases itch- and anxiety-related behaviors. In contrast, stimulation of the $GABA_A$ receptor in the amygdala results in a reduction in itch-related behavior. Neuropeptide Y receptor type 2 (NPY2R) has been found primarily in the amygdala and hypothalamus. It has been categorized as a presynaptic GCPR whose activation leads to a downstream inhibition of glutamate release. In the present study, we investigated the involvement of NPY2R-expressing amygdala neurons in itch and pain.To manipulate the activity of NPY2R-expressing neurons, we prepared NPY2R-cre mice and injected a cre-dependent AAV into the amygdala of these mice. The cre-dependent AAV carried tdTomato and chrimsonR, allowing us to activate NPY2R-expressing neurons with light and map the projection patterns of NPY2R-expressing amygdala neurons in the brain. After surgery, the intradermal injections were performed in light on and light off conditions. When the light is turned on, the NPY2R neurons are activated, and when mice were injected with 5-HT (serotonin) and histamine, the itch-related behavior was suppressed. Finally, there was no difference in mouse response in mechanical or thermal pain test. Based on these findings, we concluded that NPY2R-expressing amygdala neurons are involved in the regulation of acute itch, but not acute pain.

Title: Anoctamin 1/TMEM16A in pruritoceptors is essential for Mas-related G protein receptor-dependent itch

Authors: *H. KIM, H. KIM, S. PAK, S. LIM, U. OH;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Itch is an unpleasant sensation that evokes a desire to scratch. Pathologicconditions such as allergy or atopic dermatitis produce severe itching sensation. Mas-related G protein receptors (Mrgprs) are receptors for many native pruritogens. However, signaling pathways downstream to these receptors in dorsal root ganglion (DRG) neurons are not yet understood. We found that Anoctamin 1 (ANO1/TMEM16A), a Ca2+-activated chloride channel is a primary transduction channel mediating Mrgprs-dependentitch signals. The majority of MrgprA3 positive DRG neurons expressedANO1. Genetic ablation of Ano1 in DRG neurons (AdvCREAno1fl/fl) displayed a significant reduction in scratching behaviors in response to agonists for Mrgprs as well as in Mrgprs-dependent chronic itch models. In-vivo Ca2+ imaging revealed that chloroquine, a potent Mrgpr receptor agonist, excited DRG neurons via ANO1. Chloroquine, SLIGRL, and bilirubin activate ANO1 via MrgprA3, MrgprC11, and MrgprA1, respectively. More importantly, the overexpression of Ano1 in DRG neurons of Ano1-deficient mice rescued the impaired itching. These results demonstrate that ANO1 mediates the Mrgprs-dependent itch signaling in pruriceptors and provides clues to treating pathologic itch syndromes.

Title: Molecular determinants of central sensitization in chronic itch - electrophysiological studies

Authors: *H. LEE[1], R. D. GRAHAM[2,3], S. F. LEMPKA[2,3], B. DUAN[1];
[1]Dept. of Molecular, Cell. and Developmental Biol., [2]Dept. of Biomed. Engin., [3]Biointerfaces Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Chronic itch, a debilitating symptom of skin inflammation, is associated with sensitization of the somatosensory nervous system. Recent studies have identified the selective neural circuits that transmit acute itch; however, the mechanisms by which itch transforms into a pathological chronic state remain largely unknown. We have previously shown that Aβ

mechanoreceptors, together with spinal Urocortin 3-positive (Ucn3+) excitatory interneurons and neuropeptide Y-positive (NPY+) inhibitory interneurons, form a microcircuit that transmit and gate mechanical itch. Sensitization of this spinal circuit contributes to the development of chronic itch. Here, using whole-cell path clamp recordings, we observed increased intrinsic excitability and reduced inhibitory synaptic transmission in Ucn3+ neurons under a chronic itch condition. In contrast to Ucn3+ neurons, intrinsic excitability of NPY+ neurons were largely reduced under a chronic itch condition. To explore the molecular mechanisms underlying sensitization of this circuit, we then used single-cell qRT-PCR to examine the mRNA expression levels of voltage-gated sodium, potassium, and calcium channels in spinal Ucn3+ and NPY+ neurons under a chronic itch condition. We found that the expression levels of Nav1.6 and Cav2.3 channels were increased in Ucn3+ neurons, while the expression level of SK3 channel was decreased. By contrast, we observed that the expression levels of Nav1.6 and BK channels were decreased in NPY+ neurons. Furthermore, our ongoing computational work reveals that decreasing Nav1.6 conductance in NPY+ neurons plays a major role in opening the itch gate in this microcircuit under a chronic itch condition. However, changing SK, BK, or Cav2.3 conductance had negligible effects on sensitization of this circuit. Therefore, our results suggest that changes in Nav1.6 expression are a key component of chronic itch sensitization. The findings presented here may open a new avenue for developing pharmaceutical strategies to treat chronic itch.

Title: Loss of NPY-Y1 inhibition worsens pruritis during aging

Authors: *D. ACTON, M. D. GOULDING;
Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The sensation of itch is generated either by mechanical stimuli, such as an insect crawling across the skin, or by chemical stimuli, such as histamine released from activated mast cells. Both forms of stimulus generate the urge to scratch, which has the effect of removing harmful irritants from the skin. In healthy animals they do this by activating discrete neural pathways in the skin and spinal cord; however, dysregulated crosstalk between these pathways gives rise to chronic itch, characterized by spontaneous scratching and elevated sensitivity to

mechanical stimuli (alloknesis). Chronic itch is a common debilitating condition that becomes more prevalent during aging, and for which treatments are lacking. We recently demonstrated that neuropeptide Y (NPY) acts at the inhibitory NPY receptor type 1 (Y1) to establish thresholds for touch discrimination and mechanical itch responses in healthy mice (Bourane et al. 2014; Acton et al., 2019). Ablation of $Y1^+/Lbx1^+$ dorsal horn neurons prevents mechanical itch responses but spares chemical itch sensitivity. Conversely, pharmacological blockade of Y1 or conditional knockout of *Npy1r* in the dorsal horn strongly potentiates mechanical but not chemical itch. Here, we report that NPY-Y1 signaling strongly suppresses itch responses in models of both acute and chronic pruritis in young adult (8-week-old) mice. Using the Y1 antagonist BIBP 3226, which potentiates itch by disinhibiting $Y1^+/Lbx1^+$ dorsal horn neurons, we show that NPY derived from spinal INs suppresses alloknesis induced by intradermal histamine, as well as in dry skin and allergic contact dermatitis models of chronic itch. Aged (18-month-old) mice display elevated baseline levels of spontaneous and evoked scratching, as well as increased scratching in models of acute alloknesis and chronic itch. Remarkably, the protective effects of endogenous NPY are lost in aged mice, likely accounting for these elevated scratching responses. By contrast, aged mice remain sensitive to the selective Y1 agonist [Leu^{31}, Pro^{34}]-NPY, suggesting reduced availability of NPY, rather than loss of Y1 signaling. Consistent with this, expression of NPY but not Y1 is reduced in aged mice. Current efforts are directed at identifying the cellular processes that drive the attenuation of NPY signaling and increase itch sensitivity during aging.

Title: Role of dopamine and adenosine receptor ligands on spinal reflexes in an inducible iron-deficient model of Restless Legs Syndrome

Authors: S. WOODS[1], M. SCHAUB[1], M. DIAZ-RIOS[2], V. CASADÓ ANGUERA[3], V. CASADO[3], ***S. CLEMENS**[1];
[1]East Carolina Univ., Greenville, NC; [2]Bowdoin Col., Brunswick, ME; [3]Departament de Bioquimica i Biomedicina Mol., Univ. of Barcelona, Barcelona, Spain

Abstract: Restless Legs Syndrome (RLS) is a common sensorimotor disorder that heavily affects sleep. Dopaminergics that target the dopamine (DA) D3 receptor (D3R) subtype are one treatment option for RLS. Brain iron deficiency (BID) is tightly associated with RLS in the clinic, and animal models have shown a correlation between BID and alterations in DA D1

receptor (D1R) and adenosine (ADE) neurotransmission in the striatum. However, the effects of BID in the spinal cord remain unclear. Therefore, we here probed the effects of an iron-deficient (ID) diet on spinal reflex latencies and their modulation by select DA and ADE receptor ligands. Male and female mice (C57BL/6) were separated upon weaning into control diet cohorts and cohorts on an ID diet (Envigo Teklad TD.99397, 2-6 ppm Fe). A Hargreaves system was used to measure thermal pain reflex withdrawal latencies under control conditions (no drugs), and after i.p. injections of DA (D3R agonist: pramipexole, PPX, D1R antagonist: SCH 39166, both at 0.5 mg/kg) and ADE receptor ligands (caffeine and N6-cyclopentyl-adenosine, CPA, at 50 and 1 mg/kg, respectively). Following behavioral testing, spinal cords were harvested and probed for expression of DA and ADE receptors, and proximity ligation assays (PLAs) were performed to assess A1R-D1R receptor heteromer expression.
We found that reflex latencies decreased after 3 weeks compared to controls, suggesting increased spinal cord excitability in male and female ID cohorts. Treatment with PPX restored reflex latencies of ID animals to those of the control cohorts, but it also induced rearing activities in the ID animals. Treatment with SCH 39166 increased reflex latencies in male but not female ID animals, while treatment with CPA increased reflex latencies in both male and female ID animals, without inducing rearing behaviors. Tissue analyses revealed an increase in D1R expression and a significant decrease in A1R-D1R heteromers.
These data indicate that diet-induced iron-deficiency leads to an increase in spinal cord excitability and that DA and ADE receptor ligands can restore normal reflex latencies. We suggest that ID affects DA and ADE neuromodulation by way of A1R-D1R and possibly D1R-D3R heteromers.

Abstract: Enhanced tactile sensitivity using intracortical microstimulationLuke Osborn, Breanne Christie, David McMullen, Ambarish Pawar, Margaret Thompson, Manuel Anaya, Sliman Bensmaia, Pablo Celnik, Matthew Fifer, Francesco TenoreIntroducing low levels of noise to a weak vibrotactile signal can increase the detectability of the weak signal (Enders et al 2013). Known as stochastic resonance, this phenomenon appears to improve humans' tactile detection ability by delivering a noninformative subthreshold vibrotactile signal in addition to the stimulus of interest. Researchers showed that even remote vibrotactile noise (i.e., vibration on the wrist) has potential to enhance tactile sensitivity at the fingertips (Enders et al). Currently, it is unknown if other tactile stimuli modalities can also enhance the detectability of vibrotactile stimuli. In this study, we explored the role of cortical stimulation in improving tactile sensitivity in a human participant using a brain-computer interface. Microelectrode arrays were implanted in sensorimotor regions of the brain in a human participant with a sensory incomplete spinal cord injury (C5/C6 ASIA Impairment Scale Grade B). Intracortical microstimulation (ICMS) of primary somatosensory cortices elicited tactile sensations in the participant's hands, who also retained native tactile sensation in those same regions.In six different sites across both left and right hands, we delivered haptic stimuli using a 300 Hz vibrating motor. We measured the haptic detection thresholds while delivering subthreshold ICMS (approximately -1.5 dB) as well as with suprathreshold ICMS (>1.5 dB). The ICMS was delivered through electrodes that could activate neural populations that elicited percepts overlapping with the placement of the vibrating motor. Specifically, the sites tested on the right hand were thumb fingertip, index fingertip, base of index finger, base of middle finger, ring fingertip and on the left hand the thumb fingertip. Averaging across all sites, we found that subthreshold ICMS decreased the haptic threshold by 26% below baseline (-1.58 dB) with standard error 7.18% (0.42 dB). The suprathreshold ICMS condition increased the haptic threshold by 24% over baseline (0.50 dB) with standard error 14.40% (0.50 dB). These results show that ICMS to targeted regions of the somatosensory cortex is able to enhance native haptic sensitivity, as measured by detection thresholds, of a human participant. These findings have implications for rehabilitating, restoring, and improving native tactile sensitivity and perceptions in individuals living with spinal cord injury, deficits from stroke, or diabetic neuropathy.

Title: Manipulating the perception of artificial touch using non-informative vision

Authors: *B. CHRISTIE[1], L. OSBORN[1], D. MCMULLEN[2], A. PAWAR[3], F. TENORE[1], M. S. FIFER[1];

Abstract: The brain continuously receives information from multiple sensory pathways. These inputs are combined to form a cohesive picture of our surroundings, allowing us to perform adaptive behaviors. To interact with objects in our environment, the brain must integrate visual and tactile signals. Visual feedback can actually improve tactile acuity [1], but we still do not fully understand the neural mechanisms behind visuotactile integration. Visual and tactile signals are thought to be integrated in frontal, parietal, and subcortical regions of the brain [2]. In this study, we stimulated the primary somatosensory cortex (S1), bypassing subcortical regions such as the thalamus, to assess if vision can still affect touch when touch is delivered directly through S1.

We delivered intracortical microstimulation (ICMS) to a human subject with penetrating microelectrode arrays implanted in S1 to deliver artificial tactile stimuli to the hand [3] while the subject received non-informative visual feedback. The term “non-informative” refers to when an individual receives visual feedback of a body part that is being stimulated, but has no vision of the tactile stimulus itself. Non-informative vision has been previously shown to enhance tactile acuity [1]. We tested seven electrodes that each evoked percepts in at least two spatially discrete regions of the hand. The participant was asked to focus his gaze away from the hand or on one of the two discrete regions, and then to report where he felt tactile stimuli on a diagram of the hand. Each electrode and visual condition pairing was repeated up to nine times. We compared the reporting frequency in each region of the hand across visual conditions.

We found that the perceived locations of tactile percepts elicited by ICMS were not affected by non-informative vision. Across visual conditions, reporting frequency neither increased in attended regions nor decreased in unattended regions of the hand. Future experiments could include running control tests with vibration or electrocutaneous stimulation.

In summary, our results suggest that subcortical brain regions, such as the thalamus, may be required for integrating vision and touch, which aligns with prior literature [2]. This study also has important implications for the field of brain-computer interfaces (BCIs): some training may be required for BCI users to learn to integrate visual inputs with tactile percepts evoked by ICMS. Future experiments could evaluate if a training paradigm is necessary to learn this association, or if it could be passively learned over time with long-term use outside of the laboratory.

Title: Virtualized Touch of Holographic Objects in Augmented Reality via Intracortical Microstimulation of Human S1

Authors: *M. S. FIFER[1], L. E. OSBORN[1], D. P. MCMULLEN[2], B. P. CHRISTIE[1], A. S. PAWAR[3], S. J. BENSMAIA[4], P. A. CELNIK[3], F. V. TENORE[1];

Abstract: Augmented reality (AR) technologies enable immersive experiences with simulated virtual objects. Currently, haptic feedback in AR can be provided via wearable gloves or exoskeletons. Haptic devices may be able to relay touch information with extremely high fidelity but have substantial limitations: (1) haptic devices often occlude the skin, so they may only replace touch sensation rather than augment natural touch, (2) haptic devices are often bulky, encumbering natural dexterous finger movements. Direct electrical stimulation of the peripheral nerves and/or central nervous system may be a promising strategy for unobtrusively providing haptic feedback to individuals with sensory loss and/or commercial users as neural interfaces become more widespread. The present study explores the potential for direct neural stimulation of primary somatosensory cortex (S1) to provide haptic feedback in AR. We worked with a human subject who was implanted bilaterally with microelectrode arrays in S1. The participant retained sufficient proximal arm and hand functionality to enable interactions with holographic objects. Virtual objects (cubes) were holographically projected into the workspace via a Microsoft Hololens 2. Intracortical microstimulation (ICMS) was delivered in one of two modes: (1) a fixed-duration, fixed frequency pulse delivered to finger-specific site(s) upon that tracked finger's entry or exit from the virtual object, (2) fixed-frequency stimulation to finger-specific site(s) while that finger was within the virtual object. In initial exploratory sessions, the subject was able to physically scan the workspace and reliably hover within invisible virtual objects in either ICMS delivery mode. In subsequent sessions, the participant was able to differentiate virtual objects by their assigned haptic magnitudes (i.e., ICMS pulse magnitude). In a culminating session, the subject was able to interact with several virtual objects whose compliance was simulated via object scale change and stimulation intensity that scaled linearly with finger movement distance. In this session, the subject was reliably able to select the least

compliant virtual object (of two), and sort a set of four virtual objects by their simulated compliance.This study provides a compelling baseline experience for augmenting or bypassing touch feedback in AR scenarios via direct neural stimulation, worthy of further exploration with noninvasive and/or implanted stimulation devices. For individuals with sensory loss, neurally-enabled haptics may increase the accessibility of virtual experiences as mixed reality technologies become more widely used.

Title: Distinct neocortical mechanisms underlie human SI responses to median nerve and laser evoked peripheral activation examined with the Human Neocortical Neurosolver modeling tool

Authors: *R. V. THORPE[1], C. BLACK[2], D. A. BORTON[2], C. Y. SAAB[3,2,4], S. R. JONES[1]; [1]Neurosci., [2]Biomed. Engin., Brown Univ., Providence, RI; [3]Biomed. Engin., Cleveland Clin., Cleveland, OH; [4]Biomed. Engin., Case Western Univ., Cleveland, OH

Abstract: Non-invasive, clinically-relevant tools like magneto- and/or electro-encephalography (M/EEG) have long been used to measure electromagnetic fields associated with non-nociceptive and nociceptive processing in the human primary somatosensory cortex (SI). The physiological mechanisms that produce such macroscale signals, however, have yet to be fully articulated. We examined the neocortical circuit mechanisms contributing to previously reported innocuous median nerve (MN) and noxious laser evoked (LE) responses from human SI using the Human Neocortical Neurosolver (HNN) modeling software tool specifically designed for biophysically principled interpretation of M/EEG signals (Neymotin et al., 2020; https://hnn.brown.edu). We analyzed two datasets consisting of MEG and EEG recordings during MN and laser stimulation, respectively. Oriented current dipole inverse solution analysis revealed robust features of the respective SI MN and LE responses that were conserved across recordings from prior literature. The timing and orientation of peaks in the SI responses showed that the positive orientation of the first peak in the MN response at ~20 ms corresponds to outward deep-to-superficial electrical current flow, while the first LE response deflection occurs later at ~170 ms and is oriented in the opposite direction. Simulating the circuit-level mechanisms accounting for

these and later peaks with HNN's detailed laminar cortical column model revealed that the MN response can be simulated with a sequence of layer-specific exogenous excitatory feedforward and feedback synaptic drives. This sequence was similar to that previously reported for SI tactile evoked responses (Jones et al., 2007; Neymotin et al., 2020), with the important addition of an early excitatory feedback input to superficial layers at ~30 ms that helped generate the prominent first negative deflection in the MN response. To accurately account for the LE response, a burst of repetitive gamma-frequency (~40 Hz) supragranular feedback drives followed by a later feedforward drive was required. These novel model-derived predictions are consistent with prior reports of evoked gamma oscillations from LE responses in both humans and animals (Heid et al., 2020; Hu and Iannetti, 2019; Yue et al., 2020) and make several multiscale predictions about the laminar circuit mechanisms underlying temporal and spectral features in SI MN and LE responses. These findings can guide future studies that test and expand our predictions with invasive recordings or other imaging modalities and may ultimately help with the development of treatments for somatosensory disorders including chronic pain.

Title: The cortical representation of touch reflects extensive subcortical integration of signals from mechanoreceptor subtypes

Authors: *A. J. EMANUEL[1], B. P. LEHNERT[1], S. PANZERI[2], C. D. HARVEY[1], D. D. GINTY[1];
[1]Harvard Med. Sch., Boston, MA; [2]C.F. 97329350587 P.I. 09198791007, Inst. Italiano Di Tecnologia, Rovereto, Italy

Abstract: How are tactile signals represented and processed within the nervous system? Current models to explain how signals emanating from cutaneous mechanoreceptors generate representations of touch are based on comparisons of the tactile responses of mechanoreceptor subtypes and neurons in somatosensory cortex. We used mouse genetic manipulations to causally investigate the contributions of peripheral mechanoreceptor subtypes to cortical responses to touch. Cortical neurons exhibited remarkably homogeneous and transient responses to indentation applied to the glabrous skin of the paws and these responses resembled those of Aβ rapidly adapting low-threshold mechanoreceptors (RA-LTMRs). Concurrent disruption of signals from both Aβ RA-LTMRs and Aβ slowly adapting (SA-) LTMRs eliminated cortical responses to light indentation forces. However, disruption of signals from either subtype alone caused opposite shifts in cortical sensitivity but otherwise largely unaltered tactile responses, indicating that both subtypes contribute to normal cortical responses. Selective optogenetic activation of single action potentials in Aβ RA-LTMRs or Aβ SA-LTMRs drove low-latency responses in the majority of mechanically sensitive cortical neurons. Likewise, most somatosensory thalamic neurons were also driven by optogenetic activation of Aβ RA-LTMRs or Aβ SA-LTMRs. These findings support a new model in which signals from physiologically distinct mechanoreceptor subtypes are extensively integrated and transformed within the subcortical somatosensory system to generate cortical representations of touch.

Title: Expectation shapes neuronal response along the somatosensory pathway

Authors: G. ENGLISH[1], N. GHASEMI NEJAD[1], M. F. YANIK[2], W. VON DER BEHRENS[1]; [1]ETH Zurich, Zurich, Switzerland; [2]ETH, Zuerich, Switzerland

Abstract: Predictive coding theories hint at the existence of mechanisms that allow agents to more optimally navigate complex environments. However, experimental evidence elucidating the details of the precise neural circuitry underlying predictive coding remains limited. To address this gap, we recorded extracellular neural activity at different stations of the somatosensory hierarchy while delivering novel sensory stimulation protocols aimed at isolating the effect of precision-weighted expectations. We find that the magnitude of the neural response

across the cortical layers of both the primary and secondary somatosensory cortices scales with the error size of an interruption to a precision-weighted expectation. When the sensory background supports precise expectations about forthcoming stimuli, the local field potentials evoked by unexpected stimuli in the primary somatosensory cortex signal also the specific type of error that was encountered. Additionally, unexpected stimuli induced increased power in the beta and gamma-frequency bands in the supragranular and granular layers of the primary somatosensory cortex to subsequent stimuli, potentially representing a prediction update process that is active for up to 700 ms after the original prediction error. After the application of the NMDA antagonist Ketamine, the variation in neural response between unexpected stimuli with different precision-weighted expectations is reduced, in particular in the secondary somatosensory cortex, indicating a role for NMDA receptors in the learning of complex statistical regularities unfolding over time. Overall, our results point towards the specific cortical instances and the potential mechanisms that may be critical for predictive coding.

Title: Microstimulation and optogenetics: A combined stimulation strategy

Authors: *H. BAEZ[1], M. DUHAIN[2], M. GOMEZ-RAMIREZ[3];
[2]Neurosci., [3]Brain and Cognitive Sci., [1]Univ. of Rochester, Rochester, NY

Abstract: The ability to selectively control neural activity is key to determine the role of brain areas in perception and action. Intracortical Microstimulation (ICMS) has been a leading method for upregulating neural activity in vivo. Although ICMS has led to major discoveries, the widespread effects of the electrical current evoked by ICMS limit selectively control neural ensembles in areas lacking topographical structure. Further, ICMS only provides upregulation of neural activity, and it is indiscriminate about the stimulated cell type(s). In contrast, optogenetics provides spatially-localized and rapid control of cell-type specific (i.e., excitatory and/or inhibitory) neural circuits via light. However, behavioral effects of optogenetics in large-brain animals (e.g., monkeys) have been mixed, likely because light fails to activate a sufficient portion of the neural circuit mediating the behavior. Increasing light intensity can lead to tissue damage, and less specificity of the stimulated ensemble. To overcome these limitations, we propose a novel method that combines ICMS and optogenetics to provide refined stimulation of non-topographically aligned circuits. As proof of principle, we developed a biologically-

principled model to determine the effects of ICMS and/or optogenetics on different cell populations in area 1 of somatosensory cortex. As expected, we observed that neighboring neurons to the stimulation site were activated more strongly by ICMS or optical light. We further found that ICMS activated distant neurons with axons oriented towards the stimulated site. This effect was obviated with optogenetics by targeting opsin expression to the soma. Importantly, optimization techniques showed that ICMS+optical stimulation was the most effective method for selectively activating non-topographically aligned cell ensembles. Combined ICMS and optogenetics requires less stimulation power, providing a more targeted and less-damaging stimulation strategy as compared to each method alone. These data indicate that combined ICMS+optogenetics is a feasible and efficient approach for studying the role neural circuits in perception and action.

Title: Neural computations in the cuneate nucleus of primates

Authors: *C. M. GREENSPON[1], A. K. SURESH[1], Q. HE[2], J. M. ROSENOW[3], L. E. MILLER[4], S. J. BENSMAIA[2];
[2]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL; [3]Neurosurg., [4]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: In primates, the coding of tactile information has been studied extensively in the peripheral nerves and primary somatosensory cortex (S1). These studies reveal that the responses of individual S1 neurons reflect convergent input from multiple classes of nerve fibers, and that this input is subjected to computations. Indeed, cortical neurons exhibit spatiotemporal response properties that confer to them an idiosyncratic selectivity for specific spatiotemporal features in their inputs. The classic textbook view is that these response properties reflect computations that are effected in cortex, implying that sensory signals are not meaningfully processed in the two intervening structures - the cuneate nucleus (CN) and the thalamus. However, CN responses have not been investigated using stimuli whose representation in the nerve had been quantitatively characterized, which precludes a quantitative analysis of how tactile signals are

transformed in CN. To fill this gap, we recorded the responses evoked in individual CN neurons to a battery of tactile stimuli that have been extensively used to characterize the response properties of tactile nerve fibers and cortical neurons, including skin indentations, vibrations, random dot patterns, and scanned edges. We then compared CN responses to their upstream and downstream counterparts to assess the degree to which tactile signals are transformed in CN. We found that the responses of CN neurons were more similar to their S1 counterparts than they were to their inputs: CN neurons receive input from multiple sub-modalities, have spatially complex receptive fields, and exhibit selectivity for geometric features. Thus, the CN is not a simple relay station and instead plays a key role in the processing of tactile information.

Title: Movement gating of tactile signals in the cuneate nucleus of primates

Authors: *Q. HE[1], C. VERSTEEG[3], A. K. SURESH[1], L. E. MILLER[4], S. J. BENSMAIA[2]; [2]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL; [3]Biomed. Engin., [4]Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: A key function of sensory systems is to filter sensory input to enhance behaviorally relevant signals and suppress irrelevant ones. An instance of this filtering is the documented movement gating of cutaneous signals: During movement, the cutaneous signals triggered by the resulting skin compression and stretch are suppressed, resulting in decreased cutaneous sensitivity, measured psychophysically. The cuneate nucleus (CN) receives projections from sensorimotor cortex, which have been shown to modulate the transmission of field potentials reflecting afferent input. However, the role of this top down modulation in movement gating has not been demonstrated at the single-cell level. To fill this gap, we had rhesus macaques perform a reach-to-grasp task while we monitored neural activity in CN using chronically implanted electrode arrays. At the same time, we measured hand kinematics using a camera-based motion tracking system, and the grasp forces exerted on the manipulandum using a multi-axis sensor. Throughout the task, we delivered tactile stimuli placed over the receptive fields (RFs) of CN neurons. From the resulting behavioral and neuronal data, we assessed the degree to which CN responses to an unchanging stimulus were modulated during different task epochs. We found that

the responses of almost all cutaneous neurons with RFs on the proximal limb were suppressed during movement. This was not the case for neurons with cutaneous RFs on the hand, for proprioceptive neurons, or when movements were imposed on the arm rather than actively generated. We conclude that the movement gating of cutaneous signals is already present in the CN and is triggered by volitional movement signals, likely stemming from the cortex.

Title: Diversity of functional connectivity patterns between the fundus of the intraparietal sulcus and the primary somatosensory area S1 in awake macaque monkeys

Authors: *W.-A. SHENG[1], S. CLAVAGNIER[1], M. FROESEL[1], W. VANDUFFEL[2,3], S. BEN HAMED[1];
[1]Inst. des Sci. Cognitives, Bron, France; [2]Radiology, Harvard Med. Sch., Charlestown, MA; [3]Neurosciences, KU Leuven, Leuven, Belgium

Abstract: The functions of a cortical area are largely determined by its extrinsic connections with other brain regions. Cortical networks can be mapped anatomically with tracer injections. More recently, the correlation of BOLD fMRI signals in a resting brain has been used to reveal functional associations between regions.
The intraparietal sulcus (IPS) is involved in multisensory integration, and the ventral intraparietal area (VIP) in the IPS fundus responds to visual, vestibular, tactile and auditory signals, with tactile receptive fields over-representing the face. However, anatomical projections from areas 1, 2 and 3a (jointly defining primary somatosensory area S1) to VIP are mainly from the hand and the face/hand boundary representations. Mapping functional connections between fundal IPS and S1 reveals a complex organization of face and hand connectivity fields between VIP and S1, shedding a new light on VIP functions.
To identify sparse or local connections between VIP and S1, we proceeded as follows. Awake resting state fMRI data from 10 monkeys, both hemispheres was co-registered in a common space (voxels of 1mm3). Posterior-anterior IPS to lateral-medial S1 connectivity patterns were

identified using single-voxel seeds running along the posterior-anterior axis of IPS fundus. At the group level, these patterns reveal hand-face borders in area 3a, 3b and 2 matching the IPS tip, as described in the literature. This implies that the awake resting state connectivity measurement is a potential alternative when localizers are unavailable. Based on these borders, we observed different IPS-S1 face and hand connectivity fields: according to the IPS seed positions, the face pattern has one anterior and one posterior peak, while the hand pattern is dominated by the anterior peak.
At a finer grain, face connectivity fields among individuals are diverse. There are slightly more double-peak face than single-peak face patterns in area 3a and 3b, while the former is the dominant pattern in area 2. The single-peak patterns can be further divided into three subcategories based on their peak IPS seed position and the majority has its peak seed position in the anterior IPS.
Overall, this study indicates that fundal IPS somatosensory activities arise from heterogeneous connectivity patterns with S1, predicting distinct overarching behavioral functions.

Title: Analysis of the firing rate of layer V sensory neurons as an indicator for cryoanesthesia and thermosensation

Authors: *C. Y. LEE[1], S. R. NASON[2], A. J. BULLARD[2], C. A. CHESTEK[2], K. P. PIPE[1]; [1]Mechanical Engin., Univ. of Michigan, Ann Arbor, Ann Arbor, MI; [2]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Neural mechanisms for cold sensation and cold-induced anesthesia are important for developing non-opioid local analgesics and understanding of neuropathic diseases. Yet, coding of these mechanisms in the sensory cortex is not widely investigated. Prior studies have reported human subject scoring to imprecise cooling methods (e.g. ice, cold air) and lack quantitative data on CNS behavior to broad ranges of cold temperatures (*T*). The present work aims to identify the dynamic neural response to cutaneous thermal and mechanical stimuli using non-human primate models (rhesus, male, n=2). Animals were implanted with Utah arrays (Blackrock Microsystems) in the hand area of the primary sensory cortex, containing neurons receptive to both thermal and mechanical stimuli. The cooling device used is a custom feedback-controlled thermoelectric probe (±0.001 °C, ≤5 °C/sec, dia. 0.25 in) that allows simultaneous or independent blunt poking

and cooling of a target area. The following measurements were performed with IACUC approval over the course of 6 months: (1) baseline neural response to the environment (20°C) while the animal is in a seated and restrained position (baseline data acquired prior to all trials, with position and climate maintained), (2) response to constant *T* (-5, 0, 5, 10, 35 °C), (3) response to innocuous jabs on skin cooled to a constant *T*, with stimuli spaced irregularly over a trial period of 60-90 secs to gauge the effects of cooling on poking sensation while reducing chances of adaptation or allodynia, (4) immediately following the conclusion of (3), raising *T* to 35 °C (monkey normal skin *T*) with continued jabs, to test for adaptation vs. numbing from cold, and (5) response to rapid changes in *T* while maintaining contact. Preliminary findings show a steady decline in firing rate from a series of pokes during extended cooling, with a slight increase in firing rate once the probe *T* was raised to 35 °C. Surges in firing rate were noted at the initial contact and removal of the cold probe, and the firing rate at initial contact was consistently less than the first poking stimulus, except when *T* = 35 °C. Overall, firing rate in individual neurons as a function of *T*, contact sensation (pressure from cold tip), and time is a potential indicator of cryoanesthesia, but the magnitude of direct responses is minimal; there is a need to amplify responses to only cold and poking, and reduce other activity. Future work will include measuring responses to dynamic *T*, establishing a model that predicts neural response to cold and mechanical stimuli, and engaging human subject testing to pair human sensation scores to monkey neural data.

Title: Multi-finger representations in primary somatosensory cortex: Revising our understanding of the spatio-temporal integration properties of area 3b

Authors: *M. GOMEZ-RAMIREZ[1], S. S. HSIAO[2], N. TRZCINSKI[3];
[1]Univ. of Rochester, Rochester, NY; [2]Johns Hopkins Univ., Baltimore, MD; [3]NIH/NINDS, Bethesda, MD

Abstract: The prevailing model of somatosensory processing indicates that area 3b neurons have receptive fields (RFs) that are confined to a pad within an individual finger. Based on this RF

property and its downstream projections, area 3b is thought to primarily serve as a cortical relay site encoding tactile features comprising an object. As such, object sensing and manipulation (i.e., haptics) is believed to emerge in area 2 and beyond, which have cells with complex spatio-temporal RFs that integrate inputs across multiple fingers. However, our knowledge of 3b cells' RF size is primarily derived from anesthetized studies in non-human primates. The findings from these studies are limited because anesthesia can significantly impact the strength of neural activation, and undermine cells' responses to non-preferred digit stimulation. Similarly, the vast majority of area 3b studies in awake-behaving animals are limited because researchers failed to systematically stimulate each finger. In these awake-behaving experiments (as well as anesthetized studies), researchers typically localize the finger with the maximum response using unreliable hand held probes, and then use motorized devices to systematically stimulate the preferred finger only (i.e., the finger evoking the greatest response). Thus, the field fails to have a detailed understanding of area 3b's classical and non-classical spatio-temporal RF properties across the fingers in the hand. Here, we systematically mapped the RFs of area 3b cells by presenting bars of different orientations to digits 2, 3, 4, and 5 in awake-behaving non-human primates. Contrary to the leading tenet, we found that the vast majority of cells in area 3b have classical RFs that extend to multiple digits. We further observed that multidigit RFs evolved as a function of time, indicating that they are driven by feedback cortical mechanisms. We also found that differences in orientation preference across fingers ranged between 22.5 and 67.5 degrees, an ideal range for encoding objects with curved shapes. Taken together, these data show that area 3b plays a more integral role in generating tactile object representations than previously thought.

Title: Self-awareness from multisensory integration: neuronal evidence of mirror self-recognition in the Macaque SII

Authors: *R. BRETAS[1], M. TAOKA[1], S. HIHARA[1], A. CLEEREMANS[2], A. IRIKI[1];
[1]Lab. for Symbolic Cognitive Develop., RIKEN Ctr. for Biosystems Dynamics Res., Kobe,

Japan; [2]Consciousness, Cognition, and Computation Group (CO3), ULB Neurosci. Institute, Univ. Libre de Bruxelles, Brussels, Belgium

Abstract: Multisensory integration in the parietal cortex has been proposed as one of the mechanisms supporting bodily self-awareness. The responses of multimodal neurons in the secondary somatosensory cortex (SII) of macaque to both somatosensory and visual stimuli within the animal's peripersonal space, with receptive fields sometimes as large as the entire body, seem to account for more than a pure somatosensory function. Therefore we tested in an exploratory manner whether these responses are maintained when the stimulus is seen through a mirror, indicating a possible role in merging sensory stimuli in a self-body schema, a foundation for self-awareness.

For the experiment one female Japanese macaque was habituated to a mirror until developing the ability of mirror self-recognition. The animal was then stimulated by touch and/or movement within her peripersonal space by the experimenter, objects, or by self movement/touch while sitting in front of a full-body mirror. During the task, single neuron activity was observed bilaterally from the SII proper and parietal ventral area, with visual receptive fields being detected in 96 neurons. Of these visually responsive neurons, 31% were found to respond to stimuli seen through the mirror but out of direct view from the animal, 6% to stimulation to the mirror directly (e.g. experimenter touching the animal image in the mirror), 7% responded to the monkey touching her own body, and 5% to touching another body or object. Neurons were further grouped into self (39%) or non-self (11%) related. Other neurons showed nonspecific responses. All responses were qualitatively accessed and cross checked by two experimenters, with 12 neurons being recorded alongside a video of the task.

Our findings provide neuronal evidence of mirror self-recognition in macaques, even as an acquired skill when the animal did not show innate mirror self-recognition, corroborating behavioral indicators such as the mark test. Single cell activity in the SII, besides responding to both visual and somatosensory stimuli, could also consistently discriminate between the self and non-self. As one of the first areas in which whole-body multisensory information is integrated, the SII could be situated as a rudimentary but fundamental precursor to self-awareness. Taken together, these results place the SII in an ideal position to process a body-in-the-world map, incorporating sensory information of the external world and the self as a whole, indivisible body.

Title: Temporal Coding Along the Somatosensory Neuroaxis

Authors: *O. J. LUTZ[1], K. H. LONG[2], S. J. BENSMAIA[3];
[1]Committee on Computat. Neurosci., [2]Interdisciplinary Scientist Training Program, sp. Computat. Neurosci., [3]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: The tactile perception of vibration and texture has been shown to rely on precise and repeatable temporal spiking patterns in both the somatosensory nerves and somatosensory cortex. While the prevalence and precision of temporal information has been shown to differ in the nerves and in the brain, these have not been systematically compared. Furthermore, spike timing remains to be characterized at intermediate stages of processing along the medial lemniscal pathway, namely the cuneate nucleus and thalamus, and in higher order cortical fields, including secondary somatosensory cortex (S2) and parietal ventral area (PV). In the present study, we analyzed neuronal responses to skin vibrations and textures at each at each stage of processing along the neuraxis of rhesus macaques, from nerve through S2/PV. First, we systematically characterized the precision of temporal spiking patterns using a variety of previously developed metrics - including vector strength and harmonic ratio - and quantified the informativeness of spike timing, by comparing the performance of decoders that take timing into account to that of decoders that do not. Second, we developed neuronal models - informed by known features of somatosensory neurons and their interconnections - to evaluate the conditions under which precise spike timing can propagate through multiple synapses, given realistic levels of convergence and synaptic noise. These models replicated the reduction in the prevalence of temporal coding at successive stages of processing. Third, we assessed the degree to which stimulus information carried in temporal spiking sequences at one stage is reflected in the firing rates at the following stage. Indeed, we have shown that cortical firing rates are far more informative than are their peripheral counterparts, implying a conversion from temporal to rate codes. We sought to characterize this transformation along each stage. These analyses informed models - again inspired by known properties of neurons along the somatosensory neuraxis - that demonstrate physiologically plausible mechanisms for the observed temporal to rate transformation. Together these analytical and modeling efforts shed light on how information is carried in temporal spiking patterns and how this information is transformed as it ascends the neuraxis.

Title: Development of a non-human primate experimental setup to investigate the neural basis of visuo-haptic 3D shape perception

Authors: *W. G. SNIDER, C. E. CONNOR, D. H. O'CONNOR;
Solomon H. Snyder Dept. of Neuroscience, Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Accurate shape perception is crucial to identifying and manipulating objects in our environment. Among our senses, touch and vision are unique in that they both convey 3D geometric shape. In order to recognize shapes across sensory modalities, the brain must transform haptic and visual sensory inputs into modality-independent representations. How the brain generates modality-independent representations of shape remains unknown. Human fMRI studies have identified the lateral occipital complex (LOC) as a key area for visuo-haptic integration, yet the low spatial resolution of fMRI has failed to reveal the neural code used for representing object shape. To address this knowledge gap, we propose to study the representations of haptic and visual shapes in macaque inferotemporal cortex (IT), the putative homologue of human LOC. Specifically, we will test the hypothesis that IT utilizes the same coding scheme to represent haptic and visual shapes. To this end, we have developed an experimental setup in which macaques are presented with both haptic and visual stimuli. In this setup, a robotic arm delivers 3D-printed haptic objects within reach of the macaques, and a visual display shows images of visual objects. By matching the position and size of the haptic and visual objects, we will be able to compare shape encoding between touch and vision within the same reference frame. Furthermore, we have developed a comprehensive stimulus set to probe the neural representation of surface curvatures and medial-axis structure. Future studies will combine this experimental setup and stimulus set with neural recordings to identify visuo-haptic brain regions and explore the neural basis of visuo-haptic shape representations in IT.

Title: Texture coding in higher order somatosensory cortices

Authors: *K. H. LONG[1], A. M. VAN DRIESCHE[2], S. J. BENSMAIA[2];
[1]Interdisciplinary Sci. Training Program: Computat. Neurosci., [2]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Our sense of touch confers to us a sensitivity to texture that spans six orders in magnitude in spatial scale, from tens of nanometers to tens of millimeters. In early stages of processing, from the nerve through somatosensory cortex (SC) - including Brodmann's areas 3b, 1, and 2 - individual neurons respond promiscuously to most textures and, as a population, carry a large shared signal that drives the perceived roughness, the dominant perceptual dimension of texture. Nothing is known about how natural textures are encoded in higher order cortices, including secondary somatosensory cortex (S2) and parietal ventral cortex (PV). To fill this gap, we monitored single-unit activity in S2/PV as non-human primates performed a texture discrimination task, in which they indicated whether pairs of naturalistic textures were the same or different. We then characterized the neuronal responses at the single-cell and population levels and compared these to their counterparts in SC. First, we found that only a small fraction of S2/PV neurons respond to textures, in contrast to SC neurons, which typically do. Second, even neurons in S2/PV that do respond to textures only respond to a small subset of them, in contrast to SC neurons, which typically respond to most textures. As a result, the representation in S2/PV is higher dimensional than is its counterpart in SC. Finally, S2/PV neurons carry cognitive signals about task variables such as trial type (same, different) and the animals' eventual decision, unlike their SC counterparts. The present study constitutes the first attempt to characterize the sensory representations in S2/PV using a complex, naturalistic stimulus set.

Title: Sensory loss affects multi-region neural network dynamics in primate sensorimotor cortex

Authors: L. SHERIDAN, J. D. LAURENCE-CHASEN, *F. I. ARCE-MCSHANE;
Univ. of Chicago, Chicago, IL

Abstract: The number of people living with Alzheimer's Disease (AD) doubles every five years after the age of sixty-five. In addition to cognitive impairment, most patients with AD have difficulties in chewing and swallowing. Pathological changes in large-scale neural activity and connectivity in the orofacial sensorimotor cortex (OSMcx) beyond those expected in healthy aging may serve as neural biomarkers for AD. To identify changes in cortical activity due to diminished sensation, we evaluated the effects of absent tactile sensation in the mouth as a young and healthy non-human primate (*Macaca mulatta*) engaged in feeding behavior. Local anesthetics to sensory branches of the trigeminal nerve were used to block tactile inputs from the palate, teeth, and tongue. We recorded neuronal activity from multiple regions of OSMcx (area 3a/3b, 1/2, rostral and caudal M1) simultaneously with 3D tracking of tongue and jaw kinematics using X-Ray Reconstruction of Moving Morphology (XROMM). Neurons in OSMcx modulated their firing rates to the rhythmic tongue and jaw movements during chewing. In the absence of tactile sensation, we observed a ritardando of firing rate oscillations consistent with longer chew cycles. To evaluate the dynamics of multi-region functional connectivity, we used a data-constrained recurrent neural network (RNN) model to infer the directed interactions within and across regions (CURBD, Perich et al., 2020). By training two hundred RNNs independently, we found CURBD to show differential changes in neural network interactions following nerve block. In the absence of tactile inputs, out-degree inhibition from all regions increased significantly ($p<0.01$), except area 1/2 which significantly decreased inhibition both within area and to rostral M1 ($p<0.01$). Across all regions, area 3a/3b showed the highest increase in both excitation and inhibition with rostral M1 inhibition and within area excitation accounting for most of the increase. Lastly, influences to area 3a/3b increased; excitation to area 1/2 decreased while inhibition increased. The increased inhibition to area 3a/3b and 1/2 following nerve block came primarily from area 3a/3b. Overall, the results suggest that a broadening of multi-region network interactions may accompany diminished sensation in healthy aging. Further studies will include investigating these changes in healthy aged non-human primates and those with AD-like symptoms.

Title: Leveraging Markerless Computer Vision to Screen for Circling in Mutant Mice

Authors: *O. R. STANLEY[1], A. SWAMINATHAN[1], K. E. CULLEN[1,2,3];
[1]Dept. of Biomed. Engin., [2]Dept. of Neurosci., [3]Dept. of Otolaryngology, Johns Hopkins Univ., Baltimore, MD

Abstract: The vestibular system provides critical contributions to behavioral stability and spatial navigation. Mouse models for studying varied causes of vestibular impairment have advantages including consistent genetic strains and homology between the mouse and human vestibular systems. Mice with vestibular peripheral dysfunction commonly display an irregular locomotion pattern characterized by repetitive spinning behavior, termed "circling". Screening mice for circling can help identify mutants of interest, which may then be more extensively tested for vestibular dysfunction. However, current methods for definitively identifying animals exhibiting this behavior are limited by inconsistent ethological definitions in the literature and the expense of specialized animal-tracking tools. Here, we present a video analysis pipeline we have developed to identify instances of circling in the paths of freely exploring mice tracked using the DeepLabCut (DLC) Python package. We compare the labeling performance of several DLC neural network models trained on different amounts of manually labeled data. In addition, for each of those neural networks, we compare the performance of multiple detection algorithms as measured by their ability to match human-consensus labeling. These detection methods incorporate different geometric or temporal features of the labeled mice paths, such as the major and minor axes of putative circling instances or how long those instances take. In general, we find that surprisingly small datasets enable behavioral detection as effective as our largest dataset. In addition, we find that in our specific use case, incorporating temporal features and allowing small deviations from a strict definition enable better overall performance in detecting circling behavior. Overall, our results indicate our tool provides a convenient, quantitative screening method for mouse models of vestibular dysfunction.

Abstract: The vestibular system is essential to ensure that self-motion information is processed, giving rise to vital reflexes alongside perception. Here we investigated the feasibility of using viral vectors to express opsins within neurons in central vestibular pathways of non-human primates (NHPs). Importantly, we chose our vector constructs while considering the functional relationships and anatomical differences between our regions of interest, which span from the brainstem to the cerebral cortex. Using optogenetics would allow for fine manipulation of vestibular pathways *in vivo*, increasing the potential of our understanding of how vestibular neurons represent sensory input. Our study induced optogenetic expression through injection of two opsin adenoviruses (serotype: AAV9) specific for different central vestibular brain regions of a cynomolgus macaque: the vestibular nuclei (VN), situated in the brainstem, and the parietoinsular vestibular cortex (PIVC). Specifically, in VN, we injected a virus with a promoter specific to neurons (hSyn) containing the gene from the red-shifted opsin Jaws. In PIVC, we injected a virus with a promoter specific to cortical GABAergic interneurons (mDlx) containing the gene for Channelrhodopsin-2. Using immunohistochemical techniques, fluorescence microscopy, and image processing, we evaluated and quantified optogenetic expression. Our results demonstrate robust specificity and sensitivity of our chosen viruses to their respective target regions and neurons. With the histological confirmation of optogenetic expression, our study will set in motion the application of optogenetic techniques to future NHP studies investigating coding and information feedback along central vestibular pathways.

Title: Vestibular loss alters postural responses to platform tilts in a nonhuman primate model

Authors: *O. M. E. LEAVITT, K. E. CULLEN;
Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Individuals with bilateral vestibular loss (BVL) experience dizziness, postural instability, and gait ataxia even following rehabilitation. Vestibular prostheses aim to replace vestibular function in patients with damage to the peripheral vestibular organs by bypassing the impaired neuroepithelium and stimulating vestibular afferents. In animal models such as nonhuman primates, the vestibular prosthesis can also be used experimentally to apply direct perturbations to the vestibular system to further our understanding of how the brain processes vestibular signals during natural behaviors. In the present study, we leveraged recent developments in vestibular prostheses to improve our understanding the contribution of the vestibular system to postural control.

We first established that postural responses in normal nonhuman primates are similar to what has been reported in humans. Two rhesus monkeys, one normal and one with BVL, were habituated to a chamber mounted on a hexapod motion platform. Animals were trained to place one limb each on four force plates, head position was tracked with an IMU, and poses were estimated from video via DeepLabCut. Ramp-and-hold transient platform tilts of 10 degrees were delivered at 3 accelerations and 3 velocities in pitch and roll. Both animals began actively applying limb forces in response to platform motion within 60 ms of motion onset, and the head began to move 80 ms after onset. Thus, as in humans an initial displacement of the support surface below the subject is followed by an automatic, active response returning the subject to a stable posture that orients the head vertically with respect to gravity by tilting against the direction of platform tilt.

Second, we show that the contribution of the vestibular system is similar in monkeys and humans. In the BVL animal, limb forces and head motion were the reverse of the normal animal's. The BVL animal's head motion responses were also hypometric to normal, suggesting reluctance to move the head. This mirrors studies of postural responses in human subjects, where similarly in contrast to normal subjects, patients with BVL tend to actively destabilize posture during platform tilts by tilting with the direction of platform tilt.

Taken together our results suggest that monkeys have postural responses similar to other animals including humans, and abnormal postural responses caused by BVL affirm the necessity of vestibular signals for maintaining upright posture. Notably, this indicates that replacement of these signals via stimulation of the vestibular system by prosthesis has the potential to improve balance and allow further exploration of the mechanisms of postural control.

Title: 3d virtual enhancement as a potential confounding factor in computerized dynamic posturography

Authors: *E. SON, S. LEE, Y. KO, J. KIM;
Yonsei Univ. Col. of Med., Yongin, Korea, Republic of

Abstract: The sensory organization test (SOT) of a computerized dynamic posturography (CDP) is widely used to investigate a subject's use of the sensory systems for postural control. The latest technology utilizes 3D virtual reality environment to achieve visual reference sway during SOT, compared to conventional CDP which uses sagittal plane movement. In this study, we aimed to evaluate the effect of 3D virtual reality on SOT measurements.A retrospective study included CDP data of 30 consecutive dizzy patients with normal composite scores for their age groups. Comprehensive review of medical history and vestibular function test results were performed with the focus individual performance in VR conditions. Inter-trial differences were analyzed in each SOT condition. Comparison of vaiance among the CDP conditions were performed. Interestingly, condition 3 using VR visual sway showed increased inter-trial variability compared to conditions 1 and 2. 3D virtual reality technology can be a versatile tool for visual input manipulation compared to conventional CDP hardware that provides only sagittal plane movements. Yet, addition of 3D virtual enhancement may be a potential confounding factor in SOT, and further studies are needed to optimize its clinical implementation.

Title: Vestibular prosthesis stimulation linearly evokes eye movements over the stimulation frequency range above the maximum endogenous afferent firing rate: implications for prosthesis dynamic range

Authors: *K. WIBOONSAKSAKUL[1], C. C. DELLA SANTINA[2], K. E. CULLEN[1];
[1]Biomed. Engin., [2]Otolaryngology-Head and Neck Surgery, Johns Hopkins Univ., Baltimore, MD

Abstract: Bilateral vestibulopathy can lead to debilitating visual and postural instability in addition to constant dizziness. One approach to improve the quality of life in this patient population is a vestibular prosthesis that senses head rotation and transforms it into vestibular afferent stimulation, substituting for the damaged periphery. Early results from clinical trials, while encouraging, have shown only partial functional improvements. Specifically, the evoked vestibulo-ocular reflex (VOR) fails to fully stabilize the gaze (i.e., gain < 1). Current strategies to improve the VOR gain have notable downsides; increasing stimulation current level can lead to non-specific activation, while modulating the stimulation rate more strongly for a given head velocity can lead to earlier saturation and narrower dynamic range. One key parameter that remains uninvestigated, however, is the maximum stimulation rate. This is typically set at the maximum endogenous afferent firing rate (~350 Hz) based on the assumption that each stimulation pulse will reliably evoke a spike in the afferents. Accordingly, here we investigated the linearity of prosthesis-evoked VOR eye movements across a large stimulation frequency range. We first re-analyze a previous dataset from two monkeys implanted with the prosthesis. Though the dataset included saturations in the VOR gain, by plotting the maximum evoked eye velocity as a function of maximum stimulation rate, a linear relationship was observed up to 500 Hz (maximum in the dataset). In one monkey, we further investigated this linear range by acutely stimulating the afferents up to 1200 Hz and found a linear relationship up to 800 Hz. These results indicate that the observed saturations in VOR gain did not arise from a plateau in afferent firing rate, but rather resulted from the sigmoidal nonlinearity within the velocity-to-simulation-rate mapping that assumed a 1:1 efficacy between stimulation rate and afferent spiking. Thus, finally, we examined this efficacy assumption using a model of the VOR pathway to predict eye velocity based on stimulation rate. The model yielded accurate predictions only when stimulation efficacy was reduced to 25%, a value similar to that from afferent recordings during stimulation previously published by our group. Taken together, our results suggest that, by accounting for the actual physiological efficacy of afferents responses, the vestibular prosthesis can better utilize the range of afferent firing rates. We suggest a complementary approach combining eye movement recording and modeling can be used to optimize the prosthesis gain and dynamic range for prosthesis users in the clinic.

Title: How vestibular damage changes velocity storage

Authors: *F. KARMALI[1], **A. MADHANI**[2], R. LEWIS[3];
[1]Dept. of Otolaryngology, Harvard Med. Sch., [3]Dept. of Otolaryngology and Neurology, Harvard Med. Sch., [2]Massachusetts Eye and Ear Infirmary, Boston, MA

Abstract: The velocity storage mechanism is a centrally mediated mechanism that processes peripheral vestibular cues. One prominent aspect of velocity storage is the dynamic response to yaw rotation. Specifically, when the body is accelerated to constant velocity rotation, eye movement and perceived velocity decay with a time constant of circa 15-30 s for humans with no known vestibular pathology. The velocity storage time constant is a key diagnostic parameter for peripheral loss, with a range of 6-12.7 s suggesting unilateral hypofunction. However, despite its clinical utility, a mechanistic explanation underlying this important diagnostic parameter is lacking. It has been hypothesized that Bayesian optimization determines ideal velocity storage dynamics based on statistics of vestibular noise and experienced motion. Specifically, while a longer time constant would make the vestibulo-ocular reflex (VOR) more accurate over time, it has been hypothesized that it would simultaneously amplify neural *noise* (variability) and consequently, compromise vestibular precision. Thus, when computing the velocity storage time constant, the brain may be resolving a tradeoff between being accurate and reducing noise, *i.e.*, being precise. In this study, we applied a Bayesian optimal Kalman filter to determine the ideal velocity storage time constant for unilateral hypofunction. Modeling predicted velocity storage time constants that were substantially lower than for normal subjects and comparable to the diagnostic range for unilateral damage. Results suggested that even after peripheral damage, ipsilateral noise originating in the periphery or early central processing remains relevant in neurocomputations, which is important because little is known about the effects of peripheral damage on vestibular noise. Modeling also predicted that age-related hair cell loss and unilateral lesions interact when impacting velocity storage. Our findings suggest that the reduced velocity storage time constant seen clinically results from the brain optimizing velocity storage in response to changes in peripheral signal-to-noise ratios.

Title: Influence of caloric vestibular stimulation on tactile temporal processing.

Authors: *A. CÉDRAS[1], A. SHARP[2], B.-A. BACON[3], F. CHAMPOUX[1], M. MAHEU[1];
[1]Sch. of Speech Language Pathology and Audiol., Univ. of Montreal, Montreal, QC, Canada; [2]Dept. de réadaptation, Faculté de Médecine, Univ. Laval, Quebec, QC, Canada; [3]Dept. of Psychology, Carleton Univ., Ottawa, ON, Canada

Abstract: Influence of caloric vestibular stimulation on tactile temporal processing. Recent evidences suggest that binaural vestibular stimulation affects tactile temporal processing.However, because of the stimuli used, it remains a matter of debate whether these results are bestaccounted for by a shift in covert attention or by an asymmetrical cortical activation. Providingunilateral vestibular stimulation could help to answer this question. The objective of the presentstudy was to examine tactile temporal processing using a temporal order judgment task followingselective stimulation of the right and left vestibular system with bithermal caloric vestibularstimulation (CVS). A toatal of 24 right-handed participants received bithermal CVS either in theright ear (n=12) or the left ear (n=12). Participants held vibrators in both hands which delivered asignal temporally separated by a variable asynchrony. Participants had to report the hand wherethe vibration was perceived first. The task was performed in three different CVS conditions: 1)baseline, 2) warm CVS, and 3) cold CVS. Analysis of the logistics curves parameters - justnoticeable difference (JND) and point of subjective simultaneity (PSS) - for each participant ineach CVS conditions revealed an increase in JND greater following warm CVS. A significantincrease in JND following warm CVS was measured bilaterally. However, cold CVS increasedJND only when CVS was applied in the left ear, but not in the right ear. Finally, no influence ofCVS on PSS was observed.

Title: Subject differences in the influence of cervical muscle vibration on neck and elbow joint position sense

Authors: S. L. THOMSON, *W. E. MCILROY;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Background: Altered cervical proprioception from injury, or experimental manipulation such as neck muscle vibration, has been shown to impact spatial and postural orientation perception at the neck, but also in upper limb joints. Anecdotally, individual responses to altered cervical proprioception and its impact on joint position sense appears to vary considerably, but the nature of this variability is not well described. The current study focused on advancing understanding of the variability observed between individuals in response to neck muscle vibration. Specifically, the study explored between subject differences in the association between neck muscle vibration and joint position error (JPE) measured at the neck and the elbow. **Methods:** Young healthy adults (n=14, age 24.2 ± 6 years) participated in tests of cervical and elbow joint position sense with, without, and immediately following unilateral dorsal neck muscle vibration. JPE at the neck and elbow were compared across and within participants across the 3 vibration conditions (with, without and post vibration). **Results:** Absolute cervical JPE ($p<.0001$) and elbow JPE ($p<.0001$) increased significantly under vibration conditions across participants. Within participants, under no vibration conditions, there were moderate to strong positive relationships in JPE mean and variability (SD) during both the cervical ($r= .63$, $p=.02$) and elbow repositioning tasks ($r=.87$, $p<.0001$). There was a moderate negative relationship between JPE and the impact of vibration on JPE during the cervical ($r=-.57$, $p=.03$), but not the elbow ($r=-.17$, $p=.57$) repositioning task. Within participants there were no significant associations between cervical JPE and elbow JPE performance both with ($r=.15$, $p=.63$) and without ($r=-.24$, $p=.45$) neck vibration. **Conclusions:** The current study revealed that while neck vibration significantly impacts both cervical and elbow JPE across participants, the impact of vibration on JPE was not consistent within individuals across different joints (neck vs elbow). Importantly, the association between cervical JPE and the impact of vibration does suggest that individuals with better cervical joint position sense may be impacted to a greater extent when cervical proprioception is altered. This work highlights the need to further explore the individual determinants of cervical proprioception in order to better understand potential differences in the weighting of cervical proprioceptive information for use in postural and spatial orientation.

Title: An animal model of third window syndrome: vestibular-cochlear based explorations of dehiscence induced impairments in decision making.

Authors: O. VAN OSCH[1], B. MORRIS[1], A. TAMAKLOE[1], *J. GAY[2], A. WACKYM[1], T. MOWERY[1];
[1]Rutgers Univ., Piscataway, NJ; [2]Rutgers Univ. Behavioral and Neural Sci., Piscataway, NJ

Abstract: Background: Third window syndrome is a vestibular-cochlear disorder in humans in which a third mobile window of the otic capsule creates changes to the flow of sound pressure level energy through the perilymph/endolymph. The nature and location of this third mobile window can occur at many different sites (or multiple sites); however, the most encountered third window is congenital or acquired superior semi-circular canal dehiscence. The primary physiological symptoms include sound induced vertigo, headaches, pseudo conductive hearing loss, tinnitus, autophony while speaking, and visual problems (nystagmus, oscillopsia). At the same time, individuals experience measurable deficits in basic decision-making, short-term memory, concentration, spatial cognition, and anxiety. The cause of many of these symptoms have been well-studied; however, without an animal model a fundamental understanding of the central processing changes will not be possible with our current technologies. **Methods:** Adult Mongolian gerbils (N=18) received surgical fenestrations to the superior semi-circular canal of the left inner ear. Auditory brain stem responses were carried out prior to surgery and over 10 or more days of recovery. Some animals were trained on a basic decision-making task (amplitude-modulation (AM) rate discrimination) using an appetitive reinforcement operant conditioning procedure, prior to 3rd Window procedure (N=5). A sensitivity measure, d', was computed for each animal across training days. Histological examination of the fenestration was carried out for each animal post-hoc and compared to both ABRs and behavior. **Results:** The fenestration created a significant elevation in hearing thresholds of the left ear; especially in the lower frequency domain (1 to 4kHz). In a subset of animals, left (EXP)/right ear(CTL) comparisons via ABR show significant threshold increases at the same frequency representations. For behavior, there was a significant effect on attenuated behavior over 5 additional days of testing. That is, post-surgery animals produced more false alarms and less correct rejections but maintained the ability to perform the task (~100% hit rate) compared to pre-surgery performance. **Conclusion:** The central basis of cognitive impairments associated with these kinds of peripheral injuries in humans is unknown. These preliminary results suggest that our animal model will provide a good basis for explorations into the central etiology of some of CNS based symptoms and decision-making impairments associated with 3rd window syndrome in humans.

Title: Gap junction gene regulates choice between two temperature-dependent behaviors in C. elegans

Authors: *A. ALMORIL-PORRAS, A. C. CALVO, E. M. WISDOM, I. REN, A. ALJOBEH, J. D. HAWK, D. A. COLÓN-RAMOS;
Neurosci. and Cell Biol., Yale Univ., New Haven, CT

Abstract: Animals perform behaviors under a specific, relevant set of conditions that encompass external stimuli and internal cues experienced by the organism. In the case of plastic behaviors, prior experience can also instruct which behavior to perform, even when animals are presented with an invariant set of environmental stimuli. How animals select and switch between behavioral strategies given a set of conditions and how neuronal circuits underlie this selection is not well understood. To identify molecular underpinnings regulating this choice, we used the thermotactic behavior of the nematode *Caenorhabditis elegans*, defined as the migration to a preferred temperature instructed by previous training exposure to a given temperature. Thermotaxis can be further broken down into two behavioral strategies: wild-type animals will migrate across a temperature gradient (orthothermal migration) when placed at conditions different from the trained temperature, and they will perform long bouts of forward movement along isotherms (isothermal tracking) when they are near their preferred temperature. Here we show that gap junction genes play a key role in regulating the switch between these two behavioral strategies. Using a combination of forward and reverse genetics, we identified a gap junction mutant that fail to effectively switch strategies as they persistently perform isothermal tracking in an unfavorable context, far from their preferred temperature. We used cell-specific tools to ablate, probe and inspect the activity patterns of neurons known to play a role in thermotactic behavior in the two different contexts and determined some cellular requirements for isothermal tracking behavior. This study sets up a behavioral paradigm to probe how two different behavioral strategies might compete within a circuit and are selected to be executed by prior experience. Our findings also highlight the importance of gap junctions and electrical synapses present in neuronal circuits in mediating behavior selection.

Title: Biophysical characterization of wide-field amacrine cells in the mouse retina

Authors: *W. LEI[1], S. J. PARK[2], L. M. SNYDER[5], D. A. CLARK[3], S. E. ROSS[5], J. B. DEMB[4];
[1]Interdepartmental Neurosci. Program, [2]Ophthalmology and Visual Sci., [3]Dept. of MCDB, [4]Ophthalmology & Visual Sci., Yale Univ., New Haven, CT; [5]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Wide-field amacrine cells (WACs) represent a diverse class of interneurons that can extend neurites over one millimeter from the cell body in the mammalian retina. However, the biophysical properties, connections, and computations of WACs are poorly understood due to the difficulties of systematically targeting individual WAC types. Here we employed an intersectional genetic strategy to identify cell types in mouse retina within a diverse, genetically defined family of WACs expressing the transcription factor Bhlhb5 (B5 WACs). By combining B5-Flpo and Kappa Opioid Receptor(KOR)-cre alleles with a dual fluorescent reporter, we targeted B5-KOR WACs *in vitro* with two-photon microscopy for whole-cell patch clamp recording and dye filling. B5-KOR WACs stratify primarily in S1 and S4/5 levels of the inner plexiform layer (IPL). These WACs mostly have 5-12 neurites that branch near the soma and extend straight across the retina within a defined level of the IPL. B5-KOR WACs depolarize to either contrast increments (ON cells; S4/5) or decrements (OFF cells; S1). Depolarization was accompanied by small spikelets in some cases. We focused on an OFF type with a soma in the ganglion cell layer that stratified neurites in S1. These cells have four to six dendrites extending in two opposing directions. Somatic receptive field mapping by reverse-correlation technique revealed an anisotropic center-surround receptive field. Voltage-clamp recording further revealed that synaptic excitation and inhibition have similar anisotropic receptive fields. Subsequent pharmacological experiments showed that excitation is driven by the OFF pathway, whereas inhibition is driven by the ON pathway, i.e., cross-over inhibition, via glycine release. These experiments characterize the biophysical and physiological properties of a novel type of OFF WAC, and reveal a strategy for studying additional WAC types in the future.

Title: Light-adaptation Clamp: a biophysical tool minimizing photoreceptor adaption for studying visual processing

Authors: *Q. CHEN[1], F. RIEKE[2];
[1]Physiol. and Biophysics, [2]Univ. of Washington, Seattle, WA

Abstract: Efficient encoding of visual environments requires adaptational mechanisms that match the statistics (mean, contrast, etc.) of visual inputs to the limited dynamic range of visual neurons. Classic work shows that in steady state, adaptation takes place across visual systems, starting from the first steps in visual processing in the photoreceptors. However, steady state conditions rarely apply during natural vision; instead, the light levels encountered by visual neurons change dynamically as gaze shifts from one location to another within a single scene. We lack an understanding of the location and properties of the adaptational mechanisms that operate during dynamic natural viewing. One technical obstacle is the lack of tools to manipulate specific adaptational machinery along the visual pathways. Here, we use a biophysical model of phototransduction that captures the responses of photoreceptors to a wide range of stimuli. This model comprises a set of differential equations that describe the biochemical components of phototransduction. We verified the accuracy of this model by recording photoreceptor (rod and cone) responses to novel stimuli. We then developed a reverse-engineering paradigm (Light-adaptation Clamp, or LaC) to design stimuli which had predictable effects on the photoreceptor responses - e.g. negating the impact of nonlinearities to make the photoreceptor response depend linearly in light input. This approach allows us to alter the photoreceptor responses several ways, including: (1) predictably manipulating the kinetics of the photoreceptor responses, e.g, to compensate for differences in the kinetics of responses of different cone types; (2) removing asymmetries in the photoreceptor responses to light increments and decrements so that On and Off visual pathways receive equivalent input; (3) negating the impact of changes in light level on the gain and kinetics of the photoreceptor responses. We verify the accuracy of these designed stimuli with direct recordings of photoreceptor responses. This approach provides a new tool to manipulate inputs to the visual system in specific, predictable ways and separate photoreceptor and post-photoreceptor contributions to responses of downstream neurons and to perception.

Title: Evaluating genetic tools for the identification of ipRGCs

Authors: *M. A. FLORES-NARVAEZ, K. C. MIGUEL, R. H. IBRAHIM, T. M. SCHMIDT; Neurobio., Northwestern Univ., Evanston, IL

Abstract: Intrinsically photosensitive retinal ganglion cells (ipRGCs) are a class of retinal ganglion cell that express the photopigment melanopsin, allowing them to respond to light even in the absence of rod and cone input. ipRGCs are a heterogeneous cell population that comprises six characterized subtypes (M1-M6). The melanopsin expression varies greatly amongst the different subtypes, with some being too low to detect using immunohistochemistry or a transgenic line expressing GFP under the melanopsin promoter ($Opn4^{GFP}$). To account for this, researchers have taken advantage of the highly efficient Cre-LoxP system to account for this limitation and maximize the labeling of ipRGCs. However, the number of cells labeled by commonly used genetic reporter lines differs greatly. Therefore, we aimed to quantify and characterize the cell types labeled in conventionally used reporter lines: $Opn4^{Cre/+}$ x Z/EG (~3000 labeled cells), $Opn4^{Cre/+}$ x $ROSA^{YFP}$ (~6000 labeled cells) and $Opn4^{Cre/+}$ x $ROSA^{tdTomato}$ (~10,000 labeled cells). To do so, we performed immunohistochemistry to quantify and describe the different types of retinal cells labeled in these reporter lines. Additionally, we performed intravitreal injections of a viral Cre-dependent reporter (pAAV-hSyn-DIO-mCherry) into adult $Opn4^{Cre/+}$ mice, in which we quantified ~4,000 labeled cells. Altogether our data shows that $Opn4^{Cre/+}$ x Z/EG labeled the fewest retinal cells of the four genetic reporters studied. Moreover, we observed a substantial overlap amongst the different genetic reporters, suggesting that the cells labeled by $Opn4^{Cre/+}$ x $ROSA^{YFP}$, $Opn4^{Cre/+}$ x $ROSA^{tdTomato}$, and pAAV-hSyn-DIO-mCherry, but not by $Opn4^{Cre/+}$ x Z/EG, do express Cre. Collectively, these results indicate that the $Opn4^{Cre}$ line may manipulate a much wider population of retinal cells than the M1-M6 ipRGCs and suggests that there are potentially uncharacterized melanopsin-expressing ipRGCs in the mammalian retina.

Title: Role of the ipRGC circadian clock in visual perception

Authors: *K. C. MIGUEL[1], J. D. BHOI[1], C. P. RIBELAYGA[2], T. M. SCHMIDT[1]; [1]Neurobio., Northwestern Univ., Evanston, IL; [2]Ophthalmology & Visual Sci., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Circadian rhythms, set by cellular clocks found throughout the body, are regular, repeated biological fluctuations that function over the 24-hour day to allow animals to anticipate daily changes in their environment. One of the largest changes to an animal's environment over the course of the day is the amount of illumination, from the direct sunlight at midday to the dark of a moonless night, and the visual system must function across this broad range. Mice are known to perform better on visual tasks at certain times of day, suggesting that their visual perception is under circadian control. However, it is unclear where in the visual system and by what mechanism these changes occur. The retina, the light-sensitive tissue of the eye where light stimuli are first encoded, undergoes many cellular and molecular changes throughout the day, and so it is possible that circadian changes in visual perception may stem from the retina. Within the retina, intrinsically photosensitive retinal ganglion cells (ipRGCs) are an ideal population of cells to use to examine how cell-autonomous circadian clocks influence visual function, as they are genetically tractable and contribute to at least two visual behaviors known to be under circadian control: the pupillary light reflex (PLR) and contrast sensitivity (CS). To test the role of cellular circadian clocks in visual function, we generated a mouse line where the clock gene Bmal1 is conditionally knocked out in ipRGCs ($Opn4^{Cre}$; $Bmal1^{fx/fx}$, or Bmal1cKO mice). We found that clock-controlled gene expression was altered in ipRGCs while rhythmicity of total retinal gene expression was largely maintained. Moreover, Bmal1cKO mice showed deficits in daytime CS, suggesting that the cellular clock in ipRGCs may be responsible for driving rhythmicity in this behavior. Overall, this work will provide insight into the role of cellular clocks in multiple visual behaviors.

Title: Tbr2 is required for the maintenance but not survival of ipRGCs

Authors: *S. ABED, D. FELDHEIM;
Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: Retinal ganglion cells (RGCs) expressing the photopigment melanopsin are intrinsically photosensitive (ipRGCs) and are important for subconscious visual behaviors such as circadian rhythm entrainment, pupil constriction, and light-mediated mood regulation. Previously, we and others showed that the transcription factor Tbr2 is required during retinal development for the formation of ipRGCs. Tbr2 is also expressed in the adult retina after development, suggesting that Tbr2 may play a role in the maintenance of ipRGC function. To test this, we removed Tbr2 in adult mice and found that loss of Tbr2 results in the loss of melanopsin expression in ipRGCs but does not lead to morphological changes to their dendritic or axonal terminations or affect their survival. We next ectopically expressed Tbr2 in RGCs and found that it is not sufficient for induction of melanopsin expression in non-ipRGCs. Lastly, we found that Meis2, a transcription factor that is expressed in GABAergic cells, is expressed in almost all Tbr2-expressing displaced amacrine cells and also in a subset of Tbr2-expressing RGCs. These findings demonstrate that Tbr2 is necessary but not sufficient for melanopsin expression and that Tbr2-expressing amacrine cells are GABAergic.

Abstract: Validating a new FlpO Line to Manipulate ipRGCs**Madison Luce,** Ely Contreras[b], Tiffany M. Schmidt (PI)[aa] *Department of Neurobiology, Northwestern University, Evanston, IL, 60201*[b] *Northwestern IBIS, Evanston, IL, 60201*madisonluce2022@u.northwestern.edu | tiffany.schmidt@northwestern.eduLight regulates the mammalian vertebrate visual system to affect both image-forming and non-image forming behaviors. Light is detected by the canonical rod and cone photoreceptors, as well as intrinsically photosensitive retinal ganglion cells (ipRGCs). ipRGCs express the photopigment, melanopsin, and are a diverse population, consisting of six types (M1-M6), which differ in morphology, electrophysiological properties, central brain projections, and how they influence visual behavior. For example, M1 ipRGCs modulate the pupillary light reflex, while non-M1 ipRGCs are involved in contrast sensitivity. However, the extent to which these ipRGC subtypes differ in their gene expression and how each individual subtype contributes to visual behavior is unknown. To address this gap in knowledge, the Schmidt Lab has developed a new $Opn4^{FlpO}$ mouse line that can be used in an intersectional genetic strategy for the genetic isolation and targeting of subsets of ipRGCs. We use immunohistochemistry in the $Opn4^{FlpO}$ mouse line, crossed to multiple reporters, and find that ipRGCs are specifically labeled in this line. Moreover, our data indicate that multiple subtypes of ipRGCs express FlpO, though M4s, M5s, and M6s are labeled at lower rates in this line than the other ipRGC subtypes. Currently, we are testing AAV-based genetic reporters to further manipulate subsets of ipRGC subtypes in the $Opn4^{FlpO}$ mouse line in hope to eventually isolate these subsets. Overall, our preliminary data suggest that the $Opn4^{FlpO}$ line labels ipRGCs and can, therefore, be used effectively to target and manipulate this RGC population, which will allow us to gain better insight into the visual behaviors evoked by particular populations.

Title: Horizontal cell responses to light of variable photoperiod and intensities in Sprague-Dawley rats

Authors: *S. GUPTA, T. C. NAG;
ANATOMY, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, India

Abstract: Retinal degenerative diseases like AMD and retinitis pigmentosa are characterized by photoreceptor death, followed by changes in the inner retina, where one of the principal neuronal

type is horizontal cells (HC). We examined the morphological and neurochemical modifications in HC after light induced retinal damage (LIRD). The objective was to find out how the HC respond to outer retinal changes, in order to maintain the retinal circuitry. We exposed Sprague-Dawley rats to light of variable photoperiods and intensities and created an experimental situation that mimics retinal degenerative diseases where photoreceptor cell death is common. Adult rats (N= 30) were acclimated in 300 lux at 12 hour light: 12 hour dark (12L: 12D) photoperiod for 7 days and then exposed to 3000 lux at 12L: 12D for 2 days, followed by exposure to constant light (24L: 0D) for 2 days. Rats were then brought to 300 lux and reared for 15 days in 12L: 12D cycle. They were sacrificed at different days to see retinal HC remodeling. The identification of known markers of HC, namely calbindin D-28k (Calb) and doublecortin (DCX) immunohistochemistry and their ultrastructural changes allowed us to understand the retinal responses to light stress. In toluidine blue stained sections, swollen HC with their elongated neurites in outer plexiform layer (OPL) were seen under constant light, followed by a decrease in swelling of soma and dendritic retraction upon reverting back to ambient light of 300 lux. Calb was localized in HC and their number counted in 280 µm length of central inner nuclear layer (INL). Calb+ HC decreased in number with constant light but increased after light intensity was reversed (from 6 to 8/ 280 µm length of INL; $p<0.05$), whereas abnormal Calb+ HC increased in number with constant light and decreased with light reversal. There was an increase in total number of Calb+ HC under constant light (13/ 280 µm length of INL; $p<0.05$). DCX immunoreactivity (IR) was seen in HC, OPL and INL across all groups. Increase in IR in HC was seen in constant light group, which was still present in rats reverted back to 300 lux under 12L: 12D cycles for 5 and 15 days. Our result showed that after constant light exposure, the retina undergoes remodeling in HC soma and dendrites. This remarkable plasticity of the HC is integral to remodel the retinal circuitry altered after photoreceptor death in light stress. The increase in the number of calb+ HC may be due to their inherent property to divide under stressful conditions, which can be explained by their enhanced expression of DCX.

Title: Dendrosomatic synapses violate receptive field and connectivity rules in the mammalian retina

Authors: M. SEDLACEK[1], W. N. GRIMES[1], M. MUSGROVE[2], A. NATH[1], H. TIAN[1], M. HOON[4], F. M. RIEKE[5], J. H. SINGER[3], ***J. DIAMOND**[1];

Abstract: In the retina, neuronal morphology strongly influences visual response features. Ganglion cell (GC) dendrites ramify in distinct strata of the inner plexiform layer (IPL) so that GCs responding to light increments (ON) or decrements (OFF) receive appropriate excitatory inputs. This vertical stratification prescribes response polarity and ensures consistent connectivity between cell types, whereas the lateral extent of GC dendritic arbors typically dictates receptive field (RF) size. A2 amacrine cells are interneurons understood to mediate "cross-over" inhibition by relaying excitatory input from the ON layer to inhibitory outputs in the OFF layer. During night (scotopic) vision, A2s relay input from rod bipolar (RB) cells to ON and OFF cone bipolar (CB) cell axon terminals that contact GCs. ON signals from RBs are preserved via electrical synapses to ON CBs and inverted via inhibitory, glycinergic synapses to OFF CBs (Famiglietti and Kolb, 1975; Pourcho and Goebel, 1985; Strettoi et al., 1992; Tsukamoto et al., 2001). This circuitry reliably transmits scotopic signals to ON GCs (Smeds et al., 2019), but it remains unclear how visual signals are transmitted most reliably to OFF GCs at night.Here, we present ultrastructural analysis of mouse retina indicating that A2s make chemical synapses deep in the IPL and ganglion cell layer (GCL) onto the proximal dendrites, soma, and axon initial segments of sustained and transient OFFα (OFF_sα and OFF_tα) GCs. These synapses are made by a small subset of A2s whose distal, arboreal dendrites encounter OFFα GC somas. The synaptic outputs arise from the distal tips of the A2 arboreal dendrites, close to where A2s receive excitatory inputs from RBs, ensuring efficient signal transfer from input to output. Fluorescence imaging and electrophysiology experiments indicate that depolarizing stimuli elevate [Ca^{2+}] in A2 arboreal dendritic compartments and elicit glycinergic inhibitory postsynaptic currents (IPSCs) in OFFα GCs. Scotopic light-evoked IPSCs in OFF_sα GCs exhibit narrow RFs that do not correlate with dendritic arbor dimensions. Together, these results show that OFFα GCs receive powerful somatic inhibition that influences RF properties and that A2 synaptic organization is heterogeneous and depends on proximity to OFFα GC somas. This OFF pathway, avoiding entirely the OFF region of the IPL, challenges several tenets of retinal circuitry.

Title: Depolarization block shapes the contrast sensitivity of a newly identified retinal ganglion cell

Authors: *S. R. WIENBAR[1], G. W. SCHWARTZ[2];
[2]Ophthalmology, [1]Northwestern Univ., Chicago, IL

Abstract: The output of spiking neurons depends both on their synaptic inputs and on their intrinsic properties: principally their complement of ion channels. Retinal ganglion cells (RGCs), the spiking projection neurons of the retina, comprise over 40 different types in mice and other mammals, each tuned to different features of visual scenes. The circuits providing synaptic input to different RGC types to drive feature selectivity have been studied extensively, but there has been substantially less research aimed at understanding how the intrinsic properties of RGCs differ and how those differences impact feature selectivity. Here, we introduce an RGC type in the mouse whose contrast selectivity is critically controlled by its ion channels. We compare this new RGC type with a different RGC that receives similar synaptic input but produces qualitatively different spike output. Pharmacological experiments, imaging, and compartment modeling suggest that differences in sodium channel types and their localization allow these two RGC types to provide different information to the brain despite similar inputs.

Title: Contribution of P2X3 receptors to visual information processing in the retina

Authors: *T. ISHII[1], A. SHIMOHATA[1], C. SUZUKI[1], T. SHIMOGORI[2], M. KANEDA[1];
[1]Nippon Med. Sch., Tokyo, Japan; [2]CBS, RIKEN, Saitama, Japan

Abstract: Adenosine triphosphate (ATP) acts as a neurotransmitter in the nervous system. We have previously reported that all subtypes of P2X receptors (P2X1 - P2X7) are expressed in the mouse retina, and PPADS, an antagonist of P2X1, P2X2, P2X3 and P2X5 receptors, modulates the responses of bipolar and amacrine cells to light flash and the firing pattern of retinal ganglion cells. However, the types of P2X receptors contributing the signal processing in these neurons have not been well elucidated. In the present study, we focused on P2X3 receptors. First, we investigated the specific localization of the P2X3 receptor by *in situ* hybridization and immunohistochemistry. In the adult mouse retina, P2rx3 mRNA was expressed in the ganglion cell layer (GCL), and the immunoreactivity was found in the inner plexiform layer (IPL) and GCL, suggesting the expression of P2X3 receptors in amacrine or retinal ganglion cells in the GCL. We next examined the physiological function of P2X3 receptor in the retina using an antagonist of P2X3 receptor, A317491, In the electroretinogram, intravitreal injection of A317491 had no effects on the amplitudes of both a- and b-waves, which reflect the activity of photoreceptors and bipolar cells, respectively, whereas significantly decreased the amplitude of oscillatory potentials, which reflects the activity of amacrine cells. In multielectrode array, application of A317491 modulated the firing rate of ON and OFF-retinal ganglion cells. These results suggest that the P2X3 receptors physiologically work for the signal processing in the mouse retina.

Title: Object motion dynamics influence both feedforward and feedback motor responses during virtual catching

Authors: *T. SINGH[1], A. M. GÓMEZ-GRANADOS[2], D. A. BARANY[2], I. KURTZER[3]; [1]Kinesiology, Pennsylvania State Univ., University Park, PA; [2]Kinesiology, Univ. of Georgia, Athens, GA; [3]Biomed. Sci., New York Inst. of Technol. Col. of Osteo. Med., Old Westbury, NY

Abstract: An important window into sensorimotor function is how we catch moving objects. Studies that examined catching of free-falling objects report that the timing of the motor response is independent of the momentum of the projectile, whereas the motor response amplitude scales with projectile momentum. However, this pattern may not be a general strategy

of catching since objects accelerate under gravity in a characteristic manner (unlike object motion in the horizontal plane) and the human visual motion-processing system is not adept at encoding acceleration. Accordingly, we developed a new experimental paradigm using a robotic manipulandum and augmented reality where participants stabilized against the impact of a virtual object moving at constant velocity in the horizontal plane. Ten participants needed to apply an impulse that mirrored the object momentum to bring it to rest and received explicit feedback on their performance. In different blocks, object momentum was varied by an increase in its speed (Speed Blocks) or mass (Mass Blocks). In contrast to previous reports on free falling objects, we observed that increasing object speed caused earlier onset of arm muscle activity and limb force relative to the impending time to contact. Also, arm force increased as a function of target momentum linked to changes in speed or mass. Our results demonstrate velocity-dependent timing to catch objects and a complex pattern of scaling to momentum.

Title: Sensory processing of passive limb movement in mouse primary forelimb somatosensory and motor cortex

Authors: *I. E. STEWART, C. J. WHITMIRE, J. F. A. POULET;
Max-Delbrück Ctr. for Mol. Med. (MDC), Berlin, Germany

Abstract: Maintaining an accurate sense of limb position during movement is a key function of the somatosensory system, but the cortical circuits and coding principles of proprioception are not yet resolved. Prior work with primates has implicated both primary somatosensory (fS1) and motor (fM1) cortex in the representation of directional passive limb movements (Delhaye et al., 2018; Fetz et al., 1980; London & Miller, 2013). In contrast, far less is known in the mouse model system, which offers an array of molecular tools to investigate circuit mechanisms of sensory coding and perception. To address this, we developed a motorised passive limb movement stimulator for head-fixed mice. Mice were trained to hold a post mounted on linear

motors that generated 8 directions of horizontal linear motion comparable to classic centre-out directional movement paradigms. Behavioural tracking with contact sensors, filming, and EMG confirmed mice held the post during passive movement trials. Extracellular laminar probe recordings from fS1 and fM1 in anaesthetised and awake mice identified sensory evoked responses to directional passive limb movements as well as to vibrotactile stimulation of the forepaw. Our preliminary recordings in mouse cortex show single units that are tuned to specific directions, suggesting comparability between the encoding of passive movement in rodents and primates. Use of single unit recordings in combination with intersectional transgenics in mice promises advances in the understanding of circuit and cellular mechanisms of proprioception.

Title: The effect of the memory-guided task on the MFR amplitude

Authors: *K. NUMASAWA[1], T. MIYAMOTO[2], T. KIZUKA[2], S. ONO[2];
[1]Grad. Sch. of Comprehensive Human Sci., [2]Fac. of Hlth. and Sport Sci., Univ. of Tsukuba, Tsukuba, Japan

Abstract: It is well established that the arm trajectory during reaching movement is corrected by a target jump, which is called an automatic pilot. Moreover, a manual following response (MFR) is also known as a similar motor response, which is rapid modulation of arm movement induced by large-field visual motion during reaching a stationary target. Since the correction of arm trajectory is induced with short latency (150 ms on automatic pilot and 125 ms on MFR) from the target jump or the onset of visual motion, these are thought of as implicit motor responses. Previous studies have suggested that one of the potential mechanisms involved in this motor

response is the internal forward model where the consequence of motor command predicted by efferent copy is compared with the current state of motor action. The target jump or the visual motion generates an error signal between the efferent copy and the actual sensory consequence, it thereby corrects the arm trajectory. However, it is still uncertain whether the accuracy of motor command affects the amount of the alternation of arm trajectory. Therefore, we attempted to clarify whether the accuracy of motor command affects the arm trajectory of memory-based reaching movement by two conditions (the normal and delay condition) and MFR which is induced by a grating motion stimulus. Several previous studies using delay conditions have demonstrated that the magnitude of delay, which attenuates the accuracy of the motor command based on a memory of the target's position, affects the performance of memory-guided reaching movements and the amplitude of EEG components involved in the motor preparation. In our task, participants performed reaching movements toward a memorized-target location with a beep cue which was presented 0 or 3 s after the target disappeared (0-s delay and 3-s delay conditions). The leftward or rightward visual grating motion was applied 400 ms after the cue. We evaluated a lateral velocity of arm movements and an event-related potential (ERP) recorded during the reaching task, which reflects the motor command accuracy. Our results showed that the N170 ERP amplitude in the posterior parietal electrodes and the MFR amplitude were significantly larger for the 3-s delay condition than the 0-s delay condition. These results suggest that the motor planning accuracy affects the amount of the implicit visuomotor response. Furthermore, there was a significant within-subjects correlation between the MFR and the N170 amplitude, which could corroborate the relationship between the implicit motor response and the motor planning accuracy.

Title: The Sensorimotor System Increases Muscular Co-contraction, but not Visuomotor Feedback Gains, in Response to Visually Amplified Movement Variability

Authors: *J. A. CALALO[1], R. LOKESH[1], A. ROTH[1], S. SULLIVAN[1], J. D. WONG[3], J. A. SEMRAU[2], J. G. CASHABACK[1];
[1]Biomed. Engin., [2]Kinesiology and Applied Physiol., Univ. of Delaware, Newark, DE; [3]Univ. of Calgary, Calgary, AB, Canada

Abstract: Humans have a remarkable ability to perform precise and accurate motor actions, such as threading a needle or throwing a fastball. Naturally occurring movement variability poses a

significant challenge to the sensorimotor system when attempting to perform precise actions. Further challenging control, sensorimotor delays may allow movement variability to propagate and remain uncorrected for a period of time. Two differing, but potentially complementary views, are that the sensorimotor system regulates feedback gains or muscular co-contraction to mitigate movement variability. To our knowledge, no one has directly manipulated movement variability to support either of these differing views. We hypothesized that the sensorimotor system modulates both feedback gains and muscular co-contraction in response to movement variability and time delays. With visually amplified movement variability, we predicted greater muscular co-contraction and visuomotor feedback gains. Participants were seated with their arm placed on an exoskeleton robot. We collected surface electromyography of six upper-limb muscles. Participants moved their arm to control a cursor on a screen. They kept the cursor within the bounds of a narrow visual channel while reaching towards a target. Participants performed four conditions where we manipulated movement variability (amplified or non-amplified) and or time delay (delay or no-delay). Movement variability was visually amplified by doubling the cursor's distance from the channel centerline. Time delays were imposed by delaying cursor feedback 200ms in the lateral direction, perpendicular to movement along the visual channel. Muscular co-contraction was calculated as the minimum activation between muscle pairs. To estimate visuomotor feedback gains, on probe trials we laterally shifted the cursor and recorded applied hand force against a simulated mechanically stiff channel that prevented lateral movements. With amplified movement variability, we found greater elbow and shoulder muscular co-contraction. We found greater muscular co-contraction was related to decreased hand movement variability at the end of the reach. Time delays did not influence muscular co-contraction. Unexpectedly, we found no changes in visuomotor feedback gains in response to amplified movement variability and time delays. Our results support the idea that the sensorimotor system uses muscular co-contraction, but not visuomotor feedback gains, to regulate movement variability.

Title: Force control in young adults: effects of visual feedback length of time

Authors: *E. CHRISTOU[1], S. DELMAS[1], M. WEINTRAUB[1], Y. CHOI[1], B. YACOUBI KEYHANI[2];
[2]Applied Phsio and Kinesiology, [1]Univ. of Florida, Gainesville, FL

Abstract: Visual feedback is an essential component for force control. Indeed, with amplification of visual feedback (increased gain), young adults exhibit less force variability during constant force contractions performed in a "pursuit" mode. Pursuit visual tasks allow the participant to see their force cursor and trajectory relative to the target. The display of the past force trajectory, therefore, creates a "history" effect, with longer lengths providing more visual information and ability to anticipate and correct future force perturbations. Here, we focus to understand how the length of the history effects force variability in young adults, an area that remains entirely unexplored. We hypothesized that young adults will exhibit lower force variability when given a history of 10 s, which contains the most influential oscillation to force variability (0.1 Hz). Ten young adults maintained a steady force at 10% MVC with ankle dorsiflexion for 30 s. They performed 3 trials for four different history conditions. Participants maintained their steady force output while they were able to see the past 1 s, 2 s, 5 s, and 10 s of their force trajectory history. The gain of visual feedback was 5º for the four history conditions, which were presented in a random order. For each contraction, we quantified the mean force, standard deviation of force, and coefficient of variation of force. In addition, we examined the power spectrum of the force output from 0-1 Hz, using a 0.05 Hz resolution. The mean force was not significantly different for the four history conditions ($p>0.3$). In contrast, the standard deviation and coefficient of variation of force were significantly greater for the 10 s condition compared with the 1 s, 2 s, and 5 s conditions ($p=0.001$), which did not differ in any of the measurements among them ($p=0.5$). Similar to the force variability, the force power spectra from 0-1 Hz was different for the 10 s condition relative to the other three conditions ($p=0.001$). Specifically, the 10 s condition exhibited greater power anywhere from 0-0.7 Hz. In contrast to our hypothesis, this study provides novel evidence that 10 s force history increases force variability in young adults by amplifying the oscillations in force output below 0.7 Hz. Although the exact reason remains unclear, we hypothesize that this exacerbation in force variability may relate to increased visual information processing and voluntary corrections derived from the 10 s history.

Title: Predictive attenuation of touch and tactile gating are distinct perceptual phenomena

Authors: *K. KILTENI, H. EHRSSON;
Karolinska Institutet, Solna, Sweden

Abstract: In recent decades, research on somatosensory perception has led to two important observations. First, self-generated touches that are predicted by voluntary movements become attenuated compared to externally generated touches of the same intensity (attenuation). Second, externally generated touches feel weaker and are more difficult to detect during movement than at rest (gating). Researchers today often consider gating and attenuation to be the same suppression process; however, this assumption is unwarranted because, despite more than forty years of research, no study has combined them in a single paradigm. We quantified how people perceive self-generated and externally generated touches during movement and rest. We demonstrate that whereas voluntary movement gates the precision of both self-generated and externally generated touch, the amplitude of self-generated touch is selectively attenuated compared to externally generated touch. We further show that attenuation and gating do not interact and are not correlated, and we conclude that they represent distinct perceptual phenomena.

Title: Modulation of tactile feedback for the execution of dexterous movement

Authors: *J. M. CONNER, A. BOHANNON, M. IGARASHI, J. TANIGUCHI, N. BALTAR, E. AZIM;
MNL-E, Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: While dexterity relies on the constant transmission of sensory information, unchecked feedback can be disruptive to behavior. How somatosensory feedback from the hands is regulated as it first enters the brain, and whether this modulation exerts any influence on movement, remain unclear. Leveraging molecular-genetic access in mice, we find that tactile afferents from the hand recruit neurons in the brainstem cuneate nucleus whose activity is modulated by local inhibitory neurons. Selective manipulation of these local inhibitory circuits can bidirectionally modulate cuneate neuron responses to tactile inputs and can suppress or enhance the transmission of tactile information to downstream targets (VPL thalamus), thereby affecting behaviors that rely on movement of the hands. Further investigating whether these local circuits are subject to top-down control, we identify distinct descending cortical pathways that innervate the cuneate region in a complementary pattern. Somatosensory cortical neurons target the core tactile region of cuneate, while a large rostral cortical population drives feed-forward inhibition of tactile transmission by targeting an inhibitory shell. These findings identify a circuit basis for tactile feedback modulation, enabling the effective execution of dexterous movement.

Title: Proprioceptive acuity for location of points on the hand and digits

Authors: *W. DARLING[1], B. ZUCK[1], L. MIKHAIL[2], J. ADHIKARI[2];
[1]Hlth. and Human Physiol., [2]Univ. of Iowa, Iowa City, IA

Abstract: Several studies have suggested that proprioceptive awareness of hand dimensions and locations of prominent structures on the hand such as digit tips and knuckles are quite inaccurate (e.g., Ingram et al. 2019 Plos One 14: e0210911). For example, proprioceptive estimates of hand width (distance between knuckles of the index and little finger) assessed by visually guided pointing with the index-tip of one hand to the knuckles of the unseen hand (covered by an opaque screen) resulted in a perceived hand width about 61% greater than actual width. However, visually guided reaches to proprioceptively specified external targets may result in large radial distance errors relative to the pointing arm shoulder (e.g., Darling and Miller 1995

Exp Brain Res 93:534), perhaps explaining these large errors observed previously. Here we tested accuracy of proprioceptively guided reaches to touch right index-tip to the knuckles and digit tips of the left hand in varied hand locations in 3D space. Right index-tip and target locations were measured in 3D using a magnetic tracker with small (1.5 mm dia) sensors. In the first experiment ten blindfolded right-handed subjects were instructed to reach at comfortable speed in a single movement to touch the right index tip to the specified targets on the left hand after first providing visually guided practice for each target. In a second experiment 4 naïve subjects received no visually guided practice prior to performing proprioceptively guided comfortable speed reaches to the verbally specified target. Visually guided reaches to each target were performed only after proprioceptively guided reaches to all targets had been completed. Reaches to each target while blindfolded were accurate from the first trial in both experiments, with average errors being in the range of 2-3 cm and less than 1 cm greater than when vision was allowed (note that the sensors cannot be co-localized, meaning that minimal errors are in the range of 1-1.5 cm). Variable errors were also small, averaging less than 1 cm. Final right index-tip locations were distributed around the hand targets rather than exhibiting large biases as in the previous work using visually guided pointing to the unseen hand in a fixed position. In contrast with previous findings, proprioceptive estimates of hand width were similar to or slightly smaller than actual hand width. Overall, we observed that in proprioceptively guided movements to touch the right index-tip to targets on the left hand were accurate. In contrast with previous studies using visually guided reaching to unseen structures on the hand, there was no evidence of proprioceptive overestimation of hand width.

Title: Establishing somatosensory milestones achieved during childhood

Authors: *V. W. T. CHU[1], S. DAVIS[2], N. AMIN[2];
[1]Occup. Therapy, [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: Pediatricians and therapists are familiar with motor milestones during early childhood development. Milestones are useful in detecting motor delays, allowing for early intervention. On the other hand, we do not have similarly established milestones for somatosensory development. To begin documenting somatosensory milestones, we designed two pilot studies to

examine somatosensory development in children from 6 months to 12 years.
20 children between 6 to 60 months participated in the early childhood study. In this study, early somatosensory development was assessed in two areas: spatial awareness (reaching for visible vs unseen tactile targets), force perception and control (engaging with thin crayons). While children were able to reach for visible targets by 12 months and demonstrated object permanence by 10 months, children under 15 months did not attempt to reach for unseen targets on their body. By 24 months, most children were able to reach for unseen targets on their body and continued to refine the accuracy. In the area of force perception and control, by 12 months, most children were able to manipulate thin crayons in their hands without breaking them. However, children broke the crayons more between 24-36 months as they are exploring coloring and drawing with the crayons. By 48 months, most children mastered adequate force control to color with thin crayons.
18 children between 4 to 12 years and 11 adults participated in the school age study. In this study, somatosensory development was assessed in five activities: elbow joint position matching, index finger end-point position matching, spatial movement shape recognition, active resistive force control, and weight change detection threshold. Based on our observation, we saw that children's accuracy in performance on the elbow joint position matching and index finger end-point position matching tasks are relatively developed by 7 years old. Development of spatial movement shape recognition occurs later as the response accuracy stabilize by 10 years old to adult level. The ability to hold still resisting against a subtly changing force also develops around the same time, as the 10-12 years old group performed similar to the adults. The ability to detect changes in weight of an object in the hand appear to develop after 12 years old as the detection threshold drops significantly from the 10-12 year group to the adult group.
These two studies allowed us to establish a preliminary timeline of somatosensory development in children. In both studies, we saw that motor abilities develop prior to the related somatosensory perception, and spatial awareness appears to develop before force perception.

Title: Blockage of the cerebellar outflow to the motor cortex during multi-joint movements impairs the compensation for upper limb intersegmental interaction torques in the monkey

Authors: *N. SINHA[1,2], S. ISRAELI[1], J. DEWALD[3], Y. PRUT[1];
[1]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]Interdepartmental Neurosci., [3]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: During multi-joint movements, the central nervous system (CNS) uses predictive control to compensate for and take advantage of dynamically generated intersegmental coupling torques. The neural substrate for the inverse dynamics model, which facilitates this control, is likely distributed across the cortico-cerebellar loop. The objective of this study was to investigate the role of cerebellar outflow to the motor cortex in establishing this distributed model. We hypothesized that blockage of the cerebello-thalamo-cortical (CTC) pathway leads to incorrect compensation for coupling torques in the cortically generated muscle torque commands during planar reaching. To test this hypothesis, we trained a monkey (*M. fascicularis*) to wear an exoskeleton (KINARM) and perform center-out reaching movements in the horizontal plane to eight equidistant center-out reaching targets. The CTC pathway was reversibly blocked by high-frequency stimulation (HFS, 130 Hz) of the superior cerebellar peduncle. Kinematic data was obtained during 892 control and 310 HFS trials. Using inverse dynamics analysis, we computed the components of the net torque (i.e., muscle and interaction torques) acting at the shoulder and elbow joints during center-out reaching task. The covariance between muscle and interaction torques was significantly higher in control as compared to HFS trials for both the joints. Furthermore, the muscle to interaction angular impulse ratio (MI-IR) during movement initiation was significantly higher in HFS as compared to control trials at the shoulder joint Thus, the muscle torques incorrectly accounted for the upper limb coupling torques during HFS. Finally, we correlated MI-IR during movement initiation (response variable) with the peak tangential velocity of the hand (predictor variable). We found significant correlation between the two variables in HFS. This shows that the amount of correction for interaction torques increases with movement velocity during HFS. Overall, these results show that the CTC pathway is essential for facilitating accurate feedforward control of movement that takes into account multi-joint coupling torques.

Title: Design and Validation of a Robust and Adaptive Brain-Machine Interface Algorithm for Control of Brain States

Authors: *H. FANG[1], S. A. BERMAN[3], Y. YANG[1,2];
[1]Dept. of Electrical and Computer Engin., [2]Disability, Aging and Technol. Fac. Cluster, Univ. of Central Florida, Orlando, FL; [3]Med., Univ. of Central Florida Col. of Med., Orlando, FL

Abstract: Brain-machine interfaces (BMIs) for controlling brain states hold promise for providing new therapies for neurological and neuropsychiatric disorders. Such a BMI adjusts brain stimulation based on real-time brain activity as feedback, forming a closed-loop brain stimulation system. Many groups have proposed model-based closed-loop brain stimulation systems and tested them in simulations. Most such systems assume linear time-invariant (LTI) models for brain activity. Brain networks, however, frequently involve nonlinear, uncertain, and time-varying dynamics, which can degrade control performance or even cause instability of LTI controllers during real-time control. Here, we develop a robust and adaptive BMI control algorithm with two main innovations. First, we design a new adaptive algorithm that can track a general form of nonlinear model uncertainty and time variations. Second, we improve the robustness of the closed-loop system by designing and applying a low-pass filter on the control input, which cancels the nonlinear model uncertainty only within the bandwidth of the closed-loop system. We next provide rigorous theoretical analyses of the stability margin and the transient bounds of the BMI control algorithm. We prove that there exists a tradeoff between the stability margin and transient boundary as we vary the bandwidth of the low-pass filter. We further develop a new method for choosing the optimal filter bandwidth based on the tradeoff. We next conduct two sets of simulations to validate the proposed algorithm. First, we use deep neural networks to simulate general nonlinear and uncertain brain network activity and systematically change the network parameters to validate our theoretical analyses. Second, we use a well-established nonlinear neurophysiological model of Parkinson's disease to simulate pathological brain activity for validating the entire robust and adaptive BMI control algorithm. The neural network simulation results validate our theoretical analyses, showing the stability and robustness of the BMI control algorithm. Moreover, the BMI control algorithm successfully regulates the pathological brain activity to a therapeutic regime in the neurophysiological simulations, which shows the potential of the BMI control algorithm in developing closed-loop treatments of brain disorders. Our robust and adaptive BMI control algorithm has implications for enabling future precise-tailored and safe treatments of a wide range of neurological and neuropsychiatric disorders.

Title: Mechanisms of decreased performance from automated artifact rejection algorithms in P3 speller brain-computer interfaces

Authors: *T. SWEET, C. SCHMITZ, T. BRANDT, D. E. THOMPSON;
Electrical and Computer Engin., Kansas State Univ., Manhattan, KS

Abstract: Brain-Computer Interfaces (BCIs) can be a tool to aid in communication of people with severe paralysis. The P3 Speller BCI, based on electroencephalogram (EEG) is a noninvasive BCI for communication; unfortunately, EEG signals are susceptible to noise that is often much larger than the underlying signal. Automated artifact removal (AAR) algorithms have been developed with the intent to improve the quality of the EEG signal. In a previous study[1], we investigated the effects of several AAR algorithms on P3 Speller BCI performance and found that applying the algorithms typically resulted in lower performance. Consequently, we proposed five specific mechanisms that may contribute to the performance decrease: 1) signal sources may be renumbered or inconsistently treated during the artifact rejection process, 2) the P3 signal may be classified as noise by the AAR algorithms and removed, 3) the algorithms may lead to an ill-conditioned observation matrix, making the classifier less stable, 4) the classifier may rely on the large magnitude of eye movements in the raw signal, resulting in better performance compared to the signal with the algorithms applied, and 5) the classifier may similarly rely on the large magnitude of blink artifacts. Here, we investigate each of the five mechanisms: 1) The AAR algorithms we investigated should recombine the signal back into the time-domain before classification, eliminating the possibility of source renumbering; however, this is still under investigation, 2) While P3 amplitudes are reduced, morphology appears similar, and noise is similarly reduced, 3) While the condition numbers vary between algorithms, we find no consistent increase that could explain the performance difference, 4) early analysis shows that it is possible to track eye movement using EEG, but not with the resolution that would be required to achieve the observed BCI performance, and 5) we do find evidence that most participants typically blink in the window where the P3 would normally be present, particularly during early runs. We interpret this as evidence that original classifiers may have been partially relying on the blinks to discriminate between targets and non-targets. The AAR algorithms remove these blinks, which could reasonably explain the decrease in performance.

Title: Implication of bi-domain representation of neural signals in non-invasive brain-computer interface (BCI) decoding applications using deep learning

Authors: *O. ALI[1,2], M. SAIF-UR-REHMAN[4], K. ABDALLAH[1], T. GLASMACHERS[3], I. IOSSIFIDIS[5], C. KLAES[6];

Abstract: Brain-computer interfaces (BCIs) establish a path of communication between humans and machines by translating the neural signals to control commands. Electroencephalography (EEG) is one of the most common sources of neural signals because of its inexpensive and non-invasive nature. They are often contaminated with noise and artifacts and have low spatial resolution. Henceforth, accurate decoding and translation of EEG signals into control commands are non-trivial. Mostly, important patterns for classifying EEG signals are deeply hidden. Raw time-series is either mapped to frequency domain, or time domain features are extracted. The purpose of feature extraction is to highlight the critical information for discrimination of data for different intended actions. In BCI, often the raw signals are mapped to frequency domain. Sometimes, this mapping compromises time-frequency resolution. Therefore, a better way would be to fuse the time domain and frequency domain information. Currently, deep-learning algorithms have demonstrated success in learning hidden and significant patterns with domain fusion. However, the performance of the deep learning algorithms relies upon the quality and quantity of the data. Consequently, a better domain representation technique and an attention-based method to generate better-quality data can empower deep learning algorithms. In this study, bi-domain representation of the EEG signals is employed to learn meaningful hidden patterns. Raw EEG signals show the time-domain representation of the EEG signals; however, frequency-domain representation is obtained by a novel input formation method. Additionally, an attention-based data augmentation method is proposed to generate new training examples. The frequency domain inputs are formed using the proposed modified version of Short Time Fourier Transform (STFT), called anchored-STFT. Anchored-STFT is inspired by wavelet transform and it tries to minimize the time-frequency resolution tradeoff displayed by STFT. As a result, it forms the inputs with better time-frequency resolution compared to standard STFT. Secondly, we propose a new attention-based method to generate new training inputs. The

proposed method finds the similarity score between different features of an input and utilizes the score to generate new training inputs. We used the publicly available BCI competition IV dataset 2b for the evaluation of our methods. Preliminary evaluation on dataset of two subjects (subject 5 and subject 6) shows that our methods improve the classification accuracy by 1.2% for subject 5 and 1.5% for subject 6 compared to state-of-the-art results.

Title: Detection of balance loss from electroencephalography: a novel approach to prevent falls implementing robotic orthosis

Authors: *A. SUJATHA RAVINDRAN[1], C. MALAYA[2], M. CESTARI[1], I. JOHN[2], G. E. FRANCISCO[3], C. LAYNE[2], J. L. CONTRERAS-VIDAL[1];
[1]Electrical and Computer Engin., [2]Dept. of Hlth. and Human Performance, Univ. of Houston, Houston, TX; [3]TIRR Mem. Herman Rehabil. and Res. Ctr., Houston, TX

Abstract: Falls remain one of the leading causes of death, injury, and hospital admission particularly in the elderly and people with locomotion difficulties. Wearable robotic systems are gaining popularity to assist or rehabilitate gait in these populations. If these powered robotic orthoses (exoskeletons) are to be able to assist with preventing the fall, early detection of balance loss is required. Studies exploring the prediction of perturbations from scalp electroencephalography (EEG) are rare and there exists a major gap in our understanding of how the brain detects and processes balance perturbations to try to avoid a fall. To fill in the above knowledge gaps and advance neurotechnologies for fall prevention in exoskeletons, we conducted, to the best of our knowledge, the first neural decoding investigation of perturbations during standing with an exoskeletal suit in healthy able-bodied adults. Specifically, we acquired high-density EEG, electromyography (EMG), and kinematic (center of pressure (COP)), data from 7 healthy able-bodied participants during a standing balance perturbation task with and without subjects wearing an exoskeleton device. The subjects were exposed to fixed and random

perturbations during standing in both conditions. The timing of perturbations was randomized across trials. We found components in the perturbation evoked cortical potentials (PEPs) as early as 50-90 ms after the onset of the mechanical external perturbation, which preceded both the peak in EMG activity (~190 ms) and the peak in COP (~ 350 ms). We later used a convolutional neural network (CNN) to detect the perturbations from single trials and obtained a 5 fold cross-validation test F score of 74.23 ± 5.2 %. The CNN model was implemented with emphasis on explaining the model decisions using gradCAM. We demonstrated that the model was driven by relevant components in the PEP to infer the predictions and not artifacts. The model's explanations further aligned with the dynamic functional connectivity measure estimated using the phase difference derivative. Specifically, the nodal connectivity was higher in the occipital frontal region in the early stage of the perturbations, shifting to parietal, then to the motor, and back to the parietal channels. Moreover, we also demonstrated the feasibility of decoding continuous COP values from EEG using a gated recurrent unit model. Overall our findings suggest that the EEG signals contain short-latency neural information related to an incoming fall which may be useful for developing brain-machine interface (BMI) systems for fall prevention in neurally-controlled robotic exoskeletons.

Title: Pyramidal-tract neurons are better and faster than intra-telencephalic neurons at neuroprosthetic learning due to intrinsic cell-type differences and local circuitry

Authors: *N. VENDRELL LLOPIS[1], C. FANG[1], A. J. QÜ[1], R. M. COSTA[2], J. M. CARMENA[1];
[1]Helen Wills Neurosci. Institute, Univ. of California-Berkeley, Berkeley, CA; [2]Neurosci., Dept. of Neurosci. and Neurology, Zuckerman Mind Brain Behavior Institute, Columbia Univ., New York, NY

Abstract: During learning, communication between cortex and striatum is essential. Two different population of cortical neurons, intra-telencephalic (IT) and pyramidal tract (PT), project into striatum. Although a large amount of evidence demonstrates contrasting functional organization among both populations, it is unclear to what extent the different characteristics of each cell-type influence learning. To answer this question, we labeled different cell-types in two groups of mice and trained them to modulate the activity of either IT or PT neurons to control a brain-machine interface (BMI). We found that PT neurons can learn to control a BMI faster and reach better performance than IT neurons. Moreover, after disambiguating the impact of cell identity from other experimental features, our findings show that this is a result of characteristics inherent of being PT neurons as well as characteristics of their local circuitry in proximity to striatum.

Title: Decoding user task engagement in a long-term ECoG BCI

Authors: *Y. GRAHAM[1,2], N. NATRAJ[1,2], R. ABIRI[1,2], S. SEKO[1,2], E. F. CHANG[1], K. GANGULY[1,2];
[1]Univ. of California, San Francisco, San Francisco, CA; [2]San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: For individuals with paralysis, brain computer interfaces (BCIs) have the potential to improve motor function by translating movement-related neural signals into control signals for external devices such as cursors and prosthetic anthropomorphic upper-limb devices. Control of these devices can enable users to regain upper limb functionality, autonomy and improve their quality of life. Our lab has demonstrated that stable "plug-and-play" control of a 2D cursor is possible by leveraging the stability of electrocorticography (ECoG) and long-term closed-loop decoder adaptation. While ECoG neuroprosthetic cursor control enables patients to communicate by typing, we have found that the control can sometimes be error prone. Due to neural fluctuations in attention and maintenance of cognitive engagement, cursor control can vary from proficient to poor within a single session and even within single trials. We hypothesize that such transient errors and inconsistent control results from periods when the user is not directly engaged in the task. Thus, if we can explicitly decode user engagement and modulate direct neural control of the neuroprosthetic device, cognitive load would be reduced, and performance would improve. To study user task engagement, we looked at the spatial changes and temporal dynamics of beta frequency (13-30Hz) during a four state, four target 2D discrete cursor BCI control task. Beta frequency oscillations have been shown to play a critical role in motor functions such as reaching behaviors. Specifically, during stationary holds or moments prior to movement, beta frequencies synchronize and increase in power. In contrast, during movement initiation and execution, beta frequencies desynchronize and decrease in power. The four states of the task correspond to observation, movement preparation, active control, and idleness respectively. In this task structure we were able to capture intentional moments of engagement and disengagement. Our subject, a 38-year-old man with severe spastic tetraparesis, was implanted with a 128-channel chronic ECoG array over sensory and motor cortices. Data was collected at least once a week, with a testing day producing approximately 200-400 trials. We conducted signal magnitude and phase analysis using the Hilbert Transform as well as Singular Vector Decomposition for spatial-temporal analysis of beta with respect to the ECoG grid. We found that changes in beta frequency amplitude and beta burst rate can be used to detect movement intention immediately prior to the onset of direct BCI control.

Title: Eeg channel selection for ssvep bci speller

Authors: *H. KIM[1], K. WON[2], S. C. JUN[3];
[2]Electrical Engin. and Computer Sci., [1]Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of; [3]GIST, Gwangju, Korea, Republic of

Abstract: Title: EEG channel selection for SSVEP BCI speller**Authors:** Heegyu Kim, Kyungho Won, and Sung Chan Jun****Abstract.*** The steady-state visual evoked potential (SSVEP) represents a stable neural response evoked by repetitive visual stimuli at specific frequency around the occipital area, which is applicable to high-speed brain-computer interface (BCI) speller. EEG channels for SSVEP BCI speller are commonly chosen around parieto-occipital areas to extract features. In this work, we proposed a channel selection method for SSVEP BCI speller based on CCA (Canonical correlation analysis) coefficients, which may increase user comfort as well as reduce preparation time.Our approach for optimal channel selection is follows: first, for each channel, we performed CCA method between single-channel EEG and reference signal (sinusoidal waves) per class. This estimated CCA coefficient represents the strength of linear relationship with the reference signal. Then EEG channels were sorted in decreasing order of the averaged CCA coefficients. Finally, the five channels with the top five coefficients were selected. We used a benchmark SSVEP dataset (Wang et al., 2017) that is publicly available. In this dataset, 64-channel EEG were collected from 35 participants; they performed 6 blocks of 40-class SSVEP based BCI speller, and each block contained 40 trials (single trial per class). We applied the channel selection method to 28 EEG channels around the central, parietal, and occipital areas, and compared to the whole EEG channels around parieto-occipital areas in this dataset (‘PO7', 'PO5', 'PO3', 'POZ', 'PO4', 'PO6', 'PO8', 'O1', 'OZ', and 'O2'). The performance was evaluated using standard CCA by 6-fold cross-validation.As a result, the average detection accuracy using our channels chosen by the proposed selection approach and the whole channels were 85.40±17.22% and 88.70±9.89%, respectively. In terms of information transfer rate (ITR), our channels chosen and the whole channels achieved 82.18±24.99 bits/min and 85.45±14.86 bits/min, respectively. In addition, we observed that there was no statistical significance between our channels chosen and the whole channels around parieto-occipital areas with p=0.5998 for detection accuracy, and p=0.8442 for ITR (by Wilcoxon signed-rank test). The proposed channel selection may reduce the number of EEG channels by up to 50%, while maintaining the performance of SSVEP speller.

Abstract: A key factor in the clinical translation of brain-machine interfaces (BMI) for restoring motor function will be robustness to changes in a task. This poses a significant challenge for applications such as brain-controlled functional electrical stimulation (FES), where the patient's hand may produce the same movements with varying postures and loads. Here we investigate the impact of task changes on performance in a BMI for restoring finger control.
To address this challenge, one rhesus macaque was implanted with a Utah microelectrode array targeted to the hand area of primary motor cortex, and 10 chronic bipolar electromyography (EMG) electrodes targeting muscles of the forearm and hand. He performed a 2-degree of freedom finger task to control a virtual hand using his index finger and middle-ring-small fingers to push doors in a manipulandum. During the task, the monkey would flex or extend one or both finger groups to match virtual targets while finger flexion, electrode threshold crossing rate (TCR), and EMG were simultaneously recorded. Context changes were introduced by adding torsion springs to the manipulandum or changing the static wrist angle during the task.
Using ridge regression, models mapping TCR to kinematics and to EMG activity were trained on normal trials, i.e. trials without the context changes, and tested on off-context trials, i.e. trials with the context changes, as well as a held-out set of normal trials. Across all kinematic variables and days, using the model to predict kinematics in off-context trials resulted in a 37% (SD =

30%) increase in mean-squared error (MSE) relative to predicting kinematics in normal trials. Predicting finger flexor and extensor EMG in off-context trials also resulted in large increases in MSE relative to predicting EMG in normal trials. The magnitude of the increases in error was larger for flexor muscles than extensors. These results suggest that neither kinematics nor EMG maintain a linear relationship with neural activity across these contexts. Lastly, decoder performance was tested in real-time using a Kalman filter trained on normal runs to control the virtual hand while context changes were added. Interestingly, the context changes in online control resulted in no significant changes in target acquisition time, time orbiting the target, or path efficiency.
These results highlight that modifying a task leads to a change in motor cortex activity which reduces kinematic and EMG prediction accuracy. However, subjects may be able to adapt to this change in online control. Future work will seek to replicate these results in a second monkey and evaluate changes to BMI performance in the context of brain-controlled FES.

Title: Decoding grasp and speech signals from the cortical grasp circuit in tetraplegic human

Authors: *S. WANDELT[1], S. KELLIS[2], D. A. BJANES[1], L. BASHFORD[1], H. JO[1], I. ROSENTHAL[1], K. PEJSA[1], D. KRAMER[2], B. LEE[2], C. LIU[2], R. A. ANDERSEN[1];
[1]Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Neurorestoration Ctr. and the Departments of Neurolog. Surgery, USC, Los Angeles, CA

Abstract: Tetraplegia from spinal cord injury leaves patients paralyzed below the neck and unable to perform many activities of daily living. Brain-machine interfaces (BMIs) could give tetraplegic patients more independence by reading signals out of the brain directly and using these signals to control external devices such as robotic arms or hands. The cortical grasp network has been of particular interest because of its potential to facilitate the restoration of dexterous object manipulation. However, a network that involves such high-level cortical areas

may also provide additional information, such as the encoding of speech.
Towards understanding the role of different brain areas in the cortical grasp network, neural activity related to motor intentions for grasping was recorded in a C5-C6 tetraplegic patient in the supramarginal gyrus (SMG), the ventral premotor cortex (PMv), and the somatosensory cortex (S1). Each motor imagery trial began with a brief inter-trial interval, followed by a visual cue (picture of grasp shape) to one of five specific grasps. Then, after a delay period, the subject was instructed to imagine performing the cued grasp. In a second version of the experiment, the subject was instructed to say the name of the grasp out loud instead of motor imagery. We hypothesized that due to SMG's involvement in visual word recognition and phonological processing (Oberhuber, *Cerebral Cortex*, 2016), it would show higher neuronal modulation to speech than PMV and S1.
We found that in high-level brain areas SMG and PMV, grasps were well represented by firing rates of neuronal populations already at visual cue presentation. During motor imagery, grasps could significantly be decoded from all brain areas. A neuron-dropping analysis highlighted that at identical neuronal population sizes, SMG and PMV achieved similar decoding abilities, demonstrating their potential for grasp BMIs. During speech trials, SMG demonstrated highly significant classification accuracies, in contrast to PMV and S1, which were not able to significantly decode speech.
To conclude, these findings suggest that grasp signals can robustly be decoded from the cortical grasping circuit in human. PMV indicates a specialized role in grasping, while SMG's role is broader and extends to speech. Together, these results indicate that brain signals from high-level areas of the human cortex could be exploited for a variety of different BMI applications.

Abstract: The opportunity to develop and test invasive brain-computer interface (iBCI) decoders in closed-loop with human users is very limited, yet essential to scientific and clinical progress. To address this challenge, we are developing a new machine learning-based iBCI encoder model that produces neural firing rate signals from finger movements, allowing neurologically intact humans to perform iBCI tasks in real time. The iBCI model combines an artificial neural network (trained on non-human primate cortical firing rates) with real-time healthy human subject input (captured non-invasively using a data glove) to generate emulated M1 firing rates. The emulated neural activity can be input to any iBCI decoder and used to operate an external device. A human subject controlling a cursor with a high-dimensional (19 DoF), non-intuitive input-space of finger joint angles is conceptually analogous to that of an iBCI system controlled from an unfamiliar, non-intuitive space of motor cortex activity. The great advantage of our approach is that readily-recruited, healthy human subjects can interact with decoders in closed loop, preserving the relevant learning dynamics between humans and adaptive decoders.
We validated the proposed iBCI model using both offline measures of the emulated neurons and performance measures of subjects during closed-loop cursor control. We found that emulated neural signals representing reaching movements in different directions maintain the spatial clustering patterns of actual M1 neurons when projected into a PCA plane, as well as the rotational dynamics commonly observed with jPCA. We used a steady state Kalman filter to decode cursor velocity from the emulated firing rates, allowing subjects to perform a center-out target acquisition task to facilitate direct comparisons to human subjects in published iBCI studies. We ran 25 healthy human subjects, each on four separate days. Our subjects' performance was consistent with that of the paralyzed, electrode-implanted, human iBCI users in studies by Kim et al., 2008, Kim et al., 2011, and Simeral et al., 2011 across seven different behavioral measures. These encouraging results suggest that this real-time firing rate emulation process is a useful means to provide statistically robust sample sizes for rapid prototyping and optimization of decoding algorithms, and the study of bi-directional learning in iBCIs, ultimately improving iBCI control.

Title: Developing a Spinal Cord Model that Can Acquire and Maintain Multiple Behaviors

Authors: *R. HARDESTY[1], B. JEONG[1,2], J. R. WOLPAW[3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [2]Purdue Univ., West Lafayette, IN;
[3]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY

Abstract: The spinal cord, like the rest of the CNS, changes through life. When a new behavior is acquired, its CNS substrate or *heksor* (see Wolpaw et al. abstract) is created and, in addition, pre-existing heksors adapt to maintain their own behaviors. The new and old heksors negotiate the properties of the CNS neurons and synapses they share (Neuroscientist 16:532-549, 2010; J Physiol 596:3469-3491, 2018). For motor behaviors (behaviors with heksors that include spinal properties), this process changes the spinal cord. For example, EMG and kinematic details of locomotion may change, but its key features (e.g., right/left symmetry, posture, balance) are maintained. We are developing a model of a spinal cord-like neural network that can acquire and maintain several simple motor behaviors. We created a simple single degree-of-freedom musculoskeletal model of the elbow that approximates the normal relationship between motoneuron activity and kinematic output, i.e. behavior. Motoneuron activity is driven by a spinal-like neural network that incorporates spinal circuitry, reflexes, and a simple descending corticospinal input. The neural network architecture is based on the known circuitry of the spinal cord and has physiologically-inspired leaky integrate-and-fire neurons. In initial testing, simulated kinematics appear to be stable with no oscillatory or chaotic behavior, despite the model complexity. Additionally, this network exhibits several physiologically-appropriate characteristics, e.g. agonist motoneuron activity increases in response to muscle lengthening. Future development will optimize the neural network to complete two simple behaviors: 1) sine-wave elbow flexion/extension oscillation; 2) square-wave elbow flexion/extension oscillation. We will assess the ability of this network to learn and maintain these two behaviors by calculating for each behavior the normalized root-mean-squared error of the generated output (elbow angle) compared to the desired trajectory. Specifically, we will determine the minimum redundancy and network characteristics that are required to complete and maintain these behaviors, e.g., the minimum number of neurons or the need for signal-dependent noise. This model should provide a computational framework to: 1) assess how changes in the spinal cord affect multiple behaviors; 2) make predictions that can then be tested experimentally; and 3) suggest potential therapeutic targets for rehabilitation.

Title: Heksor - CNS substrate of an adaptive behavior: testing the concept

Authors: *J. R. WOLPAW[1], A. KAMESAR[2], A. K. THOMPSON[3], Y. CHEN[1];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Stratton VA Med. Ctr., Albany, NY; [2]Hebrew Union Col., Cincinnati, OH; [3]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC

Abstract: Over the past half-century, the hardwired CNS of 1970 has gradually become the ubiquitously plastic CNS of today, in which change is the rule not the exception. This transformation requires a new paradigm for understanding how adaptive behaviors are acquired and maintained. The core of this paradigm is a previously undefined CNS entity, here given the name *heksor* from the Greek *hexis*. *A heksor is a distributed network of neurons and synapses that produces an adaptive behavior and changes as needed to maintain the key features of the behavior, the features that make the behavior satisfactory.* Muscle activity and kinematics may change; key features are maintained. Because heksors share the CNS, their concurrent changes constitute a negotiation; they negotiate the properties of neurons and synapses that they all use. They keep the CNS in a state of negotiated equilibrium that allows each heksor to maintain the key features of its behavior (Neuroscientist 16:532-549, 2010; J Physiol 596:3469-3491, 2018). We are testing the new paradigm. The strategy is straightforward. Acquisition of a new behavior changes many CNS areas. The paradigm predicts that this plasticity comprises the new heksor underlying the new behavior, plus changes in old heksors that maintain the key features of their behaviors despite the changes in neurons/synapses they share with the new heksor.
This poster presents new human and animal data that confirm and extend earlier studies. The studies are approved by the MUSC & Stratton IRBs and the Stratton IACUC. In normal rats, a new heksor created by soleus H-reflex (HR) operant conditioning in one leg does not impair key features of locomotion (e.g., right/left symmetry in step-length & hip height); but it does change how these features are produced. Changes in the locomotion heksor (e.g., in other reflex pathways) maintain symmetry. In rats with incomplete spinal cord injury (iSCI) that impairs locomotion, a new HR heksor that improves locomotion enables negotiation among the heksors that leads to widespread beneficial change in the locomotion heksor. Studies in humans with iSCI match these results: a new HR heksor that improves locomotion (e.g., by eliminating footdrop or clonus) enables practice leading to overall improvement in locomotion. Furthermore,

in rats with iSCI, an inappropriate new HR heksor does not further impair locomotion; changes in the locomotion heksor prevent this. Finally, the long-term spinal plasticity produced by cortical stimulation appears to comprise the direct effects of stimulation plus heksor adaptations to these direct effects. These results further support the new paradigm, and may guide therapeutic development.

Title: From embodiment to enmachinment

Authors: *D. KERIVEN SERPOLLET *[1,2], A. ROQUES *[2], M. NASROUNE[2], Y. JAMES[2], P.-P. VIDAL[1,3,4];
[1]Ctr. Borelli, Univ. de Paris - ENS Paris-Saclay - CNRS - SSA, Paris, France; [2]Training & Simulation, Thales AVS France, Osny, France; [3]Hangzhou Dianzi Univ., Hangzhou, China; [4]Univ. Cattolica del SacroCuore, Rome, Italy

Abstract: * : these authors contributed equally to this work
Eye-trackers and head-trackers are robust tools to investigate how individuals interact with their environment. In the field of aeronautics, gaze control is generally used as a way to assess a pilot's performance or as a way to predict the mental workload (to prevent catastrophes from happening for instance). To the best of our knowledge, only few studies have been led on the eye-tracking data of pilots during flights. Here, we propose a study involving nine male professional helicopter pilots (age: 39 ± 5.7) equipped with an eye-tracking and a head-tracking devices in a full-flight level-D helicopter simulator in order to explore their ocular activity and gaze control during two realistic scenarios designed by expert pilots. We derived multiple gaze-related metrics that account for the pilots' current activity, experience or style. The movements of the aircraft relatively to the ground and the movements of the pilots' head were analyzed in the frontal plane (roll movements). The different roll movements of the aircraft above 10° were identified using a rupture-detection algorithm. It appeared that the movements of the aircraft and of the head were correlated, as we computed the Pearson correlation coefficient for every pilot

for both scenarios and found a positive correlation. This indicates that when the aircraft rolls to the left, the pilot's head also rolls to the left. Furthermore, a coherence analysis showed that those two signals were very coherent in the frequency range of the aircraft roll movements. Another secondary result we found is that the more experienced the pilots were, the more they relied on their flight instruments (rather than their own sensory cues) during critical flight phases. Our results suggest that the helicopter can be integrated by the pilots as extensions of their body representations, a phenomenon renewing the classical concepts of embodiment and distalization that we call 'enmachinment'. Indeed, we found, for every pilot, a pilot-specific linear relationship between the motion of the head and the motion of the helicopter. In this vision, the pilot and the machine are unified as a human-machine hybrid in which the pilot has integrated not only their own corporeal internal model but also the internal model of the helicopter (called "law of flight"). We suggest that this enmachinment will have important consequences on the training of helicopter pilots and more globally in human-machine interactions.

Title: Decisions in an innate behavioral sequence

Authors: *K. M. CURY, R. AXEL;
Columbia Univ., New York, NY

Abstract: Innate behaviors are comprised of ordered sequences of component actions that progress to satisfy drives. We have characterized the structure of egg-laying behavior in the fly and demonstrate that it consists of a sequence of component actions analogous to Nikolaas Tinbergen's "reaction chain." Tinbergen portrayed innate behaviors as a "reaction chain" in which each component action of the sequence enhances the probability of encountering "sign stimuli" that promote progression to a subsequent component. The organization of component actions into a "reaction chain" provides decision points at the junctures of component behaviors that ensure the successful progression towards the consummate act that satisfies the drive. We have identified a cluster of internal sensory neurons that provide interoceptive information about

the progression of the egg during ovipositor burrowing, the terminal behavioral component that is necessary for the subterraneous deposition of the egg. These neurons impart sensory feedback that allows burrowing to continue to egg deposition or to abort in favor of further exploration. Diminished activity of these neurons upon completed egg expulsion acts as a "sign stimulus" that results in the transition to the final phase of egg-laying, ovulation, allowing the cycle to repeat. Flexibility is therefore imposed on an innate and stereotyped sequence of motor actions to optimize the deposition and successful development of the egg.

Title: Myotomal Spread Pattern in Intraoperative Neurophysiological Monitoring of Selective Dorsal Rhizotomy

Authors: *K. KIM, S. LEE, J. LEE, K. KIM, S. HYUN, J. CHOI;
Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Introduction: Selective dorsal rhizotomy (SDR) is a surgery assuming that the cause of spasticity in cerebral palsy is related to hyperactive sensory-motor reflex arc and attempts to cut off part of the dorsal roots to reduce the afferent input. We aimed to reveal the myotomal spread pattern in which the lower extremity muscles contract during electrical stimulation of the dorsal roots or rootlets during intraoperative neurophysiological monitoring of SDR.
Methods: A total of 48 patients with cerebral palsy, who underwent SDR between April 2016 to June 2021 were included in the analysis. During SDR, recording of electromyography (EMG) was conducted in the external anal sphincter and bilateral adductor magus, vastus medialis, tibialis anterior, gastrocnemius, abductor hallucis, and biceps femoris muscles. To determine which dorsal rootlets to be sectioned, motor responses to a single stimulation of roots and tetanic stimulation of rootlets are evaluated. We present a visualization of myotomal spread pattern; distribution of muscles activated in a single and tetanic stimulation of dorsal roots and rootlets.
Results: When stimulating L2, L3, and L4 roots, there were myotomal spread patterns of co-activating adductor magnus, vastus medialis, and biceps femoris muscles in ipsilateral and contralateral sides, whereas stimulation to L5, S1, and S2 roots showed a relatively even distribution of all ipsilateral muscles (Fig 1). On the contralateral side, stimulation to L5, S1, and S2 roots produced the most activation in the biceps femoris, followed by adductor magnus and vastus medialis. There was no difference in the myotomal spread pattern in the analysis of subgroups divided by Gross Motor Function Classification System (GMFCS) and the spasticity.

Conclusion: In intraoperative neurophysiological monitoring of SDR, different myotomal spread patterns were observed in the upper and lower lumbosacral roots, irrelevant of GFMCS or spasticity. We propose that the results will help identify the function and anatomy of human locomotor patterns.

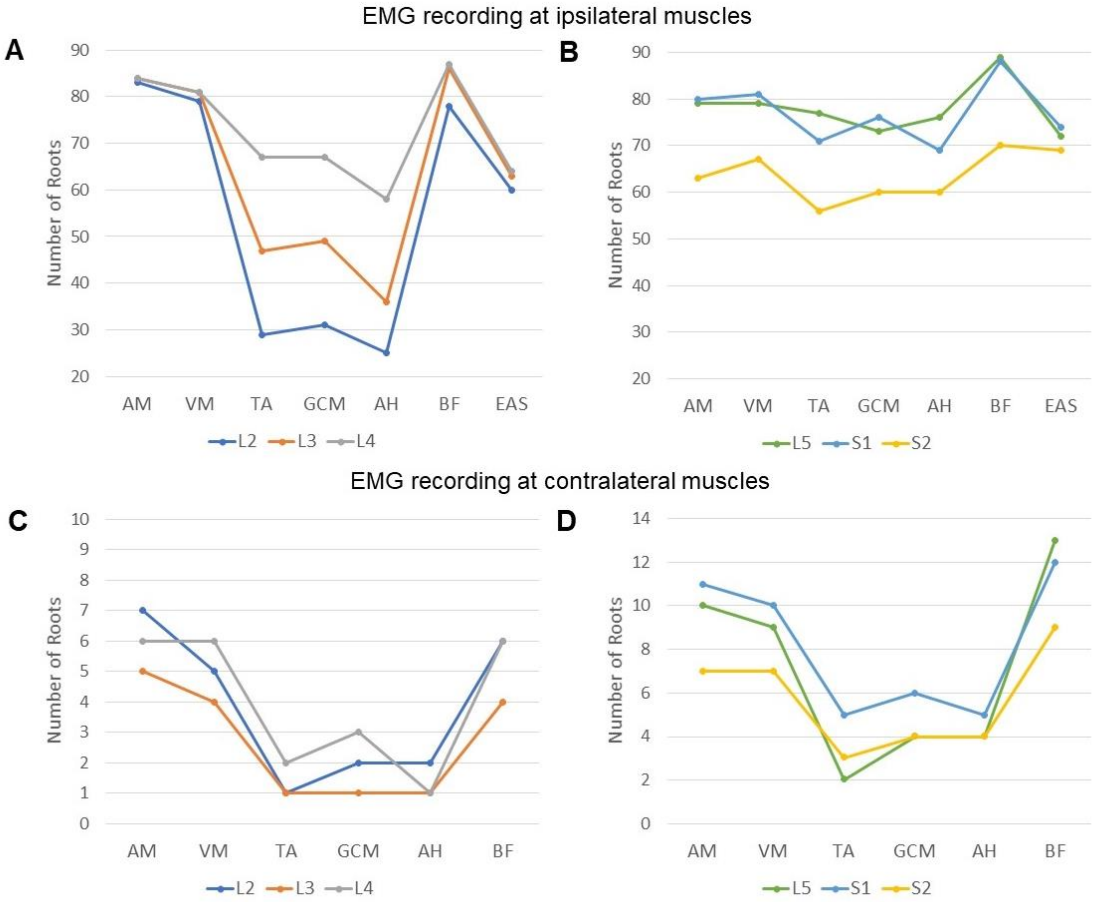

Figure 1. Myotomal spread pattern to a single stimulation of dorsal roots in ipsilateral L2-L4 (A), L5-S2 (B), contralateral L2-L4 (C), and L5-S2 (D) roots.

Title: Monitoring vigilance during resting-state fMRI using ultra-slow fluctuations in the 4th ventricle

Authors: I. S. FERNANDEZ[1], J. GONZALEZ-CASTILLO[1], D. A. HANDWERKER[1], *P. A. BANDETTINI[1,2];
[1]Section on Functional Imaging Methods, [2]FMRI Core, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Fluctuations in wakefulness and vigilance during resting-state fMRI scans can affect the estimates of functional connectivity (FC) and, if ignored, can become a substantial confound in the data. This is important to keep in mind, especially in clinical studies where fluctuation in vigilance can range across populations. However, monitoring vigilance during fMRI requires concurrent recordings, such as eye tracking or EEG, or training of complex models with potentially limited ability to generalize to other samples. Because of this, simple methods for monitoring vigilance that rely solely on fMRI data are in great demand. Here we evaluate the efficacy of an alternative, simple way of monitoring vigilance based on frequency analysis of the fMRI signal in the 4th ventricle (FV). This method is motivated by recent research suggesting that descent into sleep is accompanied by a reversal of CSF flow that translates into inflow waves at approx. 0.05Hz observable in the FV. In this project, we first test if these CSF traces can be detected in datasets with limited inflow weighting such as the 7T resting-state Human Connectome Project dataset. To aid in our analysis we relied on concurrent eye tracking data as a secondary method of monitoring vigilance. We found that despite these data not being optimized to capture inflow effects in the FV, the above-mentioned 0.05 Hz CSF inflow-related fluctuations were clearly detectable in subjects with long eye-closure periods. Not only was the signal present in these data, but the temporal evolution of its spectral power could be used to predict individual periods of eye closure with up to 70% accuracy. Further analysis uncovered similar fluctuations in large portions of gray matter that severely influence estimates of FC, leading to significant losses in sensitivity and specificity of connectivity changes across vigilance states. In summary, our results add evidence that the value of 0.05Hz fluctuations in the FV is a marker of vigilance in fMRI data. It also highlights the strong modulatory effects of wakefulness FC estimates derived from the 7T HCP sample, an important, often re-analyzed, publicly available dataset.

Title: Correspondence between changes in the BOLD signal and relative cerebral blood flow after one night of total sleep deprivation

Authors: *E. SHOKRI KOJORI[1], S. B. DEMIRAL[1], D. TOMASI[1], G.-J. WANG[1], N. D. VOLKOW[2];
[1]NIH, Bethesda, MD; [2]NIH/NIDA, Rockville, MD

Abstract: Sleep deprivation (SD) has been associated with marked changes in measures of brain activity and metabolic supply. Several fMRI studies have shown SD-related increases in low frequency (LF, < 0.1 Hz) fluctuations in the BOLD signal in the occipital, dorsal attention, and sensorimotor regions. Imaging of cerebral blood flow and glucose metabolism have also shown increases in metabolic supply in similar regions, particularly, in the visual cortex. It is not known whether SD-related changes in measures of brain activity and metabolic supply are coupled. To address this, a group of 20 healthy individuals (10 females, 22-72 years old) underwent brain imaging to index resting-state brain activity with fMRI (10 min) and to measure R1, an index of relative cerebral blood flow (rCBF), with FBB-PET (using a cerebellar reference region). The fMRI and PET data were collected once after rested wakefulness (RW) and once after one night of total SD (order of RW and SD days were randomized across participants). One male participant was excluded due to issues with the PET data. As expected, SD resulted in significant increases in the fractional amplitude of LF fluctuations (fALFF) within the visual, dorsal attention, and sensorimotor regions ($p_{FWE}< 0.05$). We have previously shown that these regions exhibit a strong coupling with the peripheral sympathetic tone and were labeled as an autonomic network (AN). SD also resulted in significant increases in rCBF primarily in the middle occipital gyrus ($p_{FWE} < 0.05$). However, SD-related changes in rCFB and fALFF were not associated in the visual regions where both measures significantly increased ($r(17) = 0.26$, $p = 0.28$). We performed a follow up analysis to characterize the relative metabolic cost (rCST): the extent that rCFB measure of metabolic supply exceeded fALFF measure of brain activity in a given region relative to the rest of brain. We found that SD significantly decreased rCST in most areas of the AN including sensorimotor and dorsal attention regions ($p_{FWE} < 0.05$). In sum, SD concurrently increased rCBF and fALFF, particularly, in the occipital cortex, yet these changes were not associated across participants. Furthermore, reductions in rCST suggested that SD-related increases in LF fluctuations within sensorimotor and dorsal attention regions were not accompanied by proportional increases in rCBF. The findings are relevant for delineating the vascular versus neuronal origin of SD-related increases in LF fluctuations in fMRI signal within the AN.

Title: The differential effects of adiposity on functional connectivity in preadolescent children

Authors: *N. E. LOGAN[1], D. R. WESTFALL[1], L. B. RAINE[2], S. ANTERAPER[3,4], L. CHADDOCK-HEYMAN[5,1], S. WHITFIELD-GABRIELI[1], A. F. KRAMER[1,5], C. H. HILLMAN[1,2];
[1]Psychology, [2]Physical Therapy, Movement, & Rehabil. Sci., Northeastern Univ., Boston, MA; [3]MIT, Cambridge, MA; [4]Carle Illinois Advanced Imaging Ctr. (CIAIC), [5]Beckman Inst., Univ. of Illinois Urbana-Champaign, Urbana-Champaign, IL

Abstract: Childhood obesity is a global health concern, with >340 million youth considered overweight or obese. In addition to contributing greatly to health care costs, excess adiposity associated with obesity is considered a major risk factor for premature mortality from cardiovascular and metabolic diseases. Adiposity is also negatively associated with cognitive and brain health. Thus, considerable efforts should be taken to reduce the negative health outcomes associated with childhood obesity. A complimentary line of research highlights the importance of cardiorespiratory fitness, a byproduct of engaging in physical activity, on an abundance of positive physical and mental health outcomes across the lifespan, including cognitive and brain health. Notably understudied, however, is the influence of adiposity and fitness on functional brain connectivity in preadolescent children, warranting further investigation. This study investigated the relationship among excess adiposity (visceral adipose tissue [VAT], subcutaneous abdominal adipose tissue [SAAT]), Body Mass Index (BMI), and fat-free cardiorespiratory fitness (FF-VO_{2max}) on resting-state functional connectivity (RSFC) in 121 (f = 68) children (7-11 years) using a data-driven whole-brain multi voxel pattern analysis (MVPA). MVPA models revealed two clusters associated with VAT and BMI measures, controlling for FF-VO_2. These clusters were then used for post-hoc whole-brain seed-to-voxel RSFC analysis. Yeo's (2011) RSFC-based 7-network cerebral cortical parcellation was used for labeling the results. Post-hoc seed-to-voxel analyses accounting for FF-VO_{2max}, IQ, sex and socioeconomic status, found robust associations of VAT and BMI with areas involved in the visual (VN), somatomotor (SMN) and frontoparietal (FPN) networks. Specifically, anticorrelations were observed within the FPN, and between the FPN and VN and SMN, for both the VAT and BMI models. No significant results were found for SAAT. These novel findings indicate that BMI and excess VAT in childhood may be selectively associated with a range of RSFC networks. The data support previously published research demonstrating a negative association between childhood obesity and brain function, and the selective association of VAT with neuroelectric

indices of cognition. Lastly, research demonstrates the FPN has also been associated with cognition in children. Consequently, these novel results extend the current literature to suggest that BMI and adiposity are differentially associated with functional connectivity in children, and these networks may also relate to cognition.

Title: Mapping glutamate in somatomotor and visual networks using novel GluCEST imaging

Authors: *M. K. PECSOK[1], J. JEE[2], V. J. SYDNOR[1], R. P. R. NANGA[5], T. D. SATTERTHWAITE[3], D. R. ROALF[4];
[1]Neurosci. Grad. Group; Dept of Psychiatry, [2]Dept of Psychiatry, [4]Neuropsychiatry, [3]Univ. of Pennsylvania, Philadelphia, PA; [5]Dept of Radiology, Perelman Sch. of Med., Philadelphia, PA

Abstract: Glutamate (Glu), the main excitatory neurotransmitter in the brain, is particularly important within the motor system. Perturbations in cortical and subcortical Glu levels been found in a range of disease states, including schizophrenia, depression, and Parkinson's Disease. While there is emerging evidence that the motor system is implicated in psychopathology, studies focusing on Glu in the motor cortex, and possible correlations with psychiatric symptoms, are lacking. Ultra high-field Glutamate Chemical Exchange Saturation Transfer (GluCEST), a novel imaging method, offers an innovative approach to examine glutamate *in vivo*. In this study, we explored Glu levels in the motor cortex as compared to other cortical areas. Furthermore, we correlated Glu levels in the motor cortex with clinical symptoms. Drawing upon data from a cohort of 47 adults who were healthy, depressed, or on the psychosis spectrum, we compared GluCEST MRI within the somatomotor network (SomMot), as defined by the Schaeffer100 atlas (Schaeffer et al., 2018), with all non-motor cortical regions (Non-Mot) and with the visual network (Vis). SomMot Glu (7.57; SD=0.72) was lower than Non-Mot (8.21; SD=0.47) or Vis (9.50; SD=1.22) (units: %GluCEST contrast; $p<.0001$; one-way ANOVA). There was greater variance in Vis than SomMot. SomMot Glu was nominally negatively correlated with PROMIS depression scores, wherein participants with higher depression scores

had lower measured Glu in SomMot. Given the robust glutamatergic inputs from the motor thalamus, we expected SomMot Glu to be higher than Vis Glu. However, the elevated Vis GluCEST signal aligns with a previous GluCEST study conducted in a different cohort, which reported high Glu in the occipital lobe. The present finding also fits with extant spectroscopy literature, which generally reports higher Glu concentrations for Vis than SomMot areas. The substantially higher Glu within the Vis may reflect the higher baseline activity in this region as is reported in previous studies of regional cerebral blood flow (e.g., Pantano et al., 1984). Slower rates of astrocyte clearance of Glu or the dense layer IV, containing glutamatergic spiny neurons, may also contribute to higher Vis Glu. Though weak, the negative correlation between SomMot GluCEST and depression scores is particularly intriguing in light of recent work drawing connections between motor system perturbations and psychopathology. Future analyses in this dataset will explore variations in baseline Glu in other functional networks, as well as the relationship between Glu levels in the SomMot and Vis and clinical or behavioral measures.

Title: Long-scale noise correlations support accurate localization of gray matter in ultra-high field fMRI with sub-millimeter resolution

Authors: *K. B. WELDON, L. T. DOWDLE, *C. A. OLMAN;
Univ. of Minnesota, Minneapolis, MN

Abstract: Achievements in ultra-high field (UHF, 7+ Tesla) technology have made it possible to demonstrate the ability of fMRI to reveal cortical columns and layer-dependent neuronal processes in humans. However, acquisition and analysis decisions at UHF have greater potential to degrade spatial accuracy than decisions for data acquired at lower field strengths. Thus,

accurate delineation of gray matter (GM) from white matter (WM) in functional images acquired at UHF is crucial in order to support spatial localization of the BOLD signal. Since spatial autocorrelations of residual noise in fMRI are tissue-dependent, we propose that fitting the spatial autocorrelation of residual noise in high-resolution gradient-recalled echo-planar imaging (GE EPI) images is a promising tool for independently localizing GM at UHF strengths. Seven healthy adults participated in one fMRI scan with submillimeter voxel resolution (0.8 mm isotropic) and one fMRI experiment with 1.4 mm isotropic resolution at 7T. The spatial autocorrelation function (ACF) maps and parameters were generated from single scans without any of the typical fMRI pre-processing steps to avoid unnecessary blurring. Functional data analysis was performed in order to model and subtract task-related signal from each dataset. We used AFNI's 3dLocalACF function to estimate the Gaussian plus mono-exponential spatial autocorrelation in the residual noise in both datasets. The c parameter, which characterizes signal not modeled by the analyses, was larger in GM regions than in WM regions in both datasets, which is consistent with vascular and neural processes. While this finding is not a universal truth that can be expected in all high-resolution datasets, the tissue-dependence of spatial autocorrelations in noise is a feature of thermal noise-limited datasets which may be useful in guiding analyses as we push the limits of fMRI resolution for neuroscience applications.

Title: Functional MRI in awake marmosets for longitudinal studies

Authors: *F. SEKI, T. YURIMOTO, T. INOUE, E. SASAKI;
Central Inst. for Exptl. Animals, Kanagawa, Japan

Abstract: Resting-state network dysfunction can serve as a relatively early indicator of neurodegenerative disorders such as Alzheimer's disease (AD). Precise evaluation using non-human experimental animals such as common marmosets is important as longitudinal studies are the possible to analyze the onset of disease. To achieve this, fMRI assessment in awake marmosets should be established. Thus, we aimed to develop a non-invasive head and body restraint suitable for small bore-size MRI to perform longitudinal fMRI in the marmosets. The restraint for marmoset MRI suitable for 7.0-T Biospec 70/16 scanner system with an inner diameter of 72 mm volume coil was produced. Fulfilled conditions were 1. Size of body/head

restraint less than 72 mm diameter, 2. fixing the head non-invasively, 3. head movement less than 0.5 mm, and 4. use of non-magnetic materials. The restraint was designated by 3D CAD and printed using a 3D printer.Functional MRI was performed for normal marmosets. The parameters were as follows: repetition/echo time; 2000/15 ms, field of view; 38.4 × 38.4 mm, image matrix; 64 × 64, slice thickness; 1 mm,21 slices,repetitions; 200. The face of the marmoset was monitored using an MRI-compatible camera throughout the experiment. The head restraint enabled less than 0.5 mm movement of the marmosets' head using only non-magnetic materials non-invasively during the scan. We analyzed BOLD responses evoked by visual and auditory stimuli as preliminary data. Parts of the primary and secondary visual cortex and auditory cortex were activated during visual and auditory stimulation, respectively. In resting-state fMRI, the brain network including the parts of the posterior cingulate cortex and intraparietal cortex was confirmed. This study developed a non-invasive awake fMRI for small bore-size MRI, less than 10 cm. Fixing the head without a post head was challenging to achieve non-invasively. Although the non-invasive fMRI platforms have been available for awake marmosets, the MRI bore size must be more than 10 cm to acquire the head data. The non-invasive awake fMRI developed does not require head data individually as it fits all marmoset heads. U-type pin used for fixing the head permitted conducting fMRI for many marmosets. Further, the presented fMRI platform could introduce any size since this was designed for minimum size MRI. As a complementary tool of existing restraints for marmosets, this would also be valuable in certain conditions, including longitudinal evaluation. Recently, we have developed the AD marmosets. This awake fMRI does not require the attachment of a head post and enables cautious longitudinal evaluation of these disease model marmosets over the years.

Title: Causal coupling between neural activity, metabolism, and behavior across the Drosophila brain

Authors: *K. MANN, S. DENY, S. GANGULI, T. CLANDININ;
Stanford Univ., Stanford, CA

Abstract: Coordinated activity across networks of neurons is a hallmark of both resting and active behavioral states in many species, including worms, flies, fish, mice and humans. These global patterns alter energy metabolism in the brain over seconds to hours, making oxygen consumption and glucose uptake widely used proxies of neural activity. However, whether changes in neural activity are causally related to changes in metabolic flux in intact circuits on the sub-second timescales associated with behavior, is unclear. Moreover, it is unclear whether differences between rest and action are associated with spatiotemporally structured changes in neuronal energy metabolism at the subcellular level. Here, we combine two-photon microscopy across the fruit fly brain with sensors that allow simultaneous measurements of neural activity and metabolic flux, across both resting and active behavioral states. We demonstrate that neural activity drives changes in metabolic flux, creating a tight coupling between these signals that can be measured across large-scale brain networks. Further, using local optogenetic perturbation, we demonstrate that even transient increases in neural activity result in rapid and persistent increases in cytosolic ATP, suggesting that neuronal metabolism predictively allocates resources to meet the energy demands of future neural activity. Finally, these studies reveal that the initiation of even minimal behavioral movements causes large-scale changes in the pattern of neural activity and energy metabolism, revealing unexpectedly widespread engagement of the central brain. As the relationship between neural activity and energy metabolism is likely evolutionarily ancient and highly conserved, these studies provide a critical foundation for using metabolic proxies to capture changes in neural activity.

Title: Modelling the BOLD response: On the insufficiency of conventional modelling approaches

Authors: *M. DANVERS, M. LONGLEY, N. RAMNANI;
Psychology, Royal Holloway Univ. of London, Egham, United Kingdom

Abstract: In event-related functional MRI (fMRI), short bursts of neuronal activity result in transient evoked haemodynamic responses (EHRs). The most common approach for detection and localisation is to construct General Linear Models (GLM) in which regressors model

expected EHR time-courses. These are typically based on a ‘canonical’ haemodynamic response function with a set of rigid assumptions about it’s timecourse. The utility of this approach depends upon the extent to which EHRs conform to these assumptions. How appropriate is this model given that EHR timecourses vary across tasks, brain areas, and individuals? We analysed EPI scans from 558 participants (CamCAN dataset: ages 18-88, 53% female; sensorimotor task involving auditory and visual stimuli and manual responses; SPM12/Matlab2019a). Three random-effects GLMs were tested, using either the canonical model (HRFc), the canonical with temporal and dispersion derivatives (HRFtd) to increase flexibility, or a more flexible Fourier basis set. Our approach also investigated experimental variance explained by one flexible model over and above the other by incorporating GLM regressors from both HRFtd and Fourier models (Figure 1A; only one condition was analysed, the seven Fourier regressors highlighted in blue, and three HRFtd regressors in red). First, consistent with our hypotheses the two flexible models explained experimental variance in more voxels within cytoarchitectonically defined primary motor cortex (4a and 4p), primary visual cortex (hOC1), anterior prefrontal cortex (Fp1), and cerebellar cortex, demonstrating the benefits of flexible modelling (Figure 1B). Second, we found that the timing of reconstructed EHRs from the flexible models did not correspond well to the canonical model (Figure 1C). Third, unexpectedly, the HRFtd model explained experimental variance more efficiently than the more flexible Fourier basis set in most regions. Our results suggest that flexible modelling is important, and that the HRFtd model is more optimal than the other approaches in most regions.

Title: Acute effect of breathing awareness meditation on breathing rate and prefrontal cortex oxygenation as measured by functional near-infrared spectroscopy

Authors: *A. PAL[1], F. MARTINEZ[1], B. KRAUSE-SORIO[1], D. G. GHAHREMANI[2], A. MALHOTRA[4], R. M. HARPER[3], H. LAVRETSKY[3], P. MACEY[1];

Abstract: Introduction: Mindfulness-based breathing awareness meditation (BA) is associated with reduced breathing rate (BR). Increased BR at the expense of tidal volume has often been associated with higher stress; BA technique could reduce stress by reducing BR. Additionally, activation of higher regulatory centers, like the prefrontal cortex (PFC), control the onset of stress associated emotional responses; thus, reduction of PFC activity would signify reduction in stress-associated emotional responses. In this study, we quantified the neural activity in response to BA meditation at left, medial and right PFC using functional near-infrared spectroscopy (fNIRS) and correlated that with changes in BR, in order to assess the stress-reduction effects of BA. **Materials and Methods:** In 18 participants (10 males, age=34±2years, BMI=25±1kg/m^2), BR was measured using a thoracic respiratory belt during the last 5 minutes of a 10-minute BA meditation task compared to 5 minutes of rest. Simultaneously, fNIRS was used to assess PFC oxygenation that correlates with neural activity. Changes in left, medial, and right PFC oxygenation during BA relative to rest were estimated and compared using repeated-measures ANOVA. In addition, changes in left, medial and right PFC oxygenation were correlated with changes in BR using Pearson's correlation. **Results:** With BA meditation, BR declined (mean±SEM, -18±9% (p<0.01)), right PFC oxygenation dropped by 1.4±0.7 times (p<0.01), medial PFC oxygenation declined by 1.2±0.4 times (p<0.05) and left PFC oxygenation non-significantly dropped by 0.7±0.3 times (p=0.16). BA task-related changes in BR significantly correlated with left PFC oxygenation at R= -0.7 (p<0.05), with no significant correlations at medial PFC (R=0.3) or at right PFC (R= -0.1).**Conclusions:** We found a decline in BR with BA meditation, consistent with previous studies. The most significant extent of BA-related changes was found in the right PFC; however, changes in the left PFC oxygenation correlated more with changes in BR. Breathing awareness meditation may reduce PFC neural activity as well as slow respiratory efforts. **Acknowledgements: NR-017435, HL135562.**

AbstractPathology-induced dropout in fMRI signals caused by local disruption of neuro-vascular coupling can compromise fMRI brain maps used for neurosurgical guidance. If not detected, such neuro-vascular uncoupling (NVU) can lead to inadvertent surgical resection of viable brain tissue. Potential NVU can be detected by mapping cerebrovascular reactivity (CVR) to blood CO2 changes induced actively by a breath-hold (BH) challenge or passively during resting-state (RS) fMRI. Holes in the CVR map that match fMRI dropouts can potentially identify sites of NVU. However, random holes do commonly occur in CVR maps even when thresholded to optimize unbiased coverage of gray/white matter. Thus, distinguishing random holes from NVU-related holes is a potential problem. To establish a normative baseline for differentiating random vs. NVU holes, we measured the spatial sampling statistics of different-size CVR holes in 9 healthy individuals. For BH fMRI, each subject's personalized respiratory response waveform was used to construct a regressor that was fit to the fMRI data for each brain voxel and the resulting amplitude was used as the CVR metric. For RS fMRI, signal power within a 0.01 - 0.08 Hz frequency band was used as the CVR metric. The spatial patterns of both metrics were individually thresholded to optimize gray vs. white matter coverage/segmentation. The frequency of occurrence of different-size holes in the resulting spatial patterns was then computed. The probability distributions of different-size holes were statistically indistinguishable

for the BH and RS CVR maps. From the frequency distributions, we determined a limiting hole size above which larger holes would be unlikely to randomly occur by chance (<5%). The BH and RS metrics had an identical hole-size limit, equal to 0.31 cm^3 (approx. 10 imaging voxels). Clinically, this establishes a potential baseline for CVR hole size that should be suspected of being NVU-related. Moreover, our results suggest that BH and RS CVR maps are comparable for assessing cerebral vasoreactivity and for identifying areas of NVU-impaired vasoreactivity.

Title: Sex difference in dendritic morphology of motoneurons innervating the external urethral sphincter in rats

Authors: *D. SENGELAUB[1], I. LAYMAN DEL RIVERO[2];
[1]Program in Neurosci., Indiana Univ. Bloomington, Bloomington, IN; [2]Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: A variety of sex differences are present in the anatomy and physiology of lower urinary tract, including differences in the bladder, urethra, and striated muscle of the external urethral sphincter muscle (EUS). As in humans, the EUS in rats is significantly smaller in females than in males. The motoneurons that innervate the rat EUS are located in the dorsolateral nucleus in the lumbosacral spinal cord. Although the number of motoneurons innervating the rat EUS does not differ across sexes, the size of the motoneuron somata is sexually dimorphic, being smaller in females than in males (McKenna and Nadelhaft, 1986). In this study, we examined another feature of EUS motoneuron morphology, the dendritic arbor, for evidence of sexual dimorphism.
Motoneurons innervating the external urethral sphincter in young adult male and female rats were labeled with cholera toxin-conjugated horseradish peroxidase (1 µL/side, 0.2%), and stereological assessments were made of motoneuron number (optical disector method) and soma size (Nucleator method) with Stereo Investigator. Dendritic arbors were reconstructed in three dimensions using Neuroluicda. Consistent with previous findings, the number of EUS motoneurons did not differ across the sexes, but somal areas of BHRP-labeled EUS motoneurons in female rats were significantly smaller (32%) that those of males. The dendritic arbors of EUS

motoneurons were strictly unilateral, with dense bundling dorsally along the lateral edge of the gray matter extending into lamina VI and VII as well as deep into the lateral funiculus; a second, medially-projecting array of dendrites coursed along the ventral margin of the gray matter and into lamina X. Although the distribution of dendrites was similar across sexes, total dendritic length in female rats was significantly shorter (34%) than that of males. Female rats had significantly less EUS motoneuron dendritic material in both the dorsolateral and medial projections, areas of important afferent drive to EUS motoneurons. The sex difference in soma size could reflect the sex difference we observed in dendritic length, with the larger dendritic arbor of EUS motoneurons in males requiring a larger soma size to support it. Furthermore, these differences in the EUS motoneurons of males and females could contribute to sex differences in urinary function or dysfunction.

Title: Unraveling the mechanism of spontaneous catecholamine release in the mesenteric lymph node

Authors: *R. BRANTLEY[1], A. E. ROSS[2];
[2]Chem. Dept., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: AbstractUnraveling the mechanism of spontaneous catecholamine release in the mesenteric lymph nodeRebekah A. Brantley and Ashley E. RossThere is a growing interest to understand neurochemical-regulated communication between the gut, gut immune system, and brain. The mesenteric lymph node (MLN) is a secondary immune organ that resides in the gastrointestinal tract to help regulate immunity in the gut. The sympathetic nervous system (SNS) innervates the T-cell rich zones MLN to facilitate pro- and anti-inflammation responses by releasing neurotransmitters which modulate immune signaling. More specifically, the neurotransmitters norepinephrine and ATP, are known to be co-released from sympathetic neurons to function as immunomodulators. Previously, our lab has discovered spontaneous rapid catecholamine release using fast-scan cyclic voltammetry (FSCV); however, the mechanism of rapid catecholamine release in the MLN remains unknown. Here, we use FSCV at carbon-fiber microelectrodes in the MLN to probe the mechanism of norepinephrine release. We show that the rapid catecholamine transients are partially dependent on calcium signaling and are regulated

by the α2-adrenergic receptor. Overall, this work will advance understanding of catecholamine signaling in the MLN and will facilitate future studies investigating the mechanism of catecholamine immunomodulation.

Title: Large-scale tissue clearing of mouse and human whole gut for three-dimensional visualization and quantification of enteric nervous system

Authors: *Y. YUN[1], D. CHEON[1], K. CHUNG[1], T. SUNG[1], S.-J. KOH[1], Y. PARK[2], S.-B. RYOO[2], K. PARK[2], H. CHOI[1];
[1]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [2]Seoul Natl. Univ. Col. of Hosp., Seoul, Korea, Republic of

Abstract: Nowadays, state-of-the-art tissue clearing methods enable to image thicker tissue section, or even whole organs imaging, by increasing tissue transparency and enhancing antigen-antibody binding. The goal of this research was to develop a 3D imaging method for the whole gastrointestinal(GI) tract that yields more information and insight about the enteric nervous system(ENS) than traditional 2D tissue section imaging. Visualization and quantification of the digestive organs(e.g. esophagus, stomach, small intestine, and colon) in the mouse and human were carried out through various techniques. A method encompassing tissue clearing, immunohistochemistry(IHC), confocal microscopy, light sheet fluorescence microscopy(LSFM), and quantitative analysis of full-thickness bowel without tissue sections has been developed for 3D imaging at high resolution. Furthermore, using surface rendering, volume rendering for all channels, fluorescence thresholding, and background subtraction, tools from in IMARIS, I was able to obtain an accurate 3D structure that can be measured volume. The multiscale structural decomposition of mouse and human ENS was clearly visualized in 3D. Tissue clearing method, which enables immunostaining of intact organs and visualizing of large volumes for 3D-reconstruction, could image the complex ENS network structure of myenteric plexus, submucosal plexus, and mucosal nerves. Similarly, the 3D ENS network structure of the esophagus(16 × 14 × 5.3 mm) and colon(1.2 × 1.3 × 1.4 mm) tissue samples were visualized in mouse and human, respectively. I investigated cholinergic ENS structure through the whole GI tract using mouse(n=3) and quantified the number of cell bodies and cell bodies per ganglion in two major layers. To identify the hubness of the myenteric plexus, I measured the number of ganglia and bridges without cell bodies that connect the ganglion. Quantitative data for

myenteric plexus and submucosal plexus showed relatively different aspects. I further succeeded in staining inhibitory neurons and excitatory neurons in mouse, respectively. This method can be adapted to mouse and human tissue clearing, which will enhance its applicability to the study of ENS structure and neural circuits. In particular, I provide a validation of this method for quantifying the number of cholinergic neurons. A quantitative analysis method of structure phenotypes in mouse will illuminate the potential usefulness of this technology as a diagnostic marker. For GI motility disorders, this novel technology will unravel the extensive spatial 3D network structure of neuro-immune interaction.

Abstract: The ENS controls a variety of gastrointestinal functions. We evaluated the translational relevance of the pig model for human colonic ENS by laser capture microdissection coupled with bulk RNA sequencing (RNA-seq) to cross-compare the transcriptomes in the myenteric and inner submucosal ganglia (MG, ISG) collected from the proximal, transverse and distal regions in 6 naïve pig (3 of each sex), and in parallel from the ascending, transverse and descending colon resected from the healthy margins of 12 patients (4 males and 8 females). The differentially expressed genes (DEG) enriched significantly ($p < 0.05$) by Gene Ontology terms with functional evidence were selected for comparisons among the segments, between MG and ISG and two species. The functional linkages (FLs) related to the orthologous DEG were extracted to reflect functional similarities across species. Nine and three pig orthologous genes

identified in the MG of human ascending and descending colon were involved in the regulatory networks in the MG of the corresponding pig colonic segments. The FLs related to these genes achieved 100% linkage coverage and represented all the characteristics of MG in the pig proximal and distal colon. These FLs accounted for 93 and 96% of all FLs of the regulatory networks responding to abdominal vagal nerve stimulation (VNS) in MG of the pig proximal and distal colon, suggesting that these two segments could serve as predictors in the translational research. The gene expression modules in the ISG and MG along the axis of pig proximal and distal colon were also characterized by bulk and single-cell RNA-seq. Effects of nitrergic neurons and glutamate-mediated synaptic plasticity were greatly enriched in the MG, which were involved in motility, while acetylcholine-dopamine balance enriched in the ISG played crucial roles in maintaining mucosal integrity. Compared with the proximal, the MG in the distal region contributed more to motility via combination of nitrergic and dopaminergic neurons, whereas MG in the proximal had greater complex neuronal wiring and cholinergic neurons played a leading role. Nitrergic neurons prevailed to regulate blood vessels with higher enrichment in ISG of distal colon. VNS affected primarily MG, especially in the proximal through cholinergic neurons and glia in the proximal and glutamatergic neurons in the distal. These data reveal for the first time the transcriptomic similarities in the colonic ENS of pig and human and regional heterogeneities in the pig, which helps to establish the use of pigs as a potential translational model for understanding of the human colonic functions and neuromodulation.

Abstract: Hepatic nerves have a complex role in synchronizing liver metabolism. We applied the 3D immuno-imaging technique iDISCO to explore the integrity of the hepatic nervous system in experimental and human non-alcoholic fatty liver disease (NAFLD). We demonstrated parallel signs of mild degeneration and axonal sprouting of sympathetic innervations in early stages of experimental NAFLD and a collapse of sympathetic arborization in steatohepatitis. The gene expression of several adrenergic receptors and the gap-junction protein CX32 were decreased, supporting a global sympathetic nerve-mediated communication impairment in experimental NAFLD livers. Human fatty livers displayed similar pattern of sympathetic nerve degeneration, correlating with the severity of NAFLD pathology. We showed that chronic sympathetic hyper-excitation is a key factor in the axonal degeneration, here genetically phenocopied in mice deficient of the Rac-1 activator Vav3. In experimental steatohepatitis, 3D imaging revealed a severe portal vein contraction, spatially correlated with the extension of the remaining nerves around the portal vein, enlightening a potential intra-hepatic neuronal mechanism of portal hypertension. These fundamental alterations in liver innervation and vasculature uncover significant novel neuronal components in NAFLD pathomechanism.

Abstract: Communication between the brain and the autonomic nervous system is integral to health, and dysregulated communication is a potential transdiagnostic factor across disorders. Human neuroimaging provides a unique opportunity to study the central brain circuits involved in autonomic regulation. However, brain-autonomic correlations have generally been studied in small samples, with heterogeneity across the autonomic measures collected in different studies. We conducted a meta-analysis of N = 151 contrasts that directly correlated brain (PET or fMRI) activity with autonomic measures from 112 studies (representing 1,543 total participants) using Multi-Level Kernel Density Analysis (MKDA). Included contrasts were weighted by their respective sample sizes, treated as random effects, and corrected at a family-wise error rate (FWER) of p&It;0.05. The results confirmed brain-autonomic relationships in both subcortical and cortical regions identified in previous studies and meta-analyses, as well as regions that were not previously reported. Analyses limited to pro-parasympathetic nervous system relationships revealed activations in previously identified regions including the basolateral amygdala and the default mode network (e.g., ventromedial prefrontal cortex and precuneus). We also found other regions that have not been consistently identified, including the putamen and the ventral attention network. Analyses limited to sympathetic nervous system relationships identified additional key areas of the diencephalon, particularly the habenula, which have been important in nonhuman experiments but not consistently identified in previous neuroimaging studies. By addressing prior methodological limitations and incorporating nearly a decade's worth of new brain imaging findings, the present meta-analysis provides an updated, comprehensive, and rigorous summary of human brain-autonomic correlations, which will serve as the basis for many future analyses and as a resource for the neuroimaging community.

Title: Sparc: towards automatic detection and classification of propagating vagal nerve activity from transcutaneous recording for autonomic neuromodulation

Authors: S. AMIN[1], R. COIMBATORE[1], M. MCKINNON[3], A. GUPTA[4], T. H. EVERETT[4], T. L. POWLEY[2], T. V. NOWAK[4], I. P. CLEMENTS[3], *M. P. WARD[5];

Abstract: Our previous work showed that gastric electric stimulation (GES) in human subjects with intractable gastroparesis evokes compound nerve action potentials (CNAPs) that can be measured using skin-mounted sensors overlying the mid-cervical vagal nerves (Ward et al., 2020). In this work, we collected body surface potential (BSP) recordings from human subjects in response to 12 combinations of GES parameters, using custom 32-channel multi-electrode arrays (MEAs) coupled to a specialized acquisition system for low-noise biopotential measurement (BioCircuit Technologies, Inc.). We used these data, along with median nerve (MN) recordings collected with the same design, to develop an algorithm that detects and classifies stimulus-evoked, propagating CNAPs from BSP recordings. The MEA recordings were analyzed as a 3D stack of 2D frames, where the third dimension is time, enabling the propagating CNAPs to be viewed as a video. Automating this process involves Dynamic Time Warping (DTW) to determine the latency, direction and speed of the propagating CNAP in 2D space. MEA recordings from MN stimulation (n = 13 sets) and a template containing distinct CNAPs were used to develop the process. Frame-by-frame DTW between the template signal and an MEA recording form a DTW matrix. Propagating is detected by thresholding the matrix data and analyzing the distribution using a histogram. The data in the lowest bin correspond to matching activity. Values corresponding to a propagating CNAP volley within the DTW matrix show sloping. We observed that for a particular polarity, a positive slope indicates that the CNAP was propagating in the same direction as the template, whereas a negative slope indicates the opposite. Once functionality was verified with MN data, we tested the algorithm on GES-evoked BSP data using a vagal CNAP template and recordings obtained from a human subject in response to a range of stimulus strengths. For the vagal template, a distinct afferent CNAP was manually segmented from a recording in response to a 10 mA stimulus. For each combination, we observed multiple instances of propagating CNAPs. The mean differences between visually and automatically detected CNAPs for the 12 GES parameter combinations were calculated, resulting in a mean and standard deviation of 1.28ms and 0.52ms. Automating the classification of propagating CNAPs (e.g., latency, speed and direction) could accelerate the development of

less invasive, more effective bioelectronics for autonomic and other disorders, especially in wearable bioelectronics. Additional verification and validation of algorithm functionality is required to fully define the potential of our approach.

Title: Multisegmental spinal sympathetic preganglionic projections to mouse paravertebral chain ganglionic neurons: anatomical considerations on neural unit size

Authors: *A. SOKOLOFF[1], M. SAWCHUK[1], C. LUGO[1], Y. LI[1], M. HALDER[1], M. L. MCKINNON[1], A. A. PRINZ[2], S. HOCHMAN[1];
[1]Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA; [2]Dept. of Biol., Emory Univ., Atlanta, GA

Abstract: Spinal cord sympathetic preganglionic neurons (SPNs) are the final arbiters of CNS sympathetic output. Many SPNs innervate the paravertebral sympathetic chain. Their axonal projections branch to issue divergent multisegmental projections on ganglionic neurons (GNs) across many segments. GNs are thought to enable amplification of CNS sympathetic commands. The ratio of GNs/SPNs has been reported to be 14:1 in mouse with each GN receiving convergent synaptic input from an average of 4.5 SPNs arising from many spinal segments. This organization has been compared to the concept of motor unit in motoneuron innervation of muscle fibers. Accordingly, the sympathetic neural unit size has been estimated to be 64 [(GNs/SPNs) x mean #SPNs synapses/GN] (Purves et al 1986 J Neurosci 6: 158-163). As synapse number was obtained with electrophysiology, recruitment assumes faithful spike propagation and transmission across all synapses in highly branched axons with modifiable conduction, so may be greatly underestimated. Individual GNs contain 100-200 anatomically-identified synapses in guinea pig (Gibbins et al 1998, JCN 402: 285-302) but this has not been examined in mouse thoracic paravertebral chain. We evaluated anatomical properties of SPN-to-GN convergence and divergence in whole mounts of adult mouse thoracic ganglia. TdTomato

reporter mouse crosses selectively labeled SPN axons (ChAT) and sparsely labeled GNs for morphologic reconstruction (TH). Additional IHC staining was used to estimate all GNs (TH) and all SPN synapses onto GNs (synapsin) as well as the fraction of synapses that originated from an individual spinal segment (after Neurobiotin [NB] injection into T7 ventral root). T5 ganglia contained 771±214 GNs (mean±SD; n=5) that had 1-7 primary dendrites (3.4±2.1; excluding GNs lacking processes). Synapsin^{+}/ChAT-Td^{+} synapses were estimated to be 116/GN. Conversely, T7 spinal SPNs labeled via NB injection had an average of 3.5, 3.7 and 2.3 synapses/GN (counted in T7, T6, and T5 ganglia, respectively). However, axonal divergence extended from T3-T12 ganglia, conversely suggesting that convergent input from other spinal segments would increase total synapse #/GN considerably. In sum, GNs in thoracic chain ganglia are innervated by many more SPNs than the 4.5 previously reported electrophysiologically. While this value is likely less than the 116 synapses/GN counted here, neural unit size and capacity for gain amplification is likely much greater than assumed. This is further supported by the wide range in spontaneous synaptic current amplitudes recorded in these GNs and their impact on synaptic gain (Prinz et al 2020, BMC Neurosci, 21(Suppl 1):P79).

Title: Metabolic effects of intranasal AdipoRon administration in obese male wistar rats

Authors: A. LAGUNES-CRUZ[1], *M. A. GUZMÁN-RUIZ[2], R. GUEVARA-GUZMAN[3]; [1]Univ. Nacional Autónoma de Mexico, MEXICO CITY, Mexico; [2]Fac. of Medicine, Physiol. Dept., Univ. Nacional Autónoma de Mexico, Mexico City, Mexico; [3]Lab. Sensorial, Dept. de Fisiología, Facultad de Medicina, Univ. Nacional Autónoma De México (UNAM), Ciudad DE Mexico, Mexico

Abstract: Signals indicating metabolic status, such as; ghrelin, leptin, insulin, and glucose are integrated in the hypothalamic arcuate nucleus. These metabolic cues can activate either the orexigenic Neuropeptide Y (NPY) and Agouti Related Peptide (AgRP) or the anorexigenic Proopiomelanocortin (POMC) expressing neurons. Thus, having regulatory effects on energy balance Although, there are other areas outside the hypothalamus that can also integrate this type

of information.The olfactory system including the olfactory epithelium and the olfactory bulb also characterizes for its ability to respond to metabolic hormones, which in these particular regions this signaling modulates olfactory sensitivity. For example, intranasal insulin administration decreases olfactory responses in humans; conversely, when ghrelin was administered, olfactory perception increases. These effects in olfactory sensitivity suggest the involvement of the olfactory system in metabolism.There is a multi synaptic connection between the olfactory bulb and the hypothalamus. Furthermore, the sensory, either visual or olfactory, perception of food rapidly changes the electrical activity of the ARC neurons, suggesting that the modulation of the responsiveness of the olfactory system modifies the activity of the hypothalamic circuits involved in the daily regulation of energy balance.The aim of the present study is to determine whether a pharmacological intervention in the olfactory system of obese rats may revert the effects of a high fat diet (HFD). For this we administered AdipoRon and agonist of the AdipoR1 and 2 adiponectin receptors. This particular hormone is an adipokine known to increase insulin sensitivity. Since AdipoR1 is highly expressed in the olfactory epithelium and the olfactory bulb we hypothesized that the intranasal administration of AdipoRon will modify odor sensitivity and enhance energy expenditure.Our results so far suggest that the intranasal administration of AdipoRon reduces olfactory sensitivity in both HFD and Control fed adult wistar rats. In addition, intranasal AdipoRon significantly decreases the glucose tolerance test of animals fed a 54% HFD for 10 weeks. Finally, we have observed changes in the expression of the proteins involved in Insulin response in the olfactory bulb and the hypothalamus of the animals treated with intranasal AdipoRon, suggesting that the intranasal administration of AdipoR1 agonists might be a potential therapeutic approach to revert the adverse metabolic effects of obesity.

Title: Role of serotonergic receptors in the leptin mediated raphe control of food intake

Authors: *N. D. MAXWELL[1], A. G. ROBU[1], A. T. SADEK[1], L. P. REAGAN[1,2], J. R. FADEL[1], C. A. GRILLO[1];

[1]Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC; [2]WJB Dorn VA Med. Ctr., Columbia, SC

Abstract: Leptin is an adipocyte-derived hormone that controls a myriad of homeostatic functions. Most notably, leptin acts on neurons in the hypothalamus through the long form of the leptin receptor to control energy homeostasis and appetite. Leptin has not only been shown to act on hypothalamic neurons, but also on other areas of the brain such as the dorsal raphe nucleus (DRN), the primary source of brain-derived serotonin (5-HT). Previously, we have described an anatomical connection between leptin sensitive neurons in the DRN and the arcuate nucleus of the hypothalamus. Additionally, we have shown that serotonin may be primarily involved in leptin's ability to reduce food intake through the DRN. Although these connections have been described anatomically and have shown to be important in the regulation of food intake, the mechanism of this signaling has yet to be fully explored. The serotonin 2C (5HT2C) receptor has been strongly implicated in the control of food intake, including as a potential target for the treatment of obesity. However, the link between the 5HT2C receptor and leptin responsive serotonergic neurons in the raphe has yet to be elucidated. In the present study, our objectives were to 1) characterize the expression and distribution of the 5HT2C receptor subtype in the hypothalamic nuclei, and 2) show the functional importance of this receptor subtype in the reduction of food intake when leptin is infused into the DRN. To complete these objectives, we used RNAScope to label 5HT2C receptor mRNA expression across the hypothalamic nuclei, as well as immunohistochemistry to further characterize the neurons that express these receptors. To show the involvement of this receptor on food intake behavior, we infused SB 242084, a 5HT2C inhibitor, intracranially followed by leptin into the DRN and measured food intake and activity. Through this work, we aim to further characterize this leptin-dependent pathway between the DRN and the hypothalamus, as well as how the leptin-mediated activation of this circuit regulates appetite.

Title: A neural circuit mechanism for mechanosensory feedback control of ingestion

Authors: *M. KIM[1], D.-Y. KIM[1], G. HEO[1], H. KIM[1], H. KIM[1], J. JIN[1], S. JUNG[1], M. AN[1], B. H. AHN[1], J. PARK[1], H.-E. PARK[1], M. LEE[1], J. LEE[1], G. J. SCHWARTZ[3], S.-Y. KIM[2]; [2]Dept. of Chem., [1]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Medicine/ Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Mechanosensory feedback from the digestive tract to the brain is critical for limiting excessive food and water intake, but the underlying gut-brain communication pathways and mechanisms remain poorly understood. Here we show that, in mice, neurons in the parabrachial nucleus that express the prodynorphin gene (hereafter, PB^{Pdyn} neurons) monitor the intake of both fluids and solids, using mechanosensory signals that arise from the upper digestive tract. Most individual PB^{Pdyn} neurons are activated by ingestion as well as the stimulation of the mouth and stomach, which indicates the representation of integrated sensory signals across distinct parts of the digestive tract. PB^{Pdyn} neurons are anatomically connected to the digestive periphery via cranial and spinal pathways; we show that, among these pathways, the vagus nerve conveys stomach-distension signals to PB^{Pdyn} neurons. Upon receipt of these signals, these neurons produce aversive and sustained appetite-suppressing signals, which discourages the initiation of feeding and drinking (fully recapitulating the symptoms of gastric distension) in part via signaling to the paraventricular hypothalamus. By contrast, inhibiting the same population of PB^{Pdyn} neurons induces overconsumption only if a drive for ingestion exists, which confirms that these neurons mediate negative feedback signaling. Our findings reveal a neural mechanism that underlies the mechanosensory monitoring of ingestion and negative feedback control of intake behaviors upon distension of the digestive tract.

Title: Using vasopressin-deficient Brattleboro rats to elucidate the role of glucagon-like peptide-1 in the control of fluid intake

Authors: *D. J. BRAKEY[1], K. C. SCHATZ[1], M. J. PAUL[1], D. DANIELS[2];
[1]Dept. of Psychology, Univ. at Buffalo-SUNY, Buffalo, NY; [2]Dept. of Psychology and Ctr. for Ingestive Behavior Res., Univ. At Buffalo - SUNY, Buffalo, NY

Abstract: Central glucagon-like peptide-1 (GLP-1) has been shown to play a role in the control of fluid intake; however, the sites of action are unknown. One problem in furthering our understanding of GLP-1's role in the control of fluid intake is that GLP-1 affects both drinking and feeding and these behaviors are intertwined. Our lab has begun using a rat with a genetic mutation that causes extreme polydipsia without affecting food intake (Brattleboro; BB) in order to disassociate these normally intertwined behaviors. We previously found that BB rats were hypersensitive to the fluid intake suppression by a GLP-1 receptor agonist, Exendin-4 (Ex4), without any differences from wild-type (WT) rats in food intake suppression by the same drug. In contrast, BB rats do not show a hypersensitive response to the GLP-1R antagonist, Exendin 9-39 (Ex9); only WT males drank more after a LV injection of Ex9 compared to vehicle. The absence of increased Ex9-induced drinking does not appear to be due to a ceiling effect, because further stimulation with hypertonic saline increased drinking in all groups. Under these stimulated conditions, Ex9 treatment did not impact drinking in any group. In addition to these behavioral experiments, we have begun to assess Ex4-induced Fos in areas commonly associated with food and fluid intakes in order to disassociate areas that may be important for the control of food, fluid, or both. In some brain regions, both sex and genotype impacted the number of Ex4-induced Fos-immunoreactive cells, although the pattern was not consistent across brain regions. For example, in the *organum vasculosum* of the *lamina terminalis* and median preoptic nucleus, Ex4 did not alter the number of Fos-immunoreactive cells in WT male or BB female rats, but there was an Ex4-induced decrease in BB male and WT female rats. In the subfornical organ, there was an Ex4-induced increase in male WT and female BB rats, but an Ex4-induced decrease in male BB and female WT rats. Lastly, in the paraventricular nucleus, there was an Ex4-induced increase in WT male rats, but a decrease in all other groups. In other regions there were no effects of sex or genotype - in the *nucleus tractus solitarius* and area postrema, there was an Ex4-induced increase in all groups. These experiments continue to provide important data that will be used to guide future studies to test for eating and drinking specific effects of GLP-1.

Abstract: The lateral hypothalamic area (LHA) regulates feeding and reward related behavior, but because of its molecular and anatomical heterogeneity, the functions of defined neuronal populations are largely unclear. Glutamatergic neurons within the LHA (LHA^{Vglut2}) negatively regulate feeding and appetitive behavior. However, this population comprises transcriptionally distinct and functionally diverse neurons that project to diverse brain regions, including the lateral habenula (LHb) and ventral tegmental area (VTA). To resolve the function of distinct LHA^{Vglut2} populations, we systematically compared their projections to the LHb and VTA using viral tracing, single-cell sequencing, electrophysiology, and *in vivo* calcium imaging. LHA^{Vglut2} neurons projecting to the LHb or VTA are anatomically, transcriptionally, electrophysiologically, and functionally distinct. While both populations encode appetitive and aversive stimuli, LHb projecting neurons are especially sensitive to satiety state and are bidirectionally modulated by the feeding hormones leptin and ghrelin. These data illuminate the functional heterogeneity of LHA^{Vglut2} neurons, suggesting that reward and aversion are differentially processed in divergent efferent pathways.

Title: Leptin effects on ATE1 expression

Authors: J. MANZANO[1], M. ALKHATATBEH[2], P. FRAYRE[2], *E. NA[2], C. BROWER[2];
[1]Biol., [2]Texas Woman's Univ., Aubrey, TX

Abstract: Arginyltransferase 1 (ATE1) is highly expressed throughout the mammalian brain and is essential for the Arg/N-degron dependent breakdown of proteins bearing acidic N-terminal amino acids. Loss of *Ate1* gene function in mice was shown to have effects on metabolism with ATE1-deficient mice expressing a lean phenotype and increased metabolism despite being hyperphagic. Leptin is an anorectic hormone produced by adipocytes. Given the metabolic phenotype of ATE1-deficient mice, we wanted to determine the effects of leptin on ATE1 expression levels in wild type mice. ATE1 expression was quantified in the hypothalamus, prefrontal cortex, hippocampus, and the cerebellum using qRT-PCR. Overnight fasted mice were injected with either PBS or leptin and samples were collected one hour post-leptin/PBS injection. Preliminary data suggest that leptin plays a role in the regulation of ATE1 expression; however the mechanism through which this occurs is not known. Future experiments will examine leptin effects on ATE1 expression in specific neuronal populations, and will explore mechanistically how the *Ate1* promoter is regulated.

Title: Loss in ATE1 may affect energy metabolism through leptin

Authors: *P. FRAYRE[1], M. A. ALKHATATBEH[1], C. S. BROWER[1], E. NA[2];
[1]Biol., [2]Psychology & Philosophy, Texas Woman's Univ., Denton, TX

Abstract: Arginyl-tRNA protein transferase 1 (ATE1) regulates protein degradation by Arg/N-end rule pathway. Previous studies have shown that deletion or downregulation of ATE1 can lead to neurodegeneration, behavioral abnormalities, hyperphagia and lower body weight. To determine how loss of ATE1 affects energy metabolism and food intake, ATE1 deficient and ATE1 containing mice were given high fat diet for 6-8 weeks. Based on our current data, we found significant sex differences in body weight and food intakes, with ATE1 deficient mice less sensitive to the obesogenic effects of high fat diet even while consuming the same amount of high fat diet as controls. Interestingly, ATE1 deficient mice exposed to high fat diet displayed lower plasma leptin levels even after normalizing to white adipose tissue (WAT) weight. We also show sex differences in ATE1 deficient female mice given acute leptin treatment. Taken together, these data indicate that loss of ATE1 affects leptin levels independent of WAT but may alter leptin sensitivity in ATE1 deficient mice.

Title: Neuroendocrine mechanisms for social buffering of autonomic responses to stress

Authors: *R. OYAMA, I. CARCEA;
Rutgers Brain Hlth. Inst., Newark, NJ

Abstract: Social interactions can buffer the negative effects of stress, and the oxytocin hormone has been previously implicated, however the mechanisms remain poorly understood. We find that the oxytocin receptor is expressed in the posterior hypothalamus, a pre-autonomic structure that can modulate heart rate in rodents and in people. Other neurons in this area, particularly those expressing the receptor for the corticotropin-releasing factor, have been shown to project to brain stem structures modulating cardiac function, and their activation increased heart rate. We predict that neurons in the posterior hypothalamus expressing the oxytocin receptor will counteract these effects on heart rate, and that their activation during stress could buffer the effects of stress on heart rate.

Title: High salt intake increases RhoA-mDia1 signalling and triggers cytoskeleton reorganization in magnocellular vasopressin neurons

Authors: *B. LI, S. JACOB-THOMAS, M. PRAGER-KHOUTORSKY;
Dept. of Physiol., McGill Univ., Montreal, QC, Canada

Abstract: High dietary salt (HDS) strongly correlates with cardiovascular diseases and is a major factor contributing to the pathogenesis of hypertension. Recent studies show that HDS leads to neurogenically-mediated increases in sympathetic activity, vascular resistance, and water and sodium retention, revealing a possible involvement of central sodium detection mechanisms in salt-dependent hypertension. Changes in plasma sodium are detected by specialized osmosensory neurons located in the supraoptic and paraventricular nuclei (SON and PVN). Under normal physiological conditions, increased plasma sodium activates SON and PVN magnocellular neurons releasing vasopressin (VP), antidiuretic hormone causing renal water retention and vasoconstriction, to achieve body fluid homeostasis. Chronic exposure to HDS is associated with excessive activation of VP neurons, leading to a VP-mediated increase in blood pressure. The mechanisms underlying excessive VP secretion in HDS are not fully understood. Magnocellular VP neurons harbor unique cytoskeletal networks comprised of a subcortical actin layer, an array of actin comet-like structures, and somatic scaffold of interweaved microtubules, regulating the sensitivity of neuronal activation. Chronic exposure to HDS increases the density of actin and microtubule networks in magnocellular VP neurons. mDia1 is the major direct RhoA effector, mediating its effects on actin and microtubule polymerization and stability. Our data suggest that RhoA and mDia1 are elevated in the SON and PVN following HDS. We hypothesize that chronic exposure to HDS causes an activation of the RhoA-mDia1 pathway to increase the cytoskeletal density and osmosensitivity of magnocellular VP neurons, leading to excessive VP secretion, volume expansion, elevated blood pressure, and hypertension.

Title: Interbrain synchrony across the brains of multiple mice

Authors: *J. LEE[1], G. LEE[2], D. KWAK[2], J. CHOI[3], S. LEE[4], H. CHOE[2];
[1]Brain and Cognitive Sci. Res. Ctr., [2]Dept. of Brain & Cognitive Sci., Daegu Gyeongbuk Inst. of Sci. and Technol., Daegu, Korea, Republic of; [3]Korea Inst. of Sci. and Tech. (KIST), Seoul, Korea, Republic of; [4]Electronics Telecommunications Res. Inst., Daejeon, Korea, Republic of

Abstract: Recent neural evidence indicates that there is interbrain synchrony across animals interacting in a naturalistic social environment. However, due to technological constraints, most studies reported synchronous neural activities from up to two animals. In this study, we used CBRAIN (collective brain research platform aided by illuminating neural activity), a minimized edge-computing solution with wireless communication capabilities, to record electrophysiological signals from multiple mice simultaneously. Four mice were allowed to interact freely with each other or were individually separated, while their behaviors and electrophysiological signals were recorded for three hours. The device implants were well-tolerated after habituation sessions as mice returned to the baseline huddling behavior, a well-known example of prosocial behavior exhibited by mice in which they spontaneously aggregate in a group. We analyzed whether the huddling behavior affects interbrain synchrony across a group of mice. Power spectral density (PSD) estimates of local field potential (LFP) recordings in the dorsomedial prefrontal cortex (dmPFC) showed differential patterns of powers at low- and high- frequencies between huddling and non-huddling groups of mice. The huddling-specific patterns were distinct from the differences arising from active/inactive disparity. Furthermore, the mice in the group condition showed correlated patterns of LFP powers in the time domain, compared to the mice in the single-mouse condition, which showed no correlation, suggesting the existence of the interbrain synchrony. To our knowledge, this is the first study that demonstrated the interbrain synchrony in a larger group of animals up to four in a naturalistic social situation.

Title: The effects of chronic social isolation in adulthood on social behaviors

Authors: *H. LEE, Y. JEONG;
Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Social isolation (SI) is a global problem that can lead to an aversive emotional state in humans and influences health across the life course. Since the global impact of the COVID-19 pandemic has increased the consequences of social isolation, it is important to investigate the effects of chronic social isolation on the ability to engage in social interaction. However, the aspects of social behaviors and related neuronal communications among social brain networks that are more sensitive to chronic social isolation in adulthood have not been fully investigated. Here, we evaluated social behaviors in chronic single-housed adult mice for 8-10 weeks to recapitulate the impacts of being socially isolated in adults. We also performed local field potential (LFP) recordings in several brain regions including the medial prefrontal cortex (mPFC) and nucleus accumbens (NAc), which are related to social cognition and behaviors. In addition, anterior insula (AI), which is important to social emotion, was also recorded and evaluated the relationships between social networks during social avoidance and interaction. We found isolation-induced social withdrawal behaviors in the chronic adult SI model during direct interaction with the juvenile conspecifics. Furthermore, chronic SI mice were divided into two groups based on the level of withdrawal behaviors: susceptible and resilient SI mice exhibited high and low social withdrawal behaviors, respectively. Although resilient SI mice showed similar sociability as those of the control group housing (GH) mice, susceptible SI mice exhibited significantly reduced sociability compared with GH or resilient SI mice. Reduced sociability in resilient SI mice is associated with decreased low theta (4-8 Hz) coherence between left AI and left mPFC or right NAc, which was not visible in resilient SI mice. In addition, decreased low theta coherence between left mPFC and right NAc was also observed. These results may not only facilitate an understanding of specific neural circuit dynamics for social behavioral changes in chronic individual housing in adulthood but may also uncover the important role of AI in representing the susceptibility to negative social experiences.

Title: Effects of oxytocin receptor antagonist on estrogens' rapid enhancing effects on social recognition in the medial amygdala

Authors: *C. SEXTON, E. CHOLERIS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Social recognition (SR) is a critical cognitive skill required for animals' successful participation in its social group and is widely regarded as necessary for individual survival. Estrogens and three of their receptors, ERα, ERβ, and GPER1 have been shown to impact SR performance. Estrogens have also been indicated to interact with other neurochemicals such as oxytocin (OT). Previous research has shown infusions of a subeffective dose of an oxytocin receptor antagonist (OTRA) into the medial amygdala (MeA) prior to an infusion of 17-β estradiol (E2) into the PVN prevents E2 rapid facilitating effects on SR. E2 and agonists for all 3 ERs rapidly facilitate SR even when infused directly in the MeA. Whether an E2/OT interaction occurs also within the MeA, is unknown. If such interactions exist, then the OTRA will block the enhancing effects of E2, at a dose that does not block the natural occurrence of SR. 10nM and 25nM doses of E2 were employed to examine possible dose differences in their ability to be blocked by the OTRA. The focus is on female mice, as estrogens have been shown to have more consistent and significant enhancement effects on SR than males. Ovariectomies are conducted to reduce circulating estrogen levels to those of diestrus, and cannulae are surgically implanted into the MeA. The test mouse is initially administered 75nM OTRA, which was previously shown to be a subeffective dose, or a vehicle of artificial cerebrospinal fluid (aCSF) into the MeA. After two minutes the test mice then receive either 25nM or 10nM of E2 or aCSF into the MeA. Next, the test mouse receives a "difficult" social recognition paradigm. Additionally, an object recognition paradigm is employed to determine whether the facilitating effects of 25nM E2 in the MeA previously found are specific for SR. It is predicted that the infusion of the OTRA will prevent the enhancing effects of E2 in the SR paradigm. Furthermore, we anticipate E2 will not facilitate object recognition in the MeA, as this region has shown to be highly specific for social information processing. Preliminary results indicate E2 when paired with aCSF facilitates SR, but when paired with the OTRA does not, supporting our hypothesis. Combined, this research program elucidates the mechanisms of estrogens, specifically those of E2, rapid enhancing effects on female SR in the MeA, which is a key component of the social brain.

Title: Performance of 3xTg-AD mice in a social task: identification of confounds in the behavioral phenotype

Authors: A. K. KLEIN, N. J. ANDERT, B. A. SULKOWSKI, *C. C. WRENN;
Col. of Pharm. and Hlth. Sci., Des Moines, IA

Abstract: Behavioral and psychological symptoms of dementia include mood disturbances, psychosis, aggression, and inappropriate social behavior. These problems occur in patients with Alzheimer's Disease (AD) and are detrimental to overall health. The 3xTg-AD mouse model of AD has been reported to have social deficits. Our study sought to explore this phenotype along with determining whether any observed social impairments result from alterations in other behavioral domains. Our first experiment tested 3xTg-AD mice in the three-chamber social task. We found that, unlike wild-type (WT) controls, 3xTg-AD mice lacked a preference for social novelty. To determine whether this impairment was specific to the social domain, we repeated the experiment using objects as stimuli rather than conspecifics. We found a similar lack of preference for a novel object in the 3xTg-AD mice showing that the social test results are generalizable to other stimuli and not specifically social. We hypothesized two possible explanations for this generalized lack of preference for novelty: a neophobic, anxiety-like phenotype or impaired habituation to stimuli. After testing these hypotheses, we found an anxiety-like phenotype in 3xTg-AD mice in the elevated-plus maze. Additionally, habituation experiments found impaired habituation to both social and non-social stimuli. These findings challenge the conclusion that observed impairments in the three-chamber social test are due to social deficits *per se.* In total, this work highlights the importance of addressing the contribution of non-social confounds to behaviors in the three-chamber social task.

Abstract: Research on prosocial rodent behavior is growing within the fields of cognitive psychology and social neuroscience. There remain essential questions about variables influencing this empathetic behavior. There are discussions and disagreements on whether this behavior is empathetically motivated and correctly labeled as prosocial or whether the behavior is motivated by social contact and curiosity. The present study utilized a helping behavior paradigm and apparatus analysis on 16 adolescent male mice offspring expressing the genotypes tau (with no promoter) or promoter (and no tau). The apparatus in this research is a modified version of the apparatus used by Sato and colleagues (2015), who demonstrated helping behavior in soaked rats. In this paradigm, a mouse can release a familiar cage mate and a non-familiar mate from a restricted water box. The number of friend and food door touches and latency to make a decision, either free the trapped conspecific or choose the food box, was recorded for each mouse. The first six days were stress-free, alternating days testing cagemates and non-cagemates. A damp bedding stressor was implemented for the last six days an hour before mice were evaluated in the apparatus. This research study sought to investigate whether empathy, sympathy, and prosocial behavior can be displayed in a mouse model. Repeated measures ANOVAs revealed several significant results were found regarding stress and empathetic behavior. Findings may aid in understanding the process of empathy and have diagnostic and therapeutic implications in understanding social and emotional impairments seen in individuals with Autistic Spectrum Disorder and substance abuse disorders.

Title: Studying the impact of Shank3-deficiency on neural circuits of social reward

Authors: *M. BARBIER[1], K. THIRTAMARA RAJAMANI[1], S. NETSER[2], S. WAGNER[3], H. HARONY-NICOLAS[1];
[1]Psychiatry, Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Sagol Dept. of Neurobio., The Integrated Brain and Behavior Res. Ctr., University of Haifa, Israel; [3]Univ. of Haifa, Haifa, Israel

Abstract: Background: Social deficits are a core symptom of autism spectrum disorder (ASD). Clinical studies have implicated the mesoaccumbens reward circuit in autism spectrum disorder. However, the causality between alterations in this system and social deficits has not been established. The ventral tegmental area (VTA), a core node of the mesolimbic circuit, is interconnected with the nucleus accumbens (NAc) via the VTA dopaminergic projections. Despite the role of the reward system in social interaction, little is known about the impact of ASD associated mutations on processing social reward and on the functional integrity of this pathway. In this work, we study the effect of a mutation in an ASD high-risk gene, *Shank3*, on the mesoaccumbens system in rats. We hypothesize that *Shank3* mutation impacts neural activity in the mesoaccumbens system, causing abnormalities in accumbal dopamine transmission and leading to impairments in processing social reward. **Methods:** To identify abnormalities in dopamine transmission in *Shank3*-deficient rats that correlate with deficits in processing social reward, we used fiber photometry to record in the VTA in combination with a dopamine sensor in the NAc during a social reward paradigm. In this paradigm we introduced two rewarding stimuli, social and food, during satiety and food deprivation and examined investigation time for each reward during the two conditions. To control for attentional deficits, we used the same paradigm, but replaced the social stimuli with a moving toy rat. To rule out reduced motivation to food or impairment in food consumption, we assessed food consumption. **Results**: We found that *Shank3*-deficient rats have deficits in processing social reward that are associated with perturbation in VTA neural activity and an intact attention and food consumption. **Conclusions**: Our study demonstrates that *Shank3*-deficient rats have a specific deficit in processing social reward and provides a first step toward understanding the role of *Shank3* in the reward system, and how *Shank3*-deficiency may leads to social deficits.

Title: Postnatal environment modulates social dominance

Authors: *K. LOPEZ[1], F. TAKI[2], J. G. TOTH[2], M. TOTH[2];
[1]Cornell Univ. / Weill Cornell Medic Neurosci. Program, New York, NY; [2]Weill Cornell Med. Col., New York, NY

Abstract: In social living groups, members compete for access to resources and mating opportunities and their repetitive interactions create a social order with dominant and subordinate individuals. Little is known about the causative factors that drive the formation of dominance hierarchies and the eventual social rank of an individual. Genetic factors can play a role, but hierarchy develops even in a genetically homogenous group of animals and under controlled laboratory conditions. This raises the possibility that an individual's social dominance is established by early environmental influences. Indeed, we found that voluntary wheel running of dams during the lactation period increased the social dominance of offspring compared to offspring from sedentary mothers, as measured by the tube test. In agreement with these findings, I found that pyramidal neurons in layer 2/3 in the prelimbic region of the medial prefrontal cortex (mPFC) of these offspring exhibited increased length and number of nodes in apical dendrites at the rostral region. This increased arborization suggests increased input to the area. Thus, the effects of physical activity by the mother extended to the non-exercising offspring. However, although runner offspring are primed for an elevated rank, its manifestation is dependent on the post-weaning environment. Post-weaning in a socially deprived state led to the offspring of runner mothers exhibiting subordination. However, their elevated rank was restored with a bout of sexual interaction in adulthood. This suggests that dominance can be programmed by the mother during the postpartum period, but this enhancement in rank develops through exposure to a social environment. Future studies aim to understand the mechanism underlying this primed socially dominant state by profiling mPFC nuclei to determine genes and molecular pathways targeted. This research may help to better understand how the maternal and the offspring environment, individually and in combination, determine social status.

Med., Budapest, Hungary; [4]Ctr. for Neuroscience, Szentágothai Res. Centre, Inst. of Physiology, Med. Sch., Univ. of Pécs, Pécs, Hungary

Abstract: Parenting is a critically important behavior in mammals associated with anxiety and occasionally with depression. Here, the role of preoptic GABAergic inhibitory neurons was addressed in parenting, anxiety and depression. Pup exposure and forced swimming resulted in similar c-Fos activational pattern in neurons expressing vesicular GABA transporter in the preoptic area in females. In males, the number of pup exposure-activated neurons was generally less, with the highest density in the central part of the medial preoptic nucleus. Chemogenetic stimulation of preoptic GABAergic cells resulted in elevated maternal motivation and caring behavior in females and mothers but aggression towards pups in males. Behavioral effects were the opposite following inhibition of preoptic GABAergic neurons suggesting their physiological relevance. In addition, increased anxiety- and depression-like behaviors were found following chemogenetic stimulation of the same neurons in females while previous pup exposure increased only anxiety-like behavior. A sexually dimorphic projection pattern of preoptic GABAergic neurons was also identified, which could mediate sex-dependent parenting and associated emotional behaviors.

Title: Rates of temporal discounting and lateral intraparietal sulcus gamma power are associated in patients with mood disorders.

Authors: *G. E. ANDERSON, D. K. GREENSTEIN, C. R. BURTON, J. R. GILBERT, E. D. BALLARD, C. A. ZARATE, Jr.;
Section on the Neurobio. and Treatment of Mood Disorders, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Impulsivity, reward processing, and psychopathology can be understood using delay discounting tasks, a neuroeconomics metric that quantifies the decline in the current value of a reward in relation to the delay of its receipt. Patients diagnosed with major depressive disorder, bipolar disorder, and suicidal ideation have been shown to value a lower current reward over a higher delayed reward (i.e., increased delay discounting) compared to healthy control participants (HCs). In addition, both human and primate studies have demonstrated that activity within the lateral intraparietal sulcus is associated with individual-specific rates of temporal discounting. Here, we extend these findings by examining electrophysiological correlates of temporal discounting in patients with a mood disorder diagnosis (MDs, *n*=28) and HCs (*n*=19), focusing on the gamma (30-58 Hz) band, a proxy measure of excitation-inhibition balance, which is often dysregulated in mood disorders. In this ongoing study, a delay discounting task was administered behaviorally alongside resting state magnetoencephalography (MEG) scanning. MDs included patients with a recent suicide attempt (i.e., within two weeks, AS, *n*=8), patients with a history of suicide attempt but no attempt or ideation within the last year (HS, *n*=20), and HCs. Prior to scanning, participants completed the the 27-item Monetary Choice Questionnaire (MCQ). An overall *k* value was calculated from the MCQ, with higher *k* values indicating higher discounting rates. Up to one week later, participants completed MEG scanning, during which they rested with their eyes closed. Synthetic aperture magnetometry was used to project gamma power using a realistic head model and covariance matrix regularization on a 5-mm grid over the entire rest period. Analysis of variance was then used to evaluate group (AS, HS, and HC) and discounting rate effects on gamma power. While there was no effect of diagnostic group on gamma power, there was an effect of discounting rate, such that individuals who demonstrated a higher *k* value (i.e., higher discounting rate of the delay) showed reduced gamma power in regions of the lateral intraparietal sulcus and frontal lobe. These findings align with previous studies, implicating this region in delay discounting, and suggest that alterations in gamma power are associated with discounting rates in both MDs and HCs. Future work will explore the temporal dynamics of gamma band changes in this region, as well as the relationship between *k* and other frequency bands. Further, we aim to evaluate the relationship between *k* and other clinical measures in our MD sample, such as impulsivity, anhedonia, and symptom severity.

Abstract: Most of psychiatric disorders, including major depressive disorder (MDD), are generally diagnosed by medical interviews and visible signs, but objective diagnostic and stratification biomarkers developed with resting-state functional magnetic resonance imaging (rs-fMRI) data is expected to contribute to more effective treatment. There is, however, no widely accepted biomarkers due to the absence of optimal analytic pipelines for the development of such biomarkers with sufficient generalization capabilities. In this study, we conducted a comprehensive evaluation of combining analytic methods in order to identify optimal pipelines for developing MDD diagnostic biomarker with generalization performance. We considered 4 processes of developing biomarkers: brain parcellation, estimation of functional connectivity (FC), site difference harmonization, and machine learning. We constructed 360 different MDD diagnostic biomarkers using a large-scale multi-site rs-fMRI dataset (138 MDD patients and 545 healthy subjects from 4 imaging sites) and evaluated classification performances with nested 10-fold cross validation method similarly to Yamashita et al. (*PLOS Biology*, 2020). To confirm the reliability of constructed biomarkers, we also conducted validation tests with the independent Japanese dataset and Russian open-source dataset respectively, and identified several biomarkers with high classification performances (AUC: 0.71~). Among these biomarkers, FCs between subcortical and somatomotor area were commonly identified as important connectivity for classification despite the differences of parcellations and FC combination. Besides, some of these biomarkers have shown the fluctuation with treatment and showed potential for monitoring biomarkers. Lastly, using the analytic pipelines for developing generalizable MDD diagnostic biomarkers, we also succeeded in the development of diagnostic biomarkers with high classification performances for the other psychiatric disorders (autism spectrum disorder and schizophrenia, AUC: 0.88~). This result suggested that our identified pipelines possess generalizability across several psychiatric disorders. Furthermore, combining constructed multiple disorder biomarkers potentially could contribute to the understanding of psychiatric disorders, not bound by conventional categorical disease classification.

Title: Psilocybin therapy enhances cognitive and neural flexibility in patients with major depressive disorder.

Authors: *M. K. DOSS[1], M. POVAŽAN[4], M. D. ROSENBERG[5], N. D. SEPEDA[1], A. K. DAVIS[6], P. H. FINAN[2], G. S. SMITH[2], J. J. PEKAR[7], P. B. BARKER[3], R. R. GRIFFITHS[1], F. S. BARRETT[1];

Kirby Res. Ctr. for Functional Brain Imaging, Kennedy Krieger Inst., Baltimore, MD

Abstract: Psilocybin has shown promise for the treatment of depression, a family of disorders often accompanied by cognitive rigidity. One mechanism by which psilocybin could reduce depressive symptomology is by increasing cognitive and neural flexibility. In an open-label study of 24 patients with major depressive disorder, we tested the enduring effects of psilocybin therapy on depression, cognitive flexibility (perseverative errors on a set-shifting task), and neural flexibility (dynamics of functional connectivity or dFC via functional magnetic resonance imaging). Psilocybin therapy reduced depression and increased cognitive flexibility for at least four weeks post-treatment, though these improvements were not correlated. One-week after psilocybin therapy, glutamate and N-acetylaspartate concentrations (via magnetic resonance

spectroscopy) were decreased in the anterior cingulate cortex (ACC), and dFC was increased between the ACC and the posterior cingulate cortex (PCC). Surprisingly, these increases in dFC between the ACC and PCC were associated with less improvements in cognitive flexibility after psilocybin therapy. Connectome-based predictive modeling demonstrated that baseline dFC emanating from the ACC predicted improvements in cognitive flexibility. In these models, greater baseline dFC was associated with better baseline cognitive flexibility but less improvements in cognitive flexibility. These findings show that psilocybin therapy in patients with depression can enhance cognitive flexibility and neural flexibility, especially of the ACC, but suggest a nuanced relationship between neural flexibility and depression symptomology. Whereas some enduring increases in neural dynamics may allow for shifting out of a maladaptively rigid state, larger persisting increases in neural dynamics may be detrimental to the efficacy of psilocybin therapy.

Title: Depression symptoms in neurological patients: Large-scale survey and lesion symptom mapping of patients with focal brain lesions

Authors: *E. BRANDT[1], N. TRAPP[1], J. BRUSS[1], O. ABU-HALAWA[1], S. LI[1], F. ALBAZRON[1], K. MANZEL[1], J. GRAFMAN[2], A. BOES[1], D. TRANEL[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Northwestern Univ., Evanston, IL

Abstract: Background. Examining depression following neurological injury is useful for our understanding of post-lesion depression and depression more generally. However, the extant literature shows inconsistent findings when it comes to the demographic and neural correlates of depressive symptoms following a neurological event. Thus, the present study aims to

characterize depression symptoms in a large sample of individuals in the chronic phase of recovery from a focal brain lesion. **Methods.** We sampled 526 individuals across two locales. The patients had focal, stable brain lesions and were in the chronic phase of recovery (> 3 months post onset). First, mean Beck Depression Inventory - Second Edition (BDI-II) scores were examined and individual demographic (gender, years of education), time (age at lesion onset, time since lesion onset), and lesion (lesion laterality, lesion etiology) factors were used to predict depressive symptoms measured by the BDI-II. Second, multivariate lesion-symptom mapping was used to identify lesion locations and networks associated with depression symptoms in order to identify lesion locations that might be associated with "risk" or "resilience" for developing depression post-lesion. **Results.** We found that on average, individuals in the chronic phase of recovery from focal brain lesions do not exhibit depressive symptoms that are appreciably different from the general population. Individual characteristics were not predictive of depressive symptoms, with the exception of age at lesion onset, where younger age at lesion onset was associated with elevated depressive symptoms. Peak "risk" regions for post-lesion depression include the bilateral insula and left prefrontal cortex. Peak "resilience" regions - viz., areas where damage was associated with lower depression - included the right ventromedial prefrontal cortex, right orbitofrontal cortex, and right inferolateral temporal cortex. Seed-based network analysis demonstrated peak "risk" region overlap with the ventral attention/salience network and the peak "resilience" region overlap with the default mode network. **Conclusion.** Depression is a heterogeneous disorder, but our results suggest that some individuals may be at increased risk for developing depression post-lesion while others are protected against the development of depression. This may be mediated by individual factors such as age at lesion onset or lesion location. These findings have important implications for the diagnosis, prognosis, and treatment of depression.

Title: Alterations in Cortical Gray Matter Associated with Cardiac Vagal Tone and Remitted Major Depressive Disorder

Authors: *S. GUPTA[1], L. M. JENKINS[3], M. KOUCHAKIDIVKOLAEI[4], K. POPURI[4], J. WU[2], Z. YE[5], L. WANG[6], S. A. LANGENECKER[7], J. P. STANGE[8];

Abstract: Major Depressive Disorder (MDD) is a highly debilitating disorder that affects at least 16% of adults in the US over their lifetime. Only a few studies have examined structural brain differences in early course remitted MDD (rMDD) and even fewer have determined whether these changes are associated with biomarkers of emotion regulation capacity. We aimed to identify structural brain differences in rMDD and determine how these differences relate to cardiac vagal tone, a measure of parasympathetic nervous system activity and regulatory capacity. T1 weighted MRI was obtained on a 3T GE scanner for 26 young adults with rMDD (mean=27.7 years, SD=4.1) and 18 healthy controls (HC) (mean=26.1 years, SD=3.8). Diagnosis was confirmed based on the DSM-5 criteria for lifetime MDD. Physiological self-regulation was measured using a Hexoskin, which collected participant biometric data, and ecological momentary assessments for 7-days. Resting respiratory sinus arrhythmia (rRSA), a measure of heart rate variability in the respiration cycle indicative of vagal tone associated with emotion regulation capacity, was measured using a Biopac MP160 and analyzed with AcqKnowledge software using the peak-valley method. Imaging data were processed through Freesurfer to calculate cortical measures with the Desikan-Killiany atlas. The groups were compared using a GLM and smoothing was performed using a kernel size of 5 mm. Multiple comparisons were corrected using the Monte Carlo Null-Z simulation with a vertex-wise cluster threshold of 1.3. Relative to HC, individuals with rMDD had a smaller surface area in the right rostral middle frontal gyrus (rRMF) (rMDD mean=6265 mm^2, SD=686; HC mean=6884 mm^2, SD=776; p=0.004). Pearson correlation found that decreased volume in rRMF was associated with lower rRSA (r=0.36, p=0.020). Our findings build on previous research identifying cortical reductions in MDD patients in the dorsolateral prefrontal cortex, which is critical for executive functioning including inhibitory control, and is hypothesized to contribute to depression via its role in top-down cognitive regulation of emotion. Decreased surface area could be indicative of neurodevelopmental pruning or experience-related reshaping. Previous studies have established that rRSA reflects the capacity for emotion regulation. Our finding suggests that the neuroanatomical underpinning for this could be the rRMF. Elucidating relationships between neuroanatomical and physiological biomarkers may have utility for understanding the etiology of MDD and may inform future preventative interventions targeting these biomarkers.

Title: Dopamine Dependent: examining the link between learning and treatment-resistant depression

Authors: *X. LIU, S. J. READ;
USC, Los Angeles, CA

Abstract: Treatment resistant depression (TRD) is a subtype of Major Depressive Disorder (MDD) that is not responsive to typical antidepressants such as SSRIs. There is some evidence that treatment responsiveness may be related to dopamine neuron dysfunction, specifically in the mesolimbic pathway. To address the gap in understanding of how this translates to behavioral and personality differences in TRD, we used several self-report scales in conjunction with a reinforcement learning task administered online to objectively measure individual variation in learning from positive and negative feedback. In Experiment 1, we found participants (N = 141) on average were better at learning the negative stimuli than the positive. Response bias during the test block was significantly correlated with the Inventory of Depression and Anxiety Symptoms-II (IDAS-II) for General Depression subscale, such that greater depression severity was related to a more negative response bias (r = -.18, p = .030). In Experiment 2, we empirically defined three underlying facets of anhedonia by factor analyzing items of the Motivation and Energy Inventory (MEI) and Temporal Experience of Pleasure Scale (TEPS) administered online to a sample of 137 participants with and without depression. The major latent factors were found to be motivation or energy, wanting or anticipation, and consummatory liking. We found that TRD was associated with significantly lower anticipation scores, whereas MDD overall was associated with significantly lower consummatory pleasure. Additionally, the TRD group had significantly lower Extraversion scores than responders. After controlling for depression severity, antidepressant responders demonstrated a significantly less negative learning bias than both the TRD group (p = .047) and control group (p = .017) on our reinforcement learning task. We postulated this was due to the effect of SSRIs; however, further research is needed to determine a causal effect.

Title: Parsing depression across the socioeconomic spectrum using neuroanatomy

Authors: *Y. HAO[1], M. J. FARAH[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. Pennsylvania, Philadelphia, PA

Abstract: Socioeconomic status (SES) is a potent risk factor for depression, with symptoms increasing by a factor of two or more between poor and middle class adults (DJ Brody, 2018). Here we ask: Is the "surplus" of depression symptoms at low SES just like those at higher levels, or does it differ? We addressed this question using data from the Human Connectome Project, with a sample of 881 healthy young adults (22 - 37 yo), with neuroanatomical, psychological and SES (income and education) data. Symptom load was the summed ratings of depression-typical symptoms from the ASEBA (LA Rescorla, 2018) scale. The anatomical feature of a priori interest was amygdala volume, which is associated with SES and depression. We used multiple regression controlling for age, gender and race to test the relations among SES, amygdala volume, and depression symptom load. Gender, age and race did not moderate any reported effects. We tested 3 different hypotheses, with different implications for the heterogeneity of depression across levels of SES. A diathesis-stress model, which describes the interaction of risk factors in psychopathology, was tested by adding an SES-amygdala volume interaction term in the regression model and was disconfirmed. A mediation model, based on previous proposals that amygdala volume accounts for the effect of SES on depression (EC Merz, 2018), was also disconfirmed, despite significant pairwise relations among SES, amygdala volume and depression symptom load in this sample. In sum, amygdala volume and SES neither synergize nor account for common variance; rather they have additive and independent effects on depression. Hence the excess of depression observed at lower levels of SES differs in its relation to amygdala volume from depression that is evenly distributed across the SES continuum. Two more tests were then undertaken to validate this difference. First, the 14 specific depression symptoms endorsed by participants were examined in relation to the two risk factors (FDR corrected). SES and amygdala volume were associated with largely nonoverlapping symptoms. Second, the role of perceived stress (NIH Toolbox) in mediating the relations between the two risk factors and depression was assessed. Stress accounts for SES effects on depression but has no relation to amygdala volume. In sum, by using amygdala volume as a marker for depression risk, we found it to be independent of SES, hence SES is a distinct risk factor, associated with different symptoms and is, in contrast to amygdala volume, accounted for in part by perceived

stress. Understanding different pathways to depression can help develop new treatment strategies on psychotherapy and antidepressant medicines.

Title: Identification of a Personalized Intracranial Biomarker of Depression and Response to DBS Therapy

Authors: A. C. FRANK[1], K. SCANGOS[2], P. S. LARSON[3], A. T. LEE[3], ***A. LEE**[2];
[1]Psychiatry and Behavioral Sci., USC, Los Angeles, CA; [2]Psychiatry and Behavioral Sci., [3]Neurolog. Surgery, UCSF, San Francisco, CA

Abstract: Deep brain stimulation (DBS) for obsessive-compulsive disorder provides improvement in symptom burden for many people with treatment-refractory OCD. However, the stimulation parameter space remains large and stimulation is currently open-loop, without responsiveness to patient's symptoms states. Here we attempted to identify neural correlates of symptom burden and assess how DBS stimulation impacts these neural signals, with consideration toward developing responsive, closed-loop DBS systems. We utilized the Medtronic Percept device to both stimulate and chronically record neural signals in the home and office setting. Data were acquired from leads placed in the BNST of a patient with comorbid depression and treatment-refractory OCD. The patient recorded symptom burden over several months by completing visual-analog surveys. DBS stimulation improved both OCD symptom burden (Y-BOCS reduction of 29%) and depression (PHQ-9 reduction of 48%). Further, we find that in the ambulatory setting, LFP power in the gamma frequency band is strongly, inversely correlated with patient ratings of depression severity (i.e. low gamma power is associated with high levels of depression). During in-office recordings, we find that DBS stimulation broadly increases LFP power, including within the gamma range. In conclusion, LFP gamma power in the BNST is strongly, inversely correlated with ratings of depression and DBS stimulation broadly increases power, including in the gamma frequency range. These results suggest a neural biomarker of depression that could be utilized to develop adaptive, closed-loop DBS.

Sci., Naresuan Univ., Phitsanulok, Thailand; [5]Biomolecular Sci. Res. Ctr., Sheffield Hallam Univ., Sheffield, United Kingdom

Abstract: Major depressive disorder (MDD) is a psychiatric disorder that relates in part to dysfunction of the glutamatergic system (Miladinovic et al., 2015). Previous study has reported that abnormal expression of glutamate receptor, NR2B subunit of N-Methyl-D-aspartic acid (NMDA) can promote depression-like behaviors in a rat epilepsy model (Peng et al., 2016). Additionally, brain-derived neurotrophic factor (BDNF) is a member of neurotrophin family which plays crucial roles in regulation of neurotransmitter systems and glutamatergic synaptic strength (Carvalho et al., 2008). Deficits of BDNF have been reported in the pathology of MDD (Phillips, 2017). Therefore, the functional polymorphisms (SNPs) of *BDNF* rs6265 and *GRIN2B* rs3764030, in genes for BDNF and NR2B proteins respectively, may be candidate risk factors for MDD. The objectives of this study were to determine the associations of functional *BDNF* rs6265, *GRIN2B* rs3764030 and its interaction with MDD in the Thai sample. The rs6265 and rs3764030 genotyping were performed in blood DNA samples of 100 MDD patients and 100 matched controls using TaqMan SNP genotyping assays. The results showed that genotype of *GRIN2B* is significantly associated with MDD (p= 0.038) with T carriers having an increased frequency (p=0.013; Odds ratio=2.07). No association was observed with *BDNF* genotype.

However, taken together, *BDNF* and *GRIN2B* risk genotypes showed a slightly stronger association with MDD (p=0.008; Odds ratio=2.31). The findings demonstrate a significant association of a single *GRIN2B*, but not *BDNF*, variant with MDD in the Thai population. The result supports the involvement of the glutamatergic system in the neurobiology of MDD. A possible interaction between the rs6265 in *BDNF* and a glutamate receptor variant in a psychiatric disorder is consistent with a previous study (Iamjan et al., 2018) in which we identified such an effect - between *GRIA3* and *BDNF* - on susceptibility to methamphetamine psychosis (Iamjan et al., 2018). Therefore, the result may suggest a relationship between BDNF and glutamate receptor function on the pathology of MDD. Alteration of BDNF activity may impair synaptic plasticity at the glutamatergic synapse (Carvalho et al., 2008), and contribute to the development of MDD. The present study provides evidence that a functional variant of *GRIN2B,* possibly interacting with *BDNF* rs6265, contribute genetic vulnerability for MDD in the Thai population; further studies with larger samples are need to confirm these findings.

Title: Positive self-bias increases with age and is reduced in patients with mood and anxiety disorders

Authors: M. MEHTA[1], S. NA[2], X. GU[2], J. MURROUGH[2], ***L. MORRIS**[1];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The sense of agency, or the belief of action ownership, is an elusive construct that impacts day-to-day experience and decision-making. Despite its relevance in a range of neuropsychiatric disorders, it is widely under-studied and remains difficult to measure objectively in patient populations. We developed and tested a novel cognitive measure of valence-modulated agency perception in 53 healthy control subjects and 20 subjects with mood or anxiety disorders (MAD), including major depressive disorder and generalized anxiety disorder. The task consisted of a simple computerized effort task for monetary rewards with performance-based trial-by-trial positive or negative feedback. Throughout the task, the visual representation of progress during effort was ambiguously but consistently perturbed by computer

interference. Trial-by-trial ratings of self-versus-other agency were collected. In line with previous work, healthy subjects demonstrated higher self-agency after receiving positive feedback, compared to negative feedback when the level of computer inference was kept constant ($p=7.3 \times 10^{-6}$). This "positive self-bias" was associated with increasing age ($R=0.29$, $p=0.02$). Patients with MAD showed reduced positive self-bias compared to healthy controls ($p=0.048$), and this reduction was associated with worse self-reported symptoms of anhedonia (Snaith-Hamilton Pleasure Scale, SHAPS) at trend level ($R=0.42$, $p=0.06$). Together this work suggests how positive and negative environmental information impacts the sense of self-agency in healthy subjects, and how it is perturbed in patients with mood and anxiety disorders.

Title: Levels of depressive and anxiety symptoms in humans predict distinct patterns of reward-seeking: A cross-species translation of an appetitive go/no-go task.

Authors: *I. D. DALY[1], R. J. TOMM[1], B. J. FORYS[1], A. R. TERPSTRA[1], L. CLARK[1,2], T. CHAKRABARTY[1,2], S. B. FLORESCO[1,2], R. M. TODD[1,2];

Abstract: Traditional methods used to classify neuropsychiatric disorders, such as depression and anxiety, are based on heterogenous symptom clusters and can often fall short of reliably predicting treatment efficacy. In part, this may be attributable to a reliance on self-report symptoms and observable signs which fail to capture the underlying pathophysiologies- and may not account for differences amongst disorder subtypes and comorbidities (i.e., anxious depression). Depression and anxiety are often characterized by impaired reward-seeking and avoidance behaviors, respectively. However, few studies investigate whether anxiety symptoms predict reward-seeking behaviors, especially when accounting for comorbidity with depressive symptoms. Furthermore, it is unclear how symptoms of depression and anxiety predict biases towards active versus inhibitory reward-seeking strategies. Here, a cross-species translation of an

appetitive go/no-go task was used to differentiate between active and inhibitory reward seeking. In this study, undergraduates with depressive and anxiety symptoms ranging from minimal to severe completed a modified go/no-go reward-seeking task (translated from a rodent paradigm). In this uninstructed learning task, visual cues signaled the response required to obtain a monetary reward. The task involved three stages: 1) An acquisition stage, where participants learned an active response; 2) An intermixed stage, where participants learned to discriminate between active and inhibitory responses; and 3) A reversal stage where the previous response rules were reversed. Participants were grouped into the highest and lowest quartiles for depressive and anxiety symptoms. Participants with higher depressive symptoms were impaired on both active and inhibitory reward-seeking trials during the reversal stage, compared to those with low depressive symptoms. In addition, those with high anxiety symptoms had increased accuracy on active reward-seeking trials compared to low anxiety participants in the intermixed stage. Most notably, these results differ from those observed in an analogous avoidance task that assessed the relationship between depressive and anxiety symptoms in active and inhibitory avoidance. This task, alongside analogous tasks that assess various aspects of reward-seeking and avoidance behaviours, may aid in our understanding of the heterogeneity and interaction of symptoms of depression and anxiety, two highly comorbid conditions.

Abstract: Depression and anxiety show notable heterogeneity in symptomatology and commonly co-exist. Comorbid anxiety in depression has been consistently associated with worse

treatment outcomes than depression without anxiety, indicating that this may be a more severe and perhaps pathophysiologically distinct subtype. Depression and anxiety are often characterized by impaired reward-seeking or avoidance behaviors, respectively. However, few studies investigate how depressive symptoms relate to avoidance behaviors, especially when accounting for comorbidity with anxiety symptoms. Additionally, it is not clear whether symptoms of depression and anxiety predict active versus inhibitory forms of avoidance. In this study, undergraduates (N_{Total} = 174) with a range of depressive (Beck Depression Inventory) and anxiety (Beck Anxiety Inventory) symptoms from low to severe completed a modified go/no-go avoidance task (reverse translation of a rodent paradigm). In this uninstructed learning task, cues were used to signal the response type (go/active vs. no-go/inhibitory) required to avoid an aversive sound. The task consisted of three-stages: 1) An acquisition stage required learning of an active avoidance response; 2) An intermixed stage required learning to flexibly discriminate between active and inhibitory avoidance responses; 3) In a reversal stage the response rules were reversed. Compared to participants with lower depressive (Low_{DEP}, *N* = 39; *M* = 4.38, *Range* = 0-7) and anxiety (Low_{ANX}, *N* = 41; *M* = 2.73, *Range* = 0-5) symptoms, participants with higher depressive ($High_{DEP}$, *N* = 44; *M* = 28.02, *Range* = 21-55) and anxiety ($High_{ANX}$, *N* = 41, *M* = 33.93, *Range* = 25-63) symptoms were impaired in active avoidance during the acquisition stage. However, this effect was driven mostly by a subset of participants that scored high in both depressive and anxiety symptoms ($High_{DEP}$ + $High_{ANX}$, *N* = 22). $High_{DEP}$ participants showed increased active avoidance accuracy in the intermixed stage compared to Low_{DEP} participants. Conversely, $High_{ANX}$ participants were impaired in active avoidance, showing decreased accuracy on Go trials during all 3 task stages compared to Low_{ANX} participants. Depressive and anxiety symptoms were not associated with differences in inhibitory avoidance during any task stage. This translational avoidance task revealed distinct avoidance profiles that were dependent on relative levels of depressive and anxiety symptoms, suggesting that it might be particularly useful in discriminating differences in avoidance behaviors in clinical populations of depression and anxiety - especially those diagnosed with comorbidities.

Title: Gender selectively moderates relationships between mood disorder symptoms and performance of effort related avoidance and reward-seeking tasks

Authors: *B. J. FORYS[1], R. J. TOMM[1], D. STAMBOLIYSKA[1], A. R. TERPSTRA[1], L. CLARK[1,2], T. CHAKRABARTY[3,2], S. B. FLORESCO[1,2], R. M. TODD[1,2];

Abstract: We must often decide how much effort to exert to avoid undesirable outcomes or obtain rewards. Past work suggests that dopamine (DA) modulates active avoidance and reward-seeking while serotonin (5HT) modulates inhibitory avoidance. Moreover, DA dysregulation in depression may limit effective effort deployment for obtaining rewards. Yet understanding the neuromodulation of such dimensional behaviours in depression is hampered by outstanding questions about the links between motivated action and inhibition and depressive symptoms, and whether these differ between males and females or with comorbid anxiety. The present study used a task back-translated from rodent studies to examine whether effort deployment on active and inhibitory avoidance (Study 1) vs. reward seeking (Study 2) predicts depression symptoms, and whether these relationships are moderated by gender. Undergraduates and paid participants (N_{Avoid} = 540, N_{Reward} = 308; N_{Female} = 376, N_{Male} = 472, M_{Age} = 23.10, SD_{Age} = 5.79) were assessed on Beck Depression Inventory (BDI-II) as well as the Beck Anxiety Inventory (BAI) to control for anxiety comorbidity, and performed an online instructed avoidance or reward-seeking task. Participants had to make multiple presses on active trials and withhold presses on inhibitory trials to avoid an unpleasant sound (Study 1) or obtain points towards a monetary reward (Study 2). Physical effort on active trials (number of presses) increased every 20 trials on a progressive ratio schedule. Participants ranged in depressive symptom levels; many scored above the threshold (>13) for moderate depression (M = 16.14, *Range* = 0-58, $N >$ *clinical threshold* = 475). In the avoidance task, gender moderated the relationship between depressive symptoms and active trial accuracy. Males had lower accuracy overall on active trials; females with more depressive symptoms had higher active trial accuracy. This pattern emerged as effort requirements increased. We found no effects of gender or depressive symptoms on inhibitory trials. In the reward-seeking task, females with higher depressive symptoms were more likely to exert effort for reward. To examine depression-effort interactions, we simulated each task with a computational model and evaluated the output's fit to our results. Our results illuminate gender differences in the relationship between depressive symptoms and motivation to actively and effortfully respond to achieve positive and avoid negative outcomes. Future studies can examine how sex/gender moderates the role of DA and 5HT in effortful avoidance and reward-seeking. Targeting goal-directed effort deployment may also be a useful clinical intervention.

Title: Approach avoidance decision making in depression and social anxiety

Authors: *A. ACUÑA[1], S. MORALES[1], L. URIARTE-GASPARI[1], N. AGUIRRE[1], E. CUÑA[2], M. GARCÍA FONTES[2], A. PÉREZ[1], V. GRADÍN[3,1], Á. CABANA[3,1], N. HUART[4];

Abstract: Approach-avoidance conflict (AAC) occurs when we make decisions that can lead to both rewarding and aversive outcomes. AAC has been implicated in the pathophysiology of Major Depression (MD) and Social Anxiety (SA), but few studies have investigated this relationship on a neural level. When AAC includes social threat and rewards, it is called social AAC (sAAC). Given that people with MD and SA suffer from social impairments, sAAC is of interest in these populations.
We used fMRI to study brain activity during sACC, in participants with MD, SA, or both disorders (MD/SA, n=52) and matched healthy controls (n=41). In our task, players are thought to be categorized as a one/two/three/four or five star players, depending on how good they are responding trivia questions. Participants are actually categorized as three star players. On every trial, participants choose between two possible options, with which category of co-player they would like to make a team. From a material point of view, choosing the higher category (approach) is better than choosing the lower one (avoidance), since this makes a stronger team. However, conflict arises because approach decisions increase the chances for the participant being the worst one in the team, which relates to social comparisons and guilt processes.
The MD/SA group reported higher negative emotions, such as embarrassment and guilt, during the task. At a neural level, for the avoidance > approach contrast, we found across participants activations spanning the anterior cingulate cortex (ACC) and medial prefrontal cortex (mPFC). These regions have been associated with the detection of conflict and with deliberate and effortful decision making. Therefore we believe their activity is related to avoidance decisions encompassing a more thoughtful and less automated process than approach decisions. Supporting this idea, we found that avoidance decisions took longer to make than approach decisions. The avoidance > approach contrast also showed between group differences in the ACC and mPFC. This difference was related to controls showing higher activity than the MD/SA group during avoidance decisions in these regions. This suggests that controls experienced more conflict and

had to put more effort when choosing to play with lower categories, while for the MD/SA group this was a more automatic decision. This idea is backed up by an interaction between group and type of decision found in reaction times, showing that between group differences were larger when choosing the avoidance option (with controls taking longer to choose) compared to choosing the approach option.
Findings highlight neural substrates underlying sAAC biases in MD and SA.

Title: Neural substrates of repetitive negative thinking: an fMRI analysis of overlapping worry and rumination signals in the brain

Authors: *N. PUCCETTI[1], E. K. MORAES[1], C. A. STAMATIS[2], K. R. TIMPANO[1], A. S. HELLER[1];
[1]Univ. of Miami, Coral Gables, FL; [2]Ctr. for Behavioral Intervention Technologies (CBITs), Dept. of Preventive Medicine, Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL

Abstract: Depression and anxiety disorders are detrimental and often co-occur. To mitigate the financial, physical, and psychological costs of this comorbidity, it is critical to understand the risk factors that explain shared and unique features of these disorders. One shared risk factor is repetitive negative thinking (RNT). We still lack a clear neurobiological model of RNT, however, because neuroimaging studies mainly 1) examine RNT's content-specific components (worry and rumination) 2) use general prompts rather than idiographic stimuli to induce RNT, and 3) conduct group-wise comparisons rather than examining the full dimension of RNT. To this end, we used idiographic worry and rumination statements to induce RNT during an fMRI scan in 37 young adults with dimensionally assessed RNT. During imaging, participants reflected on their personal worries and ruminations, as well as neutral prompts, for 16s each. We characterized RNT through a contrast of the worry and rumination conditions minus the neutral condition. This contrast showed that RNT was related to greater activity in the inferior parietal lobule, insula, putamen, thalamus, and midcingulate cortex. During the neutral condition there was greater activity in default mode network (DMN) structures, including the posterior cingulate cortex, the medial prefrontal cortex (mPFC) and the hippocampus. In addition, to determine unique features of worry and rumination, we examined a worry minus rumination contrast. Here,

rumination was associated with mPFC and anterior cingulate cortex, precuneus, and middle temporal gyrus activation. Results from the broad RNT contrast highlight that negative, perseverative thoughts are not simply a product of DMN-supported self-referential processes, but may require regions within the salience network (i.e., the insula and cingulate cortex). Moreover, the rumination-specific relations to both DMN and salience network structures suggest that worry and rumination are distinguishable from one another in the brain. These results extend the literature by characterizing both content-specific and -independent RNT neural substrates, which could ultimately inform etiological and treatment models of depression and anxiety.

Title: Passage-of-time dysphoria: a highly replicable decline in mood during rest and simple tasks that is moderated by depression

Authors: *D. C. JANGRAW[1,2], H. KEREN[2], R. L. BEDDER[5], R. B. RUTLEDGE[5], F. PEREIRA[3], A. G. THOMAS[4], D. S. PINE[2], C. Y. ZHENG[3], D. M. NIELSON[2], A. STRINGARIS[2];
[1]Univ. of Vermont, Burlington, VT; [3]Machine Learning Team, [4]Data Sci. and Sharing Team, [2]NIMH, Bethesda, MD; [5]Univ. Col. London, London, United Kingdom

Abstract: Does our mood change as time passes, and is this change different in people with depression? These questions are central to affective neuroscience, yet they remain largely unexamined. Here we demonstrate that rest and simple task periods lowered participants' mood, an effect we call “passage-of-time dysphoria.” This finding was replicated in 15 cohorts totaling 27,882 adult and adolescent participants, including preregistered analyses. Interestingly, the dysphoria was reduced in people with higher depression risk.
We first recruited 40 adults online using Amazon Mechanical Turk (MTurk) and asked them to rate their mood during a rest period before a gambling game. We observed a gradual, apparently linear decline in mood. This result was replicated in 5 other cohorts. The mean dysphoria was relatively large (13.8% after 7.3 minutes, Cohen's d=0.574). However, it was quite variable across individuals and showed only moderate stability within individuals (ICC(2,1)=0.411 across 2 weeks).

Using modified versions of the task, we showed that the decline in mood ratings was not due to these methodological confounds: the aversive nature of rating one's mood, the mood rating method's susceptibility to fatigue, the expected rest period duration, the aversive nature of multitasking, or regression to the mean. We showed that the decline also occurs in simple tasks, including a visuomotor task and a gambling game with random zero-mean outcomes.
To test the effect's generalizability, we collected similar data from 116 adolescent participants recruited in person. This group showed a mood decline not significantly different from the MTurk cohort. We also analyzed a large dataset (n=26,896) of mood ratings during a mobile app gambling task. Even in this engaging game, mood decreased with time on task. But the dysphoric effect was smaller in this group ($p= 8.10e{-}45$).
An individual's level of dysphoria was inversely related to depression risk and a computationally estimated reward sensitivity parameter, supporting the idea that depressed people feel that rest better aligns with their reduced expectations for task rewards. Rest also impacted behavior: participants were less likely to gamble at the start of a task if it was preceded by rest.
Our findings call into question neuroscience's long-held assumption of a constant affective background by demonstrating spontaneous, seemingly linear drifts in mood that occur over time. This has theoretical implications for the nature of mood and its aberrations, and methodological consequences for the design and interpretation of experiments, particularly those in which neuroimaging results might be affected by mood and confounded by time.

Title: Subjective Pain, Emotion Regulation Function, and Regional Brain Volume Reduction in Nonsuicidal Self-injury

Authors: *S.-E. LEE, H. SHIN, G. KIM, H. MOON, J.-W. HUR;
Korea Univ., Seoul, Korea, Republic of

Abstract: Background: Investigating the dynamics of pain during nonsuicidal self-injury (NSSI) is crucial to understanding why individuals choose and maintain self-destructive behaviors. Little is known, however, whether there are structural changes in the brain regions

responsible for the pain-processing of NSSI. This study aimed to examine gray matter volume changes in the NSSI group and its associations with subjective pain, frequency, versatility, and functions of NSSI. **Methods:** Individuals who reported five or more NSSI episodes in the past year (n = 63) and age- and sex-matched controls (n = 63) participated in the study. T1-weighted MRI data were obtained from all participants. Voxel-based morphometry (VBM) was done using Computational Anatomy Toolbox version 12 (CAT). To explore the brain structural differences between groups, two-sample *t*-tests, adjusting for age, sex, total intracranial volume (TIV), and scan site, were applied. Within the NSSI group, multiple regression analyses were used to examine the relationships between gray matter volumes and variables of NSSI. **Results:** We found regional gray matter volume decrements in the left opercular part of the inferior frontal gyrus (IFG), right insula, and bilateral secondary somatosensory cortex (S2). Gray matter volumes of the opercular part of the IFG showed significant negative correlations with subjective pain and toughness function of NSSI. Moreover, the volumes of the insula and S2 were negatively associated with the emotion regulation function of NSSI. **Conclusions:** Our findings highlight regional brain volume reductions among individuals who engage in NSSI in relation to pain-processing. Future studies are needed to further clarify the relationship between structural brain abnormalities, subjective pain, and emotion regulation function of NSSI.

Title: Brooding and reflection as trait predictors of mentation rate measured via wholebrain network activity transitions during resting-state fMRI: A CAN-BIND-4 analysis

Authors: *S. D. SQUIRES[1], J. TSENG[1], M. ZAMYADI[2], S. HASSEL[3], S. C. STROTHER[2], G. MACQUEEN[3], S. H. KENNEDY[4], R. V. MILEV[1], K. L. HARKNESS[1], J. POPPENK[1]; [1]Queen's Univ., Kingston, ON, Canada; [2]Baycrest Hlth. Sci. Ctr., Toronto, ON, Canada; [3]Univ. of Calgary, Calgary, AB, Canada; [4]St. Michael's Hosp., Toronto, ON, Canada

Abstract: Most of us are familiar with dwelling on our feelings and problems when we are sad. The tendency to do this is called trait depressive rumination (DR) and it is known to increase risk of psychiatric disorder in vulnerable individuals. Two kinds of DR have been proposed:

Reflection, which involves understanding one's feelings and problems, and Brooding, which involves abstract, "why me?" thoughts about obstacles and negative social comparisons. Mentation rate (MR) is the number of discrete thoughts had over time and intuition suggests it is linked to DR due to the sustained and repetitive nature of ruminative thoughts. This association's direction has been impossible to ascertain, however, due to limitations with self-report measures of MR. Does DR involve a fast MR as one rapidly changes thoughts to understand oneself and situation, or a slow MR due to fixation on one's feelings and problems? Does this depend on the kind of DR? To address these questions objectively, we turned to participants' brain network dynamics, leveraging cutting-edge neuroimaging methods that enable us to use co-occurring network activity changes to detect the moments when each participant transitions between thoughts. We calculated this network transition rate (TR) during resting-state fMRI (rsfMRI) and examined its relations with Reflection and Brooding scores from the Ruminative Responses Scale. We used archival data from the Canadian Biomarker Integration Network for Depression: Stress and Reward in Anhedonia (CAN-BIND-4) study, which were collected from 63 participants (ages 18-65, 68% female, 67% white) with no history of psychiatric disorder. Higher Reflection and Brooding scores were associated with faster and slower TR, respectively. A significant Reflection X Brooding interaction was also observed, such that higher scores in both variables predicted a faster TR than was predicted by those variables separately. This analysis is the first to use an objective approximation of MR, TR, to demonstrate how different forms of DR, Reflection and Brooding, may be linked respectively to diverse and restricted thought content over time. Additionally, we speculate that the higher TR in those who both brood and reflect may represent a greater number of network transitions due to switching among these and other modes of thought, but this must be verified with further research. These observations elucidate how different kinds of repetitive thought defined in the psychology literature can be differentiated based on objective neuroscience metrics like TR. By leveraging both fields in such a way, we inch closer towards identifying a biopsychologically supported taxonomy of repetitive thought.

Title: Longitudinal Disruption of Sleep Structure by Electroconvulsive Therapy

Authors: *M. KAFASHAN, A. K. LABONTE, O. HYCHE, T. NGUYEN, S. SUBRAMANIAN, N. B. FARBER, B. J. PALANCA;
Washington Univ. Sch. of Med. in St. Louis, St. Louis, MO

Abstract: Sleep plays an essential role in maintaining homeostasis of cognitive function through synaptic plasticity. Slow oscillations are hallmarks of electroencephalographic (EEG) during slow-wave sleep and define non-rapid eye movement sleep (NREM) stage N3. Sleep slow-wave activity (SWA) is associated with memory formation and synaptic plasticity. A decrease in sleep SWA has been observed in patients with major depressive disorder. Electroconvulsive therapy (ECT) is an effective therapy for treatment-resistant depression (TRD), defined as the lack of response to at least two antidepressant pharmacologic agents. Therapeutic effects of ECT stem from the induction of generalized seizures during general anesthesia; however, underlying mechanisms remain unclear. We hypothesize that ECT alters the expression of sleep slow waves to facilitate synaptic reconfiguration in pathologic neural circuits underlying psychiatric illnesses. In this study, we assessed sleep macrostructure and microstructure longitudinally. Wireless wearable devices, Dreem (Rhythm, New York USA), were used to acquire sleep EEG data and to address previous technical impediments to the study of longitudinal changes in SWA in the outpatient setting. Participants provided overnight sleep EEG the day after each ECT session. Sleep EEG data were also acquired for a minimum of one night prior to the first ECT session, providing a true baseline measure. Sleep records were scored as rapid eye movement (REM) and non-rapid eye movement (NREM) stages N1-N3, using modified American Academy of Sleep Medicine guidelines. Severity of depression was quantified utilizing the Quick Inventory of Depressive Symptomatology-16 (QIDS) before each ECT session, serially up to a 7-week index course of the treatment. SWA was quantified as the average 0.5-4 Hz frontal EEG power per minute during N3 sleep. We acquired 111 sleep records from 10 subjects in the first year of this study, in which 81 records were scorable. The proportion of N3 sleep was linearly correlated with treatment number (linear mixed-effects model with QIDS score as a covariate, $R^2=0.44$, $P=0.003$). Similarly, SWA increased over the course of therapy (linear mixed-effects model with QIDS score as a covariate, $R^2=0.41$, $P=0.035$). This study confirms the feasibility of using wireless wearable devices for the longitudinal assessment of sleep structure over the course of ECT in TRD patients. Furthermore, our findings might shed light on other non-invasive interventions targeting sleep structure in patients with psychiatric illnesses.

Title: Effects of bullying on anxiety symptoms in adolescents: Parental warmth as a potential buffer

Authors: *S. PAULISIN[1], B. BORG[2], J. EVANSKI[2], H. SCHACTER[2], H. MARUSAK[2];
[1]Sch. Of Med., [2]Wayne State Univ., Detroit, MI

Abstract: *Effects of bullying on anxiety symptoms in adolescents: Parental warmth as a potential buffer*
Shelley Paulisin, Breanna Borg, Julia Evanski, Hannah Schacter, Ph.D. and Hilary Marusak, Ph.D.
Anxiety disorders are the most common psychiatric disorder, affecting nearly one in three, and commonly begin during adolescence. Peer victimization, or bullying, is common (10-30%) among adolescents and has been shown to increase risk of anxiety disorders. Prior research suggests that a healthy parent-child relationship may protect adolescents from anxiety. Here, we examine whether peer victimization is associated with anxiety symptoms in early adolescents, and whether parental warmth can buffer the effects of peer victimization on anxiety. One-hundred and fifty early adolescents (M±SD = 12±1.5, 45% female) and one parent/guardian completed online surveys. Adolescents self-reported on peer victimization, anxiety symptoms, and parental warmth using validated questionnaires, including the Revised Personal Experiences Checklist (De Los Reyes & Prinstein, 2004), Screen for Child Anxiety Related Disorders (Birmaher et al., 1997; Monga et al., 2000), and the Parent Child Relationship Scale (Pianta, 1992), respectively. Correlation analyses were used to examine bivariate associations among peer victimization, anxiety, and parental warmth, and hierarchical regression was used to test for interactive effects of peer victimization and parental warmth on anxiety. Peer victimization was positively associated with anxiety symptoms, and negatively associated with parental warmth. Parental warmth was also negatively associated with anxiety. There was no significant interaction between peer victimization and parental warmth on child anxiety symptoms. All results remained consistent when controlling for age and gender. These results suggest that peer victimization may increase risk of adolescent anxiety. Although parental warmth was associated with lower anxiety, we did not find evidence that parental warmth can buffer the negative effects of peer victimization on anxiety. These findings highlight the need to improve mental health outcomes in victims of bullying. They also suggest that parents, in general, can play an important role in supporting adolescents' mental health.

Title: Neural and Behavioral Predictors of Chronic Social Defeat Stress

Authors: *D. MURRA[1], A. FITZPATRICK[2], K. L. HILDE[2], H. KHALIL[2], H. AKIL[2], S. J. WATSON, Jr.[2];
[1]Univ. of Michigan Neurosci. Grad. Program, Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Chronic Social Defeat Stress (CSDS) has been widely used as an animal model that captures individual variation following a social stressor. In response to repeated psychological and physical stress, mice diverge into separate populations of social reactivity post-stress: resilient (socially interactive) and susceptible (socially avoidant) animals. A rich body of work reveals distinct neurobiological and behavioral consequences of this experience that map onto the resilient and susceptible phenotypes. By contrast, we have less insight into the factors that drive the eventual split in stress response; we cannot predict which group of mice will emerge as either susceptible or resilient to CSDS. To address this challenge, we focused on behaviorally characterizing resilient and susceptible mice prior to, during, and following CSDS. We found that behavioral coping strategies used by the mice during the initial stress encounter distinguish resilient and susceptible animals. Based on these findings, we asked whether these coping styles that were deployed early on by the two groups were reflective of distinct pre-existing brain-wide neural activity patterns. Our hypothesis is that brain-wide activity patterns and behavioral coping mechanisms that emerge during the initial defeat encounter can be used to predict the eventual social reactivity phenotype. Together, our work aims to provide an integrative characterization of the neural and behavioral signatures associated with resiliency and susceptibility in this social stress model.

Title: Activation of hypothalamic POMC neurons is sufficient and necessary to induce depression-related behaviors

Authors: X. FANG, ***Y. CHEN**, J. WANG, Z. ZHANG, Y. BAI, K. DENNEY, M. GUO, L. GAN, N. WEINTRAUB, Y. LEI, X.-Y. LU;
Med. Col. of Georgia At Augusta Univ., Augusta, GA

Abstract: How distinct neuronal populations participate in mediating maladaptive changes induced by stress exposure and contribute to the onset and development of depression remain unclear. Here, we examined the activity of hypothalamic proopiomelanocortin (POMC) neurons in brain slices from control mice and mice exposed to chronic unpredictable stress (CUS). POMC neurons spontaneously generate action potentials at relatively low rates under control conditions. Following exposure to 10 days of CUS, POMC neuron firing became more frequent and regular. This high-frequency firing correlated with reduced GABA-mediated spontaneous inhibitory postsynaptic currents (IPSCs) and increased intrinsic neuronal excitability in POMC neurons. Under non-stressed conditions, while acute chemogenetic activation of POMC neurons alone failed to alter depression-related behaviors, repeated activation of POMC neurons reduced sucrose preference after 3 days and induced the full spectrum of depression-like behavioral deficits after 10 days, mimicking the effects of chronic exposure to unpredictable stress. In mice subjected to subthreshold levels of unpredictable stress, acute activation of POMC neurons decreased sucrose preference and increased despair behavior. Importantly, inhibition of POMC neurons was sufficient to reverse CUS-induced anhedonic and despair behaviors. Collectively, these results indicate a causal relationship between hyperactivity of POMC neurons and depressive-like behaviors and suggest that dampening POMC neuronal activity can be used as a novel strategy to alleviate depression symptoms.

Title: Identification of a novel cell-type specific mood-modulating protein, Neurensin-2

Authors: *G. UMSCHWEIF[1,2], L. MEDRIHAN[2], W. WANG[2], A. GUILLÉN-SAMANDER[3], Y. SAGI[2], P. GREENGARD[2];

Abstract: Major depressive disorder (MDD) is a leading cause of disability. Despite the high prevalence of MDD and its devastating impact on society, the pathophysiology of this condition is poorly understood. One of the hallmarks of MDD is molecular, functional, and morphological impairments in the hippocampus. Recent studies suggest that two subtypes of hippocampal GABAergic interneurons, the cholecystokinin (CCK) and parvalbumin (PV) interneurons, play key roles in both depression and its treatments. Nonetheless, little is known about the underlying molecular mechanisms by which these cells mediate emotional behaviors. By applying Translating Ribosome Affinity Purification (TRAP) from these cells, we discovered a new cell-type specific signaling pathway that regulates emotional behavior. We found that in CCK and PV interneurons, the chromatin modulator SMARCA3 inhibits the expression level of a novel depression-associated gene, Nrsn2. This gene encodes Neurensin-2, a vesicular protein which is highly and selectively expressed in hippocampal CCK and PV interneurons. We found that Neurensin-2 expression in the hippocampus is dynamic and bidirectionally responds to chronic stress and to chronic treatment with antidepressants, suggesting that Neurensin-2 is a cell-type specific mood modulator. Indeed, we show that overexpression of Neurensin-2 in CCK interneurons results in depressive-like behaviors, whereas down-regulation of Neurensin-2 in PV interneurons is essential for the behavioral response to chronic treatment with antidepressants. Moreover, Neurensin-2 knockout mice are resilient to chronic stress, indicating that Neurensin-2 inhibition is sufficient to prevent depression and anxiety. Mechanistically, we show that Neurensin-2 associates with endosomes and postsynaptic proteins and regulates the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors signaling. Together, we introduce a novel cell-type specific protein which directly and bidirectionally affects both cellular function and emotional behavior. These findings implicate Neurensin-2 in the pathophysiology and future treatments of neuropsychiatric disorders such as MDD.

Title: Neurobiological mechanisms that influence emotional reactivity: a developmental study of the hippocampus

Authors: *S. COLEMAN[1], K. L. HILDE[2], P. M. MARAS[2], M. H. HAGENAUER[1], A. V. STEFANOV[1], I. BIRT[1], V. KUMAR[2], E. K. HEBDA-BAUER[1], S. J. WATSON, Jr.[1], H. AKIL[1]; [2]Mol. and Behavioral Neurosci. Inst., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Debilitating psychiatric disorders such as major depression and chronic anxiety have a major personal and societal impact. Both prevention and treatment strategies require a better understanding of the relationship between genetic predisposition and brain function. For instance, while it is known that there is a genetic component to emotional reactivity, the neurobiological mechanisms through which gene expression patterns shape these behavioral traits remain largely unknown. Using a selective breeding model in rodents, this study aims to elucidate potential cellular mechanisms that link genetic predisposition and the emergence of vulnerable or resilient behavioral traits.

Our laboratory has selectively bred rats for over 60 generations in order to select for locomotor responses to novelty, ultimately generating a robust behavioral model of emotional reactivity and temperament. Bred low responder (bLR) animals and bred high responder (bHR) animals represent extreme ends of emotional reactivity. bLRs represent an internalizing phenotype, are behaviorally inhibited, with a high level of anxiety- and depressive-like behaviors. In contrast, bHRs represent an externalizing phenotype, with low behavioral inhibition and high levels of impulsivity.

Our lab has characterized genetic variants as well as hippocampal gene expression changes in the bLR/bHR model and identified candidate genes that differentiate between the lines. A top candidate gene is the Bone Morphogenetic Protein 4 (Bmp4), which has diverse roles in nervous system development. Preliminary results demonstrate that differences in Bmp4 in the bLR/bHR model arise early in life and are maintained throughout the lifetime of the animals. We perform a comprehensive analysis of cell-type composition and gene expression in the bLR/bHR model using a combination of multiplexed fluorescent in situ hybridization, immunohistochemistry, and confocal imaging. We test the hypothesis that Bmp4 is important for establishing cell-type balance within the developing hippocampus, and that these differences, in turn, play a role in shaping adult behavior.

Abstract: Circular RNAs (circRNAs) are formed by back-splicing of pre-mRNA transcripts to generate a circularized product, many of which may have regulatory functions in the brain. Functional deficits in medium spiny neurons (MSNs) in the nucleus accumbens (NAc) may contribute to behavioral abnormalities in depression and other stress-related disorders. Here, we investigated the role of circRNAs in the NAc in regulating stress-induced behavioral deficits. We found that expression of circRIMS2, which is derived from exons 20-22 of the RIMS2 gene, was increased in postmortem NAc from male, but not female, patients who had suffered from major depressive disorder prior to death. Similar increases in cirRIMS2 were detected in the NAc of male mice subjected to social defeat stress (SDS). circRIMS2 overexpression in the NAc, accomplished using an AAVDJ-sEF1a-ZKSCAN1-circRIMS2-sYFP vector, decreased the expression of depression-like deficits in anxiety and reward-related behaviors in male mice subjected to SDS or restraint stress. Single-cell RNA sequencing (scRNAseq) was performed using 10X Chromium on NAc tissue from stressed and unstressed male mice. Stress induced profound alterations in the expression of genes relevant to mitochondrial-mediated bioenergetics including mitochondrial solute carriers, transcriptional plasticity that was reversed by circRIMS2 overexpression. Currently, we are exploring the role of circRIMS2-regulated mitochondrial genes with respect to stress-induced behavioral abnormalities.

Title: Hippocampal differential gene expression converges across animal models of mood disorder: Results from an interactive meta-analysis pipeline encompassing five animal models

Authors: *Y. SANNAH[1], H. KHALIL[1], M. H. HAGENAUER[1], J. MARROCCO[2], C. AYDIN[1], Q. WEI[1], F. MENG[1], C. NASCA[2], E. J. NESTLER[3], M. MEANEY[4], S. J. WATSON[1], H. AKIL[1];

Abstract: The Hope for Depression Research Foundation (HDRF) focuses on the neurobiology of mood disorders and brings together several research groups which have been conducting transcriptomic studies within different animal models used for the study of depression. Each animal model typically represents one dimension of a plethora of changes that might be occurring within the brains of depressed individuals, so integrating the results from across these studies is essential to gain a better understanding of mood disorders. To facilitate comparison, we created an interactive meta-analysis pipeline that allows the user to identify consistent gene expression signatures across custom-defined sets of animal models, conditions, transcriptional platforms, and brain regions. To illustrate utility, we tested this pipeline using thirteen microarray and RNA-seq data sets derived from either the hippocampus or dentate gyrus of five animal models: selectively-bred high responder (HR) and low responder (LR) rats, Flinders sensitive and resistant rats, mice with glucocorticoid receptor overexpression (early life and lifetime), chronic social defeat stress (CSDS) mice, and chronic corticosterone-treated mice (total n=146). To ensure comparability, the raw data from each study were first run through a standardized pipeline for annotation, quality control, and data preprocessing. We calculated the effect size (Hedge's *g*) for each gene from each study from the moderated t-statistic obtained as the result of a differential expression analysis conducted within the limma or limma-voom

pipeline. This effect size was then used within a random effects meta-analysis model. Interestingly, we found 27 candidate genes (FDR < 0.1) which showed similar differential expression in the hippocampus across these animal models of mood disorder despite the fact that a superficial comparison indicated minimal intersection between the top results from each individual study. These differentially expressed genes were highly skewed towards down-regulation (89%) and especially enriched within two particular hippocampal cell types: 63% enriched within astrocytes, 30% within ependymal cells. Gene Set Enrichment Analysis similarly indicated a particular enrichment within cell type related gene sets, including a down regulation within gene sets specific to the choroid plexus, ependyma, astrocytes, interneurons, polydendrocytes, and oligodendrocytes, and upregulation within gene sets specific to CA1 pyramidal neurons. These results illustrate the power of integrating results from numerous distinct models to understand the neurobiology of mood disorder.

Title: Potential role of DCC-positive neurons in the adult prefrontal cortex projecting to the nucleus accumbens shell in susceptibility to social defeat stress

Authors: *A. MAHMUD[1], G. A. HERNANDEZ[2], C. FLORES[2];
[1]Integrated Program in Neurosci. (IPN), McGill Univ., Verdun, QC, Canada; [2]Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: A consistent trait of depression-like behavioural states in humans and mice is elevated levels of the guidance cue receptor gene *DCC* in the prefrontal cortex (PFC). In fact, DCC receptors in the PFC play a causal role in susceptibility and resilience to chronic social defeat stress (CSDS) in adult mice, but the underlying mechanisms remain to be discovered. DCC receptors refine neuronal connectivity and plasticity throughout the lifespan, even in adulthood, by controlling axon arborization, dendritic arborization, and synapse formation. Here we

assessed whether DCC receptors play a role in stress susceptibility by modifying the architecture and connectivity of selective PFC pyramidal neuronal circuits. Using the retrograde tracer cholera toxin subunit B in adult male and female mice, we show that DCC-positive neurons in infralimbic (IL) and prelimbic (PrL) subregions of the PFC prominently innervate the nucleus accumbens core (NAcC) and nucleus accumbens shell (NAcS). We then examined CSDS-induced changes in dendritic spine density in DCC-positive neurons in the PFC projecting to the NAcS, by bilaterally microinfusing the AAVrg-CAG-GFP virus in the NAcS of adult male mice 3 weeks before CSDS exposure. Compared to control and resilient mice, susceptible mice show a reduction in thin and mushroom spine density in apical dendrites, but not in basal dendrites of NAcS-projecting DCC-positive pyramidal neurons. Moreover, compared to control and resilient mice, susceptible mice show reduced mushroom spine density in apical dendrites, but not in basal dendrites of PFC-NAcS DCC-positive projecting neurons. To evaluate the role of DCC receptor in PFC-NAcS pyramidal neurons in CSDS susceptibility, we deleted DCC in these neurons using $DCC^{lox/lox}$ mice and a Cre-dependent retrograde virus. Our preliminary findings show that deletion of DCC in PFC-NAcS circuitry induces resilience to CSDS. Our findings suggest that DCC receptors in adult PFC pyramidal neurons projecting to the NAcS play a causal role in susceptibility to social defeat stress in adulthood by inducing changes in their dendritic spine architecture.

Title: Gene expression changes in serotonin neurons due to Chronic Stress

Authors: A. ZHANG, *M. MANNERS;
Univ. of the Sci., Philadelphia, PA

Abstract: Major Depressive Disorder (MDD) is a serious medical issue in the United States with over 16 million adults suffering from one or more major depressive episodes at any given time. Current antidepressant therapy is inadequate; with delayed efficacy and undesirable side effects, there is a clear unmet medical need for those requiring fast acting and continuous antidepressant therapy. Susceptibility to depression is related to decreased serotonin release, alterations in receptor levels, or impaired signal transduction. Serotonin neuron circuity can be studied by measuring neuronal firing, serotonin synaptic release, and serotonin receptor occupancy at presynaptic terminal regions. Another approach to identifying neurobiological mechanisms affected by chronic stress is to determine gene expression activity and functional networks and

pathways affected by stress. We utilized a mouse expressing enhanced green fluorescent protein (eGFP)-tagged ribosomes specifically in serotonergic neurons, which enabled visualization and isolation of mRNA being actively translated into protein using the translating ribosomal affinity purification (TRAP) method. An unpredictable chronic mild stressors (UCMS) protocol was conducted for 14 days to establish chronic stress, and the behavioral effects of stress were confirmed using the novelty suppressed feeding test and sucrose consumption test, and stress-induced weight loss was also observed. In order to explore gene expression changes in serotonin neurons due to chronic stress, TRAP was conducted on the dorsal raphe nucleus and actively translating mRNA were isolated. We identified expression of serotonin neuron-specific transcripts and differentially expressed genes due to chronic stress using TRAP-qPCR. Next Generation Sequencing will be conducted to expand our preliminary findings and identify differentially expressed transcripts, gene families, and networks affected by chronic stress in serotonin neurons. This work could determine novel underlying mechanisms important in the physiological and behavioral response to stress, and determine gene expression signatures in serotonin neurons.

Title: Role of pre-existing connectomic differences in driving susceptibility and resilience to chronic social defeat stress in mice

Authors: *K. ANDERSON[1], A. LIPSHUTZ[2], A. MANGANARO[1], P. ROGU[1], V. SALTZ[3], J. Y. ZHANG[1], Y. GROSSMAN[4], D. DUMITRIU[1];
[1]Columbia Univ., New York, NY; [2]Barnard, New York, NY; [3]Williams Col., Williamstown, MA; [4]Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Stress is unavoidable, but there is inherit variability in stress responses across individuals. Some are susceptible while others display natural resilience. Stress is often a precipitating factor in the development of many preventable disorders, including depression and mood disorders. Understanding the neurobiological basis of the individual variability in stress can inform novel interventions and pathways to prevention. Many studies are accumulating evidence that suggests stress susceptibility and resiliency are not opposing responses but

represent distinct neural mechanisms. However, it is unclear if this neural circuitry is different prior to stress and if these differences pre-dispose individuals towards susceptibility or resiliency. In this study, we aim to uncover the pre-existing neural circuity that mediates individual differences in divergent stress responses. We utilize a chronic social defeat stress (CSDS) paradigm, a highly validated model of rodent stress that produces divergent responses. We expanded our paradigm to include females. In CSDS, aggressor male urine is applied to both male and female mice and a pair is exposed to an aggressor for 10 minutes followed by co-housing with an aggressor. This process repeats for 10 days total and is followed by a social interaction (SI) test. There is a reliable population spilt (n= 106) with 60% of females (SI res 1.61 ± 0.19, SI sus 0.62 ± 0.082) and 50% of males displaying resilient behavior (SI res 2.06 ± 0.29, SI sus 0.77 ± 0.44). To uncover pre-existing circuity, we previously validated an acute social defeat stress (ASDS) model. In ASDS, mice are exposed to 3 consecutive 5-minute bouts of defeat followed by SI 1-hour later. Here, we utilize both paradigms along with a TRAP2 mouse model that allows for temporal-targeting of activated neurons following an injection with tamoxifen with an indelible marker in combination with immunohistochemistry for a marker of cellular activation. We have validated the optimal trapping timeline through mass spectrometry of tamoxifen uptake into the brain (n=142, 14.42 ± 2.7 & 10.69 ± 1.07 μg/mLs at 120 & 150 mins for males & females) and western blot analysis of the Cre-ER protein in the amygdala following a defeat session (n=58, 86.4 +/-7.2 & 83.4 ± 2.9 μg at 90 mins for males & females). Using this timeline, we TRAP neurons during an acute stressor to capture initial stress-activated ensemble and compare it to cFos-activated neurons in the same individual after CSDS. By comparing these two time points in stress exposure, we provide evidence on how pre-existing connectivity patterns contribute to the consolidation of a chronic stressor in resilient versus susceptible mice.

Title: Effects of reproductive experience on cost-benefit decision making in females

Authors: *M. FARAJI[1], J. L. BIZON[2], B. SETLOW[1];
[1]Psychiatry, [2]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Effects of reproductive experience on cost-benefit decision making in females
Mojdeh Faraji[1,3], Jennifer L. Bizon[2,3], Barry Setlow[1,3]

Departments of [1]Psychiatry, [2]Neuroscience, [3]Center for Addiction Research and EducationUniversity of Florida, Gainesville Florida

After decades of neglect, a growing body of behavioral neuroscience research is including female subjects, with significant findings that underscore the importance of this inclusion. These efforts, however, have largely neglected the variable of reproductive experience, in that almost all studies employ reproductively naïve animals. In particular, the majority of women undergo reproductive/maternal experience at some point in their lives, and pregnancy and childbirth are associated with alterations in risks of several psychiatric disorders. Research in rodents shows that maternal experience affects spatial learning and other aspects of hippocampal function. In contrast, there has been little or no investigation of how reproductive experience affects cost-benefit decision making, despite the relevance of this aspect of cognition for psychiatric disorders. To begin to address these issues, female Long-Evans rats (nulliparous, n=8; parous, n=8) were evaluated in tests of risky and impulsive decision making in standard operant chambers. Rats in the parous group were mated, gave birth, and nursed for 21 days until pup weaning, whereas rats in the nulliparous group were unmated. One week after weaning, rats began behavioral testing. Rats were initially tested in a delay discounting task, in which they chose between a small immediate food reward and a large food reward delivered after a variable delay period ranging from 0 to 60 s. There were no differences between parous and nulliparous rats in their preference for the large, delayed reward, suggesting no effects of reproductive experience on impulsive choice. In contrast, in a risky decision-making task, in which rats chose between a small, “safe” food reward and a large food reward accompanied by variable risks of mild shock punishment, parous rats showed significantly greater choice of the large, risky reward compared to the nulliparous rats. These latter data suggest that reproductive experience enhances risk-taking behavior. To determine whether enhanced risk taking in parous rats is due to greater food motivation, rats were tested on a progressive ratio schedule of reinforcement. There were no differences between groups, however, indicating comparable motivation to obtain the food rewards in the risky decision-making task. Together, these results show selective effects of reproductive experience on cost-benefit decision making.

Title: Temporally-specific inhibition of ventral tegmental area dopamine neurons during decision making under risk of punishment.

Authors: *W. PYON, S. BLAES, C. ORSINI, J. BARRETT, H. HOLIK, S. SINGHAL, C. FRAZIER, B. SETLOW, J. BIZON;
Univ. of Florida, Gainesville, FL

Abstract: Decision making represents an incredibly complex behavior that necessitates numerous different brain regions working in tandem to obtain a desired outcome. As our own understanding of dopamine's role in the brain improves, it is also becoming clear that the ventral tegmental area (VTA) plays a fundamental role in dictating how we make these decisions. To further elucidate the functional role of the dopamine in decision making, male and female tyrosine hydroxylase-cre rats were utilized to selectively drive halorhodopsin expression localized to dopaminergic neurons of the VTA. Rats were then trained on a risky decision-making task (RDT) in which they were tasked with repeatedly selecting between one of two levers: a small reward lever that dispensed one food pellet or a large reward lever that dispensed two food pellets accompanied by variable risks of mild footshock delivery (0%, 25%, 75%). After reaching stable choice performance, rats were implanted with optic fibers targeting the VTA through which 560 nm laser light was delivered to selectively inhibit dopaminergic neurons of the VTA during discrete timepoints during the choice process (during deliberation prior to lever selection, during receipt of the small reward, during receipt of the large reward with or without punishment, or during the intertrial interval). Preliminary findings show that inhibition of VTA dopamine neurons selectively during receipt of the large reward in the absence of punishment causes rats to become more likely to choose the small safe reward on subsequent trials. This shift toward risk-averse behavior is supported by our current understanding of reward prediction error signaling, with inhibition of dopamine neuron activity appearing to mimic a reduction of tonic firing as a result of negative prediction error.

Title: Hormonal regulation of dopaminergic signaling and value-based decision-making

Authors: *C. GOLDEN, A. MAH, C. M. CONSTANTINOPLE;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Value-based decision-making behavior varies across the reproductive cycle in women, but the underlying neural mechanisms of these effects are not well-understood. In reinforcement learning models of decision-making, a subject learns the value of an option from experience and updates that value based on reward prediction errors (RPE), or the difference between what was expected and what actually happened. Dopamine released in the nucleus accumbens core (NAcc) represents RPEs. Estradiol and progesterone activate dopaminergic signaling, suggesting that this modulation may be responsible for the influence of the reproductive cycle on value-based decision-making. We examined value-based decision-making in female rats over their estrous cycle with a novel task wherein they deliberate between waiting for an unspecified amount of time for a reward or moving on to the next trial. The length of time they wait provides an analog readout of subjective value. We manipulated rats' reward expectations over trials by varying the magnitude of rewards they recently received (local reward context). During estrus, rats' subjective value is more sensitive to local reward context. Mass spectrometry identified the downregulation of two proteins (Smpd3 and Sl6a4) involved in dopamine reuptake in the NAcc during estrus. Given this data, we hypothesized that dopamine release would be enhanced during estrus, perhaps leading to larger RPEs, which could account for behavioral differences in estrus. To estimate trial-by-trial RPE, we generated a behavioral model that includes principles of reinforcement learning. Using fiber photometry and a dopamine sensor, we observed dopaminergic encoding of RPE after the reward-predicting cue. This encoding of RPE was stronger during estrus compared to other stages, as suggested by our proteomic results. Altogether, these findings suggest that gonadal hormones promote the downregulation of proteins that mediate dopamine reuptake in the NAcc in estrus, leading to enhanced encoding of RPEs and learning. Moreover, we have identified novel molecular targets of hormonal regulation of dopamine signaling. Finally, we emphasize that this computational, decision theoretic approach provides a principled framework for interpreting behavioral, neural, and molecular profiling data, and represents a powerful approach for studying endocrine systems in the brain.

Title: Gambling cues facilitate ropinirole-induced deficits in decision making by blocking protective adaptions in midbrain dopamine neurons and the prelimbic cortex

Authors: *S. RAMAIAH, L. MORTAZAVI, T. HYNES, C. CHERNOFF, H. BRODIE, B. A. HATHAWAY, B. RUSSELL, S. KAUR, C. WINSTANLEY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The alluring lights and sounds of modern electronic gambling machines may contribute to their addictive potential. Indeed, the addition of casino-like cues to laboratory-based gambling tasks increases risk-taking in both humans and rats. These heavily-cued probabilistic schedules of reinforcement may drive the mesolimbic dopamine system, causing neuroadaptations that promote risk-taking. Supporting the idea that repeated agonism of the dopamine system can promote risk-taking and problem gambling is evidence that the D2/3 receptor agonists ropinirole and pramipexole (used in the treatment of Parkinson's) can induce impulse control and addiction disorders in a significant minority of patients. We, therefore, asked whether chronic administration of ropinirole could amplify cue-induced risk-taking and impulsivity in a translationally valid model of gambling-like behaviour - the rat gambling task. We furthermore asked whether the presence of cues in the task would exacerbate the deleterious effect of ropinirole treatment. To this end, we implanted rats with osmotic minipumps to chronically deliver ropinirole or saline. The instrumented rats were then trained in either the cued or uncued rat gambling tasks. In both versions of the task, chronic ropinirole increased impulsivity, but only in the cued task was risk-taking exacerbated. Following cessation of ropinirole treatment, enhanced risk-taking persisted in the cued task and, surprisingly, emerged in the uncued gambling task. Ex-vivo analyses of neuronal activity patterns (i.e., c-Fos immunohistochemistry) provided evidence as to why, in the absence of cues, rats were spared from ropinirole-induced deficits in decision making. Specifically, the activity of midbrain dopamine neurons was reduced in ropinirole-treated animals trained in the uncued task, likely in compensation to pharmacological dopamine agonism. Ropinirole furthermore provoked an increase in prelimbic activity in the uncued task, which may indicate the compensatory recruitment circuits that titrate dopamine release at the terminal level. In the absence of ropinirole, these adaptions could lead to a hypodopaminergic (i.e., reward-deficient) state, explaining the increased risk-taking following cessation of ropinirole treatment.

Abstract: Selecting optimal actions in decision making according to the current sensory input is essential for animals. One prevailing model underlying this behavioral process is based on the idea that the ultimate aim of choice is to maximize utility or reward. In addition to this, adaptive behavior requires animals to generate the internal model of their environment and to take actions to minimize surprise (*i.e.* improbability or prediction error) about the state they encounter in comparison with the state predicted from the internal model. How these principles are actually adopted by animals and are reflected in their behavior remains unknown. We addressed this question using the closed-loop virtual reality-2photon calcium imaging system, in which the scenery presented to adult zebrafish by the surrounding displays moved backwardly in response to the tail beat of the fish. In the virtual reality, fish was trained for active and passive avoidance. The activity of excitatory neurons expressing G-CaMP7 in the dorsal pallium of the telencephalon during the training was imaged. The adult zebrafish can learn various adaptive behaviors and has the dorsal pallium-basal ganglia circuit implicated in behavioral selection. In the active avoidance, fish had to escape from the region surrounded by blue walls to the region in their front surrounded by red walls to avoid electric shock. In the passive avoidance, fish had to stay in the red wall region where the tasks started. Analysis of the dorsal pallium's neural activity by non-negative matrix factorization revealed neural ensembles assigning rules to the colors of the surrounding walls (e.g. blue color is dangerous, or red color is safe). Furthermore, conversion

of the virtual reality system to the open-loop condition, where the scenery did not respond to the fish tail beat, revealed that one-third of learner fish generated another ensemble encoding the prediction error of the perceived scenery's status compared with the predicted favorable status. Intriguingly, the fish with both ensembles escaped more efficiently than the fish with the former ensemble alone, implicating that the latter ensemble in fact guided zebrafish to take action to minimize this prediction error.Our results suggest that some zebrafish, if not all, can use both of the two principles for achieving safe escape in active avoidance, *i.e.* value maximization and surprise minimization. Further, under limited time constraint of the trials, zebrafish using both principles exhibit optimized escape behavior compared with zebrafish behaving with only the reward-based principle.

Title: A new assay to study the genetic and neuronal process behind decision making in fruit flies

Authors: *C. E. LADD, J. H. SIMPSON;
Molecular, Cellular, and Developmental Biol., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Decision making is a vitally important, but poorly understood part of human and animal life. Humans with Parkinson’s disease, Conduct Disorder, and Alcohol Use Disorder show defects in decision making, so a better understanding of the mechanisms could eventually have clinical impact. To study the underlying neuronal and genetic process of decision making, I have established a new assay using the fruit fly, *Drosophila melanogaster* that presents pairs of competing stimuli to induce flies to choose between grooming, courting, and feeding. The assay does not require training, reward, or punishment. Since all of these behaviors are innate, natural, and advantageous under different circumstances, the assay creates three decisions that lack a “correct” answer. I use varying contextual conditions to determine how the behavior changes with response to increasing and decreasing drive strengths. I found that there is no simple hierarchy of needs between the three behaviors. The flies alternate between behaviors to satisfy competing drives. As competing drives become closer in strength, the incidences of alternations increase until the fly is rapidly and continuously switching between behaviors. I also found that the three behaviors are not mutually exclusive acts (e.g. a hungry and dirty fly will groom while

eating). As the respective drive strengths become closer, an increase in moments of simultaneous behaviors occurs.
Previous fly decision-making assays have identified genes and neurons that affect sensory detection thresholds or contextual states (such as hunger levels or mating drive). I will test the candidates from these assays (FoxP and Leukokinin receptor mutants and mushroom body and central complex neurons) to see if decision-making in general is impaired, or if the process is specific to each decision. The advantages of the fly for genetic screens and neural circuit mapping, employed in this the new assay, will help illuminate the neural basis for decision making.

Title: Dopaminergic modulation of decision-making guided by delayed punishment

Authors: *G. L. MINNES[1], A. J. WIENER[1], A. E. LILEY[1], D. B. GABRIEL[2], N. W. SIMON[2]; [2]Psychology, [1]Univ. of Memphis, Memphis, TN

Abstract: Effective decision-making requires evaluation of the rewards and consequences associated with each available option. Critically, negative outcomes often occur later in time, leading to underestimation, or “discounting”, of these delayed consequences. To investigate sensitivity to immediate vs delayed punishment during cost/benefit decision-making in rats, we developed the Delayed Punishment Decision-making Task (DPDT). In brief, rats choose between two levers, one resulting in a single-pellet reward, and the other resulting in a three-pellet reward accompanied by a mild foot shock punishment. The shock is initially delivered immediately following a decision; as the session progresses, punishment is preceded by a systematically increasing delay (0, 4, 8, 12, 16 s). On average, rats increase choice of the punished option as delay increases, indicative of discounting of delayed punishment. Here, we tested the effects of systemic administration of dopaminergic drugs on sensitivity to delayed punishment in male and female adult rats. We observed that cocaine, a dopamine and norepinephrine reuptake inhibitor, caused a dose-dependent reduction in choice of delayed but not immediate punishment. Interestingly, this effect was more pronounced in females than males. Selective D1 dopamine receptor activation or blockade did not affect decision-making making, whereas D2 dopamine receptor activation reduced punishment discounting comparably to

cocaine. D2 dopamine receptor blockade had no effects on punishment driven decision-making. Collectively, these data demonstrate that dopamine transmission modulates sensitivity to delayed punishment, and this is likely regulated by D2 dopamine receptor activation.

Title: Orbitofrontal Cortex and Basolateral Amygdala Regulate Decision-making Guided by Delayed vs. Immediate Punishment

Authors: *A. E. LILEY[1], L. M. CLARK[2], E. D. EDDINS[3], S. E. CARTWRIGHT[1], D. B. GABRIEL[1], N. W. SIMON[1];
[1]Psychology, Univ. of Memphis, Memphis, TN; [2]Rhodes Col., Memphis, TN; [3]Univ. of Mississippi, Oxford, MS

Abstract: Undervaluation of negative consequences is observed in multiple psychiatric disorders, and often engenders detrimental health, financial, and social outcomes. The majority of the preclinical research on punished reward-seeking utilizes punishment that occurs immediately after a decision; however, real-world punishment often occurs long after a decision has been made. We developed the rat Delayed Punishment Decision-making Task (DPDT), which reveals that rats avoid rewards associated with immediate punishment, but increase choice of the same reward/punishment combination when punishment is delayed. Therefore, as in humans, rats underestimate, or "discount", delayed punishment. Here, we investigated the role of lateral orbitofrontal cortex (lOFC) and basolateral amygdala (BLA) in the discounting of delayed punishment. Male and female rats (n=45) were trained in DPDT with either ascending (0,4,8,12,16s) or descending delays (16,12,8,4,0s), then lOFC or BLA were pharmacologically inactivated prior to task performance. We observed that lOFC inactivation did not affect choice of rewards associated with immediate punishment, but decreased choice of delayed punishment. Interestingly, this effect was observed in the standard DPDT with ascending delays, but did not occur with reversed contingencies. BLA inactivation evoked complex effects on decision-making, driving increased choice of punished rewards with short delays, and reduced choice of punishment with longer delays. These data suggest that lOFC conditionally regulates the

discounting of delayed punishment, and may serve as therapeutic target in disorders characterized by insensitivity to delayed consequences.

Title: Neuronal activity in lateral orbitofrontal cortex predicts risk of punishment during decision-making in rats

Authors: *D. B. K. GABRIEL[1], F. HAVUGIMANA[1], A. E. LILEY[1], I. AGUILAR[1], G. MINNES[1], G. R. JOHNSON[1], M. YEASIN[2], N. W. SIMON[1];

Abstract: Risky decision-making is defined as preference for rewards associated with the risk of negative consequences. The rat risky decision-making task (RDT) captures this phenotype by presenting subjects with choice between either a small food reward or a large reward potentially accompanied by a mild footshock. Lateral orbitofrontal cortex (lOFC) has been identified as a brain region that regulates punishment-based risky decision-making; however, the functional neuronal activity in lOFC that encodes risk level and risky choice remains unknown. Here, we employed single-unit electrophysiology to record extracellular neuronal activity from lOFC of rat during a version of RDT optimized for electrophysiology. In this task, rats were required to hold a 1 sec response, which we define as a "deliberation hold", before levers were extended for reward choice. Following this deliberation period, subjects chose first between small (1 pellet) and large (3 pellet) rewards, then in a second block progress to small rewards vs. large rewards with 50% risk of footshock. We recorded from 148 units in lOFC and observed that subsets of units were either activated or inhibited by specific task events, with this selectivity being altered by risk level and reward magnitude. Notably, during the "pre-decision" period (.5 sec immediately before choice), units were activated prior to large reward choice during safe but not risky trials, suggesting that lOFC signals information about reward safety immediately prior to a decision. Additionally, a subset of units was suppressed during post-decision anticipation of small rewards but was unaffected during anticipation of large rewards regardless of risk level, suggesting that these neurons encode information about impending reward magnitude. Finally,

we applied a parameter-optimized Random Forest classifier to predict the presence of risk of punishment during any given trial using neural features from different events in the decision-making process. We observed that neuronal activity during the deliberation hold displayed the highest classification accuracy of all task events (96.53%), suggesting that lOFC activity encodes risk level prior to a decision. Furthermore, combining lOFC neuronal activity across all relevant task events was more effective at predicting risk than any individual event (98.2% accuracy). In summary, lOFC neurons encode multiple events during risky decision-making in rats, and lOFC activity predicts both presence/absence of risk and reward magnitude. This suggests that manipulating lOFC activity may serve as a promising treatment to increase awareness of risky outcomes during decision-making.

Title: Nutrient-sensitive reinforcement learning in rhesus monkeys

Authors: *F.-Y. HUANG[1], F. GRABENHORST[1,2];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Wellcome Trust-MRC Inst. of Metabolic Sci., Cambridge, United Kingdom

Abstract: Animals make adaptive food choices to acquire essential nutrients for survival. In reinforcement learning (RL), animals choose by assigning values to objects and update these values with experience. This framework has been instrumental in identifying neural mechanisms of learning and decision-making. However, canonical RL models do not address how learning depends on biologically critical constituents of food rewards, such as nutrients, and how internal physiological states modulate adaptive food choices. Here, we addressed these questions in rhesus monkeys (*Macaca mulatta*) choosing nutrient-defined food rewards under varying reward probabilities. We trained two adult male monkeys in a probabilistic reversal learning task involving four nutrient-defined liquids (monkey Ya: 17-19 kg, age: 6 years, N = 4,684 trials; monkey Ym: 12-13 kg, age 6 years, N = 5,321 trials). Specifically, these liquids were prepared with 2 x 2 fat and sugar levels to examine the effects of fat and sugar on learning and decision-making. All liquids were cued by fixed but novel visual stimuli within each testing session and

were matched in flavor (blackcurrant or peach), temperature, and other ingredients (protein, salt, etc). Therefore, differential learning and choice patterns could only be attributed to the specific nutrient content of the liquids, rather than preference for the visual stimuli or other attributes of the liquids. We found that the nutrient composition of rewards strongly influenced monkeys' choices and learning. The animals preferred rewards high in nutrient content and showed individual preferences for fat and sugar. These nutrient preferences affected how the animals adapted to changing reward probabilities: the monkeys learned faster from preferred nutrient rewards and chose them frequently even when they were associated with lower reward probability. Although more recent experiences generally had a stronger influence on monkeys' choices, the impact of reward history depended on the rewards' nutrient composition and individual nutrient preferences. From these data, we propose a nutrient-sensitive RL model that separately updates the value of fat and sugar components based on subjective nutrient preferences and integrates them into scalar reward values to explain the monkeys' choices. Our findings suggest that preference for nutrient constituents contributes to subjective valuation, learning, and choice of food rewards. Incorporating nutrient value functions into RL models enhances their biological validity and helps reveal unrecognized nutrient-specific learning and decision computations.

Title: The connectome of primate lateral prefrontal cortex

Authors: *R. XU, N. P. BICHOT, A. TAKAHASHI, R. DESIMONE;
Dept. of Brain and Cognitive Sciences, McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: Lateral prefrontal cortex (LPFC) plays an important role in executive control, but how it interacts with the rest of the cortex remains unclear. To address this, we densely mapped the cortical connectome of LPFC, using electrical microstimulation combined with functional MRI (EM-fMRI).
Two macaque monkeys were scanned in 3T magnets under propofol anesthesia. In each animal, we stimulated ~100 sites within ~15x20 mm^2 of cortex in caudal-to-mid LPFC, which likely overlaps with areas 9, 46, 8, 45, and 12. At each stimulation site, we collected up to 34 mins of MION signals at 2-mm isotropic resolution. We delivered 500-μA current pulses at 333 Hz for

210 ms per second in 30-sec blocks. The parameters were tuned to optimize contrast-to-noise ratio.
When downsampled to the level of cytoarchitectonic areas, the dense connectome was highly consistent with a state-of-the-art inter-areal connectome mapped by tracing (Markov et al., 2014), even for long-range connections. Furthermore, the EM-fMRI data exhibited statistical traits comparable to tracing, such as 1) following log-normal distribution; 2) decaying exponentially as inter-areal distance increases; 3) showing a wide range of connection weights that are highly characteristic across areas and rather consistent across subjects.
Importantly, utilizing the high density of spatial sampling (extrapolating to ~2500 sites/hemisphere/animal if applied to the entire cortex), we were able to capture significant and systematic differences of connections across adjacent LPFC sites, whereas sparser sampling could have missed such differences, or worse, have been misleading due to aliasing. We found isomorphic mappings between LPFC and five major processing domains comprising most of the cerebral cortex except early sensory and motor areas. As one moves in an orderly fashion across LPFC sites, the bulk of their connections progress systematically on the cortical surface of each domain. Taken together, the LPFC grid of stimulation sites topographically mapped to separate grids of activation sites in the five domains, coarsely resembling how the visual cortex maps the retina. The temporal and parietal maps largely overlapped in LPFC, potentially allowing integration of the ventral and dorsal streams, and the other maps overlapped at least partially. Thus, the LPFC contains overlapping, millimeter-scale maps that mirror the organization of major cortical processing domains, supporting LPFC's role in coordinating activity within and across these domains.

Title: Mapping of stimulus-response associations in the macaque prefrontal cortex: contribution of putative pyramidal cells and interneurons

Authors: *F. CECCARELLI[1,2], A. GENOVESIO[1];
[1]Dept. of Physiol. and Pharmacol., Sapienza Univ., Rome, Italy; [2]PhD program in Behavioral Neuroscience, Sapienza Univ., Rome, Italy

Abstract: Prefrontal cortex (PFC) plays a key role in several cognitive processes related to goal-directed behavior, including working memory and mapping associations between stimuli and responses. Several neurophysiological studies have elucidated the involvement of different areas

within the PFC in these processes. However, relatively little is known at the microcircuitry level, especially how local cell-types contribute to these processes. We investigated the population coding proprieties of dorsolateral and mediolateral neurons of PFC classified as broad-spiking (BS) putative pyramidal cells (390 cells) and narrow-spiking (NS) putative inhibitory interneurons (278 cells) according to the trough-to-peak duration feature of their extracellular waveforms. The recording was performed while two rhesus macaques performed a stimulus-response association task where during each trial, after a fixation period, one of the three instruction stimuli (IS) and three potential targets appeared for a delay period. Then the IS disappeared and served as go-signal to perform a saccade toward one of the three targets. After a period of maintenance of the target fixation, a reward was delivered if the correct target was chosen. We applied a decoding algorithm to quantify the ability of the BS and NS populations to encode the associations during the delay period where monkeys were required to generate the correct response associated with the stimulus and retain it in memory until the subsequent execution phase. We found that NS population encoded associations more strongly in the early phase of the delay (150-400ms) than BS population. Next, we investigated how BS and NS populations represented the associations over time according to a static or dynamic temporal coding scheme during such a memory period. For this purpose, we used a cross-temporal decoding approach in which the decoder was trained and tested using different time periods. A direct comparison of the population coding schemes during delay highlighted how the coding scheme is characterized by a dynamic coding in NS population compared to BS population, where the representation was static. These findings shed light on the cellular mechanisms underlying local processing of associative information, suggesting an essential role of interneurons through a specific coding scheme compared to pyramidal neurons.

Title: Neuronal congruency signals in macaque frontal cortex

Authors: *T. YAO[1], W. VANDUFFEL[2,1];
[1]KU Leuven, Leuven, Belgium; [2]Radiology, Harvard Med. Sch., Charlestown, MA

Abstract: Cognitive control is crucial for flexible and goal-directed behavior, allowing subjects to swiftly adapt to ever-changing environments and circumstances. Conflict tasks (e.g., Stroop, Simon, Flanker, and Wisconsin card sorting tasks) have been instrumental to study cognitive control. The hallmark of such conflict tasks is a behavioral congruency effect, whereby subjects respond faster and more accurate in congruent (e.g. blue printed in blue in the Stroop task) than incongruent trials (e.g. blue printed in red). Despite almost a century of research since Stroop's original conflict study in 1935, however, the exact neuronal mechanisms underlying congruency effects are still poorly understood. To investigate how the congruency signal developed in the frontal cortex, we trained two monkeys to perform a novel rule-based attention-conflict task, which required the monkeys to covertly attend to a target and detect its dimming by pressing a button while ignoring distractor stimuli. The target was determined by a combination of a task rule-cue (color or spatial rule), and a color-cue (pink or red). A trial was considered congruent or incongruent when the two rules indicated the same or a different target location under both rules for a given color-cue.By recording single unit activity in the frontal eye fields (FEF), an area critically involved in spatial attention and target selection, we discovered a neuronal congruency representation which was composed of a concurrent facilitation effect in task-relevant neurons (when the target was in the neurons' RF, the neurons responded higher in the congruent trials than incongruent trials) and an interference effect in task-irrelevant neurons (when the distractor was in the neurons' RF, the neurons responded higher in the incongruent trials than congruent trials). Compared to the incongruent trials, the neuronal facilitation effect increases the signal, while the interference effect decreases noise to detect the target in the congruent trials. By combining the facilitation and interference effect, a better signal to noise ratio to detect the target is achieved in congruent than in incongruent trials in FEF, which causes better behavioral performance in congruent trials. Based on our results, the neuronal facilitation and interference effect can explain behavioral congruency effects of most, if not all, conflict tasks. Meanwhile, our results explain observed imaging and low spatial-resolution electrophysiological (fMRI, EEG, EMG) data obtained using conflict tasks in humans. These results significantly advance our understanding of the neuronal mechanisms underlying conflict processing and cognitive control.

Title: Movements do not dominate neural dynamics in the macaque prefrontal cortex

Authors: *S. TREMBLAY[1], C. TESTARD[1], R. DITULLIO[1], J. INCHAUSPÉ[2], M. PETRIDES[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]McGill Univ., Montreal, QC, Canada

Abstract: Cognitive neurophysiology experiments in laboratory macaques commonly place movement restraints for practical purposes. Hence, most of what we know about the single neuron basis of cognition in the primate brain often does not account for the influence of non-task-related movements (i.e., "uninstructed") - though these movements co-occur with cognitive processing in natural settings. In parallel, evidence from mice show that uninstructed movements, when measured, dominate cortical dynamics during task performance (Musall et al. 2019, Nat. Neuro), which questions the interpretation of many primate cognitive neurophysiology experiments. Here, we addressed this concern by investigating neural activity in monkeys performing a classical cognitive task while free to move their body, head and eyes. We video-tracked instructed (i.e., task-based) and uninstructed movements while recording from Utah arrays implanted in prefrontal area 8A (N=4,414 units) - a region causally involved in the cognitive task monkeys performed. Single-neuron analyses and ensemble-based machine learning demonstrated that cognitive signals can be decoded with single-trial resolution and high accuracy despite free movement in monkeys. Moreover, replicating Musall et al.'s analytical approach, we found that uninstructed movements did not explain most of the neural variability, as opposed to what was found in mice. Instead, cognitive task variables dominated neural dynamics, though movements still explained a significant amount of variance. These findings demonstrate that single-trial neural dynamics in the monkey prefrontal cortex reliably encode cognitive processing even during free movement.

Title: Neuronal synchronization between the primate anterior cingulate cortex and the amygdala underlying vicarious reward

Authors: *P. PUTNAM[1], C.-C. J. CHU[1], N. A. FAGAN[1], O. DAL MONTE[2], S. W. CHANG[1]; [2]Dept. of Psychology, [1]Yale Univ., New Haven, CT

Abstract: Vicarious reinforcement powerfully impacts social learning and decision-making. Research largely supports the role of the anterior cingulate cortex (ACC) in processing vicarious reward, but its network-level coordination with other brain structures is unclear. We investigated neuronal synchrony between the gyrus of ACC and the basolateral amygdala (BLA) while monkeys delivered rewards either to themselves (self) or to a conspecific (other). To examine neural synchrony, we computed spike-field coherence from simultaneous electrophysiological recordings of the ACC and BLA. Upon delivery of the reward, coherence between the spikes in ACC and the local field potential in BLA increased in in the gamma frequency band (30-50 Hz) for rewards delivered to other, but not self. By contrast, coherence between the spikes in ACC and the local field potential in BLA increased in the alpha/beta frequency band (8-20 Hz) for rewards delivered to self, but not others. These enhancements in coherence were time-locked to the onset of reward delivery and crucially relied upon dissociated frequency bands for processing reward to self or other in an agent-specific manner. Moreover, the increase in ACC-BLA coherence for other's reward was specifically found during reward delivery following free-choice trials, in which monkeys actively expressed other-regarding preference and was not present following forced-choice trials with only a single outcome option. Our results therefore support that vicarious reward processing in the ACC-BLA circuits occurs through a frequency-selective communication channel that is distinct from processing self-reward during social decision-making. Together, these findings emphasize the role of network-level coordination between ACC and BLA facilitating vicarious reward processing following prosocial decisions.

Title: A causal role of the primate prefrontal cortex in social gaze monitoring: evidence from closed-loop microstimulation

Authors: *S. FAN[1], O. DAL MONTE[1,5], N. A. FAGAN[1], A. NAIR[1], C. C. J. CHU[1], M. B. ZHOU[1], P. T. PUTNAM[1], S. W. CHANG[1,2,3,4];

Abstract: Social gaze interaction serves an important function in communicating social information. The primate prefrontal cortex has been implicated in multiple social behaviors, including social learning and decision-making, as well as higher-order face processing. Yet, how the prefrontal areas encode social information used for real-life social gaze interaction remains elusive. We recorded single-unit activity from three prefrontal cortical areas during spontaneous social gaze interaction between pairs of macaques - the orbitofrontal cortex (OFC, n=241), rostral anterior cingulate gyrus (ACCg, n=236), and dorsomedial prefrontal cortex (dmPFC, n=187). Notably, many neurons in these areas parametrically tracked the recorded monkey's gaze positions relative to the partner monkey's eyes ('Self-distance'), the partner monkey's gaze positions relative to the recorded monkey's eyes ('Other-distance'), and the distance between the gaze positions of the two monkeys ('Joint-distance'), supporting a single-cell mechanism of social gaze monitoring. To further test if these prefrontal areas causally contribute to social gaze monitoring based on tracking social gaze distance, we applied closed-loop microstimulations in each of these areas (n=15 sites per area). Microstimulations (100 Hz, 75 microA, 200 msec with a probability of 50%) were delivered contingently upon the precise moment of looking at the partner's eyes in the social condition or random dot motion stimuli in the non-social condition. Microstimulations led the monkey to look closer to the partner by significantly decreasing 'Self-distance'. Critically, this facilitation of attention was specific to the social condition and occurred in the absence of any change in saccade kinematics. Moreover, microstimulations in OFC greatly increased the likelihood of fixating on partner's face, indicated by a gain change of the social attention decay curve, as well as both increased frequency and longer duration of fixations on the face. Taken together, all three prefrontal areas, OFC, ACCg and dmPFC, were causally involved in social gaze monitoring based on tracking where one looked relative to another social agent, with OFC exhibiting the strongest effect that specifically increased fixations on partner's face. These results suggested that multiple prefrontal areas within the primate social interaction networks causally contribute to social gaze interaction.

Title: Neurons in the macaque amygdala encode face animacy and self-relevant gaze shift

Authors: *K. ARAI[1,2], M. ISODA[1,2], T. NINOMIYA[1,2];
[1]Dept. of Syst. Neurosci., Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan; [2]Dept. of Physiological Sci., The Grad. Univ. for Advanced Studies (SOKENDAI), Hayama, Kanagawa, Japan

Abstract: With the development of animation and computer graphics technology, people are exposed to various kinds of faces, ranging from realistic faces (high animacy) to cartoon-like faces (low animacy). Human observers are readily capable of extracting socially-relevant information (e.g., gaze direction) from both real and artificial faces. The neural basis of this cognitive capability remains unknown. To address this issue, we performed behavioral and electrophysiological experiments while monkeys were presented with face stimuli with three different degrees of animacy. A high-animacy face stimulus was a frontal face image of a real monkey. A low-animacy face stimulus was created by replacing the eyes, nose, and mouth of the high-animacy face image with simple diagrams. These two images were morphed into a middle-animacy face stimulus. Each face stimulus had one of three eye directions: direct (D), left (L), and right (R). Each trial began when a fixation point (FP) appeared at the center of a display. After the monkey had fixated at the FP for 500 ms, one of the face stimuli was presented at the display center. The monkey was then required to hold fixation at the FP for another 1000 ms. At 500 ms from the stimulus onset, the eye direction of the face shifted in either of three ways: *toward* (L to D or R to D), *averted* (D to L or D to R), or *non-related* (L to R or R to L). Successful central fixation was followed by a reward after a 500-ms delay. Single-unit activity was recorded in the amygdala, a brain region known for processing facial information. Of 1335 neurons recorded, 502 were classified as task-related. Among these, activities of 113 neurons (22%) were modulated by the face animacy. Neurons preferring the high and low animacy were predominant and equally common (n = 44/113 for both populations), while neurons preferring the middle-animacy face were in the minority (n = 25/113). Most of the neurons modulated by gaze direction (n = 39/49) or gaze shift (n = 52/58) were insensitive to the face animacy. Furthermore, the gaze shift-related neurons were modulated most strongly in the *toward* (n = 26/58) or *averted* conditions (n = 21/58). The present results indicate that there are two distinct populations in the amygdala: neurons encoding face animacy and neurons encoding self-relevant gaze shift of observed faces. The amygdala may provide a neural mechanism with which observers are capable of processing important social signals from real and artificial faces.

Title: Extending Fano Factor to naturalistic paradigms: neural variability is suppressed during spontaneous gaze interactions

Authors: *M. ZHOU[1], S. FAN[1], O. DAL MONTE[1,5], N. FAGAN[1], A. NAIR[1], C. C. CHU[1], P. PUTNAM[1], S. W. CHANG[1,2,3,4];
[1]Dept. of Psychology, [2]Dept. of Neuroscience, Sch. of Med., [3]Kavli Inst. of Neuroscience, Sch. of Med., [4]Wu Tsai Inst., Yale Univ., New Haven, CT; [5]Dept. of Psychology, Univ. of Turin, Torino, Italy

Abstract: Fano factor (FF) is a measure extensively used to characterize variability, calculated as a neuron's spike-count variance over the spike-count mean. Most previous studies assumed that FF remains mostly stable across trials (Gur et al., 1997; Carandini, 2004), but later work has suggested that stimulus onset drives a decline in the variability of neural activity in several brain regions across multiple processing domains (Churchland et al., 2010). Here, we extend this finding and show that the decline in FF is not limited to structured stimuli or task events, but also applies to naturalistic behavioral paradigms such as social gaze interaction. In this study, we recorded single-unit activity from four brain regions implicated in social behaviors, including the basolateral amygdala (BLA, n=537), orbitofrontal cortex (OFC, n=241), rostral anterior cingulate gyrus (ACCg, n=236), and dorsomedial prefrontal cortex (dmPFC, n=187) while pairs of macaques engaged in spontaneous, face-to-face, social gaze interaction, without any task constraints or reward contingencies. For each neuron, we characterized its FF trace by computing the variance of spike counts across trials and observed different types of modulation. To quantify neurons with decreasing or increasing FF modulation, we fitted a linear regression on each neuron's FF trace from 200 msec before to 350 msec after the onset of gaze events associated with looking at the conspecific's eyes, face, or non-social objects. There were greater proportions of BLA and OFC neurons that exhibited significantly decreasing (rather than increasing) firing-rate variability when looking at a partner monkey's eyes or face. In contrast, there was no difference in such proportion in ACCg or dmPFC. Crucially, this decrease in neural variability in BLA and OFC was specific to social gaze events, and not observed when looking at a non-social object. Furthermore, these findings remained robust across various time windows used to examine the decline in neural variability. These results suggest that BLA and OFC firing-rate variances can be stabilized by looking at a social agent during spontaneous social gaze exchanges. More broadly, our findings indicate that the phenomenon of neural variability

reduction in the brain is not limited to processing structured experimental stimuli or task but is also observed during naturalistic behaviors.

Title: Anterior cingulate cortex encodes functionally distinct error signals

Authors: *A. SAJAD[1], S. P. ERRINGTON[1], J. D. SCHALL[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Ctr. for Vision Research, Vision Sci. to Application, Dept. of Biol., York Univ., Toronto, TN, Canada

Abstract: Anterior Cingulate Cortex (ACC) is central to the adaptive control of behavior, monitoring outcomes, and comparing them against predictions. Discrepancies between outcomes and predictions can result in different forms of error signals: An internally generated one upon executing an incorrect response (Error), a prediction error signal based on an unexpected feedback cue (FPE), and a reward prediction error (RPE). These types of error computations are demonstrated in the ACC but the degree to which their neural substrates overlap remains unclear. To address this, we sampled neural activity using linear electrode arrays, from the dorsal (area 6/32) and ventral (area 24c) banks of the ACC of two macaques performing a saccade stop-signal task. Subjects were required to generate a saccade to a peripheral target, but to inhibit this planned saccade when a stop-signal appeared. The stop-signal timing was adjusted to ensure ~50% successful inhibition on stop trials. Following the response, an auditory tone indicated whether reward will be provided. Reward amount was asymmetric for the two directions with the association flipped on a block-by-block basis. Errors occurred when monkeys generated saccade despite the appearance of stop-signal. FPE occurred when a correct saccade was followed by the feedback tone indicating no upcoming reward. RPE occurred immediately after block switch when the monkey received more (positive RPE) or less (negative RPE) reward than expected.

Analysis of a preliminary sample of 538 units recorded from 992 linear electrode contacts across 18 sites, revealed units signaling Error, FPE, and RPE in ACC. These signals were commonly found in distinct neurons and although some multiplexing occurred, no systematic patterns emerged. Furthermore, some Error neurons also exhibited modulation following predictable negative feedback tone on Error trials but not following unpredictable tone on FPE trials, suggesting a role in error validation. These results suggest that different modes of error processing involve distinct but partially overlapping functional units within ACC. These findings can guide models of ACC function and contribute to interpretations of non-invasive electrophysiological indices, namely the Error- and Feedback-Related Negativity.

Title: Neural mass model based study of frontal-temporal theta oscillations in human subjects during the performance of a cognitive control task

Authors: A. ROSS[1], K. FARNES[1], A. C. PAULK[2], A. S. WIDGE[3], S. S. CASH[4], J. E. TORRES-REVERON[1], ***I. BASU**[1];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Massachusetts Gen. Hosp., Boston, MA; [3]Psychiatry, Univ. of Minnesota, Minneapolis, MN; [4]Dept Neurol, Mass Genl Hosp, Boston, MA

Abstract: Neuropsychiatric disorders are the number one cause of disability and health-related economic burden in the United States. This is partly because established therapies primarily focus on diagnostic labels and not necessarily brain circuits underlying functional deficits. A more robust approach would be to use objective psychological constructs that act as “ingredients” of a given patient’s dysfunction. Cognitive control, the ability to rapidly shift one's attention and behavioral strategy in response to environmental changes is often compromised across mood and anxiety disorders. One of the well validated behavior paradigms for tapping into the cognitive control circuits is a cognitive interference task, where subjects must suppress a natural response to follow a less intuitive rule, slower response on these tasks indicate difficulty exerting control to overcome response conflict. Conflict evokes robust electrophysiologic signatures, such as theta (4-8 Hz) oscillations in the prefrontal cortex (PFC). Although the cingulate and PFC are well established as being involved during tasks requiring executive control, the underlying neural mechanisms of conflict evoked theta oscillations in the PFC are

not clear. The objective of this work is to use a neural mass model (NMM) to find feasible cortical networks generating theta oscillations during conflict processing in human subjects. We used intracranial EEG (iEEG) recorded from dorsolateral PFC (dlPFC) and temporal lobe (TL) of human subjects with intractable epilepsy undergoing invasive monitoring, while they performed a multi-source interference task (MSIT). MSIT requires subjects to identify which of three numbers (0-3) is different than its neighbors. In high conflict trials, the unique number is out of position and is flanked by distractors while in low conflict trials, it corresponds to the position and is flanked by zeros. We used a dynamic causal modeling (DCM) framework to simulate dlPFC-TL theta using a Jansen-Rit NMM. We found significant evidence for a TL input into the dlPFC during the initial 500 ms of conflict processing compared to a bidirectional connection between the dlPFC and TL. We conclude that a neural mass modeling framework can be used to elucidate candidate mechanisms of neural oscillations underlying conflict resolution in human subjects. This can be used to find feasible target mechanisms for designing therapy in patients with compromised cognitive control. This framework can also be expanded to serve as an in-silico test bed for designing and testing neuromodulatory interventions such as electrical stimulation for improving cognitive control in mood/anxiety disorders.

Title: The geometry of domain-general performance monitoring in the human medial frontal cortex

Authors: Z. FU, 91125[1,4], D. BEAM[4], J. M. CHUNG[5], C. M. REED[5], A. N. MAMELAK[4], R. ADOLPHS[2], U. RUTISHAUSER[4,3];

Abstract: Humans can flexibly control their behaviors to achieve various goals. This process can be conceptualized as a feedback control loop: the course and outcomes of goal-directed actions are monitored for deviations from intended goals, and behavioral and physiological adaptations are initiated to compensate for such deviations. An important open question is how such behavioral optimization can generalize across many different tasks while also support specialized functions of single tasks. We study the neural representation of performance monitoring by recording single neuron activity in the medial frontal cortex (MFC) of epilepsy patients. Subjects performed the Stroop task and the Multi-source Interference Task (MSIT). The Stroop task involves Stroop conflict, while the MSIT involves Simon and Flanker conflict. The data set contains over 1000 MFC neurons from 34 patients. We found that subjects' behavior is well described by a Bayesian conflict learning model, in which the conflict probability is estimated iteratively on a trial-by-trial basis. We found neurons encoding conflict retrospectively and neurons encoding predicted demand for control, both of which are signals that are predicted by our Bayesian model. Neurons encoding the predicted demand for control, which in our model is the prior distribution for the conflict probability, appeared to be biophysically distinct as they demonstrate long-range temporal correlation in the baseline spike counts and have thinner spikes compared to other groups of neurons. Neurons encoding error, conflict and predicted demand for control in one or both tasks coexisted in the same population. Collectively, these neurons gave rise to a representational geometry that simultaneously allowed generalization between different tasks while maintaining maximal separation of within-task conditions, such as separating the four different types of conflict conditions within MSIT. Neural representations of conflict were additive: when two conflicts occur on the same trial, its neural representation approximately equals the sum of the representations of the constituent conflicts. These findings reveal how the MFC representation of evaluative signals are both abstract and specific, suggesting a mechanism for computing and maintaining estimated demand for control across trials and tasks.

Title: Midfrontal theta increase in conflict task reflects deactivation in midline area 9

Authors: *E. BELDZIK, A. DOMAGALIK, T. MAREK;
Jagiellonian Univ., Krakow, Poland

Abstract: Both conflict and error processing in the human brain have been linked to the midfrontal theta (4-8 Hz) increase as indicated by EEG studies and greater hemodynamic activity in the anterior cingulate cortex (ACC) as indicated by fMRI studies. Conveniently, the source of midfrontal cognitive theta was estimated in or nearby ACC. However, studies using concurrent EEG and fMRI recordings in resting-state found only a negative relationship of theta power and BOLD signal. This negative correlation was observed in brain regions typically showing task-related deactivations. In this study, we used a simultaneous EEG-fMRI technique to investigate a trial-by-trial coupling between theta power and hemodynamic activity during the performance of two conflict tasks. Independent component analysis (ICA) was applied to select individual midfrontal EEG components, whereas group ICA was applied to fMRI data to obtain a functional parcellation of the frontal cortex. Theta power was coupled with the peak of hemodynamic responses using a linear mixed-effect model. Our goal was to obtain a source of conflict- and error-related theta activity. The fMRI results revealed several brain regions showing greater activity for correct incongruent trials than congruent ones and far greater activity for erroneous trials, including pre-supplementary motor area, anterior insular cortex, and ACC. Despite the presence of these task-engaged regions, conflict theta showed only a negative correlation to BOLD signal in the midline area 9, a region exhibiting conflict-sensitive deactivation. Conversely, error-related theta showed a positive relationship to activity in the ACC. Our results provide evidence that pre-response midfrontal theta reflects cortical inhibition of area 9, and this process strongly affects the timing of the reactions and supports successful conflict resolution. In contrast, post-response theta reflects ACC activity, which signals the commitment of an error. Our findings highlight that conflict- and error-related theta oscillations represent fundamentally different processes.

Title: Human cingulate cortex during planning and production of natural speech

Authors: *K. IBAYASHI[1,2], K. NOURSKI[2], A. RAMÍREZ-CÁRDENAS[2], M. STEINSCHNEIDER[3], J. D. W. GREENLEE[2];
[1]Neurosurg., Jichi Med. Univ., Shimotsuke, Japan; [2]Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [3]Neurol., Albert Einstein Col. of Med., Bronx, NY

Abstract: The role of human cingulate cortex during speech has been under investigated. Previous reports based on nonhuman primates' vocalization could give us insight about this region's role during human speech production. Some lesion studies and electrical stimulation studies in human suggest the involvement of anterior cingulate cortex in speech production in a causal manner, but the high-resolution dynamics and its relation to other canonical speech areas such as ventrolateral prefrontal cortex (vlPFC) or sensorimotor cortex (SMC) remains unclear. We here report the functional role of cingulate cortex during naturalistic question-and-answer-based dialogue task. The neural signal was recorded from depth electrode contacts (cingulate cortex) and subdural grid/strip electrode (lateral cortices) that were implanted in 11 subjects with intractable epilepsy. All the patients underwent intracranial electrode placement for the purpose of epileptic foci detection. All the subjects had above average cognitive function based on the pre-operative neuropsychological screening. The task was run in a shielded room in the epilepsy monitoring unit located at the University of Iowa Hospital. The neural activity was recorded by the Neuralynx Pegasus system, and the vocal response during the dialogue task was recorded from TASCAM recorder. Each utterance was timestamped using PRATT software. We analyzed high frequency (70-150Hz) activity power from cingulate cortex both during speech production phase (-200ms re subject's answer onset to answer offset) and speech planning phase (0ms re interviewer's question offset to -200ms re subject's answer onset). Only utterances that were correctly answered were used for production analysis, and the questions ending with critical information was used for planning analysis. The temporal dynamics of the high frequency response in cingulate cortex was compared with other canonical speech related cortices. We then compared the responses between two phases of the dialogue (planning/production) by using a production-planning index to see whether the response seen was phase specific in each cingulate subregion. Our results showed that anterior cingulate cortex (ACC) has a higher preference for production whereas posterior cingulate cortex (PCC) showed higher preference for planning. The peak patency of response in PCC preceded that of vLPFC and SMC. The findings show clear evidence of the involvement of cingulate cortex during speech planning and production.

Title: Layer-specific deactivation of prefrontal cortex as a causal test of predictive coding

Authors: *A. J. MAJOR[1], A. M. BASTOS[2], E. K. MILLER[1];
[1]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [2]Vanderbilt Univ., Nashville, TN

Abstract: In conditions such as autism spectrum disorder and schizophrenia, abnormal neurodevelopment leads to altered laminar cortical architecture. The laminar organization of cortex has attracted growing interest and is critical to microcircuit function and interregional communication. For example, in a recent model of Predictive Coding, superficial cortical layers propagate sensory feedforward signals via gamma rhythms (> 35 Hz) to higher-order cortex and deep layers send feedback signals via alpha/beta rhythms (10-30 Hz) to sensory regions (Bastos et al., *PNAS*, 2020). Alpha/beta and gamma rhythms are anti-correlated. Feedback alpha/beta signals from prefrontal cortex (PFC) are thought to suppress feedforward sensory information in sensory cortex. This project is a causal test of this layer-specific model of Predictive Coding, known as *Predictive Routing*.
Using custom laminar probes, we have developed an experimental paradigm to selectivity suppress either superficial or deep PFC cortical layers using $GABA_A$ receptor agonist muscimol while simultaneously recording from all layers of multiple rhesus cortical areas. Muscimol deactivation of deep-layer PFC is hypothesized to suppress feedback alpha/beta signals and thus remove the suppressive effect of PFC onto sensory regions such as visual area V4. In support of the model, preliminary data show deactivation of deep-layer PFC resulted in heightened V4 gamma and spiking activity. This work will provide a causal test to a prevalent model of laminar cortical processing and yield specific insights into conditions related to sensory filtering, such as autism spectrum disorder and schizophrenia.

Title: Neural dynamics of abstract rule encoding in macaque prefrontal areas: Recording simultaneously from multiple chronically implanted multi-electrode arrays

Authors: *J. M. GALEAZZI, M. AINSWORTH, C. PEDREIRA, M. J. BUCKLEY;
Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Previous studies identified different prefrontal areas contributing in different ways to rule-guided behavior in the context of a Wisconsin Card Sorting Test (WCST) analog for macaque monkey; dorsolateral prefrontal cortex (dlPFC) is necessary to maintain a specific abstract rule in working memory, ventrolateral prefrontal cortex (vlPFC) supports rule maintenance in general, and orbitofrontal frontal cortex (OFC) is needed to rapidly update representations of rule value based on reward. (Buckley et al., 2009; Mansouri et al., 2009). Furthermore, recent studies on role of the frontopolar cortex (FPC) suggest it contributes to representing the relative value of unchosen alternatives, including but not limited to rules (Mansouri et al., 2017). As neuronal activity from these different areas was not previously recorded simultaneously we do not yet understand the underlying computations and functional interactions operating within and between these regions. We present here the first study that simultaneously applies multi-area multi-electrode recording techniques to four different frontal regions implicated in rule-guided behaviour. Multi-electrode micro-arrays ('Utah arrays') were chronically implanted in dlPFC, vlPFC, OFC and FPC of two rhesus macaques, allowing us to simultaneously record single and multiunit activity and local field potential (LFP) from all four regions together while the animals performed a WCST analog. Here we present preliminary results from these recordings showing the neural activities underlying task performance. We obtained a typical daily yield of 100-200 separable units/clusters from all arrays combined, with single and multiunit activity responsive to different task-relevant components. For example, we found a variety of pre-reward and post-reward unit responses in dlPFC, vlPFC, OFC, and FPC with different onsets and durations. We present here the extent to which different aspects of the task can be accurately decoded from the neural activity recorded on each of the arrays employing a variety of commonly used machine learning classification algorithms. Lastly, we also show the differences of time evolving neural trajectories of population activity in a low dimensional state space.

Title: Reward-based decision making in freely-moving Marmosets

Authors: *E. SCHOENBECK[1], K. J. MASTRO[2,1], L. STANWICKS[1], B. A. STEVENS[2,1]; [1]The Broad Inst., Cambridge, MA; [2]Harvard Med. Sch. Neurobio., Boston Children's Hosp., Boston, MA

Abstract: The ability to flexibly adapt one's behavior in an ever-changing environment is necessary for survival. To maximize positive and/or reduce negative outcomes, we must balance the need to explore for new information and exploit known action-outcome relationships. From mice to humans to computers, reinforcement learning has become a fundamental area of study and provides a dynamic landscape to probe the decision making process. Moreover, to capitalize on the emergence of genetic and viral tools, the Common Marmoset has received renewed interest across neuroscience for its potential to link findings between primate and non-primates. In this study, we established a touchscreen apparatus that can be permanently affixed to the marmoset home-cage and allows for the assessment of reward-based decision making. We have trained a cohort of marmosets on simple (Match to Sample) to more complex (Multi-armed bandit) cognitive tasks. By incorporating the touchscreen apparatus into the home-cage, we found that marmosets will perform upwards to 500-800 trials per training session (3-4 hours). We demonstrate that marmosets can successfully learn a rule, increase their rate of learning with experience, and generalize their knowledge of the task to novel sets of stimuli. In the next series of experiments, marmosets will be presented with a probabilistic version of the multi-armed bandit task where the probability of being rewarded will shift within a session. Together, this data will provide important insights into the marmoset behavioral strategies employed in reward-based decision making that will set the stage to compare across conditions and species.

Title: Distinct mnemonic functions of intermediate hippocampus in male rats

Authors: *K. E. WHITLEY, S. B. BRIGGS, M. B. PARENT;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: In rodents, the hippocampus is functionally divided along its longitudinal axis into dorsal and ventral poles. Generally, dorsal hippocampal (dHC) neurons are necessary for episodic and spatial memory, whereas ventral hippocampal (vHC) neurons are essential for affective and motivational processes and emotional memory. dHC and vHC have different anatomical connections, cellular and circuit properties, and patterns of gene expression that likely contribute to the different functions that they serve. Compared to dHC and vHC, relatively little is known regarding the function of the intermediate region of the hippocampus (iHC). Gene expression and anatomical connections in iHC do not overlap completely with those of dHC and vHC, suggesting that iHC may have functions that differ from dHC and vHC. In support, other researchers have shown that permanent lesions of iHC, but not dHC or vHC, impair rapid place learning in the water maze. The goal of the current project was to determine whether reversibly inactivating iHC would impair memory that is known to be dependent on dHC (spontaneous alternation; SA), vHC (temporal ordering of odors; TO-O), or both (inhibitory avoidance [IA], spatial and temporal episodic memory task; EMT). Male Sprague-Dawley rats were implanted with bilateral cannulae aimed at iHC. After at least 1 week of recovery, one cohort (n = 8-10/group) was given infusions of muscimol (0.05 ug in 0.5 ul) 15 min prior to SA testing, EMT testing, and IA training (at least 48 hrs between tests; infusions counterbalanced across behavioral tests). A second cohort (n = 8-10/group) was given these infusions prior to TO-O training and rapid place water maze training. Our preliminary data indicate that, like chronic lesions, reversible inactivation of iHC impairs rapid place learning. More importantly, the same manipulation does not appear to affect memory in dHC and vHC-dependent memory tasks. These findings support the possibility that iHC plays a distinct role in memory that is different from dHC and vHC.

Title: Local integration of long-range inputs from the lateral entorhinal cortex in hippocampal area CA3 drives dendritic non-linearities and somatic output

Authors: *V. ROBERT, R. DE LA TORRE, K. O'NEIL, J. BASU;
New York Univ. Langone Med. Ctr., New York, NY

Abstract: Functional interactions between the entorhinal cortex and the hippocampus are crucial for the formation and recall of episodic memories. Multimodal sensory inputs, specifically spatial from the medial entorhinal cortex (MEC) and contextual from the lateral entorhinal cortex (LEC), are projected to and processed by several parallel circuits within the hippocampus. While cortico-hippocampal interactions at the level of dentate gyrus (DG) and area CA1 are well studied, the functional connectivity and circuit dynamics between LEC and area CA3 remain unknown. By integrating direct long-range LEC inputs with local feedforward DG and feedback CA3 inputs, area CA3 is poised to gate hippocampal information flow and mnemonic function. Non-linear dendritic integration of LEC inputs in CA3 pyramidal cells could underlie the flexibility of spatial representations displayed by CA3 ensembles. Here we use dual color optogenetic circuit mapping in acute slices and behavioral manipulations in vivo to dissect the functional role of excitatory and inhibitory inputs from LEC to area CA3 and test the circuit level interactions that shape CA3 output. We found that CA3 interneurons located in the apical dendritic layers received monosynaptic connections from both LEC glutamatergic and GABAergic projections. LEC excitatory inputs drove spiking in these interneurons, whereas LEC inhibitory inputs shunted interneuron excitability. In CA3 pyramidal cells, LEC excitatory inputs evoked monosynaptic excitation, as well as disynaptic inhibition which acted to prevent excessive excitation and CA3 output. Next, we combined optical stimulation of LEC excitatory and inhibitory projections with electrical stimulation of DG mossy fibers and CA3 recurrent collaterals to assess the dendritic and somatic integration of these inputs and the resulting drive of CA3 output. Although single input stimulation did not elicit CA3 pyramidal cell spiking, LEC excitatory projections could drive CA3 output when paired with local inputs, and additional stimulation of LEC inhibitory projections further boosted CA3 output. Dendritic recordings from CA3 pyramidal cells suggest that this disinhibitory effect may facilitate the generation of dendritic spikes, which ultimately impact somatic excitability. These results demonstrate that the LEC input can drive CA3 output when coordinated with local input activity, highlighting the role of dendritic integration of LEC signals in CA3 dendrites. To assess the role of this circuit in hippocampal learning and memory functions, we are currently manipulating LEC excitatory and inhibitory inputs in vivo during hippocampal-dependent behavioral tasks.

Title: Automatic detection, segmentation, and de-mixing of dendritic regions of interest in 2-photon calcium data

Authors: *J. J. MOORE[1,2], D. CHKLOVSKII[2], J. BASU[1];
[1]NYU Sch. of Med., New York, NY; [2]Ctr. for Computat. Neurosci., Flatiron Inst., New York, NY

Abstract: Neurons maintain large dendritic arbors which support non-linear input integration that shapes neural dynamics and can greatly boost the computational power of individual neurons. Population 2-photon calcium imaging typically focuses on the activity of neural somata, but several brain regions, such as hippocampal area CA3, superficial neocortex, and cerebellum, afford imaging of multiple dendrites at once. To analyze these data, dendritic regions of interest (ROIs) are currently manually identified, a laborious and error-prone process that takes hours of skilled work. Thus, there is a widespread need for tools to automatically detect and segment dendritic ROIs and link them to their parent soma.

Dendritic segmentation poses a number of unique challenges not faced by somatic segmentation. Variable morphology of dendrites within and across different brain regions severely restricts possible geometric assumptions. While a soma may be treated as one compartment, extended dendrites may have propagating spikes or otherwise asynchronous activity across an entire branch. Additionally, densely labeled preparations feature overlapping dendrites, necessitating robust de-mixing techniques to separate independent signals.

Sparse constrained non-negative matrix factorization (sCNMF) has been used to identify and de-mix dendrites in dense fields of view, but the results require random initialization and can be difficult to map to individual neurons. We modified the sCNMF initialization procedure to cluster regions of contiguous simultaneously active pixels. We obtained ROIs that are deterministic and traceable to the parent soma, with efficient time and memory requirements.

To demonstrate generality, we have applied our algorithm to several fields of view in mouse hippocampus in CA3, CA2, and CA1, using GCaMP6s, 6f, and 7b, with a wide range of expression densities, dendritic morphologies, and signal-to-noise ratios. The resulting ROIs are comparable to those manually drawn by a human expert and are robust to moderate levels of noise and overlap. Our approach has few tunable free parameters, which are easily interpretable and generally transferable between imaging preparations.

We present our dendritic detection algorithm as an extension of the CaImAn imaging suite, enabling easy and robust processing of dendritic data in an accessible, open-source manner. We are optimistic that this will encourage more studies of dendritic function from a diverse array of investigators, accelerating the field's understanding of the importance and utility of dendritic activity.

Title: Lateral entorhinal cortex: a cortical input that drives strong dendritic excitation, inhibition, and disinhibition onto CA1 pyramidal neurons

Authors: *O. BILASH, J. BASU;
New York Univ. Neurosci. & Physiol., New York, NY

Abstract: The functional interaction between the entorhinal cortex (EC) and hippocampus (HC) is critical for episodic memory formation. Direct projections from the medial and lateral entorhinal cortex (MEC and LEC) provide the hippocampus with spatial and non-spatial (contextual) sensory information, respectively. Previous studies have largely focused on MEC-HC interactions, and only recently have behavioral studies started to demonstrate that LEC is involved in olfactory learning, novelty- and object-related learning, and contextual learning. Still, the circuit-level functional interactions between LEC and the hippocampus remains underexplored. Our study examines how distal dendritic input from LEC modulates hippocampal information flow through non-linear dendritic computations and excitation-inhibition balance. Using slice electrophysiology and optogenetics, we demonstrated that glutamatergic LEC projections drive excitation onto CA1 PNs, while simultaneously recruiting strong feed-forward inhibition. LEC inputs elicited subthreshold post-synaptic potentials in CA1 PNs, but were not strong enough to elicit action potentials. Interestingly, using dendritic recordings, we found that

optogenetic stimulation of LEC axons in CA1 can drive dendritic spikes in CA1 PN distal dendrites. To better understand the mechanism underlying the LEC-driven dendritic spikes, we probed the GABAergic microcircuit elements recruited by LEC inputs. Using targeted recordings from GABAergic neuron-specific transgenic mice, we found that LEC inputs recruit specific inhibitory neurons (INs) in area CA1, including VIP+ INs and CCK+ INs. Given the disinhibitory nature of VIP+ INs described in the hippocampus and neocortex literature, we proposed that LEC inputs gate dendritic spikes in CA1 PNs by engaging this local disinhibitory microcircuit. Optogenetic silencing of VIP+ INs in CA1 revealed a subtle but consistent effect on LEC-driven dendritic activity. Currently, we are developing a computational model to elucidate the details of the disinhibitory gating mechanism. Given that *in vitro* and *in vivo* studies have previously demonstrated the role of dendritic spikes in plasticity, our findings suggest that LEC plays an important role in promoting supralinear dendritic computations, thus enabling it to influence long-term representation in the hippocampus. In summary, our study provides a comprehensive overview of how a distal dendritic input from the cortex can differentially activate various local circuit elements, including pyramidal neuron somata, dendrites, and various GABAergic interneurons.

Title: Emergence of sensory and memory representations in the hippocampus and prefrontal cortex of mice

Authors: *B. SOUZA[1], J. KLEE[1], L. MAZZUCATO[2], F. BATTAGLIA[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands;
[2]Inst. of Neurosci., Univ. of Oregon, Oregon, OR

Abstract: The hippocampus and the medial prefrontal cortex (mPFC) are both known to modulate their activity in response to different stimuli and rewards in a variety of paradigms. Because those two areas are intimately connected to episodic and working memory, it has been hypothesized that they encode relevant features of the environment by developing neural representations that can be accessed in the absence of the stimulus. Despite some evidence endorsing this hypothesis, the nature of those representations and whether representations in the two areas interact remain unknown. In trace conditioning, animals learn to associate a

conditioned stimulus (CS) and a reward separated by a delay (trace period). Although the neural activity in both areas can be linked to memory representation formation, it is unknown how their coordinated neural activity may maintain the stimulus-action map evoked during the CS until the behavior is expressed. In this work, we address this issue using auditory trace conditioning in head-fixed mice to record simultaneous activity from hippocampal area CA1 and mPFC. First, we found that both CA1 and mPFC encoded time within the trial via the emergence of neuronal sequences at the beginning of stimulus presentation. Interestingly, this time-structured pattern appeared in PFC since early learning sessions, while it emerged in CA1 only after learning. Moreover, the temporal patterns associated with the stimulus onset in PFC were also evoked at reward onset. This echo of the stimulus representation during reward disappeared after learning, suggesting a disentangle of the representation of stimulus and reward. We also found that the representation of the stimulus identity was strong and stable in mPFC, emerging with the stimulus onset, while it was weaker in CA1, mildly increasing during the trace period. To investigate whether the weaker representation in CA1 could be due to a more dynamical activation of its representations, we used Hidden-Markov models to estimate the network states. Interestingly, we could still find states in CA1 encoding trial-type identity. Finally, we found that awake sharp-wave ripples deferentially shaped the reactivation of CA1 and PFC assemblies - increasing reactivations within and across sessions, respectively. Also, CA1 assemblies that encoded stimulus identity during trace were more reactivated during ripples. Together, those results clarify the dynamics of stimulus encoding in the mPFC-hippocampal circuit, suggesting the hippocampus is important to sustain the CS representation during the trace period (i.e., in the absence of the stimulus), while mPFC might be needed for creating the stimulus-reward association.

Abstract: Memories are thought to be encoded in populations of neurons called memory trace or engram cells. However, little is known about the dynamics of these cells because of the difficulty in observing them repeatedly over long periods of time in vivo. To overcome this limitation, we present a genetically-encoded RNA indicator (GERI) for intravital chronic imaging of endogenous Arc mRNA—a popular marker for memory trace cells. We used our GERI to identify Arc-positive neurons in real time without the delay associated with reporter protein expression in conventional approaches. We found that Arc-positive neuronal populations rapidly turned over within two days in CA1, whereas ~4% of neurons in the retrosplenial cortex (RSC) consistently expressed Arc following contextual fear conditioning and repeated memory retrievals. Dual imaging of GERI and calcium indicator in CA1 of mice navigating a virtual reality environment revealed that only the overlapping population of neurons expressing Arc during encoding and retrieval exhibited relatively high calcium activity in a context-specific manner. This in vivo RNA imaging approach opens the possibility to unravel the dynamics of the neuronal population underlying various learning and memory processes.

Title: Genesis of multi-modal representations in the entorhinal cortex during working memory

Authors: *C. DORIAN[1], J. TAXIDIS[2], S. CHEUNG[2], K. SAFARYAN[3], P. GOLSHANI[4]; [1]Univ. of California, Los Angeles Interdepartmental Ph.D. Program In Neurosci., Los Angeles, CA; [3]Departments of Physics and Astronomy, Neurology, Neurobio., [2]UCLA, Los Angeles, CA; [4]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: The medial and lateral entorhinal cortices (MEC and LEC) play an important role in coding spatial features of the environment, and their projections to hippocampus are critical for driving hippocampal representations. These structures are also important for maintenance of working memory representations when working memory load increases. Yet, how the activity patterns of these entorhinal projections to hippocampus change during the learning and stable performance of non-spatial working memory tasks is still not understood. Do these projections carry distinct sensory and temporal information? To answer these questions, we have optimized methods for performing calcium imaging of LEC temporoammonic axons expressing GCaMP7s

and terminating in the stratum lacunosum moleculare layer of the dorsal hippocampal CA1 region during the performance of a non-match to sample olfactory working memory task. We find that the large majority of axons showing significant firing fields were active during the presentation of a specific odor. Rare axons had odor-specific firing during the delay period. We will compare these response properties to those from MEC to determine whether the two structures play distinct roles in coding for sensory and temporal information and how their activity patterns change with learning. We will also assay the effects of LEC and MEC inhibition on learning and stable performance. These experiments will yield insights on the distinct and complementary roles of MEC and LEC in learning and maintenance of working memory related sensory and temporal information.

Title: "Looking past the foggy ruins of time": Hippocampal and Non-Hippocampal contributions to Long-Term Memory

Authors: *K. ROBERTS[1], D. MCCALLUM[1], N. M. FOURNIER[2], R. J. SUTHERLAND[4], H. LEHMANN[3];
[2]Dept. of Psychology, [3]Psychology, [1]Trent Univ., Peterborough, ON, Canada; [4]Univ. Lethbridge, Lethbridge Alberta, AB, Canada

Abstract: Scoville and Milner (1957) were the first to clearly state that episodic memories can transition from a hippocampal-dependent to a hippocampal-independent state, a process now termed long-term systems consolidation. Their key observation supporting this process was the temporally graded retrograde amnesia in patient H.M., meaning his loss of memories for events that occurred in the 2-4 years prior to his hippocampal resection and not those that preceded that period. However, measurements of H.M.'s retrograde amnesia changed over the following years with his memory loss progressively encompassing longer periods. By the early 2000s, a little prior to his death, H.M.'s retrograde amnesia presented with a flat gradient with perhaps only one spared episodic memory. A few hypotheses have been put forth to account for this accelerated memory decay in H.M., including that the non-hippocampal systems alone are insufficient to maintain consolidated long-term memories. The current study examined this

possibility in rats by assessing decay of a context fear memory that had become independent of the hippocampus over distributed learning. In Experiment 1, we replicate the common finding that hippocampal lesions cause retrograde amnesia for a context fear memory acquired within a single conditioning session. In Experiment 2, we show that the same conditioning experience distributed over five days mitigates the amnesic effects of the lesions and creates a hippocampal-independent memory. Retention tests in these rats, however, continued every five weeks, and by the fourth and fifth test, the lesion rats were showing memory impairments. In Experiment 3, we again examined decay of the hippocampal-independent memory but reduced the number of tests to limit the influence of extinction. During the first retention test, the lesion rats again showed intact memory, but they were impaired when tested a second time 20 weeks later. These findings could be explained by dual stores (hippocampus and non-hippocampus) normally synergistically contributing to the recall or by continued interactions between systems. Experiment 4 examined this by damaging the hippocampus 18 weeks after the distributed learning - matching a period sufficient to cause decay in Experiment 2. No memory deficits were observed following the lesions, suggesting the context fear established in the non-hippocampal system did not show any evidence of decay and ruling out a dual-store account. Combined, our findings point to an explanation for the changes in retrograde amnesia reported in H.M. across studies and provides new evidence of persistent interaction between the hippocampus and other memory systems.

Title: Reconsolidation of procedural learning does not operate at a rapid micro-timescale level

Authors: *J. HERSZAGE[1], M. BÖNSTRUP[2], L. G. COHEN[3], N. CENSOR[1];
[1]Sch. of Psychological Sciences, Sagol Sch. of Neurosci., Tel-Aviv Univ., Tel Aviv, Israel; [2]Dept. of Neurol., Univ. of Leipzig, Leipzig, Germany; [3]Human Cortical Physiol. and Neurorehabilitation Section, NINDS, NIH, Bethesda, MD

Abstract: Memory consolidation typically refers to stabilization of the encoded memory or offline gains in skill performance, a process which commonly requires hours or days from completion of training. However, recent evidence has shown that consolidation occurs also in

early stages of skill learning, at a micro-timescale (Bönstrup et al., 2019). Thus, while consolidated memories usually show offline learning gains between sessions, offline learning gains in micro-consolidated memories were evident between trials in early stages of a single session. In light of abundant evidence showing that consolidated memories are susceptible to modifications following their reactivation through reconsolidation (Nader and Hardt, 2009), here we asked whether micro-consolidated memories are also susceptible to modifications through rapid 'micro-reconsolidation', thus even at initial stages of learning. In a set of experiments, we collected crowdsourced motor sequence learning (Karni et al., 1995) data from 459 participants recruited from the Amazon Mechanical Turk platform (MTurk), to test whether post-reactivation (1) interference and (2) enhancement occur through rapid micro-reconsolidation. Since memories were shown to be susceptible to interference following reactivation (Walker et al., 2003; de Beukelaar et al., 2014), *Experiment 1* tested whether micro-consolidated memories are more susceptible to interference within a micro-reconsolidation time window. Participants underwent rapid micro-consolidation (Bönstrup et al., 2019) of the motor sequence task. Then, an interfering sequence was presented interleaved with brief reactivations of the original sequence. Retest was compared to a control group without reactivations. Since reactivations were recently shown to induce learning of motor skills (Herszage et al., 2021), *Experiment 2* tested if micro-consolidated memories can benefit from micro-reconsolidation to produce enhanced learning gains. Following micro-consolidation, the memory was reactivated repeatedly to induce learning. Retest was compared to a control group without reactivations. The results of both experiments indicate that micro-consolidated memories are not susceptible to interference nor to enhancement within a rapid micro-reconsolidation time window, relative to controls. This set of evidence suggests that memory reconsolidation might be dependent on consolidation processing occurring at the macro-scale, requiring hours or days to occur.

Title: Restoring persistent accessibility to memories after sleep deprivation-induced amnesia

Authors: *Y. G. BOLSIUS[1], P. R. A. HECKMAN[1,2], F. RAVEN[1,3], E. L. MEIJER[1], M. J. H. KAS[1], S. RAMIREZ[4], P. MEERLO[1], R. HAVEKES[1];
[1]Univ. of Groningen, Groningen, Netherlands; [2]Univ. of Maastricht, Maastricht, Netherlands; [3]Univ. of Michigan, Ann Arbor, MI; [4]Boston Univ., Boston, MA

Abstract: Sleep deprivation is a common problem in our modern 24/7 society. Loss of sleep negatively impacts brain function and in particular cognitive processes that require the hippocampus. In fact, a brief period of sleep deprivation immediately after a hippocampal learning trial leads to memory deficits. It is unclear, however, whether sleep deprivation leads to an absolute loss of information or, alternatively, affects the retrievability of this information stored under suboptimal sleep deprivation conditions. In the current study, we addressed this question using memory engram labeling techniques in combination with optogenetics. Male c-fos tTA mice were injected with a TRE-ChR2-mCherry virus in the dentate gyrus, allowing us to specifically tag and reactivate hippocampal memory engrams. To assess the impact of sleep deprivation on spatial memory processes, we used the object-location memory task with 6 hours of sleep deprivation immediately after the training trial. In line with previous work, we found that sleep deprivation hampered the detection of spatial novelty (*i.e.* the relocated object). However, optogenetic activation of the memory engram preceding the test session resulted in a successful detection of the spatial novelty. This observation suggests that sleep deprivation does not lead to the loss of information but, rather impacts the retrievability of memories formed under sleep deprivation conditions. As a next step, we investigated whether these deficits in memory retrievability could be reversed by treatment with the clinically-approved phosphodiesterase 4 (PDE4) inhibitor roflumilast, which increases the cAMP levels. Systemic treatment with roflumilast preceding the test session rescued the sleep deprivation-induced memory retrievability impairment. Lastly, we combined optogenetic engram stimulation with PDE4 inhibitor treatment to test whether we could make object-location memories stored under sleep deprivation conditions accessible for natural retrieval again. When engram activation and roflumilast treatment were combined three days following training and subsequent sleep deprivation, it resulted in a more persistent memory trace that allowed for natural retrieval several days later. Our studies demonstrate that sleep deprivation does not necessarily cause memory loss, but instead leads to the suboptimal storage of information that is difficult to retrieve. We also provide proof of principle that these suboptimally stored memories can be made accessible again far beyond the learning episode and that the clinically-approved PDE4 inhibitor roflumilast may be used to successfully retrieve information thought to be lost.

Title: Innate anxiety influences learning strategies in Barnes maze.

Authors: *L. DÍAZ[1], A. UGARTE[1], C. CORTES[2], J. EGUIBAR[3];
[1]Inst. de Fisiologia, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico; [2]B. Univ. Autonoma de Puebla, Puebla, Mexico; [3]Benemerita Univ. Autonoma De Puebla, Puebla, Pue., Mexico

Abstract: We selected two sublines from Sprague-Dawley (SD) rats one with a high-spontaneous yawning (HY) with a mean of 20 yawns/h, and the other with a low-yawning (LY) frequency with just 2 yawns/h. LY rats are more stress-sensitive than HY when tested in the open-field arena because they ambulated less and had more fecal boli. Additionally, in the Barnes maze LY showed an impairment in their long-term memory with respect to HY and SD male rats. It is well stablished that the intensity of stressor can enhance or impair memory consolidation and influence the strategy used by subjects to solve spatial tasks. The aim of this study was to determine if LY innate anxiety and HY resilience influences learning strategies. We use SD, LY and HY male rats (8 rats/group), they were maintained under standard animal room conditions. All experiments were done between 1000 to 1300 in the Barnes maze, training consisted in six trials per day during two consecutive days, on day one with extra-maze cues subjects (Ss) learned a fixed position of the escape box (spatial strategy), on day two a black and white striped cue was attached to goal box, their position varied in each trial and extra-maze cues were removed (stimulus-response strategy). Ss learned both strategies in random order. Short-term memory (STM) was evaluated on day three, two goal boxes were present one of them with the striped cue attached, extra maze cues were present, three consecutive trials were given to the Ss and the box preference was used as criteria to evaluate the strategy. Long-term memory (LTM) was evaluated seven days later following the same procedures as in STM. The escape latency and number of errors were measured too. We obtained that in stimulus-response training LY males take more time to find the escape box with respect to HY and SD ($P<0.05$). In STM HY and SD rats used a stimulus-response strategy with respect to LY, which preferred spatial strategy ($P<0.001$). In LTM LY used more frequent stimulus-response strategy with respect to the spatial one ($P<0.01$). We conclude that anxiety promotes spatial strategy use in LY and performance of learning strategies in Barnes maze can change along time.

Title: Examining reward-enhancement of memory consolidation from earning points competitively

Authors: *E. GRANDOIT, P. J. REBER;
Northwestern Univ., Evanston, IL

Abstract: Associating reward with objects after study has been previously shown to improve human memory consolidation. Here we aimed to extend this finding to recognition memory for object locations after a reward task based on competitively earning points on a time-estimation challenge unrelated to object locations. Participants (n=45) learned a series of object-location associations for stimuli placed around a 2D ring (5 lists of 8 item-location pairs, 80 total stimuli presented twice each). After study, participants earned points-based rewards through a 3-second time estimation task. For half the object-location items, the reward was high value (750-2000 points) and for the other half, reward was low value (50 points). A competitive leaderboard, avatars, and storytelling were also introduced to increase the salience of reward. We hypothesized that the high reward value would enhance consolidation of memory for those object-location items on a delayed memory test. Memory for the object-location and item-recognition (with confidence judgments) of studied items were assessed both at the end of the learning and reward session and after a 24-hour delay. For the object-location tests, immediate memory for the high and low reward conditions was similar (high reward, M=68.4%, SE = 3.0%; low, M= 69.6%, SE = 2.6%), as were scores on the immediate memory item-recognition tests (high confidence hits-false alarms: high, M=35.6%, SE=4.9%; low, M=37.1%, SE=4.4%). For the delayed tests, object-location memory was slightly higher for the more rewarded condition (high, 62.2%, SE=3.0%; low, 59.1%, SE=3.2%), and item-recognition memory was also slightly higher for the more rewarded condition (high confidence hits-false alarms: high, M=21.9%, SE=3.8%; low, M=18.1%, SE=3.3%). However, the advantage for the high reward condition was not statistically reliable for either test. The effect of memory consolidation enhancement by the experience of high reward after study was observed to be of a very modest size here compared to prior reports. One possibility is that a points-based reward task may be less salient than a more robust incentive (e.g., monetary) and reduce the effect on memory consolidation. Another possible explanation for the reduced memory-enhancing effect observed here could be in the methodological details such as the inter-item spacing of the reward trials following memory study. Understanding the key methodological criteria that influence how and when the experience of reward enhances memory consolidation will eventually allow for this idea to be integrated into effective learning and educational interventions.

Title: Interactions among different types of saliences explain the change in habitual gaze behavior after long-term retention time

Authors: *Y. RA, S. HWANG, S. PAENG, H. F. KIM;
Sch. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Remembering values for decision-making is critical for survival. However, memory is often forgotten, affecting animals' behaviors. Although primates including humans and monkeys are known to show habitual gaze toward high-valued objects, it remains unclear how value memory changes over periods of time, and how this memory change alters habitual behavior. To address these questions, we trained human subjects to learn object values for 5 days, and their value memory was examined with habitual gaze task more than a month after the last learning. We found that subjects showed habitual gaze bias toward learned good objects 1 day after learning, as previously described (Kang et al., 2021). Interestingly, this gaze preference changed into the preference for both good and bad objects 30 days of retention time after the last learning. A computational model with reward value-driven salience is difficult to address this habitual gaze preference 30 days after learning. We therefore hypothesized that the brain processes both positive and negative values-driven salience to guide the preference for both good and bad objects after 30 days of retention (Madan et al., 2012). Indeed, we found that the selective change of habitual gaze was best explained by a three-layer model, which includes perceptual salience (PS), reward value-driven salience (RS), and both positive and negative value-driven salience (BS). We additionally found that the contribution of BS increases while that of RS decreases after long-term retention period. To further investigate a possible advantage of the habitual gaze driven by BS, we designed a simulation of the Bayesian learning under forgetting the value memory. Our simulation results suggest that BS-driven gazes facilitate re-learning the forgotten values of objects compared to the other gaze strategies (i.e. RS-driven gazes). Our data provide an insight into how the interaction among different components of saliences contribute to habitual gaze behaviors across time and its possible advantages for re-learning. Title: Peripheral lipopolysaccharide impairs the acquisition and consolidation processes of lithium chloride-induced anticipatory nausea in adult male rats.

Authors: *I. BISHNOI, M. KAVALIERS, K.-P. OSSENKOPP;
Western Univ., London, ON, Canada

Abstract: Introduction. Lipopolysaccharide (LPS), a cell wall component of Gram-negative bacteria, impairs learning and memory in a variety of behavioural tasks including, but not limited to, fear conditioning in rats. However, these studies use tasks that cannot readily discriminate between LPS-induced locomotor deficits, a sickness behaviour associated with LPS, and its effects on learning and memory. In order to more reliably study LPS' effects on learning and memory, the current study used the LiCl-induced anticipatory nausea paradigm (ANP). In the LiCl-induced ANP, the unconditioned stimulus (LiCl) becomes associated with a context, leading to reflexive disgust behaviours (e.g., gaping) surfacing when exposed to the context alone (conditioned stimulus). As such, this task is not influenced by LPS-induced locomotor deficits. In the current study, peripheral LPS effects on the resulting memory acquisition, consolidation processes and extinction were studied in the LiCl-induced ANP. **Methods.** *Acquisition.* 32 adult male Long Evans rats were divided into 4 groups (NaCl-NaCl, LPS-NaCl, LPS-LiCl, NaCl-LiCl). On conditioning days 1, 4, 7 and 10, rats were intraperitoneally (ip) injected with LPS (200 μg/kg) or NaCl 90 mins before LiCl (ip, 127 mg/kg) or NaCl and immediately placed into a distinct context for a 30 min trial. *Consolidation.* 32 adult male Long Evans rats were divided into 4 groups (NaCl-NaCl, NaCl-LPS, LiCl-LPS, LiCl-NaCl). On conditioning days 1, 4, 7 and 10, rats were ip injected with LiCl (127 mg/kg) or NaCl and immediately placed into a distinct context for a 30 min trial. After this, rats were immediately ip injected with LPS (200 μg/kg) or NaCl. *Extinction.* Both acquisition and consolidation conditioning days were followed with four no injections test days (13, 16, 18 & 22). **Results.** Compared to rats that were not pretreated with LPS before LiCl treatment, LPS given 90 mins before the LiCl-induced ANP impaired the acquisition of anticipatory nausea (*ps*<.05). Additionally, compared to rats that were not given LPS after the LiCl-induced ANP, LPS administered immediately after the LiCl-induced ANP impaired the consolidation processes of anticipatory nausea (*ps*<.05). After day 13, a rapid extinction of disgust behaviour was found in LiCl treated rats in both experiments. **Implications.** Immune system activation with the immunogen LPS significantly impairs both the acquisition and consolidation of LiCl-induced anticipatory nausea. Additionally, the effects of LiCl-induced anticipatory nausea extinguish

rapidly during the no injection extinction period. These findings confirm the impairing effects of LPS on learning and memory per se.

Title: Caloric Restriction and Fasting Diets have Negligible, or Potentially Damaging, Effects on Cognition in Diversity Outbred Mice

Authors: *A. OUELLETTE[1,2], N. HADAD[1], A. DEIGHAN[1], L. ROBINSON[1], A. FREUND[3], G. CHURCHILL[1], C. KACZOROWSKI[1,3];
[1]The Jackson Lab., Bar Harbor, ME; [2]The Univ. of Maine, Orono, ME; [3]Calico Life Sciences, LLC, South San Francisco, CA

Abstract: Aging remains the greatest risk factor for developing Alzheimer's disease (AD). Given the projected increase in lifespan across the globe, the risk of developing AD is expected to increase, along with significant economic and social burden. As such, the demand for interventions that increase cognitive longevity in parallel with lifespan is high. Several studies have reported that caloric-restriction (CR) or fasting increase lifespan and improve cognition in humans and models of aging, but others have reported no beneficial effect of CR on cognition. These discrepancies may be explained by uncontrolled environmental factors inherent in large human studies, and the lack of genetic diversity in previous animal studies where effects of CR or fasting on cognitive longevity studies in one inbred strain of mice may not generalize to other mouse strains, let alone to humans.
In this study, we compare the effects of Ad Lib, 1 day fast, 2 day fast, 20% CR and 40% CR on Y-maze working memory and contextual fear memory (CFM) in a genetically diverse population of mice - the Diversity Outbred (DO). We observed no benefit of CR or fasting on working memory or CFM at 24 months, despite expected increase in %live mice at 24 months. Actually, the 40% CR group exhibited impaired long-term CFM compared to groups fasted for 1 and 2 days. These results emphasize the importance of identifying therapeutics to enhance cognitive longevity, as CR enhancement of lifespan may not generalize to cognitive abilities.
We also performed QTL mapping of CFM outcomes with diet as an interactive covariate; when

comparing diets that enhance lifespan in the DO population but do not confer cognitive deficits (i.e. 20% CR, 1-day and 2-day fasting) we identified a locus on chromosome 10 that overlaps with the gene *Slc16a7*. Allele association mapping reveals a strong influence of founder allele on CFM variance, with B6 alleles associating with worsened outcomes and WSB with enhanced outcomes. Future work will involve validating the role of *Slc16a7* as an effective mediator of both life- and health span.

Title: Dha prevents diet-induced memory impairments and inflammatory gene expression in aged rats and cultured microglial cells

Authors: *M. BUTLER[1], N. P. DEEMS[1], S. M. MUSCAT[1], N. MASSA[1], C. M. BUTT[2], M. A. BELURY[1], R. M. BARRIENTOS[1];
[1]Ohio State Univ., Columbus, OH; [2]Inotiv, Inc, Boulder, CO

Abstract: It is known that diets high in refined carbohydrates can lead to impairments in brain aging and cognitive performance, but the underlying mechanisms of these impairments are not well understood. Our lab has previously demonstrated that aging is associated with a decrease in the omega-3 polyunsaturated fatty acid docosahexaenoic acid (DHA) in the rat brain. DHA is involved in many beneficial functions in the brain including neuronal signaling, altering membrane structure and function, lipid mediator production, and regulating immune cells to resolve inflammation. Thus, this age-dependent decrease in DHA may contribute to diet-induced memory impairments and inflammation observed previously. Here, we studied the impact of a refined-ingredients diet, with and without DHA, on learning and memory and inflammatory gene expression in aged rats. In addition, we examined the impact of DHA on microglia-mediated inflammation *in vitro*. Our data indicate that consuming a diet high in refined carbohydrates for one month led to memory impairments and increased inflammatory gene expression in the hippocampus of aged, but not young rats, relative to control rats fed the standard chow diet. In

contrast, the same processed diet supplemented with DHA produced no changes in memory or inflammatory gene expression in either young or aged rats, suggesting that DHA may mitigate the impact of diet-induced memory deficits via neuroimmune mechanisms in aged rats. It is important to note that in addition to reduced complex carbohydrates and fiber, processed foods are also often high in saturated fatty acids, (SFAs) such as palmitic acid (PA). *In vitro*, BV2 microglial cells treated with PA exhibited increased inflammatory gene expression relative to vehicle-treated cells. Furthermore, DHA pretreatment prevented these SFA-induced responses. Together, these data suggest that DHA can prevent diet-induced behavioral and cellular changes elicited by processed ingredients and SFAs, respectively.

Title: Repetitive transcranial magnetic stimulation improvement of memory consolidation is time of day dependent

Authors: A. HEATH[1], J. ZEITZER[1], *M. MCNERNEY[2];
[1]Stanford Univ. Sch. of Med., Palo Alto, CA; [2]VA, Palo Alto, CA

Abstract: Brain stimulation is known to have specific effects on memory and the protein pathways involved in memory. We have previously shown the ability for 10Hz repetitive transcranial magnetic stimulation (rTMS) to improve memory consolidation in mice when tested on their object recognition recall after 72 hours. This experiment also showed changes to the phosphorylation of CREB and CAMKII proteins at the synapse. These proteins are involved in sleep memory consolidation and undergo circadian cycles of their phosphorylation in the brain. As abnormal sleep and circadian rhythm can have disruptive effects on learning and memory, there is a potential that rTMS could have altered effects on memory at different times in the circadian cycle. Therefore, we hypothesized that rTMS given either during the light or dark cycle of a mouse's circadian rhythm will have differential effects on its ability to improve memory. We first implanted male B6129SF2/J mice (n=43, under a 12-hour light/12-hour dark cycle starting at 0630) with a cranial attachment to secure the rTMS coil so that the mice could be given consistent stimulation to the frontal area whilst freely moving. Mice were either experimented on at 0900 (Light-Sham n=11, Light-rTMS n=11) or at 2100 (Dark-Sham n=10, Dark-rTMS n=11).

Mice first underwent familiarization phase of the object recognition test and then given treatment +3, +24, +48 hours following the test. Treatment consisted of 600 pulses of intermittent theta burst (iTBS) rTMS stimulation or sham treatment. At +72 hours mice were tested for their exploration of the novel vs familiar object. During the light cycle, the mice which received the iTBS stimulation, not the Sham, explored the novel object more than the familiar object. Interestingly, in the dark cycle the iTBS and Sham stimulation demonstrated good object recognition memory, both exploring the novel object significantly more than the familiar object. These results show that rTMS improved memory consolidation only when it was disrupted during the light sleep phase. Additional results examining the glutamatergic receptors, synaptic pathways and circadian rhythm changes that have occurred will be discussed. These results will help us determine the circadian specific effects of rTMS that can help improve memory when it is disrupted in the sleep cycle.

Title: Impact of Reproductive Stage on Working Memory Circuitry

Authors: *E. MURATA[1], L. PRITSCHET[1], E. JACOBS[1,2];
[1]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA;
[2]Neurosci. Res. Inst., Univ. of California Santa Barbara, Santa Barbara, CA

Abstract: Sex steroid hormones are neuromodulators of learning and memory (Taxier & Frick, 2020). During the menopausal transition, 17β-estradiol and progesterone production declines by ~90%, while gonadotropin [Follicle Stimulating Hormone (FSH), Luteinizing Hormone (LH)] levels rise considerably. However, cognitive neuroscience studies have largely overlooked the relationship between the brain and endocrine system despite the fact that the brain is an endocrine organ. The UCSB Healthy Midlife Aging Study, a multimodal neuroimaging study, works to fill this unexplored area by characterizing the neural and cognitive changes that unfold in midlife, as a function of endocrine aging. In this analysis, we examined the impact of menopausal status on working memory (WM) performance and task-evoked fMRI activity. Midlife adults (current *n*=88, age range: 45-55 years, mean age: 51.5 years, 65% women) from

the Santa Barbara community underwent in-person neuropsychological evaluations, an MRI scan, and serological hormone assessments. Reproductive stage (pre, peri-, post-menopause) was determined via STRAW-10 guidelines. Participants completed an n-back WM paradigm (cf. Jacobs et al., 2011) during fMRI scanning to assess sustained activity in WM circuity as a function of load (0, 2, 3-back blocks) and transient changes in response to specific trial types with an increasing demand for cognitive control (non-targets, targets, lures). Behaviorally, across all women, lower 17β-estradiol was associated with longer response times when WM demands were taxed (e.g., 2-back condition [$t(43)=-2.76$, $p<0.01$, $r=-0.39$] and lure trials [$t(43)=-3.40$, $p<0.01$, $r=-0.46$]; but not during the 0-back control condition [$t(42)=-0.83$, $p=0.41$, $r=-0.13$]). Similarly, increased FSH, an indicator of advanced reproductive stage, was associated with longer WM-related response times (e.g., 2-back [$t(43)=2.55$, $p<0.05$, $r=0.36$]; lure trials [$t(43)=2.03$, $p<0.05$, $r=0.30$]). In an exploratory analysis at $p<0.001_{unc}$ (k=10*)*, postmenopausal women exhibited greater task-evoked activity in right middle frontal gyrus (MFG; cluster coordinates: 24, 14, 34) relative to premenopausal women as well as perimenopausal women (22, 12, 34). FSH levels were positively associated with activity in a near-identical cluster in MFG (24,12, 38). Together, these findings suggest that advancing reproductive stage is associated with increased WM-related prefrontal cortex activity, perhaps as a compensatory mechanism that sustains task accuracy or as an indicator of neural inefficiency. These findings begin to address the critical knowledge gap in women's brain health.

Title: Hippocampus-synthesized estrogen and androgen rapidly modulate dendritic spines and LTP in non-genomic manner

Authors: *S. KAWATO, M. SOMA, M. OGIUE-IKEDA;
Univ. of Tokyo, Tokyo, Japan

Abstract: We demonstrated (1) hippocampal synthesis of estrogen and androgen, and (2) non-genomic synaptic modulation by these sex-steroids. [Synthesis] We showed expression as well as neuronal/synaptic localization of essential enzymes in the adult male rat hippocampus. Mass-spectrometric analysis demonstrated that hippocampal levels of estradiol (E2), testosterone (T),

dihydrotestosterone (DHT) were around 8 nM for all, higher than in plasma. Castration significantly decreased T and DHT in the hippocampus. Castration did not decrease male hippocampal E2, indicating that E2 is synthesized from hippocampal T. Female hippocampal levels of E2 (0.5-4 nM), and T (1 nM) were less than male, but much higher than in plasma. [Synaptic Modulation] E2-induced rapid non-genomic modulation (1 h) was demonstrated by analysis of spinogenesis and LTP of adult male rat hippocampal 'acute' slices (steroid-depleted slices). Spine analysis was performed for pyramidal neurons in hippocampal slices. The density of spines and their head diameters were obtained by mathematical software Spiso-3D which identifies spines by calculating geometrical parameters. E2 at 1 nM rapidly increased the density of small-head spines, in CA1. T and DHT increased the density of small-head and large-head spines. Signaling pathways are: synaptic ERalpha or AR→LIMK, MAPK, PKA, PKC, Src →cofilin or cortactin → actin polymerization→ new spines. LTP analysis showed that 1 nM E2 induced full-LTP (E2-LTP) upon sub-threshold stimulation, although without E2 the sub-threshold stimulation did not induce full-LTP. Kinase inhibitors against MAPK, PKA, PKC blocked E2-LTP. Rapid E2 synthesis can also be measured with LTP in hippocampal slices. Title: Androgen modulation of behavioural flexibility in male rats

Authors: *V. M. LO, C. R. KELSEY, S. B. FLORESCO, K. K. SOMA;
Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Behavioural flexibility, the ability to adapt behaviour in response to environmental changes, is regulated by the mesocorticolimbic system. Strategy set shifting is one form of behavioural flexibility, and in preclinical rodent assays, subjects initially learn to use one rule to receive a reward (e.g. select the lever denoted by a visual cue, or a "cue rule"), but then must switch to a new discrimination strategy (e.g. select the lever in one position, irrespective of the

position of the visual cue, or a “response rule”). Androgens, such as testosterone (T), are produced locally within the mesocorticolimbic system, and T treatment impairs set shifting. Our previous studies show that decreasing androgens with the androgen synthesis inhibitor abiraterone acetate (ABI) improves behavioural flexibility in male rats performing a strategy set-shifting task using a cue-response shift. However, the effect size of ABI treatment was relatively small. In the present study, we assess different set-shifting procedures intended to make the shift more difficult for control animals and examine whether this may potentially increase the effect size of ABI treatment. In so doing, we modified the strategy set-shifting task to be more difficult and determined the effect of ABI on the original (cue-response shift) and modified (response-cue shift) paradigms. In the first study, rats were assigned to one of six different set shifting tasks, which required them to perform either the cue-response shift or response-cue shift with variable numbers of minimum learning trials when learning the first discrimination, and varied whether the set-shift on the following day was preceded by 20 reminder trials prior to the shift. Rats performing the response-cue shift required a significantly greater number of trials to criterion to complete the task and made significantly more total errors, perseverative errors, and never-reinforced errors to criterion, compared to rats performing the cue-response shift. These results show that the response-cue shift is significantly more difficult for rats. In the second study, rats were assigned to (1) ABI or vehicle treatment and (2) the cue-response shift or the response-cue shift. Data analysis for the second study is ongoing. Together, the data will clarify the effects of androgens on behavioural flexibility and the mesocorticolimbic system.

Title: The effects of long-term oral tamoxifen administration on anxiety and cognition in Long-Evans Hooded female rats: a potential role for BDNF?

Authors: S. M. BLOSSOM[1], A. R. HALLIDAY[1], G. ROTH[1], K. DOMENECH[1], P. ABRAMENKO[1], K. POLLACK[1], G. PASCAL[1], L. BEHBEHANI[1], *L. BEEN[2], M. KELLY[1]; [1]Psychology, [2]Haverford Col., Haverford, PA

Abstract: Long-term administration of tamoxifen (Tam), a selective estrogen receptor modulator (SERM), is a common adjuvant therapy for estrogen receptor-positive breast cancers. Though initial protocols recommended 5 years of treatment, current protocols often recommend up to 10 years of Tam therapy to reduce the risk of cancer recurrence. Clinical studies have reported significant alterations in mood and cognition during Tam treatment. However, the impact of

long-term modulation of estrogen receptors by Tam on cognitive health has not been adequately studied. To better understand the impact of Tam on the brain and behavior, this study used custom medicated food pellets (Envigo) to model long-term oral administration of Tam to adult female Long-Evans Hooded rats. Following 10-13 weeks of Tam chow (n = 16) or standard chow (n = 16), rats underwent behavioral testing for several cognitive and affective measures, including the elevated plus maze, open field, and novel object recognition. At the conclusion of the study, animals were sacrificed by intracardial perfusion. Importantly, long-term oral Tam administration resulted in clinically-relevant levels of Tam in plasma, demonstrating that this method of administration is a robust model for long-term oral Tam therapy. Consistent with reports of increased anxiety in people prescribed long-term Tam therapy, we observed an anxiogenic influence of Tam in the open field and elevated plus tests. Specifically, rats in the Tam group demonstrated a higher tendency of thigmotaxis than control rats, spending significantly more time in the periphery versus the center of the open-field apparatus, and significantly more time in the closed arms versus the open arms of the elevated plus. To better understand the mechanistic underpinnings of TAM's influence on behavior, we are currently exploring the potential role of long-term oral Tam administration on the expression of Brain Derived Neurotrophic Factor (BDNF) in several estrogen-sensitive brain regions. We are targeting BDNF because previous research has demonstrated that BDNF-synthesizing neurons co-localize with estrogen receptors in the forebrain. Given that Tam acts as a modulator of estrogen receptors, BDNF expression may be an important readout of the effects of long-term oral TAM administration on behaviorally-relevant neuroplasticity. Brain analyses are ongoing and may point to downstream targets for further investigation.

Title: Ovarian hormones tune amygdala inhibition to drive anxiety-like behavior across the estrous cycle

Authors: *A. L. FARTHING, A. L. BUNCE, G. L. RYHERD, E. K. LUCAS;
Mol. Biomed. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Fluctuations of ovarian hormones during the female reproductive cycle influence emotional processing and have been shown to modulate anxiety behavior in humans and rodents. In the context of anxiety disorders, higher levels of ovarian hormones are associated with less severe symptoms. Similarly, female rodents display decreased anxiety-like behavior in the proestrus phase of the estrous cycle when ovarian hormone levels are high. Currently, the cellular mechanisms driving the anxiolytic effect of proestrus remain unknown. Activity of the basolateral amygdala (BLA), the emotional switchboard of the brain, is tightly regulated by GABAergic parvalbumin-expressing interneurons (PVIs), which are also known to express ovarian hormone receptors. We therefore hypothesized that ovarian hormones regulate BLA PVI activity to drive anxiety-like behavior across the estrous cycle. Using whole-cell patch clamp electrophysiology, we first demonstrated that BLA PVIs exhibit hyperpolarized resting membrane potential and display reduced frequency, but not amplitude, of miniature excitatory postsynaptic currents in proestrus compared to diestrus. This indicates that BLA PVIs have reduced function when ovarian hormone levels are high. We next hypothesized that increasing BLA PVI activity would eliminate the anxiolytic effects of proestrus. Using the Cre-dependent excitatory DREADD hM3D, we bilaterally targeted the BLA of male and female PV-IRES-Cre mice. We first validated that systemic administration of clozapine-N-oxide induced equivalent c-fos expression in male versus female BLA PVIs. We then tested the effects of BLA PVI activation in males and females in proestrus versus diestrus on the elevated plus maze, open field, and social interaction tests. We found that activation of BLA PVIs reversed the anxiolytic effects of proestrus while having no effects on elevated plus maze or open field performance in males or diestrus females. On the social interaction test, PVI activation decreased social preference in females, independent of estrous cycle stage. Our data supports a model for decreased BLA PVI activity in females during proestrus. Contrary to current models, our data suggest that increased BLA PVI activity promotes, rather than inhibits, anxiety-like behavior. Our work implicates a role for cycling ovarian hormones in regulating the critical balance of excitation and inhibition in the BLA and its ultimate impacts on affective behavior.

Title: Pubertal estradiol regulates development of adult anxiety- and depressive- behavior in female mice

Authors: *E. M. WOODWARD[1], L. COUTELLIER[1,2];
[1]Dept. of Neurosci., [2]Dept. of Psychology, The Ohio State Univ., Columbus, OH

Abstract: Neuropsychiatric disorders are equally diagnosed in men and women until puberty, when the incidence of mood disorders including anxiety and major depressive disorder in women rises to over two times that of men. This suggests that puberty may be a time of sexually dimorphic neurobiological development that leaves females more vulnerable to neuropsychiatric disease. A potential mechanism leading to this sex-specific vulnerability may be reorganization of structures responsible for regulating stress responsivity, such as the prefrontal cortex (PFC). Previous work in our lab has shown that in adult mice, stress increases the activity of prefrontal parvalbumin (PV) interneurons in females only, a change that is causally responsible for increased anxiety. Sex-specific differences in sensitivity to stress of prefrontal PV+ cells may develop during puberty. Since others have found that the pubertal increase in female gonadal hormone 17β-estradiol and its receptor estrogen receptor beta (ERβ) are required for prefrontal maturation of inhibitory neurotransmission, here we propose 17β-estradiol acts on ERβ on PV+ cells to promote their maturation. We hypothesize that female vulnerability to stress-induced anxiety in adulthood develops during puberty via the organizing actions of 17β-estradiol binding ERβ on PV+ interneurons in the PFC. To test this hypothesis, female C57Bl6 mice underwent ovariectomy (OVX) or sham surgery at a prepubertal timepoint (P25) and were supplemented with 17β-estradiol or vehicle once daily throughout the end of the experiment. In adulthood, mice underwent four weeks of unpredictable chronic mild stress (UCMS) followed by assessment of anxiety- and depressive-like behaviors. OVX mice not supplemented with estradiol had reduced anxiety-like behavior in the marble burying test and increased depressive-like behavior in the splash test, effects that are independent of UCMS. These behavioral results suggest that the organizing actions of 17β-estradiol during puberty are necessary to facilitate maturation of a normal emotional phenotype regardless of stress exposure. Further analyses will determine the potential role of PV+ cells in this process.

Title: High-amplitude co-fluctuations in cortical activity are linked to concentrations of reproductive hormones over the menstrual cycle

Authors: *S. GREENWELL[1], J. FASKOWITZ[2], L. A. PRITSCHET[4], T. SANTANDER[5], E. G. JACOBS[6], R. BETZEL[3];
[1]Dept. of Psychological and Brain Sciences, Indiana Univ., Bloomington, IN, IN; [2]Psychological and Brain Sci., [3]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [4]Psychological and Brain Sci., [5]Psychological & Brain Sci., [6]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Many studies have demonstrated associations between hormones involved in the menstrual cycle and brain function, including cortical activity and functional connectivity, but the relationship between transient changes in hormone concentration and fast fluctuations in brain connectivity are not well understood. Here, we leverage fMRI "edge time series"—a novel method for estimating functional connectivity at a framewise timescale – to investigate the relationship between high-amplitude network states and daily variation in sex hormones (estradiol and progesterone) and gonadotropins (luteinizing hormone and follicle-stimulating hormone) in a "densely sampled" single individual over the course of two complete menstrual cycles, one natural and the other during a hormone regimen (60 MRI scans, in total). We find that concentrations of gonadotropins are associated with the instance of high-amplitude states of network connectivity, particularly during states of opposing activation of default-mode/control and attention/sensory systems. Further, we find that edge-level variations within these high-amplitude states are associated with concentrations of both sex hormones and gonadotropins. Our results were robust across two processing pipelines, one that included global signal regression as a processing step and the other that did not. We also found that our results were consistent when data from each menstrual cycle was analyzed separately and after systematically removing data from each to ensure that our results were not driven by outliers from a single scan session. We conclude that transient changes in hormone levels during the menstrual cycle are related to high-amplitude network states of cortical functional connectivity, indicating a possible route for these hormones to influence daily changes in cognition and behavior.

Title: Progesterone receptor expression in developing medial prefrontal cortex of rats.

Authors: *P. GRANEY[1], C. K. WAGNER[2];
[1]Univ. At Albany, Albany, NY; [2]Univ. Albany, Albany, NY

Abstract: During development, progesterone receptors (PR) are transiently expressed in virtually all regions of the neocortex, beginning in the subplate at embryonic day 18 (E18), followed by expression in layer V at postnatal day 3 (P3) and in layers II/III by P6. PR expression is essentially absent in neocortex by P28. PR is also expressed in the developing medial prefrontal cortex (mPFC), in layer III from P6 until P30, but does not appear to be expressed in layer V. However, PR expression in the subplate of mPFC has not been well characterized. Subplate is a transient structure that emerges at E18 in rodents and receives the first afferent synapses arriving in cortex. Disruption in the development and function of subplate in rodents disrupts cortical organization and has been implicated in neurodevelopmental disorders in humans. The presence or absence of PR in the perinatal mPFC subplate could have significant implications for understanding the normal development of mPFC connectivity. mPFC was collected from neonatal rats on the day of birth (P1), P2, P5, P6, P7, and P10, sectioned on a freezing microtome and immunocytochemistry for PR was performed using primary antisera (DAKO) that recognizes both PR_A and PR_B. A semi-quantitative analysis of PR-ir levels within cells of mPFC subplate was conducted using a scale from 0-5 with 5 representing the darkest stained cells and a score of 0.50 being considered just detectable levels. Results indicate that PR expression in the subplate of frontal cortical areas was detectable at P1 with a peak mean score of 4.89. PR expression in mPFC was greatest within the anterior cingulate cortex (AC) where it was detectable at P1 (mean score = 1.44), gradually increasing until a peak at P6 (mean score = 2.86). PR within the prelimbic (PL) mPFC was detectable by P5 (mean score = 0.90), peaking at P6 (mean score = 1.71). PR within the infralimbic cortex (IC) did not exceed a mean of 0.50 for any of the days examined. PR within the subplate of all three subregions was absent by P10. While PR is expressed in the subplate of PL and IL during the first week of development, it is clearly expressed at lower levels per cell compared to the subplate of AC or the subplate of other regions of frontal cortex. PR is also at lower levels in PL and IL subplate compared to expression levels in layer 3 of these regions. These preliminary findings suggest that the role of PR in the development of mPFC may be less dependent on subplate expression than other regions and that effects of progestins on mPFC-dependent behaviors may be primarily mediated by PR activity in layer 3 and in dopaminergic afferents from the ventral tegmental area.

Title: Nandrolone Use During Adolescence Increases Cocaine Sensitization And Impairs Reproductive Function In Adult Female Rats

Authors: *C. J. RIVERO[1], J. A. FREIRE[1], P. SIACA[2], I. SANTIAGO[3], A. C. SEGARRA[1]; [1]Physiol., UPR Med. Sci. Campus, San Juan, Puerto Rico; [2]Biol., UPR Rio Piedras Campus, San Juan, Puerto Rico; [3]Neurosci., Case Western Reserve Univercity, Cleveland, OH

Abstract: Anabolic androgenic steroids (AAS) are drugs that mimic the chemical structure of testosterone. The most commonly AAS used by young adults is nandrolone. Use of AAS has been associated with increased risk of steroid dependence, mood disorders and polysubstance use. Indeed, cocaine use in this population is approximately 33% compared to 4.9% in the rest of the population. The effect that use of nandrolone during adolescence has on female motivational behaviors and on the reproductive system has not been investigated. Adolescent female rats were divided into two groups, one that received nandrolone decanoate (20mg/kg/sc) and another that received sesame oil (vehicle) for 10 successive days starting on day 28. On day 38 rats were tested on an Open Field and on day 39 in an Elevated Plus Maze. On day 40, the rats were then divided into 2 additional groups for a total of 4 groups: Oil-Saline, ND-Saline, Oil-Cocaine and ND-Cocaine and tested for locomotor sensitization to cocaine. From days 1-5 and at days 13 and 23 rats received an injection of cocaine (15 mg/kg/ip) or saline. Their locomotor response to cocaine was measured at days 1, 5, 13 and 23. Our data show that nandrolone treated rats have increased time spent in center of open field and augmented locomotor response to cocaine on days 5 and 13 compared to oil treated rats. This suggests that nandrolone increases risk taking behavior and the psychoactive properties of cocaine. In addition, in the ovaries it reduced weight and induced the formation of cysts. In the Uterus, it increased weight and hindered endometrial growth. These data show that exposure to supra-physiological levels of androgens during adolescence induces neurochemical changes in brain circuitry that regulate emotional and addictive behaviors increasing the psychoactive properties of cocaine. Nandrolone severely impairs reproductive system function, inducing formation of ovarian cysts and uterine dysfunction. This effect is exacerbated when paired with cocaine.

Title: Effects of Mycobacterium vaccae NCTC11659 treatment on fear extinction in female rats in the fear-potentiated startle paradigm

Authors: *A. K. LUTHENS[1], A. K. LEE[1], J. E. HASSELL, JR[3], C. L. FOXX[1], A. L. ARNOLD[1], C. A. LOWRY[1,2,4,5,6];

Center,, Aurora, CO; [6]Military and Veteran Microbiome Consortium for Res. and Educ., Aurora, CO

Abstract: Prior research in our laboratory has shown that preimmunizations with a whole-cell, heat-killed preparation of *Mycobacterium vaccae* NCTC 11659 (*M. vaccae*) in rats reduces stress-induced resistance to fear extinction in the fear-potentiated startle paradigm (FPS) (Fox et al., 2017). More recently, we demonstrated that *M. vaccae* immunizations reduced stress-induced resistance to both within-session and between-session fear extinction in the FPS (Hassell et al., 2019), which may have implications on future treatments for posttraumatic stress disorder (PTSD). These studies did not include any female rats, however. To confirm these results in both male and female populations, we measured interactions between *M. vaccae* and emotional behavior in FPS for adult Female Sprague-Dawley® rats (N=24) (strain code 400, Charles River, Wilmington, MA, USA). Fear conditioning took place over two days. For three consecutive weeks following fear conditioning, the rats received weekly subcutaneous injections of *M. vaccae* (n=12) or borate buffered saline (BBS) vehicle (n=12). One week after the final injection, there were six days of extinction training. Estrous cycle staging also took place on day 6 of extinction training. Here, we show that preimmunizations with *Mycobacterium vaccae* NCTC 11659 reduced stress-induced resistance to within-session extinction on day 1 of extinction training as in previous studies. Unlike the results of previous studies, however, *M. vaccae* preimmunization had no effect on between-session extinction in female rats. We additionally show that treatment with *M. vaccae* did not alter the distribution of estrous cycle stage. Overall, the results of the current study suggest that *M. vaccae* has stress-resilient properties and may be useful as a treatment for PTSD. However, these results suggest that sex differences exist in emotional behavioral responses to *Mycobacterium vaccae* NCTC 11659 in the FPS paradigm.

Title: Understanding the origins of brain motion in behaving mice

Authors: *C. S. GARBORG[1], Q. ZHANG[2], Y.-J. KIM[1], F. COSTANZO[2], P. J. DREW[2]; [1]Dept. of Biomed. Engin., [2]Dept. of Engin. Sci. and Mechanics, Pennsylvania State Univ., University Park, PA

Abstract: The brain moves within the skull, but the origin and physiological impact of this movement are not understood. Because brain movement is a ubiquitous confound for both human and animal imaging, it is important to understand the nature and drivers of this brain motion. Furthermore, the movement of the brain may aid in the circulation of cerebrospinal fluid (CSF), which could serve to transport metabolic waste out of the brain. Despite the relevance of brain motion to many aspects of neuroscience and brain function, we know remarkably little about the drivers of this motion, or its nature. One intriguing possibility is brain motion is caused by pressure changes in the abdomen, generated by abdominal muscle contraction, that are transmitted to the brain and spinal cord. To quantify brain motion, we used high-speed, multi-plane two-photon microscopy in awake mice free to locomote on a spherical treadmill. We quantified abdominal muscle activity using electromyography (EMG) recordings in external oblique abdominal muscles, as well as the EKG and respiratory rate. During voluntary locomotion, we observed contraction of abdominal muscles and found robust, rostral displacement of the brain, along with smaller lateral movements. These abdominal contraction-linked brain movements were orders of magnitude larger than those driven by respiratory or cardiac pulsations. Our results suggest that brain motion in the behaving animal is tied to abdominal muscle contractions.

Inn., Università del Salento, 73100 Lecce, Italy*Corresponding authors: cinzia.montinaro@iit.it; massimo.devittorio@iit.it; ferruccio.pisanello@iit.itThe advent of high-efficiency genetically-encoded optical indicators of neural activity has widened theuse of fiber photometry (FP) [1-4], enabling *in vivo* detection of functional fluorescence with simple optical fibers. This has found applications for monitoring calcium transients, membrane potentials, neurotransmittersconcentration as well as the intracellular biochemical state of neurons with fluorescence lifetime photometry[5-8]. FP is commonly implemented using the same fiber to excite and generate fluorescence, and bothexcitation and fluorescence photons undergo to tissue attenuation and scattering. Despite the influence of thefiber's constitutive parameters on the detection volume has been estimated [9,10], its dependence on the opticalproperties of the probed region is often over-looked. In this work, we describe a method to link the anatomyof the brain structures to the fiber photometry collection volume. We used a two-photon microscope (Fig. 1A)to measure the illumination and collection fields of a fiber optics inserted in 300 μm-thick coronal brainslices (mouse line *Thy1-GCaMP6s*). We compared light collection volume in the cerebral cortex, thehippocampus and the striatum , obtaining a quantitative estimation of the fiber photometryefficiency field (ρ) [9]. In light of these results, we report how the shape of ρ is influenced by thecytoarchitecture of the investigated regions (Fig. 1B), highlighting inter/intra-region differences, with primarydifferences on the photons detection depth.**REFERENCES**1. Abstract: Quantification and localization of vascular amyloid in three dimensions promotes understanding of spatial patterns of vascular amyloid deposition and disease progression in experimental models of cerebral amyloid angiopathy (CAA). Serial two-photon tomography (STPT) is suited to this task in murine models because it produces 3D datasets of the whole mouse brain in a matter of hours. Here, we present the pipeline we developed for machine learning classification of vascular and parenchymal amyloid, registration to standard atlases, and quantification across identified brain regions. We used traditional histological sectioning and slide mounted imaging to compare published methods for fluorescent amyloid and vascular labeling. Vascular and parenchymal amyloid deposits are labelled by an intraperitoneal injection of methoxy-x04 the day prior to euthanasia. Cerebral vessels are visualized by transcardial perfusion of Rhodamine-B isothiocyanate in gelatin. Labeled brains are next imaged using STPT and rendered in 3D to appreciate regional amyloid distribution. Volumetric image datasets are quantified using a modification of our custom designed image analysis pipeline utilizing supervised machine learning for pixel classification as vascular or parenchymal amyloid. Classified signals are registered into the Allen Institute for Brain Science Common Coordinate Framework version 3.0 (CCF v3.0). Our strategy produces images amenable to automatic classification and quantification of parenchymal and vascular amyloid deposits throughout the brain, useful for high-throughput studies on rodent models of CAA.

A 3D probability map representing the brain of a 52-week-old female Tg2576 mouse. Vascular amyloid is labelled in green and parenchymal amyloid is blue.

Abstract: Voltage imaging and all-optical electrophysiology in human induced pluripotent stem cell (hiPSC)-derived neurons have opened unprecedented opportunities for high-throughput phenotyping of neuronal activity in the context of the unique genetic background of individual patients. While prior all-optical electrophysiology studies relied on genetically encoded voltage indicators, here, we demonstrate a protocol that generates robust and reproducible results using the synthetic voltage sensor BeRST-1.Our imaging setup consisted of a body of an inverted epifluorescence microscope with a custom illumination light path (**Fig. 1A**). We established the protocol using primary cultures of dissociated rat neurons co-labeled with BeRST-1 and the calcium indicator OGB1 (**Fig. 1B**); co-labeling with OGB1 was critical for quick and efficient evaluation of the level of spiking activity and for choosing fields of view for subsequent voltage imaging. In parallel, we customized culture protocols to obtain healthy, active, and spatially uniform monolayer cultures of differentiated hiPSC-derived neurons. Again, co-labeling with OGB1 was critical for visual inspection providing a feedback for optimization of cell culture procedures (**Fig. 1C**). We applied our imaging protocol to three control human cell lines and observed clear differences in the firing pattern including the firing rate and bursting behavior (**Fig. 1D-E**). This finding advocates for use of isogenic controls in disease-related studies and poses a challenge to hiPSC-based studies of polygenic brain disorders. Finally, we used lentivirus to express the optogenetic actuator CheRiff in human neurons for demonstration of all-optical electrophysiology (**Fig. 1F**). In the future, we envision that the same protocol, including fixation following all-optical-electrophysiology, will be used for single-cell-resolved in situ RNA hybridization providing a link from the functional phenotype to the underlying gene expression profile.

Abstract: Cortical neurons integrate information to generate diverse response properties employing recurrent and persistent activity at different timescales (Spitmaan et al., PNAS (2020), 117(36), 22522-22531; Murray et al., Nat. Neurosci. (2014), 17 (12), 1661-1663). The expansion of the neocortical mantle in primates, including the prefrontal cortex, has accompanied increased capacity for cognitive control and executive functions, such as working memory, where persistent activity in cortical neurons encodes sensory, cognitive and response parameters. However, less is known about the role of intrinsic temporal profile and time constants of cortical neuron activation across mammalian species in subserving higher-order cognitive functions. Two-photon Ca^{2+} imaging provides an attractive methodology to further address the issues of diversity in cortical neuronal activation profiles. Here, we describe experiments where we transfected mouse and primate association cortex with retrograde AAV expressing gCAMP6f under the CAMKII promoter and studied activation profiles based on Ca^{2+} imaging of pyramidal neurons in cortical slices upon electrical and pharmacological stimulation. We report that pyramidal neurons in the vicinity of the electrode show diverse responses to different electrical stimulation pulses, with consistent dose response profiles. We found neurons where Ca^{2+} responses were augmented or attenuated upon stimulation. Increasing stimulation frequency with identical stimulation duration increased the Ca^{2+} response in a stimulation frequency-dependent manner, and the durations of the induced responses were more prolonged at higher stimulation frequencies, and in some cases, in the order of minutes. Moreover, pharmacologically-mediated stimulation showed the presence of both positively and inversely correlated spontaneous Ca^{2+} responses between pairs of pyramidal cells, presumably due to their connectivity in the local circuitry. Previous studies employing weaker electrical microstimulation with two-photon Ca^{2+} imaging in vivo have suggested that recruitment of neurons by microstimulation primarily occurs due to stimulation of axons in the vicinity of the electrode (Histed et al., Neuron (2009), 63, 508-522). We will discuss our results with higher current strengths in brain slices in this context.

Title: Microendoscopic calcium imaging of the primary visual cortex of behaving macaques

Authors: *M. OGUCHI[1], J. JIASEN[1], T. W. YOSHIOKA[1], Y. R. TANAKA[1], K.-I. INOUE[2], M. TAKADA[2], T. KIKUSUI[3], K. NOMOTO[4], M. SAKAGAMI[1];

Abstract: Macaque monkeys have long been used as experimental models to understand the neural mechanisms of the human brain. Recently, calcium imaging with genetically encoded calcium indicator has been applied to the macaque brain. Calcium imaging allows the simultaneous recording of a number of neurons and thus is a powerful tool for understanding the function of local neural circuits at the mesoscopic scale. In primates, two-photon microscopy has been mainly used in calcium imaging studies to record neural activity from the cortical surface. In rodents, microendoscopic calcium imaging, which implants a gradient index lens into the brain and observes neural activity through a miniaturized fluorescent microscope, is also widely used, producing a number of innovative results concerning various brain areas, including deep neural nuclei. Although there also has been a report on the application of microendoscopic calcium imaging to marmosets, its application to macaque monkeys has not yet been reported. In this study, we applied microendoscopic calcium imaging to macaque monkeys targeting the primary visual cortex (V1), where neurons can be easily activated by presenting visual stimuli. We incorporated the calcium indicator GCaMP6s into a mosic adeno-associated virus vector packaged with AAV1 and AAV2 capsid protein (AAV2.1). We injected this virus into the bilateral V1 of three macaques and observed highly efficient infection in these regions. Prism lenses, which were equipped with a triangular prism at the tip of a rod lens, were implanted into the vector injection sites. Miniaturized microscopy through prism lenses revealed fluorescence changes in four hemispheres from two of the three monkeys and was able to identify dozens of neurons in three of these four hemispheres. For these two monkeys, Gabor patches with different orientations were presented in the peripheral field of view during fixation to examine the stimulus response. Observed V1 neurons had receptive fields at the corresponding positions on the retinotopic map and showed significant selective responses to specific orientations. We also successfully decoded the orientation of the visual stimulus and tracked the cells across days. In summary, we successfully recorded neuronal populations simultaneously in the macaque V1

using microendoscopy, and the observed cell populations showed response patterns consistent with the established V1 neuronal properties. These results indicate that microendoscopic calcium imaging is a powerful recording method for the macaque brain.

Title: In vivo voltage imaging during behavior combined with transcriptomics enables dissection of interneuron subtypes in the mouse motor cortex

Authors: *A. SINGH[1,2], T. WANG[1], A. ABDELFATTAH[3], E. SCHREITER[1], K. SVOBODA[1]; [1]Howard Hughes Med. Inst. Janelia Res. Campus, Ashburn, VA; [2]Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Brown Univ., Providence, RI

Abstract: Recent advances in single-cell transcriptomics have enabled the construction of a transcriptomic taxonomy of cortical neurons[1]. A key question in neuroscience is to what extent the behavior-related activity of individual neurons is determined by their transcriptional profiles. Can the function of a neuron be predicted by its transcriptomic type, and vice-versa? To answer this question, we need to measure the activity of particular transcriptomic types in behaving animals. We focus on GABAergic interneurons in superficial layers of the motor cortex, a transcriptionally diverse neural population whose function is not well understood. In order to obtain rich dynamics, we study mice performing a delayed-response task with sensory, motor and short-term memory components. In this task, preparatory activity during the delay epoch is maintained by a cortico-thalamocortical loop[2]. Movement initiation is triggered by ascending signals from the midbrainviathalamus[3]. Motor cortex GABAergic interneurons receive thalamocortical input and likely prevent runaway excitation in thalamocortical loops and trigger motor commands through disinhibition. We perform voltage imaging using Voltron, which allows measurement of spikes and subthreshold activity with millisecond time scale resolution in tens of neurons at a time[4]. After the imaging experiment we use multiplexed fluorescence *in situ* hybridization (mFISH) to retrospectively identify the transcriptomic types of the imaged neurons. By combining these methods, we obtain a unique dataset that includes detailed functional characterization and transcriptomic identity. Preliminary results show that superficial

GABAergic neurons are selective for trial epoch, activity of neurons within a sub-class is highly correlated, and spiking patterns are correlated with the expression of marker genes for specific transcriptomic types.

Title: Virtual imaging of cortex-wide brain activity through decoding from locally recorded neural potentials

Authors: *X. LIU, C. REN, M. WILSON, J.-H. KIM, Y. LU, M. RAMEZANI, T. KOMIYAMA, D. KUZUM;
Univ. of California San Diego, San Diego, CA

Abstract: In both basic neuroscience research and clinical applications, electrical recordings of neural activity from brain surface have been widely employed to investigate neural circuit functions and treat neurological disorders. Traditionally, these surface potentials have been believed to mainly reflect local neural activity. Little is known about how informative they could be for neural activities across multiple cortical regions. To investigate that, we performed simultaneous local electrical recording and wide-field calcium imaging in awake head-fixed

mice. By developing a recurrent neural network model, we successfully decoded the mean activity of different cortical regions from locally recorded surface potentials. We also investigated the predictive power of multiple frequency bands of surface potentials and found that all the frequency bands were informative for large-scale brain activity. Despite the close spacing between adjacent recording channels, the recorded surface potentials provided complementary information about the large-scale cortical activity. Finally, we demonstrated the successful virtual imaging of whole dorsal cortex activity at pixel-level using locally recorded surface potentials. Therefore, in contrast with the prevailing view, we showed that the locally recorded neural potentials indeed contain rich information of the large-scale neural activities, which could be recovered using a neural network model.

Title: Ultra-small, fully-transparent, high-density graphene microelectrode arrays for multimodal experiments combining electrophysiology with optical imaging

Authors: *M. N. WILSON, J.-H. KIM, X. LIU, M. RAMEZANI, C. REN, C. DE-EKNAMKUL, T. KOMIYAMA, D. KUZUM;
Univ. of California San Diego, La Jolla, CA

Abstract: Optical technologies such as multi-photon microscopy and optogenetics have transformed basic neuroscience research by allowing high resolution recording and manipulation of neuronal activity. Combining optical techniques with electrophysiological recordings is of critical importance to harness high temporal resolution of electrical recordings along with the spatial resolution and cell specificity of optical techniques. Transparent microelectrode technologies were developed to integrate electrical recordings with optical methods. However,

previous demonstrations of transparent electrodes have been limited to small densities (16-electrodes) and large microelectrode dimensions (~100 μm) due to the pinhole defects in graphene wires and high quantum capacitance of monolayer graphene, respectively. Here, we overcome both limitations and present a new transparent graphene electrode technology based on double layer graphene with interlayer doping. We demonstrate that double layer graphene with interlayer doping achieves low sheet resistance and free of pinhole defects allowing patterning of thin and long transparent graphene wires to build high density arrays. That also eliminates the need for patterning metal wires surrounding transparent arrays, which are not desirable for light induced artifacts. Using this new technology, we have successfully overcome quantum capacitance using Pt nanoparticles and demonstrated fully-transparent 64-channel low impedance graphene arrays with electrodes scaled down to 20 μm, important for recording units and local high frequency activity. We performed multimodal experiments combining simultaneous electrical recordings and two-photon calcium imaging from visual cortex in transgenic mice. Our results show that ultra-small fully transparent graphene arrays can record neural activity with high signal-to-noise ratio during optical imaging. By performing two-photon imaging at two different depths, we investigated the relationship between the surface potentials and the underlying neural activity. Our high density fully transparent graphene electrode technology facilitates a more comprehensive investigation of cortical dynamics across different spatiotemporal scales.

Title: Flexible, insertable, and transparent microelectrodes (Neuro-FITM) for investigating cortical-hippocampal interactions

Authors: *J.-H. KIM, X. LIU, C. REN, Y. LU, Y. LIU, S. LEUTGEB, T. KOMIYAMA, D. KUZUM;
UCSD, La Jolla, CA

Abstract: Communications between neocortex and hippocampus are crucial for many cognitive processes. However, due to the difficulty of simultaneous recordings of these regions, the coordinations between large-scale cortical dynamics and hippocampal activity are not well-understood. Here we present a Flexible, Insertable, and Transparent Microelectrode array technology ('Neuro-FITM') to investigate the cortical-hippocampal coordinations during hippocampal sharp-wave ripples (SWRs). By performing simultaneous electrical recordings of local field potentials and neural spiking from hippocampus and wide-field calcium imaging of large-scale cortex, we found that diverse cortical activity patterns accompanied SWRs. In most cases, hippocampal SWRs happened after cortical activations. Our multimodal experiments showed that, during SWRs, hippocampal neural population exhibited selective spiking activity associated with distinct cortical activity patterns. These results suggest that the interaction between hippocampus and large-scale cortical activity is selective and diverse during SWRs. Our technology can be broadly applied to comprehensive investigations of interactions between cortex and other subcortical structures.

Title: Esee-shells: polymer skulls with integrated transparent electrode arrays for cortex-wide opto-electrophysiological recordings

Authors: *P. D. DONALDSON, Z. S. NAVABI, R. E. CARTER, L. GHANBARI, T. J. EBNER, S. B. KODANDARAMAIAH, S. L. SWISHER;
Univ. of Minnesota, Minneapolis, MN

Abstract: Electrophysiological and optical imaging provide complementary neural sensing capabilities - electrophysiological recordings have the highest temporal resolution, while optical imaging allows for recording the activities of genetically defined populations at high spatial resolution. Combining these complementary, yet orthogonal modalities to perform large-scale, multimodal sensing of neural activity across the entire cortex would be very powerful. We have previously developed transparent polymer skulls which allow chronic optical access to over 45 mm^2 of the dorsal cortex of the mouse (Ghanbari et al., *Nature Communications* 2019). Here we show that transparent, reconfigurable, inkjet-printed electrocorticography (ECoG) electrode arrays can be seamlessly integrated into the complex 3-dimensional inner surface of the polymer skulls, resulting in a chronically implantable device (eSee-Shells) which enables multi-modal recordings across the cortex. Ten-channel electrode arrays were inkjet-printed using poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and encapsulated with Parylene C. Benchtop characterization indicated electrode impedances of ~20 kOhms in saline at 1 kHz and optical transparency through the electrodes of ~75% at the GFP emission wavelength (509 nm). eSee-Shells were implanted on transgenic mice expressing the calcium indicator GCaMP6f in cortical excitatory cells and provided a robust opto-electrophysiological interface for over 100 days. We have performed simultaneous mesoscale calcium imaging and ECoG recordings under anesthesia as well as in awake animals presented with sensory stimuli. Finally, eSee-Shells implanted on mice sparsely expressing GCaMP6s in a subset of L2/3 excitatory neurons show sufficient clarity and transparency to observe single-cell calcium transients directly below the electrode pads. Additionally, the discrimination of awake somatosensory evoked responses based on simultaneous whisking behavior shows behavioral-state dependent responses in both modalities, and intra- and inter- modality correlation and coherence analyses of spontaneous multi-modal recordings reveal diverse relationships during awake and anesthetized states. This ability to directly study the relationships between electrophysiological signals and optical reporters across large areas of the mouse cortex will ultimately allow more elaborate investigations of neural circuitry, aiding in the development of therapies for a variety of neurological and psychiatric disorders.

Title: Evaluation of Ready-to-Use Quick-Neuron™ Plate - MEA 48

Authors: *T. NAKAYAMA[1], M. SEO[2], T. ARATANI[1], M. AZUMA[1];
[1]Biomed. Business Ctr., RICOH COMPANY, LTD., Kawasaki-city, Japan; [2]Elixirgen Scientific, Inc., Baltimore, MD

Abstract: [Background] The significant difference between animal models and humans is one of major reasons for project closures of drug discovery and development in central nervous system (CNS) field. And, it is also well known that *in vitro*/ *in vivo* animal models are often insufficient to predict drug efficacies and toxicities in human. To overcome this challenge, many assay methods with the human induced pluripotent stem cell (iPSC) derived neurons are being reported. Multielectrode array (MEA) is one of the well-known methods to evaluate nerve functions. However, MEA has some challenges. For example, it's a lot of effort to do the iPSC preparation and maintenance on MEA plate. And, it takes a long time and know-hows to optimize the conditions because it's difficult to stably evaluate drug efficacy and toxicity. To solve these challenges, we have developed the Quick-Neuron™ Plate - MEA48, which is the ready-to-use plate. [Objective] In this study, we evaluated the practicality Quick-Neuron™ Plate - MEA48 in drug discovery projects from the following viewpoints. 1. Long distance transporting, 2. Pharmacological responses, 3. Reaction to existing drugs which have anti-epileptic activity [Results] 1. Transporting test - Quick-Neuron™ Plate - MEA48 which was transported from Japan to the US showed almost the same network bust pattern as before transportation. And, the transported plate also showed sufficient response to 4-AP (K+ channel blocker). 2. Pharmacological responses - Quick-Neuron™ Plate - MEA48 showed the expected neuronal responses to representative neurotransmitters or receptor antagonists. 3. Reaction to existing drugs which have anti-epileptic activity - the anti-epileptic drugs which act on ion channels reduced the number of spontaneous neuronal firing on Quick-Neuron™ Plate - MEA48. [Conclusion] In this study, we showed Quick-Neuron™ Plate-MEA 48 has good transportability and responds to various neurotransmitters, receptor antagonists and anti-epileptic drugs. These results suggested that Quick-Neuron™ Plate-MEA 48 can be used for drug efficacy testing and/ or drug toxicity testing in CNS field such as anti-epilepsy screening or convulsive toxicity.

Title: A Novel Approach to Study Gamma-Band Coherence in Ex Vivo brain slices using perforated MEAs

Authors: *J. RODRIGUEZ[1], P. M. JENKINS[2], D. L. PRITCHETT[4], K. S. JONES[3]; [1]Univ. of Michigan, Ypsilanti, MI; [2]Dept. of Pharmacology, Dept. of Psychiatry, [3]Pharmacol., Univ. of Michigan, Ann Arbor, MI; [4]Biol., Howard Univ., Washington, DC

Abstract: Oscillations play crucial roles in many cognitive processes such as memory formation and attention. GABAergic interneurons can synchronize neuronal activity leading to gamma oscillations (30-60 Hz). Abnormalities in oscillatory activity in the hippocampus have been implicated in the pathology of some mental health disorders including schizophrenia and bipolar disorder, however the neurobiological mechanism underlying these abnormal oscillations are not yet fully understood. We set out to develop a reliable approach to study gamma oscillations in *ex vivo* hippocampal preparations using a 60-channel perforated microelectrode arrays (pMEAs). We utilized the pMEAs to record the electrical activity in multiple sites from hippocampal brain sections while allowing for rapid exchange and delivery of pharmacological agents. Bath application of kainate rapidly induced and maintained oscillatory activity in the CA1 and CA3 regions of the hippocampus. Kainate-induced oscillations were quickly abolished by the GABAA receptor antagonist, bicuculline. We demonstrated the usefulness of this approach by characterizing gamma oscillations evoked in hippocampal sections from a transgenic mouse model with Ank3-dependent inhibitory synaptic dysfunction. Sections prepared from mutant mice exhibited an increase in the coherence of gamma power within CA1 despite a reduction in gamma band power. Future studies will focus on determining how different neurotransmitters systems contribute to the induction and maintenance of kainate-induced oscillations in hippocampal sections from wild type and disease relevant animal models.

Abstract: Detailed electrical activity measurement of neural networks is essential for understanding brain functions and elucidating neurological disorders. CMOS-MEA is excellent in detecting detailed electrical activity patterns of brain slices and cultured neural networks due to the large number of electrodes. In this study, we investigated the electrical activity characteristics of brain slices, human brain organoids, and cultured neural networks using CMOS-MEA with 236,880 electrodes, which have the highest specifications in the world. In the measurement of brain slices, we succeeded in measuring the interregional propagation of the hippocampus and cerebral cortex in detail, and detected changes in β-wave generation patterns and propagation patterns due to drug administration. In sensory neuron measurement, calculation of axon conduction velocity in single neuron and change in propagation velocity due to drug administration were detected. In human iPS cell-derived central nervous system networks and human cerebral organoids, network activity was detected on a cell-by-cell basis, and changes in propagation patterns due to drug administration were detected. It was found that CMOS-MEA with 236,880 electrodes and a large measurement area can measure the electrical activity characteristics of ex vivo and in vitro neural networks and single neuron in detail. It was suggested that big data with high temporal resolution is effective for elucidation of neural circuit function and drug evaluation based on new neural activity information.

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disease that affects 10 million people worldwide and over 1 million people in the United States. Structural magnetic resonance imaging (MRI) offers the potential to discover diagnostic and predictive biomarkers of PD; and can also assess cortical and subcortical brain atrophy non-invasively. Here we developed a deep learning model to classify PD based on brain MRI. We analyzed the benchmark Parkinson's Progression Markers Initiative (PPMI) dataset (N = 471; 341 PD/130 healthy age-matched controls; 308M/163F; age 30.6-84.9). We partitioned 70% of the PPMI data for training, 20% for validation and 10% as the in-distribution test set. We also analyzed balanced subsets of independent data from the University of Pennsylvania (UPenn) as the out-of-distribution test dataset (N = 117; 104 PD/13 controls; 75M/42F; age 50-84). The MRI were preprocessed with nonparametric intensity normalization (N4 bias field correction), brain extraction, linear registration to a template and isometric voxel resampling to 2mm. As a baseline approach, we implemented a machine learning (ML) pipeline to extract 93 key radiomics features [1] including textural features based on first-order statistical; co-occurrence matrices which we used to train a random forest-based classifier. Our proposed 3D convolutional neural network (CNN) model uses each 3D T1-MRI volume as input. The model was trained for 50 epochs with early stopping. We used a binary cross-entropy loss, the Adam optimizer with weight decay and dropout. The validation subset was used to optimize the deep neural network's hyperparameters. We also used image rotations for data augmentation. The CNN model achieved an average receiver-operator characteristic curve-area under the curve (ROC-AUC) of 0.606 over multiple runs on the PPMI test set compared to the ML classifier's average ROC-AUC of 0.489. In tests on independent UPenn data, the CNN yielded an average ROC-AUC of 0.583 and the ML classifier yielded only 0.471. The CNN outperformed the ML approach and generalized better to new, unseen MRI from a different center. Training and testing our models on a more balanced dataset, as well as multimodal neuroimaging data, may improve performance. The proposed model could assist in early detection of PD using T1 MRI and help to identify disease-relevant biomarkers. Reference: [1] J. J. M. van Griethuysen, A. Title: Neurophysiological correlates of countermanding saccade deficits in Parkinson's disease

Authors: *M. LEUNG[1], A. J. SACHS[2];
[2]Neurosurg., [1]Ottawa Hosp. Res. Inst., Ottawa, ON, Canada

Abstract: Eye movements are convenient indicators of basal ganglia (BG) function and eye movement abnormalities are common in Parkinson’s Disease (PD). The oculomotor system is an appealing model motor system because saccades are ballistic and stereotyped (each saccade is associated with a unique set of muscle contractions) allowing better correlation of movement and movement preparation with neural signals, comparison across subjects, and more trials in a limited amount of experimental time. The cortical and subcortical structures involved in the saccadic system require tight regulation in the BG-thalamocortical loop, and this regulation degenerates gradually in PD due to decreased dopaminergic innervation from the substantia nigra pars compacta (SNc). The saccadic system can be evaluated through tasks completed with prosaccades (saccades toward a target), antisaccades (saccades opposite to a cued target), and cognitive tasks involving response inhibition (stop-signal task). We developed a stop-signal task in Virtual Reality (VR) that probes the subject’s ability to recruit the neural processes involved in action selection and response inhibition, and have verified that we could identify key signature changes in the EEG profile during left and right saccade, countermand, and antisaccades in healthy subjects. Independent Component Analysis (ICA) provided spatial filters for determining source signals involved in response inhibition, and subsequently utilizing the fitting-oscillations-one-over-f (FOOOF) algorithm on these sources yielded subject-specific oscillatory ranges. These ranges were applied in the construction of subject-specific machine learning (ML) models

for differentiating between task conditions, such as saccade types, by biasing the model with a favored range that was unique between subjects. The average F1 score for all subjects from their respective ML pipelines was 0.92 when evaluated against testing data. This pipeline has been approved for use in the clinic on PD patients, towards the process of elucidating neurophysiological correlates of PD and developing an adaptive deep brain stimulation (aDBS) solution.

Title: Predicting and suppressing non-stationary, pathological neural oscillation in Parkinsonian rats with high efficacy by an adaptive, wireless neuromodulator

Authors: *H. CHEN[1], B.-H. CHANG[1], C.-H. CHIEN[3], H.-H. HO[3], Y.-T. HUANG[1], R. PERUMAL[1], S.-R. YEH[2];
[1]Electrical Engin., [2]Life Sci., Natl. Tsing Hua Univ., HsinChu, Taiwan; [3]BioPro Scientific, HsinChu, Taiwan

Abstract: The high-voltage spindle (HVS) is a spike-and-wave, neural oscillation that has been identified as a pathological signature related to the dopamine depletion in Parkinsonian rats. It is of great interests to investigate whether suppressing HVSs helps to improve the motor deficits associated with the HVS, or even to delay the progression of the Parkinson's disease. As each HVS episode occurs randomly and lasts for only a few seconds, an adaptive neuromodulator is demanded for predicting the onset of HVSs and suppressing the HVSs by deep-brain stimulation at precise timing. This presentation will introduce an adaptive neuromodulator consisting of a lightweight(~4g) neuro-interfacing headstage and a wireless data hub. The proposed algorithm for detecting the HVS is based on the autoregressive modelling at interval (ARt), whose parameters are adaptable on-line by a Kalman-filter framework. In our pilot study, the algorithm is proved able to predict the onset of HVS with high precision (96%) and short latency (61ms). This study further implements the algorithm in the wireless neuromodulator for experiments with freely-moving Parkinsonian rats. The ARt model is realized in the microcontroller embedded in the headstage to predict the onset of HVS in real time, and stimulation on the subthalamic nucleus is triggered automatically whenever an HVS onset is alarmed. In parallel, the recorded neural activity is transmitted wirelessly to the data hub, wherein the Kalman-filter framework is

implemented to re-estimate optimal model parameters for detecting the HVS reliably. The re-estimated parameters are then uploaded to the headstage regularly, so as to adapt the ARt model in response to the uncertain changes of neural activities from one day to another. Such machine-learning capability is also crucial for applying the ARt model to detecting HVSs in different brain regions or different rats. On the other hand, the wireless, lightweight headstage facilitates the investigation on whether the motor deficits associated with HVSs are ameliorated at the same time. The adaptive neuromodulator is proved able to suppress HVSs with high efficacy. The efficacy refers to the finding that stimulation duration as short as 0.2s is already sufficient for suppressing the HVS effectively, even though the mean duration of HVS episodes is 4.3s. This intriguing finding indicates that precise control on the timing of brain stimulation is crucial for increasing stimulation efficacy while reducing stimulation dosage and thus its side-effects. Moreover, the proposed algorithm and adaptive neuromodulator is applicable to detecting different pathological signatures of other neural disorders.

Title: Magnetic resonance imaging and cell density correlates in the substantia nigra pars compacta of parkinsonism patients

Authors: *M. L. JOHNSON, E. W. WANG, G. L. BROWN, M. M. LEWIS, G. DU, L. C. JELLEN, C. PU, H. CHEN, L. KONG, X. HUANG;
Penn State Hlth., Hershey, PA

Abstract: Background: Previous studies have shown that quantitative MRI metrics are sensitive to microstructure and susceptibility changes in the SNc of parkinsonism patients. These are

mainly lower SNc fractional anisotropy (FA), higher apparent transverse relaxation rate (R2*), and higher quantitative susceptibility mapping (QSM). The exact pathologies underlying these signals, however, remain unclear.Methods: This study included 33 parkinsonism patients and three controls with both *in vivo* MRI scans and post-mortem neuropathologic assessment. SNc diffusion metrics of FA, mean diffusivity (MD), axial diffusivity (AD), radial diffusivity (RD), and free water fraction (FW) were determined, as were the susceptibility metrics R2* and QSM. Archival hematoxylin and eosin-stained midbrain slides were whole-slide scanned at 40× magnification. Slide scans were color- and intensity-normalized. A blinded rater then semi-automatically quantified neuromelanin-positive (NM+) neuron and glial cell densities in the SNc using ImageJ. Associations between MRI and cell densities were examined using semi-partial Pearson correlations where cell densities were regressed on the MRI-pathology interval.Results: SNc FA associated positively with NM+ neuron density residuals ($r = 0.35$, $df = 31$, $P = 0.047$). SNc R2* and QSM each associated positively with glial cell density residuals ($r = 0.71$, $df = 24$, $P < 0.0001$ and $r = 0.70$; $df = 24$; $P < 0.0001$, respectively). The FA-NM+ neuron density and R2*/QSM-glial cell density associations were not improved by additional adjustments for glial cell density and NM+ neuron density, respectively. AD, MD, RD, and FW did not associate with either cell density metric.Conclusion: This is the largest parkinsonism study to date to examine *in vivo* MRI associations with post-mortem neuropathology. The results suggest that lower FA may reflect dopaminergic neuron loss in the SNc, and higher MRI susceptibility reflects iron accumulation distributed to glial cells. Both histologic associations confirm that MRI is sensitive to key changes in the SNc associated with neurodegeneration, and validate its clinical and translational value.

Abstract: The Alzheimer's disease (AD) drug development pipeline has been marked by repeated failures and a lack of portfolio diversity. With the shadow of AD on our society growing longer, it is becoming evident that clinical care for treatment and prevention of AD will be possible only when we have multiple drugs available that operate across multiple disease-causing biological pathways in order to effectively reduce the burden of AD. The Emory-Sage-SGC TREAT-AD Center was established with the aim of developing reagents for a diverse portfolio of potential AD target hypotheses and to use open science practices to speed up drug development for new therapies. The Emory-Sage-SGC TREAT-AD Center has identified a diverse set of novel AD targets derived from systems biology studies with in the Accelerating Medicines Partnership in AD (AMP-AD) consortium and further evaluated using data from multiple AD consortia and existing literature. Targets nominated through the AMP-AD consortium were mapped to mechanistic hypotheses and prioritized based on unbiased bioinformatic assessments across multiple lines of evidence. By using a systems biology and bioinformatic analyses approach, we can search for multiple ideal targets to perturb for potential AD drug development versus one target at a time. To accelerate this process, the Center is generating and openly distributing experimental tools for use in target validation to advance or reject therapeutic hypotheses. Distribution of all data and Target Enabling Packages that include expression constructs, knockout cell lines, assays, antibody validation data, and crystal structures for 20 proteins per year identified within these mechanisms will be publicly shared through standard repositories and cataloged on the ADKnowledge Portal (https://adknowledgeportal.org). The open drug discovery approach of TREAT-AD (https://treatad.org/) is aimed to de-risk potential AD therapeutics by catalyzing robust and independent evaluation of a diverse portfolio of promising yet untested AD therapeutic hypotheses.

Title: Acute localization of maximum beta power within the subthalamic nucleus using clinic local field potential recordings reveals minimal variability in the peak frequenc

Authors: *S. LEWIS[1], L. HIRT[2], M. CASE[4], C. PULLIAM[4], J. EUBANKS[5], S. GOETZ[5], R. S. RAIKE[5], S. OJEMANN[3], D. KRAMER[3], D. KERN[3,2], J. A. THOMPSON[3,2];

Abstract: Neuromodulation via deep brain stimulation (DBS) is a highly effective therapy for movement disorders such as Parkinson's disease (PD). A recent technological advance, *in vivo* local field potential (LFP) recording from the implanted DBS electrode using the clinical pulse generator, permits investigation of neurophysiological biomarkers of PD. These biomarkers are relevant to optimizing stimulation parameters and tailoring stimulation to address specific symptom profiles. In this study, we focused on assessing a common pathophysiological biomarker, increased beta band power, in the context of optimizing the anatomic localization and efficiency of stimulation parameters during a standard therapeutic monopolar review. In n = 3 patients diagnosed with PD, implanted with bilateral DBS targeting the subthalamic nucleus (STN), we conducted 3 differential electrode measurements (30-60 second recording, 2-5-minute interval between measurements) to quantify the relative beta power (13 - 30 Hz) along the linear array of electrode contacts of both hemispheres. Following the identification of the bipolar electrode pair with the highest beta power, we compared the mean and standard deviation of the 3 repeated recordings, across hemisphere, to assess the consistency. We observed that for this pilot cohort of patients with PD, across all subjects, significant variability was observed in 5/18 contact pair comparisons, with hemispheres in 2 subjects exhibiting no difference ($p < 0.05$; using a Kolmogorov-Smirnov test to compare distributions [P1: (L) 1/3 (R) 1/3, P2: (L) 0/3 (R) 1/3, P3: (L) 0/3, (R) 2/3)]. Finally, we noted a significant asymmetry in the presence of beta power magnitude between the hemispheres ($F_{1,15478} = 1536$, $p < 0.001$). We found that *in vivo* assessment of a pathophysiological biomarker (peak beta power to determine the therapeutic contact) predicated on LFP information recorded from a DBS electrode (up to 5 years post-surgery) may inform therapeutic stimulation parameters.

Title: Automatic extraction of kinematic motifs captured with markerless tracking during deep brain stimulation implantation

Authors: *S. BAKER[1], S. OJEMANN[2], D. KRAMER[2], D. S. KERN[3], J. A. THOMPSON[3]; [1]Colorado Col., Colorado Springs, CO; [2]Dept. of Neurol., [3]Dept. of Neurol. & Neurosurg., Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Optimal placement of deep brain stimulation (DBS) electrodes for the treatment of movements disorders, including Parkinson's disease (PD), can involve intraoperative assessment of neural activity during upper limb movements. Conventional motor mapping procedures during DBS surgery have remained largely unchanged. Given advancements in machine learning, we pursued a novel approach to objective quantification of movement over time using "markerless tracking" during the surgery. Patients (n=9) underwent DBS implantation, targeted to the subthalamic nucleus (STN), as treatment for PD. Two cameras were oriented (one facing the patient at the end of the operating table and the second contralateral to the limb under investigation) to record kinesthetic testing evaluated by a movement disorders neurologist during various active and passive upper limb movements. After intraoperative video data collection, 21 labels were applied to patients' digits and palm on a subset of frames from each recording (700-912 frames per surgery, 1.52-5% of total frame count) and trained using the Python-based suite DeepLabCut. Training was realized with the *resnet-50* convolutional neural network (pretrained to human behavior) until a Huber loss plateau ($\mu = 0.022$), equating to a mean iteration count of 224,250. Refinement of additional parameters permitted acceptable accuracy in tracking, and suboptimal pose estimations were discarded. Post-hoc data analyses used Matlab to extract kinematic data, including Euclidean distance (ED), acceleration, and velocity. From these metrics, we defined an objective movement threshold, and used extracted ED epochs that represented specific patient movements such as hand clenches and raised arm postures to begin development of a movement categorization pipeline. We assessed exemplar sets of ED epochs from three behaviors to fit the polynomial $-a(x^2 - c) + b$. Each behavioral cluster's three coefficients were significantly different from one another, as suggested by independent-samples t-tests (all $p<0.001$, two-tailed) with Dunn's indices among pairwise coefficients ranging from DI: 0.059-0.3889. These preliminary results suggest accurate and precise capture of neuromotor behavior during surgical interventions for PD as well as development at objective behavioral categorization, which may be used improve surgical targeting, optimize DBS therapy, or develop novel DBS targets.

Title: Microglial imaging with MRI diffusion radiomics

Authors: *A. P. SINGH, V. S. JAIN, J.-P. J. YU;
Dept. of Radiology, Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI

Abstract: MR imaging with neurite orientation dispersion and density imaging (NODDI) has provided new opportunities to interrogate the composition of the axonal and extra-axonal compartments of the brain. Previous work from our group has shown the high sensitivity, but low specificity, of the extra-axonal NODDI parameter orientation dispersion index (ODI) to microglial density. We demonstrate the first application of radiomics in NODDI to track changes in microglial density using a well-characterized murine model of colony stimulating factor 1 receptor (CSF1R) inhibition resulting in microglial depletion throughout the brain. 12-week-old C57BL/6J male mice depleted of microglia with PLX5622 (a CSF1R small molecule inhibitor) were sacrificed 1- and 7-days following withdrawal of treatment (n=24; 12 control, 12 experimental). Following high-resolution, multi-shell *ex-vivo* diffusion imaging, all images underwent standard image preprocessing and spatial normalization. Images were then masked and segmented with a standard atlas. ODI was calculated for the right hippocampus (HC), amygdala (Am), and globus pallidus (GP). Regions of interest (ROI) were processed using the python library *PyRadiomics* (bin width=0.1) to generate original and wavelet-transformed first-order statistics and image texture matrices for a total of 792 calculated features per ROI. Student's *t*-tests were performed to compare the mean value of features across conditions and FDR-corrected to determine significantly different features. Statistical analyses were performed using python *scipy* and *statsmodels* libraries. Significant differences in radiomic features of ODI were found in all analyzed ROIs between day 1 treated (microglial depleted animals) and control animals (# of significant differences: HC = 102, Am = 160, GP = 21; FDR p-value < 0.05). No significant differences were found in any of the ROIs at the day 7 timepoint. These findings correlate with histologically confirmed changes in microglial density at the examined timepoints. Previous mean ODI intensity comparisons did not correspond with the known biology, with no significant difference in right HC or GP at day 1 (2/3 ROIs incorrect) and significant difference in right GP at day 7 (1/3 ROIs incorrect). Radiomic features generated from the NODDI model are sensitive to changes in microglial density. Texture matrices and other first-order statistics provide greater imaging specificity corresponding to underlying biological changes than mean intensity alone. Our results highlight the increased specificity and potential utility of radiomic analyses to capture important cellular changes in healthy and diseased brains.

Title: Evaluation of axonal injury with filtered diffusion weighted magnetic resonance imaging in cervical spondylotic myelopathy

Authors: *S. MURPHY, R. FURGER, S. SHABANI, S. KURPAD, M. BUDDE;
Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Diffusion tensor imaging (DTI) has gained popularity in studying microstructural changes in the spinal cord of patients with degenerative cervical spondylotic myelopathy (CSM). While DTI is sensitive to microscopic pathologies in the injured spinal cord, it lacks specificity because many different pathologies can cause DTI changes. CSM is characterized by a complex pathophysiology. Axonal injury is believed to be a main correlate to function, but it is accompanied by substantial edema or myelomalacia. DTI is unable to distinguish these features. Recently, filtered Diffusion Weighted Imaging (fDWI) has been demonstrated to have greater specificity for axonal injury by using one diffusion gradient pair to suppress or 'filter' non-axonal signals and a second to explore the axonal-specific diffusion changes. In this study, we evaluate the sensitivity of fDWI compared to DTI in studying axonal injury in patients with CSM. We hypothesis that fDWI will have greater sensitivity to axonal damage compared to DTI for patients with CSM. All MRI diffusion weighted images (DWI) were obtained on a GE 3T MRI for 22 CSM patients prior to surgery. Diffusion tensor imaging was obtained using 25 directions and a b-value of 800 s/mm^2. Filtered diffusion imaging employed two pairs of diffusion weighted pulses using 26 directions and a b-value of 2000 s/mm^2 tailored specifically for the spinal cord. The change in axial diffusion from above the site of greatest compression to the site of greatest compression was compared between fDWI ($fADC_{||}$) and DTI (AD) to investigate the impact of edema and other artifacts on each acquisition. $fADC_{||}$ showed a greater reduction (-38.13±24.82) at the level of maximal compression compared to AD (-6.67±14.47). In addition, fDWI showed a significantly greater decrease in the axial diffusion for patients with evidence of edema (-50.97±25.60%) compared to patients without edema (-29.18±21.02%) ($p = 0.044$). These findings were not observed using AD derived from DTI which showed no change with (-6.06±1.38%) and without (-7.10±16.89%) the presence of edema ($p = 0.889$). The results showed that DTI and fDWI exhibit divergent features in CSM patients. The decrease in $fADC_{||}$ at the site of maximal compression with and without edema is suggestive of axonal injury and highlights the ability of fDWI to capture more specific information regarding the status of the chronically compressed spinal cord. These trends illustrate the translational potential of using fDWI and may prove useful for improved prognostication in larger studies of CSM.

Abstract: Microglia, the immune sentinel of the central nervous system (CNS), are generated from yolk sac erythromyeloid progenitors that populate the developing CNS. Interestingly, a specific type of bone marrow-derived monocyte is able to express a yolk sac microglial signature and populate CNS in disease. Here we have examined human bone marrow (hBM) in an attempt to identify novel cell sources for generating microglia-like cells to use in cell-based therapies and in vitro modeling. We demonstrate that hBM stroma harbors a progenitor cell that we name stromal microglial progenitor (STR-MP). STR-MP single-cell gene analysis revealed the expression of the consensus genetic microglial signature and microglial-specific genes present in development and CNS pathologies. STR-MPs can be expanded and generate microglia-like cells in vitro, which we name stromal microglia (STRM). STR-M cells show phagocytic ability, classically activate, and survive and phagocyte in human brain tissue. Thus, our results reveal that hBM harbors a source of microglia-like precursors that can be used in patient-centered fast derivative approaches.

Title: Exploring transcriptional dynamics of neural differentiation in an induced pluripotent stem cell model.

Authors: *A. ZUCCO[1], Y. ZHANG[1], C. HILL[2], S. DELIARD[1], A. GARDINI[1];
[1]The Wistar Inst., Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The formation of complex tissue and organ systems through development requires tightly regulated programs of coordinated gene expression. These patterns of gene expression are mediated by a network of different genomic elements, including enhancer regions and other regulatory elements distal to promoters and the gene body itself. Many of these distal elements are poorly characterized, and the role of different regulatory factors at these regions remains to be described. To better describe this epigenetic landscape during differentiation we utilize human induced pluripotent stem cells (hiPSCs) to best recapitulate neuronal stem cell development in-vitro. Coupled with next generation whole genome sequencing we have built snapshots of enhancer activation across the timeline of differentiation from pluripotency to hiPSC-derived neuronal cells. Here we show distinct shifts in both chromatin accessibility and activation as differentiation proceeds, and that these shifts predict activity at nearby genes in a checkpoint specific manner through differentiation. We further show that alterations in the transcriptional regulatory complex Integrator resulted in abnormal neuronal differentiation and decreased activation of enhancer elements, suggesting that Integrator may play a larger role in regulating differentiation than previously recognized. Our data reveal for the first time how subunits of the Integrator complex modulate activation of a neuronal-specific enhancer.

Title: Relationship between neural activity and differentiation in Hydra revealed through 3D functional imaging

Authors: *A. ESCOBAR[1], A. S. PRIMACK[2], C. JULIANO[2], J. T. ROBINSON[1];
[1]Rice Univ., Houston, TX; [2]Univ. of California, Davis, CA

Abstract: Hydra is an emergent model organism in neuroscience with key advantages to study regeneration, such as a simple body plan, limited number of cell types and the ability to regenerate large portions of the body. However, little is known about the relative timing of neural differentiation and recovery of neural circuit function during regeneration. Here we developed a dual-expression transgenic Hydra line that expresses a cell-type-specific red fluorescent protein (tdTomato) in ec5 neurons that are present in the foot of the animal, and a calcium indicator (GCaMP) in all neurons. Using SCAPE (Swept Confocally Aligned Planar Excitation) microscopy we were able to track single cell calcium dynamics in 3D during regeneration of the foot. We found that between 4 and 30 hours post amputation (hpa) Hydra shows unsynchronized spontaneous neural activity along with the absence of tdTomato-positive cells in the peduncle. Between 32 and 40 hpa we observe an emergence of tdTomato-positive cells with low level of synchrony followed by an increase in the number of tdTomato-positive cells and significant increase in synchronization. This synchronous activity is the hallmark of a fully regenerated neural circuit in the Hydra foot. These data suggest that during Hydra regeneration, certain neuronal cells make terminal fate decisions prior to re-establishing their functional role in the nervous system. Thus, in Hydra there are likely additional molecular mechanisms that connect molecular differentiation to functional neural activity after cells are committed to a specific fate. This ability to reproducibly study functional neural regeneration at specific times relative to molecular differentiation events makes Hydra a potentially powerful model system for understanding the key molecular and functional processes involved in neuroregeneration following injury.

Title: Understanding Hox gene regulation in response to Wnt signaling during motor neuron differentiation

Authors: *N. KRUTOVSKA[1], B. RAGIPANI[2], D. P. RAHE[2], E. O. MAZZONI[2];
[1]Hunter College, CUNY, New York, NY; [2]Dept. of Biol., New York Univ., New York, NY

Abstract: Abstract: Understanding patterning and neuronal subtype diversity in the developing neuraxis is at the crux of understanding neuronal diversity. The vertebrate Hox gene family assigns a positional identity to differentiating neurons along the spinal cord to differentiate into anatomically appropriate subtypes. Hox genes are organized in compact clusters surrounded by distal regulatory elements. During development, retinoic acid (RA) and Wnt signaling activate rostral and caudal Hox genes, respectively. Preliminary data demonstrate that regulatory elements within the Hox cluster are sufficient to induce Hox gene expression in response to RA signaling. However, it is not known if the Hox cluster without long-distance regulatory elements can respond to Wnt signaling as well. Differentiating mouse embryonic stem cells (mESCs) respond to RA by activating rostral Hox genes. Thus, we first aimed to establish a differentiation protocol that will rely on Wnt signaling to activate caudal Hox genes. The cells were treated with different concentrations of the Wnt signaling activator CHIR 99021, a GSK3β inhibitor. Additionally, we treated the cultures with a Sonic Hedgehog Agonist (SAG) to induce ventral spinal cord fate. This approach allowed us to develop a homogenous cell culture model and identify the proper dosage amount needed to activate the posterior hox region and grow neuronal cells. Next, we tested if a transposed minimal Hox cluster, devoid of any distal regulatory elements, would respond to Wnt signaling. With the dosages of CHIR 99021 and SAG needed to activate the endogenous posterior hox genes, we can also confirm that a minimal Hox cluster could activate caudal Hox gene expression responding to Wnt signaling. These results suggest the intrinsic ability for the HoxA cluster to decode positional information in the absence of enhancers or other long-range information outside the cluster. This study provides insights on the mechanisms of posterior Hox induction through Wnt activation in regulating transcription and patterning signals for neuronal differentiation.

Title: Ferulic Acid Enhance Neuronal Differentiation In Hippocampal Stem Cells Derived Neurospheres

Authors: *M. S. RAO, S. SHIVANANDAN;
Fac. of Medicine, Kuwait Univ., Jabriya, Kuwait

Abstract: ***Introduction and objectives:*** Asafoetida is an oleo-gum-resin obtained from the exudates of the roots of the plant *Ferula asafoetida*. Ferulic acid (FA, 4-hydroxy-3-methoxycinnamic acid) is the active component in asafetida. FA has been shown to be neuro stimulant, enhance neuronal stem cells proliferation in the hippocampus. Objective of the present experiment was to investigate the effects of FA on neuronal differentiation of progenitor cells in the hippocampal stem cells derived neurospheres. **Methods:** Stem cell culture was made from embryonic day18 hippocampal cells. Neurospheres were grown for one week and were divided into control (C), and three ferulic acid treatment groups (FA-5µM, FA-10µM and FA-15µM), Control neurospheres remained without any further treatment, FA-5µM, FA-10µM and FA-15µM groups were treated with 5µM,10µM and 15µM ferulic acid respectively for one week. Triplicate cultures were maintained for each group. After treatment, the neurospheres were grown in differentiation media for one week. Cultures were terminated, and immunostaied for TuJ-1, (Neuronal marker), GFAP (astrocytic marker) to label the neurons and astrocytes. Number of neurons and astrocytes differentiated in each neurosphere were quantified. Data were expressed as mean±SEM analyzed with one-way ANOVA. **Results:** Number of differentiated neurons from the neurosphere that are treated with 10µM and 15µM ferulic acid are found to be significantly (30-40%, $p<0.01$) more compared to control group. 5µM ferulic acid had no effect on neuronal differentiation. Number of differentiated astrocytes from the neurosphere that are treated with 10µM and 15µM ferulic acid are also found to be marginally increased (10-20%, $p<0.05$) compared to control group. 5µM ferulic acid had no effect on astrocyte differentiation. **Conclusion:** These results suggest neuron and astrocytes stimulatory role of ferulic acid in neurosphere. It facilitates the differentiation of neurons and astrocytes in the neurosphere.

Title: Long non-coding RNA Lacuna regulates neuronal differentiation of neural stem cells

Authors: *E. NINOU, A. MICHAIL, P. K. POLITIS;
Biomed. Res. Foundation, Acad. of Athens, Athens, Greece

Abstract: Although long non-coding RNAs (lncRNAs) is one of the most abundant classes of RNAs encoded within the mammalian genome and are highly expressed in the adult brain, they remain poorly characterized and their roles in the brain development are not well understood. Here we identify the lncRNA *Lacuna* as a negative regulator of neuronal differentiation in the neural stem/progenitor cells (NSCs) during mouse brain development. In particular, we show that *Lacuna* is transcribed from a genomic locus near to the *Tbr2/Eomes* gene, a key player in the transition of intermediate progenitor cells towards the induction of neuronal differentiation. *Lacuna* RNA expression peaks at the developmental time window between E14.5 and E16.5, consistent with a role in neural differentiation. Overexpression experiments in ex vivo cultured NSCs from murine cortex suggest that *Lacuna* is sufficient to inhibit neuronal differentiation, induce the number of Nestin+ and Olig2+ cells, without affecting proliferation or apoptosis of NSCs. CRISPR/dCas9-KRAB mediated knockdown of *Lacuna* gene expression leads to the opposite phenotype by inducing neuronal differentiation and suppressing Nestin+ and Olig2+ cells, again without any effect on proliferation or apoptosis of NSCs. Interestingly, despite the negative action of *Lacuna* on neurogenesis, its knockdown inhibits T*br2/Eomes* transcription, implying a simultaneous, but opposite, role in facilitating the *Tbr2/Eomes* gene expression. Collectively, our observations indicate a critical function of *Lacuna* in the gene regulation networks that fine tune the rate of neuronal differentiation in the mammalian NSCs.

Title: The effect of feedback timing on learning in children with atypical language development

Authors: *I. FITZPATRICK, Y. ARBEL, A. GUL;
MGH Inst. of Hlth. Professions, Charlestown, MA

Abstract: The study was designed to evaluate the effect of feedback timing on learning in school-age children with resolved and persistent developmental language disorder (DLD). Fifteen participants (mean age = 10.7) completed a declarative paired-associate learning task under two conditions. In both conditions, participants learned through trial and error guided by performance feedback. The timing of the feedback was manipulated in the two conditions with the immediate condition presenting feedback 1000ms after the participant's response and the delayed condition presenting feedback 7000ms after the participant's response. Previous research proposes that immediate feedback is linked to the implicit learning system, a system that is hypothesized to be impaired in children with DLD, while delayed feedback is linked to the declarative learning system. Participants' electrophysiological data were recorded during the learning tasks, and their accuracy was evaluated at the end of each task through a test that was free of feedback. Participants completed the Clinical Evaluation of Language Fundamentals (CELF-5), and their Core Language Score (CLS) was used as a measure of language skills. EEG data were time-locked to the presentation of feedback, and two event-related potentials (ERPs), the Feedback Related Negativity (FRN) and the N170, were evaluated. No difference in test accuracy between the two feedback conditions was found. Correlational analysis indicated that language scores positively correlated with test accuracy when feedback was delayed. The results of a mixed ANOVA of the FRN and N170 suggested that while there were no differences in the amplitude of the FRN across conditions, the N170 amplitude was larger in the delayed feedback condition. Correlational analysis indicated that smaller N170 was found associated with higher accuracy in the immediate feedback condition. Taken together, these findings suggest that feedback-based learning that relies on the declarative system (i.e., when feedback is delayed) depends on language skills, and that the activation of the declarative system, as reflected by the N170 when feedback is immediate, is associated with poorer test accuracy.

Title: Relationship between neighborhood poverty and externalizing symptoms in children: mediation and moderation by environmental factors and brain structure

Authors: *M. MAXWELL[1], D. M. BARCH[2], R. TAYLOR[3];
[1]Washington Univ. In St. Louis, Saint Louis, MO; [2]Dept Psychol & Psychiatry, Washington Univ., Saint Louis, MO; [3]Washington Univ. in St. Louis, St. Louis, MO

Abstract: Increased rates of internalizing and externalizing behaviors have been observed in children from more impoverished neighborhoods, and correlates of neighborhood poverty such as toxin levels, altered brain structure, or exposure to crime may contribute to this relationship. Additionally, receipt of socioemotional support as a protective factor can mitigate the impact of adversity on children's developmental outcomes. The goal of this project is to examine the extent to which neighborhood poverty relates to children's mental health outcomes independent of household socioeconomic status, and to determine whether toxin levels and brain volume serially mediate this relationship and whether socioemotional support moderates it. Data from the Adolescent Brain Cognitive Development study were obtained for 8,623 9-10 year old children; neighborhood poverty was measured using nine census tract variables from the Area Deprivation Index and mental health symptoms were assessed by the Child Behavior Checklist. Toxin levels included particulate matter, nitrogen dioxide, and lead risk measured by the NASA SEDAC while amygdala, dlPFC, and intracranial volumes were obtained by MRI. Socioemotional support consisted of parent, peer, and school sources assessed by various questionnaires. Generalized linear models and structural equation modeling tested for evidence of a mediation and moderation. Increased neighborhood poverty was significantly associated with increased externalizing symptoms, and reductions in intracranial volume mediated this relationship. Increased parental support as indexed by the Parental Monitoring Survey attenuated this relationship, but only for children lower in poverty. These results highlight the importance of identifying environmental and neurological markers that may increase risk for later psychopathology in order to better inform holistic interventions designed to reduce the burden of mental illness.

Title: Reduced amygdala responsivity to fear in children with antisocial behaviour that persists after treatment

Authors: *S. O' BRIEN[1], A. SETHI[1], M. MEHTA[1], C. ECKER[1], N. BLACKWOOD[1], M. PETRINOVIC[1], S. SCOTT[1], M. CATANI[1], E. VIDING[2], J. BLAIR[3], D. MURPHY[1], M. CRAIG[1];
[1]King's Col. London, London, United Kingdom; [2]Univ. Col. London, London, United Kingdom; [3]Boys Town Natl. Res. Hosp., Boys Town, NE

Abstract: Reduced amygdala responsivity to fear in children with antisocial behaviour that persists after treatment.
Background: Parenting interventions reduce antisocial behaviour in some children with conduct problems (CP), but not others. Understanding the neural basis for this disparity is important because persistent antisocial behaviour is associated with lifelong morbidity and places a huge burden on our health, and criminal justice, systems. One of the most highly replicated neural correlates of antisocial behaviour is amygdala hypoactivity to another person's fear.
Objective: We aimed to assess whether amygdala hypoactivity to fear in CP children is remediated after successful treatment, and/or if it is a specific marker for persistent antisocial behaviour.
Design: We conducted a prospective, case-control, study of CP and typically developing (TD) boys. Both groups completed two MRI scanning sessions, separated by 18±5.8 weeks, with antisocial behaviour assessed at each visit. Parents of CP boys also engaged in a parenting intervention between sessions.
Setting: Parenting interventions referrals from Child and Adolescent Mental Health Services, Local Authorities, Charities, & Social Enterprises
Participants: Participants included parents, and their CP sons, following referral to a parenting intervention group, and TD boys recruited from the same schools and geographical regions
Exposure: Parenting interventions delivered for 12-14 weeks.
Main Outcomes and Measures: We used functional MRI to compare amygdala activity to fearful faces in TD boys, with CP boys whose antisocial behaviour improved or persisted following a parenting intervention.
Results: Final MRI data was available for 57 CP and 36 TD boys. Amygdala hypoactivity to fear was only observed in CP boys with antisocial behaviour that persisted following a parenting intervention, and was absent in CP boys with antisocial behaviour that improved.
Conclusions and Relevance: Our findings suggest amygdala hypoactivity to fear is a marker for antisocial behaviour that is resistant to change following a parenting intervention, and a putative target for future treatments.

Title: A closer look at impairments of time perception function in individuals with attention-deficit/ hyperactivity disorder

Authors: *Y. EGASHIRA[1], S. HAYASHI[1], M. UKEZONO[1], S. UONO[1], Y. KAGA[2], Y. KITAMURA[3], Y. KITA[4], Y. YAMASHITA[5], T. OKADA[1], M. INAGAKI[6];
[1]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [2]Fac. of Med., Univ. of Yamanashi, Yamanashi, Japan; [3]Grad. Sch. of Design, Kyushu Univ., Fukuoka, Japan; [4]Mori Arinori Ctr. for Higher Educ. and Global Mobility, Hitotsubashi Univ., Tokyo, Japan; [5]Sch. of Med., Kurume Univ., Fukuoka, Japan; [6]Tottori prefectural Tottori Rehabil. Ctr., Tottori, Japan

Abstract: Individuals with attention deficit/ hyperactivity disorder (ADHD) have impairments of time or timing perception. The studies in typically developing individuals (TD) have shown functional segregation that basal ganglia and cerebellum networks were involved in the sub-second timing tasks, whereas the supra-second timing tasks activated cortical structures, such as the supplementary motor area and prefrontal cortex. Individuals with ADHD show deficiencies in time perception for both sub- and supra-second range, which are reflected in performances of behavioral experiments, e.g., a standard deviation (SD) of trial-to-trial performance and duration discrimination accuracy. This study explored temporal cognitive dysfunction specific to ADHD in both sub- and supra-second range. Twenty-one children with ADHD (age: 9.0± 1.1) and 20 typically developing children (age: 10.3± 1.2) participated in this study. For sub-second time perception, the duration discrimination task (DD) was conducted. The participants detected a target tone among three tones, consisted of two pure tones with 1200 ms as standard and one target tone with 400, 700, 800, 900, 1000 or 1100 ms. For supra-second time perception, the duration estimation task (DE) was conducted. The participants were asked to keep pressing a button for reproducing the same duration of time as the preceding stimuli (5 seconds). This study protocol was approved by the Ethics Committee of National Center of Neurology and Psychiatry. As a result, in the DD, the discrimination rate of children with ADHD (63.8± 21.8%) was lower than that of TD (80.2± 5.6%). In the DE, children with ADHD had fewer successful attempts (15.3± 5.8/30) to reproduce the presentation time of the preceding stimuli than TD children (20.0± 4.3/30), though there is no significant difference in mean duration of the button press between groups (ADHD: 4819 ms, TD: 4710 ms). Furthermore, the SD of the button-press duration of the third session was smaller than that of the first session in both groups, but the SD

of children with ADHD was larger than that of TD in the latter half of each session. Our results coincide with previous evidence that ADHD has time perceptive deficits in sub- and supra-second range. While convergent response in the length of the button press suggests that children with ADHD have an ability to learn motor timing in supra-second range, the large SD and no mean difference of button-press duration in children with ADHD may reflect less tolerance in performing the task. This study suggests the importance of considering task characteristics for understanding temporal cognitive function in ADHD.

Title: Identifying dyslexia: Link between maze learning and dyslexia susceptibility gene, DCDC2, in young children

Authors: *L. A. GABEL[1], K. VOSS[2], E. JOHNSON[4], E. R. LINDSTRÖM[5], Y.-C. YU[3], D. T. TRUONG[6], E. M. MURRAY[2], K. CARIÑO[2], K. SHYNTASSOV[3], C. M. NIELSEN[5], D. CARROLL[3], S. PANIAGUA[7], J. R. GRUEN[8];
[1]Neurosci. & Psychology, [2]Neurosci., [3]Electrical & Computer Engin., Lafayette Col., Easton, PA; [4]Dept. of Special Educ., Boise State Univ., Boise, ID; [5]Dept. of Educ. and Human Services, Lehigh Univ., Bethlehem, PA; [6]Dept. of Pediatrics, [7]Dept. of Genet., Yale Univ., New Haven, CT; [8]Dept. of Pediatrics & Dept. of Genet., Yale Sch. of Med., New Haven, CT

Abstract: Dyslexia is a common learning disability that affects processing of written language despite adequate intelligence and educational background. If learning disabilities remain untreated, a child may experience long term social and emotional problems which influence future success in all aspects of their life. Dyslexia has a 60% heritability rate, and genetic studies have identified multiple dyslexia susceptibility genes (DSGs). DSGs, such as *DCDC2*, are consistently associated with the risk and severity of reading disability (RD). Altered neural connectivity within temporo-parietal regions of the brain are associated with specific variants of DSGs in individuals with RD. Genetically altering DSG expression in mice results in visual and

auditory processing deficits as well as neurophysiological and neuroanatomical disruptions. Previously, we demonstrated that learning deficits associated with RD can be translated across species using virtual environments. In this two-year longitudinal study, we demonstrate that performance on a virtual Hebb-Williams maze in pre-readers, is able to predict future reading impairment, and the genetic risk strengthens, but is not dependent on, this relationship. Using computational modeling of students' actions using maze locations and latency values, prediction results can be integrated into the test for real-time feedback of the performance in the form of at-risk percentages for reading impairment. A participant's performance in each trial was based on an accumulated score of the step-by-step distance between the participant's actual location and the nearest ground truth location in the maze throughout the trial. The better a participant performs in a trial, the lower the calculated score. Further examination of performance scores indicated that gender and age are two key factors in performance on this task. We are currently developing a computational model with deep learning capability to identify children at risk for reading impairment. Due to the lack of oral reporting and use of letters, this easy-to-use tool may be particularly valuable in a remote working environment, as well as working with vulnerable populations such as English language learners.

Abstract: Attention deficit hyperactivity disorder (ADHD) is a neurodevelopmental disorder in which patients present inattention, hyperactivity and impulsivity. The condition has its onset during childhood, although some patients are diagnosed until adulthood. Moreover, more than 50

% of children diagnosed with ADHD continue with this condition as adults. Studies on the ADHD neurophysiological correlates address mainly pediatric patients, while comparatively fewer studies have been performed on adults. Some studies on adults report different results when compared with those performed on children, suggesting a variation due to age in the pathophysiology of this condition. Herein we analyzed brain electrical activity in young adults at risk of ADHD (n=46) who rated negative for alcohol use disorders, depression and suicide risk, comparing them versus controls (n=45). Brain activity was measured through quantitative electroencephalography. We analyzed absolute power (AP), relative power (RP) and mean frequency (MF) of delta, theta, alpha and beta frequency bands. We found that subjects at risk of ADHD presented decreased alpha AP at central region. While we found decreased alpha activity, as reported previously for ADHD children, we did not observe increased slow wave activity, as frequently reported for children and adolescents with ADHD. Our results support an age associated variation in the neurophysiological correlates of ADHD.

Title: Effect of the Neurologist's verbal behavior on the follow-up behavior of the ADHD patient

Authors: *G. OCHOA-ZENDEJAS, O. NÚÑEZ-GAYTÁN, R. GONZALEZ-CASTAÑEDA, A. GÁLVEZ-CONTRERAS, I. VARGAS-DE LA CRUZ;
Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Background: Lack of adherence to treatment is one of the most common problems in child neurologist care interventions (Sola, 2015). The number for non-compliance with ADHD treatment are worrying, ranging between 15% and 87% (Treuer et al., 2016). Adherence includes behaviors such as attendance at scheduled follow-up appointments, participation in health programs, and seeking care (Gil, Belda & Piñeiro, 1999). Although, there are a few research work about treatment factors related with adherence (Dilla, Valladares, Lizan and Sacristán 2009; WHO, 2003). Studies are still lacking in the identification of the doctor's verbal behavior related with a better patient's follow-up. We propose to incorporate a rigorous methodology that has been applied in the study of psychotherapy (Frojan et al., 2008). This methodology analyses the verbal behavior emitted along the treatment. **Purpose:** To identify the difference between the doctor's verbalization pattern in cases where there is a second appointment and in cases where

that is not the case. **Methods:** The methodology used was observational. The neurologist's verbal behavior was categorized using the SISC-INTER-CVT coding system (Ruiz-Sancho, 2011). The coding and analysis were carried out with the Behavioral Observation Research Interactive Software (BORIS) 7.4.11. SPSS software (22.0) was used for statistical analysis. The reliability of the categorization (inter and intra-judge) was calculated (percentage of agreement and the Kappa Cohen index). The participants were the neurologist and 40 children (7 girls and 33 boys), aged 4 to 9 years old. All the children had a diagnosis of Attention Deficit Hyperactivity Disorder assessed by the neurologist, considering the diagnostic criteria of the DSM-V. **Results:** The non-parametric Mann-Whitney U test was applied to analyze the statistically significant differences between the groups. In the non-attendance group cases there were more Punishment-type verbalizations (Z=-3.767, p= 0.000); while in the attendance group cases there were more informative-type verbalizations (Z=-2.281, p=0.023) and, although there were not statistically differences, there were more instruction-type verbalizations. **Conclusions:** Due to the characteristics of the study, the results can only point out some hypotheses to probe in future research. The verbalizations emitted by the neurologist can be an important factor to take into account in the patient's attendence or not-attendance to the medical appointments. The methodology used in the study seems a suitable research tool for the analysis of the doctor's verbal behavior and to clarify its role in the patient's adherence.

Abstract: Central nervous system stimulants are commonly prescribed for individuals with attention-deficit/hyperactivity disorder (ADHD). Studies suggest that stimulant medications such as norepinephrine-dopamine reuptake inhibitors used to treat ADHD are associated with enhanced performance on creativity tasks. Specifically, stimulants have been shown to enhance fluency, flexibility, and originality scores on the Torrance Test of Creative Thinking, a standardized measure of creativity, in ADHD. Stimulants have also been shown to enhance verbal fluency in adults with ADHD, with no effect on convergent thinking abilities. Recent findings led to questioning the specific roles of norepinephrine and dopamine on creative cognition in ADHD. Furthermore, baseline heart rate variability (HRV), a measure of autonomic nervous system functioning, may be related to creativity in ADHD. However, the full range of effects of stimulant medication on HRV pertaining to creativity in those with ADHD is not known. In the present study, seventeen adults with ADHD attended two sessions: one after taking their prescribed stimulant dose, and one after withholding the dose. Resting autonomic nervous system functioning was assessed using HRV at both visits. Participants completed convergent problem-solving and divergent generative tasks at both sessions in a counterbalanced fashion. We hypothesize 1) that an inverted u-shape relationship exists between HRV and creativity in adults with ADHD. We also expect 2) HRV will be lower on the day stimulant medication is taken compared to control. These results have the potential to reveal important autonomic nervous system relationships with creativity in ADHD.

Title: Brain white matter microstructure and ADHD: A tensor distribution function analysis

Authors: *S. BETTS, J. VILLALON-REINA, L. SALMINEN, P. M. THOMPSON;
Stevens Inst. for Neuroimaging & Informatics, Univ. of Southern California (USC), Marina Del Rey, CA

Abstract: Introduction: Converging evidence suggests that abnormalities in fronto-striatal-cerebellar circuitry contribute to behavioral abnormalities in Attention Deficit Hyperactivity Disorder (ADHD). Diffusion magnetic resonance imaging (dMRI) allows detailed examination of cortico-subcortical white matter (WM) tracts, yielding indices of the network abnormalities thought to arise in ADHD. Altogether, dMRI studies of children and adolescents with ADHD show age-dependent patterns of altered fractional anisotropy (FA), indicative of a developmental delay in neurite density and/or fiber dispersion, in regions associated with executive function and attention. However, findings are inconsistent regarding the direction of effects, regions implicated, and their connection to specific functional deficits of ADHD. Although FA derived from the single-tensor model (FA^{DTI}) is the most widely used metric to characterize (WM) microarchitecture, it is possible that discrepancies in the ADHD literature are partly driven by known limitations in the FA measurement, which performs poorly in regions with crossing fibers. The tensor distribution function (TDF) is an alternative FA measurement that may be used to model multiple underlying fibers by representing the diffusion profile as a probabilistic mixture of tensors. We aimed to reconcile discrepancies in the literature by comparing the ability of FA^{DTI} and TDF-derived FA (FA^{TDF}) to predict ADHD symptom severity in a large sample of adolescents from the Adolescent Brain Cognitive Development (ABCD) Study. Methods: We analyzed brain and behavioral data from 745 children (ages 8.9-11 years, 341F/404M) from the ABCD Study. As ABCD consists of many groups of siblings, we selected one participant from each family to avoid confounding effects of relatedness. Raw scores from the ADHD DSM5 scale of the child behavior checklist (CBCL) were used to evaluate ADHD symptom severity as the primary outcome measure. Higher CBCL scores were predicted by higher FA^{TDF} of the body and genu of the corpus callosum, bilateral anterior corona radiata, bilateral superior corona radiata, bilateral posterior thalamic radiation, bilateral tapetum, and by an average of FA^{TDF} across all ROIs. No associations were found between FA^{DTI} and ADHD symptomatology. Collectively our results show that FA^{TDF} offers superior performance over the traditional single-tensor FA measurement, further emphasizing the utility of FA^{TDF} for assessing microstructural brain alterations in heterogeneous and complex conditions such as ADHD.

Title: Linking neuronal stem cells to circuit wiring decisions in the Drosophila larval motor system

Authors: *J. L. MENG[1], Y. WANG[2], R. A. CARRILLO[2], E. S. HECKSCHER[3];
[2]Dept. of Mol. Genet. and Cell Biol., [3]Mol. Genet. and Cell Biol., [1]Univ. of Chicago, Chicago, IL

Abstract: How circuit wiring is specified is a key question in developmental neurobiology. Previously, using the Drosophila motor system as a model, we found the classic temporal transcription factor Hunchback acts in NB7-1 neuronal stem cells to control the number of NB7-1 neuronal progeny form functional synapses on dorsal muscles (Meng et al., 2019). However, it is unknown to what extent control of motor neuron-to-muscle synaptic partnerships is a general feature of temporal transcription factors. Here, we perform additional temporal transcription factor manipulations—prolonging expression of Hunchback in NB3-1, as well as precociously expressing Pdm and Castor in NB7-1. We use confocal microscopy, calcium imaging, and electrophysiology to show that in every manipulation there are permanent alterations in neuromuscular synaptic partnerships. Our data show temporal transcription factors, as a group of molecules, are potent determinants of synaptic partner choice and therefore ultimately control circuit membership.

Title: Phrenic-specific transcriptional programs shape respiratory motor output

Authors: *A. N. VAGNOZZI[1], K. GARG[1], C. DEWITZ[2], M. T. MOORE[1], J. M. CREGG[1], L. JEANNOTTE[3], N. ZAMPIERI[2], L. T. LANDMESSER[1], P. PHILIPPIDOU[1];

Abstract: Breathing is the most essential motor behavior. The frequency and amplitude of breathing movements are controlled by neural networks residing in the brainstem and spinal cord. Degeneration of these networks leads to respiratory disorders, such as central sleep apneas, and, eventually, respiratory failure. In mammals, contraction of the diaphragm muscle is vital for driving airflow into the lungs during inspiration. Diaphragm contraction is controlled by a single motor input, phrenic motor neurons (MNs) in the cervical spinal cord, making this MN population a critical node in the respiratory network. Despite their essential role, the molecular determinants that control the patterns of phrenic MN activity and their integration into respiratory circuits are largely unknown. We show that Hox5 transcription factors are required for robust and efficient breathing. Hox5 loss renders mice vulnerable to respiratory dysfunction in the first two weeks of life, suggesting that Hox5 mutations may contribute to early life respiratory conditions, such as sudden infant death syndrome (SIDS). We show that Hox5 proteins establish phrenic MN clustering and topography through the regulation of a network of cell adhesion molecules. We find that a subset of cadherins are specifically expressed in phrenic MNs and that loss of cadherin function through conditional disruption of downstream β/γ-catenin signaling leads to phrenic MN cell body disorganization and dendrite displacement. Remarkably, after MN-specific deletion of Hox5 genes, phrenic MN firing becomes asynchronous and erratic due to the selective loss of inhibitory inputs to phrenic MNs. Our results demonstrate that Hox5 transcription factors determine phrenic MN topography and connectivity to generate robust breathing behaviors. Our findings support a model where MN-intrinsic transcriptional programs shape the pattern of motor output by orchestrating distinct aspects of MN connectivity.

Title: Effects of Mechanical Force on Motor system Development in postnatal mouse with Sciatic Denervation

Authors: *Y. USAMI[1], Y. MINEGISHI[2], H. FUNAKOSHI[1], K. TAKAHATA[1], T. KOKUBUN[3];

[1]Grad. Course of Hlth. and Social Services, Grad. Sch. of Saitama Prefectural Univ., koshigaya, Japan; [2]Grad. Course of Hlth. and Social Services, Grad. Sch. of Saitama Prefectural Univ., Koshigaya-shi, Japan; [3]Physical Therapy, Saitama Prefectural Univ., Koshigaya-Shi, Japan

Abstract: INTRODUCTION : The musculoskeletal system is an efficient assembly of tissues that coordinate to enable movement by an order from the central nervous system. Musculoskeletal development needs mechanical stimulation, yet little is known that the electrical signals from a peripheral nerve to muscle affect tendon development. Here, we use a model of the Sciatic Denervation to investigate the impact of electrical signals from the peripheral nerve on musculoskeletal system development in postnatal mice.
METHODS : We used C57BL/6 mice aged postnatal day seven. The sciatic nerves of the lateral hind limbs were cut (Sciatic Denervation: DN). The Contralateral limb was sham-operated (Sham) as a control(n=6/group). We evaluated the muscle and tendon development factors at 3,7,14 post-operated days (POD). The muscle and tendon were examined to determine the expression of Scx is a bHLH transcription factor expressed in tendon cells from progenitor stages and through development, and TGF-b associate with growth factor. For histological evaluation, the limbs were sectioned focus on the Achilles Tendon at 12 μm thickness and stained with Alcian blue, Hematoxylin and eosin, and Picrosirius red to visualize collagen.
RESULTS : Our results show the tendon markers Scx were decreased in DN group tendons compared to sham group as time proceeds.On the other hand, expression of Scx in Sham group tendons increased from from POD3 to POD7 and decreased from POD7 to POD14. TGF-b expression in the tendon at POD3 was higher DN group than Sham group. Histological sections results for the DN group at POD14 suggested clear atrophy of skeletal muscle. The DN group at POD14 caused an immature collagen arrangement in the tendon tissue.
DISCUSSION : We focus on the role of electrical signals from peripheral nerves in motor system development using postnatal mice. Expression of Scx in DN group decreased from POD3 to POD14, so that means electrical signals from peripheral nerves promote Scx expression in postnatal tendon development. We show the functional role of the sciatic nerve in the soleus and gastrocnemius muscle, and these dysfunctions affect achilles tendon development. Signals by the peripheral nerve provide a contraction for the muscle, leading to tensile stress for the tendon. Peripheral nerve resection inhibited the postnatal growth of muscle and tendons. This study demonstrates that mechanical loading or electrical signals from the peripheral nerve affects the postnatal development of musculoskeltal systems.

Title: Sensory coding of limb kinematics in motor cortex across a key developmental transition.

Authors: *R. M. GLANZ, J. C. DOOLEY, G. SOKOLOFF, M. S. BLUMBERG;
Univ. of Iowa, Iowa City, IA

Abstract: Primary motor cortex (M1) plays key roles in the production of movements and in motor learning in adults, but in early development it functions instead as a prototypical *sensory* structure. Throughout the first postnatal week in rats, M1 is strongly activated by self-generated limb movements—especially by the twitches that occur during active (or REM) sleep. Here, we quantify the kinematic features of forelimb movements to reveal receptive-field properties of individual units within the forelimb region of M1. At postnatal day (P) 8, nearly all units were strongly modulated by movement amplitude, especially during active sleep: Large twitches produced significantly more M1 activity than did small twitches. By P12, however, only a minority of units continued to exhibit amplitude-tuning, regardless of sleep-wake state. At both ages, movement direction also modulated M1 activity, though to a lesser extent. Finally, at P12, M1 population-level activity became sparse and decorrelated, accompanied by a substantial reduction in the frequency of "all-or-nothing" M1 responses to limb movements observed at P8. These changes in M1 activity were not due to the disappearance of spindle bursts (10-20 Hz thalamocortical oscillations) before P12. Currently, we are extending this work to identify the mechanisms responsible for the transition to decorrelated activity at P12. Our findings thus far reveal a transition toward a more complex and informationally rich representation of movement long before M1 develops its motor functionality.

Title: Theta rhythmicity during REM sleep functionally integrates behavior with neural activity in primary motor cortex and red nucleus in preweanling rats

Authors: *J. C. DOOLEY, G. SOKOLOFF, M. S. BLUMBERG;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Myoclonic twitches are abundantly produced during REM sleep in skeletal muscles across the body. In infant rats, movements are produced by the red nucleus (RN), with the RN both sending motor commands and receiving sensory feedback from twitches. The RN's role in producing twitches contrasts with that of primary motor cortex (M1), which does not generate motor commands at early postnatal ages. Instead, M1 functions as a sensory structure, processing sensory feedback from self-generated movements, including twitches. By postnatal day (P) 12, the RN also begins to exhibit a continuous theta rhythm (~6 Hz) during REM sleep that promotes sensorimotor integration with other brain areas. At P12, however, REM-associated theta is not present in M1. Because we know that in adult rats, both the RN and M1 collaborate to control movement, we hypothesized that theta emerges in M1 to facilitate coordination of movement-related activity in both structures. To test whether theta promotes sensorimotor integration in the RN and M1, we recorded local field potentials and unit activity in the RN and the forelimb region of M1 in unanesthetized preweanling rats from P12 through P20. Rats were head-fixed but were able to locomote and cycle freely between sleep and wake. Neurons in both the RN and M1 continued to show twitch-related activity through P20. Further, as predicted, we observed the developmental emergence of REM-associated theta oscillations in M1 by P20 that were coherent with theta in the RN. Additionally, neural activity was phase-locked to theta; surprisingly, twitches were also phase-locked to theta, with twitches being more likely during the troughs of the oscillation. Finally, forelimb twitches—but not hindlimb, whisker, or tail twitches—were associated with phase-dependent nesting of fast gamma oscillations (80-100 Hz) within theta in M1. Taken together, these results show how theta during REM sleep promotes the developmental integration of behavior with activity in M1 and the RN. Because the nested fast gamma oscillations in forelimb M1 were specific to forelimb twitches, these results also implicate twitches and twitch-related activity in the development of somatotopically precise functional connectivity between the RN and M1.

Title: Investigation of a human disease variant in GSX2 which alters DNA binding specificity and leads to basal ganglia agenesis

Authors: *L. TWEEDIE[1,2], J. SALOMONE[1,2], S. QIN[1], B. CAIN[1], B. GEBELEIN[1], K. CAMPBELL[1];
[1]Dept. of Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Med. Scientist Training Program, Univ. of Cincinnati Col. of Med., Cincinnati, OH

Abstract: The striatum, a major component of the basal ganglia, is known to derive largely from neural progenitors in the lateral ganglionic eminence (LGE) during embryogenesis. Gsx2, a homeobox transcription factor, is necessary for the correct patterning of neural progenitors in the LGE and ultimately the specification of distinct neuronal subtypes, such as striatal projection neurons. Mice carrying germline *Gsx2* null alleles show severe agenesis of the striatum and do not survive after birth. A recent report in humans (De Mori et al., (2019) *Brain*, 142:2965-2978), identified a homozygous null allele and another homozygous mutation within the GSX2 homeodomain (HD) which changes the "Q" to "R" at amino acid 251 (i.e. $GSX2^{Q251R}$). Both mutations resulted in viable children with similar severe agenesis of the basal ganglia and neurological symptoms including spastic tetraparesis, dystonia, and intellectual impairment. Preliminary electrophoretic mobility shift assays (EMSAs) using mouse Gsx2 with an analogous mutation (i.e. $Gsx2^{Q252R}$) show that this mutant protein can bind a subset of DNA sequences normally bound by WT Gsx2, but with an altered sequence preference more closely analogous to K50 HD factors (e.g. Otx2) than the usual Q50 HD sites of Gsx2. We therefore hypothesized that the $Gsx2^{Q252R}$ mutation leads to aberrant DNA binding and thus a modified gene regulatory network (GRN) which alters LGE progenitor specification and differentiation. To determine the impact of this human variant on basal ganglia development, we generated a mouse model of the $Gsx2^{Q252R}$ HD variant using CRISPR-Cas9. Importantly, the $Gsx2^{Q252R}$ protein is nuclear localized and expressed in progenitors of the mutant LGE. Preliminary characterization of these mutant mice indicates an intermediate phenotype between *Gsx2* null and WT animals, both for gene expression changes and striatal size. These data support the idea that the $Gsx2^{Q252R}$protein maintains proper regulation of some target genes but does not regulate, or inappropriately regulates, other genes. To better understand the impact of this HD variant on the *Gsx2* GRN, we utilized CRISPR-Cas9 to introduce the human variant on a $^{2xFLAG}Gsx2$ background. Future studies will use these $^{2xFLAG}Gsx2^{Q252R}$ mice for CUT&RUN analysis to determine the genomic DNA binding profile of this variant and compare it with our recent findings for WT ^{2xFLAG}Gsx2 (Salomone et al., (2021) *Genes & Development*, 35:157-174). Finally, as $Gsx2^{Q252R/Q252R}$ mice are viable postnatally (unlike germline null *Gsx2* mice), these mice will provide a powerful model to investigate behavioral changes as a result of this mutation.

Title: A pioneering role for striatonigral projections in the formation of the internal capsule and cerebral peduncle: Lessons from Isl1 conditional knockouts

Authors: *J. EHRMAN[1,3], P. MERCHAN-SALA[1], L. A. EHRMAN[2], R. R. WACLAW[2], K. J. CAMPBELL[1];
[1]Developmental Biol., [2]Exptl. Hematology and Cancer Biol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Med. Scientist Training Program, Univ. of Cincinnati Col. of Med., Cincinnati, OH

Abstract: The basal ganglia are a group of subcortical nuclei with known roles in the coordination of voluntary motor programs, aspects of cognition, and the selection of appropriate social behaviors. The striatum is the principle input nucleus of the basal ganglia; disruptions in striatal connectivity are thus implicated in the motor, cognitive, and social dysfunction characterizing neurodevelopmental disorders including autism spectrum disorder and attention-deficit/hyperactivity disorder. Additionally, striatonigral (striatal direct pathway) projections form in close proximity to the ascending (thalamocortical) and descending (corticofugal) tracts of the internal capsule, suggesting that malformed striatal circuits may disrupt adjacent axon trajectories and thereby contribute to the pathology of these developmental disorders. Despite these notions, both the molecular mechanisms underlying striatal circuit assembly and the contributions of striatonigral axons to the establishment of other critical circuits traversing the internal capsule/cerebral peduncle remain understudied. Using *Sox8-EGFP* (striatal direct pathway) and *Fezf2-TdTomato* (corticofugal pathway) BAC transgenic reporter mice in combination with immunohistochemical markers, we show that striatonigral axons precede corticofugal and thalamocortical fiber entry into the internal capsule and forming cerebral peduncle. Thus, striatonigral axons are well positioned to guide the trajectories of descending cortical fibers. To investigate the impact of direct pathway malformation on the development of internal capsule axon tracts, we are using telencephalon- or ventral forebrain-specific *Isl1* conditional knockout (cKO) mice which exhibit selective, early death of striatonigral neurons and disrupted direct pathway axon outgrowth. Both types of *Isl1* cKO mutants show striking defects in descending cortical axons, despite the fact that Isl1 is not expressed in these projection neurons. To examine the molecular processes mediating these axonal trajectory defects, we generated an RNAseq dataset from the embryonic *Isl1* cKO striatum. We have identified and validated differentially expressed genes with roles in cell adhesion, growth cone dynamics, and extracellular matrix composition, focusing on those previously implicated in neurological disorders. Taken together, our findings support a novel role for the striatal direct pathway in pioneering the internal capsule/cerebral peduncle and suggest abnormal development of basal ganglia circuits may contribute to secondary defects in cortical trajectories adding to the pathology of common neurodevelopmental disorders.

Title: Convergence of Drosophila cognitive dysfunction disease models: Corkscrew/SHP2 phosphatase activity in synaptic transmission

Authors: *S. N. LEAHY[1], D. J. VITA[1], C. SONG[1], K. BROADIE[1,2,3];
[1]Biol. Sci., [2]Vanderbilt Brain Inst., Vanderbilt Univ., Nashville, TN; [3]Kennedy Ctr. for Res. on Human Develop., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Corkscrew (Csw; human SHP2) is a protein tyrosine phosphatase that acts downstream of receptor tyrosine kinase (RTK) function as a core regulator of MAPK/ERK signaling. Gain-of-function (GOF) and loss-of-function (LOF) mutants disrupt this key signaling to cause Noonan Syndrome (NS) and Noonan Syndrome with Multiple Lentigines (NSML), respectively. NS and NSML patients are known to manifest a wide variety of shared symptoms, including cognitive dysfunction. This GOF/LOF phenotype convergence is hypothesized to be caused by the increased MAPK/ERK signaling characterizing both diseases, although the exact cause of the cognitive dysfunction is unknown. To address hypothesized synaptic foundations of these cognitive deficits, we dissected Csw/SHP2 roles with disease-relevant mutations at the *Drosophila* neuromuscular junction (NMJ) model glutamatergic synapse. Using two-electrode voltage-clamp (TEVC), we find both GOF and LOF Csw/SHP2 mutations cause significantly increased glutamatergic neurotransmission as measured by excitatory junction current (EJC) recordings (LOF: n=>10 p=<0.0001; GOF: n=>10 p=0.02). We find the Csw/SHP2 requirement to be presynaptic based on evidence from miniature EJC (mEJC) analyses and targeted RNAi knockdown (mEJC: n=>10 p=0.008; RNAi: n=>10 p=0.001). We also find loss of Csw/SHP2 disrupts synaptic vesicle (SV) availability in fatigue and facilitation analyses, suggesting that Csw/SHP2 regulates transmission strength via control of SV availability (fatigue: n=6,7 p=<0.0001; facilitation: n=16,21 p=<0.0001). Additionally, we find the Csw/SHP2 functional role dependent on regulation of synaptic MAPK/ERK signaling. Importantly, we find Csw/SHP2 interacts with Fragile X Mental Retardation Protein (FMRP), an mRNA-binding protein that regulates activity-dependent translation of synaptic proteins, and whose epigenetic silencing causes Fragile X Syndrome (FXS), the most common heritable

intellectual disability and autism spectrum disorder. We find genetic evidence that Csw/SHP2 and FMRP interact to control synaptic function (n=>20 p=<0.0001). Our mEJC analyses indicate FMRP and Csw/SHP2 interact in presynaptic mechanisms of SV release (n=>15 p=0.0001). Importantly, synaptic pERK levels are elevated in both Csw/SHP2 and FMRP mutants. This work has revealed a previously unexplored role for Csw/SHP2 at the synapse, established disease relevant mutations disrupt synaptic function, and discovered an interaction between FMRP and Csw/SHP2, indicating a mechanistic connection between previously unlinked FXS and NS/NSML disorders.

Title: Hyperpolarization-activated cyclic nucleotide-gated channels regulate response probability in the terminals of parvalbumin positive basket cells

Authors: *T. BOCK[1], E. W. BUSS[1], O. M. LOFARO[1], B. SANTORO[2], S. A. SIEGELBAUM[3]; [1]Dept. of Neurosci., Columbia Univ., New York, NY; [2]Dept. of Neurosci., Columbia Univ. Press, New York, NY; [3]Dept of Neurosci., Columbia Univ. Coll P & S, New York, NY

Abstract: Hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels generate the cationic current I_h, which has been found to regulate the excitability of neuronal networks. The function of HCN channels depends, in part, on their subcellular localization. HCN channels are abundantly expressed in the dendrites of pyramidal neurons in hippocampal area CA1 where they act as an inhibitory constraint on dendritic integration and synaptic plasticity. HCN1 is also strongly expressed in presynaptic terminals of parvalbumin-positive (PV+) inhibitory neuron basket cells (PVBC), which provide strong inhibitory control over hippocampal activity. Previous electrophysiological studies in our lab found that application of HCN channel blockers ZD7288 and Ivabradine strongly inhibit IPSCs in CA1 pyramidal neurons evoked by either electrical stimulation or PVBC-specific optogenetic stimulation (see Buss et al., SfN Abstract 2018). To directly investigate the impact of HCN channels in presynaptic terminals, we performed 2-photon imaging in acute brain slices of mice, expressing the fluorescent calcium reporter GCaMP6s specifically in the terminals of PVBCs within CA1. Fast excitatory transmission was blocked with D-APV and CNQX . Bath application of ZD7288 strongly reduced the amplitude of dF/F transients in PVBC terminals elicited by a train of 5 pulses of

electrical stimulation (30 Hz) delivered to the stratum pyramidale. To determine whether this effect was due to a reduction in the Ca^{2+} response to a presynaptic action potential or to a reduction in the probability that the stimulation would elicit an action potential, we examine responses to single electrical stimuli. We found that the Ca^{2+} response of individual terminals to single stimuli was probabilistic; some stimuli elicited a measurable response (successes) and some stimuli failed to elicit a response (failures). ZD7288 did not reduce the amplitude of the successful responses to single electrical stimuli, but rather decreased the probability with which single stimuli evoked a successful response. Thus we conclude that HCN channels in the axonal terminals of PVBCs upregulate the probability of terminal activation (and thus vesicle release) rather than the amplitude of the Ca^{2+} response to such activation.

Title: Angiotensin-converting enzyme non-canonically constrains opioid-sensitive synaptic transmission in nucleus accumbens

Authors: *B. H. TRIEU, B. C. REMMERS, C. TODDES, D. D. BRANDNER, S. S. MORE, P. E. ROTHWELL;
Univ. of Minnesota, Minneapolis, MN

Abstract: Angiotensin-converting enzyme (ACE) is canonically known to regulate blood pressure by cleaving angiotensin I to form angiotensin II peptide primarily in the lungs. However, ACE is also highly expressed in the striatum and particularly enriched in medium spiny projection neurons expressing the Drd1 dopamine receptor (D1-MSNs) that form the striatonigral pathway. The physiological function of neuronally-expressing ACE is unknown though it has been previously reported to degrade neuropeptides. Using a combination of electrophysiology and targeted tandem mass spectrometry in female and male mice, we show

that ACE negatively regulates endogenous Met-enkephalin-Arg-Phe ("MERF"), an overlooked enkephalin opioid peptide that potently constrains excitatory synaptic transmission in a cell-type specific manner. Captopril, a clinically-approved ACE inhibitor, blocked this non-canonical mechanism to enhance mu opioid receptor activation and subsequently induced long-term depression of presynaptic glutamate release onto D1-MSNs. The physiological impact of ACE inhibition on striatal circuits is reflected in behavioral assays that demonstrated reduced conditioned place preference caused by fentanyl but increased reciprocal social interaction following captopril administration in female and male mice. These results provide preclinical evidence for a class of cardiovascular medications that could be repositioned and redesigned toward brain diseases characterized by aberrant striatal pathophysiology.

Title: Aging alters mitochondrial morphology in cholinergic terminals in the basolateral amygdala.

Authors: *D. FREEMAN[1], D. A. TALMAGE[2], L. ROLE[1];
[1]Natl. Inst. of Neurolog. Dis. and Stroke, Bethesda, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Cholinergic projection neurons innervate diverse regions of the brain in highly complex axonal arbors that require a steady energy supply provided primarily through mitochondrial respiration. Axonal mitochondria are morphologically distinct from those in the soma and their structure is specialized to support synaptic activity. Aged mitochondria lose their functional and structural integrity and mitochondrial dysfunction is an early molecular feature of several neurodegenerative diseases including Alzheimer's disease (AD). The effect of aging on the integrity of cholinergic mitochondria has not been explored. The degeneration of cholinergic terminal fields projecting from the basal forebrain is a hallmark of AD, and yet the dynamics of mitochondria in cholinergic axons is minimally understood. The goal of this study was to examine the effects of aging on axonal mitochondrial morphology and localization in cholinergic projections. We used old (30 weeks) and young (4 weeks) mice genetically labeled by the expression of cholinergic acetyltransferase (ChaT) promoter driven tau-GFP for easy

identification of cholinergic axons in fixed coronal sections of the basolateral amygdala (BLA). Mitochondria were labeled with a fluorescent antibody against the voltage-dependent anion channel (VDAC) located on the outer mitochondrial membrane. To compare cholinergic axons versus other axons, mitochondria will be examined in non-ChaT-tau GFP labeled axons stained with pan-axonal markers. We observed an increase in mitochondrial size in cholinergic axons compared to non-cholinergic axons. Cholinergic mitochondria also appeared less spherical than non-cholinergic across ages. Aging further increased mitochondrial size and altered the distribution of spherical and elongated axonal mitochondria. Since mitochondrial size and shape can determine motility and calcium uptake at the pre-synapse, it is hypothesized that changes in mitochondrial morphology alters synaptic activity and axonal branching. These data will provide insights into the dynamics of mitochondria within cholinergic terminal fields and will might reveal key aspects of mitochondrial dysfunction in neurodegeneration and Alzheimer's disease.

Title: The effect of bidirectional regulation of O-GlcNAcylation on neural circuitry

Authors: *S. PHILLIPS, L. MCMAHON;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Effective neuronal circuitry relies on the balance of excitation to inhibition (E/I). E/I imbalances are found in various neurodegenerative diseases like autism spectrum disorders and Alzheimer's disease. Targeting the mechanisms that contribute to and reestablish the E/I balance in the normal and diseased brain provide a fundamental understanding of neuronal circuit function. Our lab has begun to address this by examining the role of protein O-GlcNAcylation and its bidirectional effects on hippocampal excitatory and inhibitory transmission. O-GlcNAcylation is a post-translational modification that involves the O-linked attachment of β-N-acetylglucosamine to Ser/Thr residues on proteins. O-GlcNAc transferase (OGT) and O-GlcNAcase (OGA) add and remove the O-GlcNAc moiety on proteins respectively and is tightly regulated by UDP-N-acetylglucosamine (UDP-GlcNAc) availability via the Hexosamine Biosynthetic Pathway (HBP). Because OGT and OGA are highly abundant in the hippocampus, targeting both enzymes to modify O-GlcNAc plays a significant role in hippocampal synaptic

transmission and neuronal inhibition. Using brain slice electrophysiology, we previously reported that an acute increase in O-GlcNAc using glucosamine, a HBP substrate, or the OGA inhibitor Thiamet-G (TMG), induces O-GlcNAc modification of GluA2 AMPAR subunits triggering an NMDAR independent LTD and dampens pathological hyperexcitability at CA3-CA1 synapses (Taylor et al., 2014 and Stewart et al., 2017). Additionally, an acute increase in O-GlcNAc also induces a LTD of GABAAR mediated transmission and decreases spontaneous IPSC amplitude and frequency. However, the net effect is an overall decrease in the E/I ratio resulting in decreased excitability. While there are several highly selective inhibitors of OGA, identifying effective and specific OGT inhibitors presents its challenges. In this study, we are investigating whether pharmacological inhibition of OGT using OSMI-4 modifies the strength of basal excitatory and inhibitory transmission as well as prevent glucosamine induced LTD at excitatory and inhibitory synapses in rat hippocampal slices. Our preliminary results show that OSMI-4 partially blocks glucosamine-induced depression of sIPSC amplitude, indicating that bidirectional changes of O-GlcNAc regulates hippocampal synaptic transmission and solidify the therapeutic benefits of decreasing O-GlcNAc levels in disease states the exhibit increased O-GlcNAcylation.

Title: Dehydration-induced glutamatergic excitation of the hypothalamic paraventricular nucleus (PVN) dynamically increases local inhibitory GABAergic transmission

Authors: *J. YAMAGUCHI, T. TRUONG, M. A. ANDRADE, G. M. TONEY;
Physiol., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Presympathetic neurons (PSNs) of the hypothalamic PVN mostly lack basal firing in unstressed animals due to the dominance of local GABAergic inhibition. We previously determined that synaptic inhibition of PVN PSNs by GABA is actively maintained by excitatory amino acid transporter 3 (EAAT3)-mediated uptake of L-glutamate (Glu) into synaptic terminals of GABA neurons in the surrounding peri-nuclear zone (PNZ). We termed this mechanism Glu-GABA strengthening (GGS). Here we tested the hypothesis that a physiological challenge that increases sympathetic nerve activity through lamina terminalis glutamatergic excitation of PVN

does so by disrupting the GGS mechanism. Male C57Bl/6 mice were euhydrated (EUH) or water deprived (WD) for 48 h. Contrary to our hypothesis, western blot analysis revealed increased, not decreased, PVN EAAT3 in WD (132 ± 1.2%) compared to EUH (100 ± 9.5 %) mice (P = 0.0210, n=8/group). This result, together with our previous report of reduced PVN expression of the glial Glu transporter GLT-1 (EAAT2) in WD rats, suggests that Glu clearance in PVN is shifted during dehydration from glial uptake by EAAT2 to neuronal uptake by EAAT3, which would be predicted to increase, not disrupt, PVN GGS. To quantify the potential impact of this, mice were instrumented with telemetry transmitters to record arterial pressure and were subsequently WD. As expected, mean arterial pressure (MAP) in WD mice increased from 109.2 ± 2.6 mmHg at baseline to 120.5 ± 2.6 mmHg after 48 h. Unexpectedly, MAP fell below baseline (103.4 ± 3.3 mmHg) upon rehydration, raising the possibility that this could reflect exaggerated PVN GGS that persists upon relative silencing of glutamatergic excitation. To investigate this possibility, we recorded evoked inhibitory post synaptic currents (eIPSCs) and generated a cumulative amplitude curve from 1000 stimuli delivered at 5 Hz to the GABAergic PNZ. The slope (-pA/stimulus) of this relation in WD mice was compared to that in mice lacking GGS due to CRISPR-Cas9 knockdown of EAAT3 expression in PNZ GABA neurons of vGAT-spCas9 mice. Early during the stimulus train (stimuli 1-100), slope values were similar for PSNs from WD (186 ± 0.9) and $PNZ^{EAAT3\text{-}KD}$ (180 ± 0.9) mice. By contrast, the late phase (stimuli 901-1000) slope value in the WD group (52 ± 0.2) was 3X greater than in the $PNZ^{EAAT3\text{-}KD}$ (17 ± 0.1) group. The latter indicates that eIPSCs in WD mice are resistant to rundown/depression and, contrary to our hypothesis, suggests that PVN GGS is enhanced, not diminished, by dehydration. We posit that enhanced PVN GGS may be critical for preserving synaptic homeostasis and preventing excessive PVN-driven sympathoexcitation during dehydration.

Title: Role of a6-nicotinic receptors in alcohol-induced GABAergic synaptic plasticity in cholinergic interneurons in the nucleus accumbens

Authors: *H. A. WADSWORTH[1], E. Q. ANDERSON[1], J. K. MOEN[2], A. M. LEE[3], J. MCINTOSH[4], J. WU[5], J. T. YORGASON[1], S. C. STEFFENSEN[1];

[1]Brigham Young Univ., Provo, UT; [3]Pharmacol., [2]Univ. of Minnesota, Minneapolis, MN; [4]Univ. Utah, Salt Lake Cty, UT; [5]Barrow Neurolog Inst., Phoenix, AZ

Abstract: The prevailing view is that enhancement of dopamine (DA) transmission in the mesolimbic system, consisting of DA neurons in the ventral tegmental area (VTA) that project to the nucleus accumbens (NAc), underlies the reward properties of ethanol (EtOH) and nicotine (NIC). We have shown previously that EtOH modulation of DA release in the NAc is mediated by α6-containing nicotinic acetylcholine receptors (α6*-nAChRs), that α6*-nAChRs mediate low-dose EtOH effects on VTA GABA neurons and EtOH preference, and that α6*-nAChRs may be a molecular target for low-dose EtOH. Thus, the most sensitive target for reward-relevant EtOH modulation of mesolimbic DA transmission and the involvement of α6*-nAChRs in the mesolimbic DA reward system remains to be elucidated. The aim of this study was to evaluate EtOH effects on GABAergic modulation of VTA GABA neurons and VTA GABAergic input to cholinergic interneurons (CINs). Injecting DIO channel rhodopsin-2 (ChR2) viral constructs into the VTA of VGAT Cre mice, we found that VTA GABA neurons send an inhibitory projection to CINs, replicating what has been demonstrated by others. Low-dose EtOH enhanced GABAergic input to VTA GABA neurons via typical $GABA_A$ receptors that was blocked by knockdown of α6*-nAChRs by α6shRNA or superfusion of the α6-conotoxin MII[H9A;L15A]. VTA GABA neurons expressing α6*-nAChRs projected to NAc CINs and EtOH reduced GABAergic input to CINs via atypical $GABA_A$Rs. Ethanol enhanced CIN firing rate which was blocked by knockdown of α6*-nAChRs or MII. This study also investigated plasticity at this VTA-NAc GABAergic synapse. The baseline firing rate of CINs was markedly enhanced by knockdown of α6*-nAChRs, CINs were not activated by EtOH in EtOH-dependent mice, and low frequency stimulation (LFS; 1 Hz, 240 pulses) caused inhibitory long-term depression at this synapse (CIN-iLTD) which was blocked by knockdown of α6*-nAChRs, MII, atypical GABA receptor antagonists, and in EtOH-dependent mice. Taken together, these findings suggest that EtOH affects the VTA GABAergic projection to CINs via α6*-nAChRs and that atypical GABA receptors play a role in plasticity associated with chronic EtOH at this synapse.

Title: Volatile anesthetics interfere with presynaptic cGMP signaling in mouse hippocampal neurons

Authors: *I. A. SPEIGEL[1], V. OSMAN[2], H. C. HEMMINGS JR[3];
[1]Dept. of Anesthesiol., [2]Dept. of Pharmacol., Weill Cornell Med., New York, NY; [3]Dept Anesthesiol & Pharm, Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Volatile anesthetics alter essential presynaptic functions including Ca^{2+} influx and neurotransmitter release, promoting unconsciousness and amnesia. Nitric oxide and cyclic guanosine monophosphate (NO/cGMP) signaling is implicated in several presynaptic mechanisms, and animal models of disrupted NO/cGMP signaling have altered sensitivity to volatile anesthetics. We investigated these pathways in relation to volatile anesthetic action in hippocampal neurons using pharmacological tools and genetically encoded biosensors for interrogating cGMP levels. Using the fluorescent biosensor cGull we found that activity-driven NMDAR-independent presynaptic cGMP transients were depressed by isoflurane or sevoflurane. Isoflurane and sevoflurane depression of action potential-evoked increases in presynaptic Ca2+ and SV exocytosis was blunted in neurons expressing the cGMP scavenger sponGEE, an effect recapitulated by inhibiting HCN1, a cGMP modulated effector that normally facilitates glutamate release. HCN1 had a distinct contribution to isoflurane depression of GCaMP6f-measured presynaptic Ca^{2+} in somatostatin^{+} and VIP^{+} interneurons, which differ in expression of cGMP signaling components. We propose that volatile anesthetics depress presynaptic cGMP signaling and downstream effectors like HCN1 which normally sustain presynaptic function and excitability, enabling volatile anesthetics to depress neurotransmission via second messenger signaling.

Title: Synaptotagmin-7a potentiates facilitation of $Ca_v2.1$ channels

Authors: *A. DJILLANI, W. CATTERALL;
Univ. Of Washington, Seattle, WA

Abstract: Voltage-gated calcium channel $Ca_v2.1$ undergoes Ca^{2+}-dependent facilitation and inactivation, which play key roles in short-term and long-term synaptic plasticity. In the

presynaptic terminal, $Ca_v2.1$ channels conduct P/Q-type Ca^{2+} currents and form large complexes with up to one hundred presynaptic proteins, including synaptotagmins. Synaptotagmin-7, a high Ca^{2+} affinity sensor, is essential to mediate synaptic plasticity in several types of synapses. In this study, we have investigated the role that synaptotagmin-7α, the main isoform in the brain, may play in regulation of $Ca_v2.1$ channel facilitation by calmodulin and neuronal Ca^{2+} sensor proteins. We found that synaptotagmin-7α co-immunoprecipitates with the α_{1A} subunit of $Ca_v2.1$ channels in lysates from mouse brain presynaptic membranes and from co-transfected tsA-201 cells through interaction with the synaptic protein interaction (synprint) site in the intracellular linker between domains II and III. Interaction of $Ca_v2.1$ with synaptotagmin-7α potentiates facilitation in several paired-pulse and repetitive-stimulation protocols and accelerates the onset of facilitation. In addition, synaptotagmin-7α induces a significant depolarizing shift in the voltage-dependence of activation of $Ca_v2.1$ and decreases the peak Ca^{2+} current amplitude due to enhanced Ca^{2+}-dependent inactivation. Our results taken together identify a new interaction between $Ca_v2.1$ channels and synaptotagmin-7α in vivo and in vitro, mediated through the synprint site, which potentiates $Ca_v2.1$ facilitation and modulates other aspects of $Ca_v2.1$ channel function in the brain. This unexpected protein interaction reveals a mechanism for convergent regulation of $Ca_v2.1$ function and synaptic facilitation by neural Ca^{2+} sensor proteins and synaptotagmin-7, providing
new insights into the role of $Ca_v2.1$ channel modulation in synaptic plasticity. Supported by NIH Research Grant R35 NS111573.

Title: Cross-talk between active zones is essential for short-term plasticity in hippocampal mossy fiber

Authors: *N. SINGH, S. NADKARNI;
Indian Inst. of Sci. Educ. and Res. Pune, Pune, India

Abstract: Granule cells in the dentate gyrus are an important junction for information processing and transfer in the hippocampus. These cells project onto CA3 pyramidal neurons via mossy fibers (MF). MFs have a complex ultrastructural organization: multiple active zones (AZ)

coupled to voltage-dependent calcium channels (VDCC) and an associated readily-releasable pool (RRP) of vesicles. This synapse shows characteristic forms of short-term plasticity (STP) essential for its role as a transmission line and a pattern separator. Upon stimulation it rapidly transitions from a low release probability (Pr) to a high Pr synapse. Loose coupling between active zones and VDCC, and large inter-AZ distance maintains low basal release probability—necessary for large facilitation—despite a large number of AZs. Large RRP size ensures that the vesicles do not deplete at high release probability. However, the implication of this elaborate synaptic design on STP is not well understood.We developed a physiologically realistic spatial model of the MF bouton to explore the role of the structural and biochemical properties that orchestrate synaptic signaling and plasticity. Our study quantitatively describes the synaptic basis for short-term plasticity at MF. MFs, unlike the CA3 presynaptic terminal, have several release sites, each seemingly associated with a distinct source of calcium. Accordingly, most studies consider MF as an extension of the CA3 terminal with multiple autonomous lines of signal transmission. In a direct contrast, our in-silico approach shows not only that calcium crosstalk across multiple release sites exists, but also that this communication is crucial for the observed plasticity. Apart from the coupling between the release sites, the biophysical properties specific to a family of calcium sensors for vesicle release, synaptotagmin-7 (Syt7), and local buffer saturation contribute to the observed facilitation. Furthermore, we show that this synapse can multiplex between the autonomous activity of AZs and coupled activity of AZs during a train stimulus that affects release transients and consequential information transmission.

Title: Enhancement of input frequency dependent information integration in hippocampal granule cell.

Authors: *N. NAKAJIMA[1], T. KAMIJO[2], H. HAYAKAWA[1], T. AIHARA[1];
[1]Tamagawa Univ., Tokyo, Japan; [2]Grad. school of medicine, Univ. of the Ryukyus, Okinawa, Japan

Abstract: Hippocampal dentate granule cell (GC) was received spatial (place) and non-spatial (e.g., odor) information via entorhinal cortex (EC). Spatial information is input from medial EC (MEC) through the medial perforant pathway (MPP) to the medial dendrite (MD) of GC. On the other hand, non-spatial information is input from lateral EC (LEC) through the lateral perforant pathway (LPP) to the distal dendrite (DD) of GC. It was known that theta and gamma rhythmic

inputs from MEC and LEC are received MD and DD during associate learning, respectively. However, it is not clear how the GC integrate information for these inputs. First, to investigate the frequency-response characteristics of MD and DD, electrophysiological experiments were performed using rat hippocampal slices. A pulse train consisted of 10 pulses at 10-40 Hz was applied to DD and MD of GC through the LPP and MPP, respectively. D-AP5, NMDA receptor antagonist, was applied to block synaptic plasticity by high frequency stimulation. In addition, picrotoxin, GABAA receptor antagonist was applied. As the physiological experimental result, responses were transiently decreased at MD of GC, in the both cases, with and without inhibitory inputs. On the other hand, DD showed sustained responses to 10-30 Hz. However, when inhibitory inputs were blocked, DD did not show sustained response. Next, computer simulation was performed using a multi-compartment model of the GC by using NUERON simulator. The model was fixed by parameter fitting for the physiological experimental data. MD and DD were applied theta burst (8 Hz) and random pulse input (10-40 Hz, gamma), respectively. As the computational result, the temporal-pattern sensitivity for burst inputs was not clear when theta burst was applied to MD. When random pulse inputs were simultaneously applied to DD at 10 Hz, GC activation for theta burst was enhanced. Moreover, 20Hz-30Hz random pulse inputs were simultaneously applied to DD, GC activation was more facilitated so that temporal pattern sensitivity for theta burst was clearly observed. However, 40 Hz random pulse inputs were simultaneously applied to DD, temporal pattern sensitivity for theta burst was broad. Our results suggest that temporal-pattern processing of spatial information was enhanced by non-spatial information at 10-30 Hz in GC.

Title: The lateral perforant path as a low-pass filter to the dentate gyrus: substrates and LTP-related interactions

Authors: *J. QUINTANILLA[1], B. G. GUNN[2], J. C. LAUTERBORN[3], Y. JIA[1], C. D. COX[4], C. M. GALL[5], G. LYNCH[1];
[1]Univ. of California, Irvine, Irvine, CA; [3]Dept Anat. & Neurobio., [4]Anat. and Neurobio., [2]Univ. of California Irvine, Irvine, CA; [5]Anat. and Neurobio., Univ. of California, Irvine, CA

Abstract: Despite its critical role in episodic memory, little is known about how the lateral perforant path (LPP) filters and transforms incoming signals from cortex to hippocampus. The present studies used hippocampal slices from mouse (C57BL6) to investigate such transformations across the first node of the hippocampal circuit, the dentate gyrus (DG), using short trains of stimulation delivered to the LPP at frequencies corresponding to three prominent cortical rhythms. A ten-pulse train applied at 5 Hz (theta frequency) caused a modest enhancement of DG fEPSPs that fell to baseline levels (pulse 10: 97 ± 3% baseline, n=21), while gamma (50 Hz) stimulation quickly drove DG responses to below baseline levels (pulse 10: 57± 3%, n=22). Beta trains (20 Hz) produced intermediate effects (pulse 10: 93 ± 3%, n=22.). Outputs (population-spikes) of the target granule cells underwent parallel but larger within-train changes. By lowering the external calcium levels, we tested whether reducing the initial release probability (*p*) attenuated the within train suppression observed following LPP-stimulation at higher frequencies. Reducing extracellular calcium shifted the gamma frequency response profile from a marked depression to consistent facilitation (pulse 10: 148 ± 8%, n=13) with similar increases to theta (pulse 10: 127 ± 10%, n=10) and beta (pulse 10: 178 ± 10%, n=12) stimulation. Interestingly, treatment with the $GABA_AR$ antagonist, picrotoxin, had no significant influence on the depression seen at gamma stimulation. Within this system, long-term potentiation (LTP) is dependent upon stable presynaptic modifications that result in reductions in the paired pulse ratio (Wang et al. 2016) indicating an increase in *p*. Based on the results mentioned above, an increase in *p* would be expected to enhance train suppression, effectively altering the short-term plasticity within the synapses. Indeed, induction of LTP enhanced LPP responses but, as a result, also exaggerated presynaptic filtering to gamma stimulation (pulse 10: 45 ± 5%, n=7). Together, these findings describe unusual properties of LPP terminals that function as a low pass filter. The within-train suppression of responses to gamma stimulation was associated with factors in the presynaptic element as opposed to the recruitment of GABAergic inhibition, and evidence for enhancement of this suppression with LTP reveals novel consequences to memory-related synaptic plasticity to network function.

Title: Dysfunctional longitudinal dentate gyrus network in hearing loss-induced anxiety

Authors: *S. PAK, S. YANG, D. CHO;
City Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Anxiety is a characteristic comorbidity of noise-induced hearing loss (NIHL). NIHL causes physiological changes within the dentate gyrus (DG), a subfield of the hippocampus that is known to modulate anxiety. However, it remains unclear which DG circuit underlies hearing loss-induced anxiety. Here, we utilize an NIHL mouse model to investigate short- and long-term synaptic plasticity in DG networks. Animals with NIHL demonstrate increased anxiety-like behaviors which are similar to those observed in response to chronic restraint stress. This behavior is concurrent with enhanced synaptic responsiveness and the suppression of short- and long-term synaptic plasticity in the longitudinal DG-DG network, but not in the transverse DG-CA3 connection. These findings suggest that DG-related diseases can be typified by synaptic alterations of the longitudinal DG-DG network.

Title: Predictable fluctuations in synaptic strength due to natural variation in presynaptic firing rate

Authors: *N. REN[1], A. GHANBARI[2], G. WEI[1], I. H. STEVENSON[1];
[1]Univ. of Connecticut, Storrs, CT; [2]The Jackson Lab., Farmington, CT

Abstract: Many *in vitro* studies have shown how synaptic strength can vary with presynaptic spike timing due to short-term synaptic plasticity (STP). Synapses with short-term depression (STD), for instance, should be weaker when presynaptic firing rates are higher and stronger when rates are lower. However, it is still unclear how the natural fluctuations in presynaptic firing affect synaptic strength *in vivo*. Here we examine natural fluctuations in synaptic strength *in vivo* using large-scale spike recordings from the Allen Institute Neuropixels dataset. Using cross-correlations between neuron pairs, we detect >9,000 putative excitatory synaptic connections between ~4 million neuron pairs using a convolutional jitter method. We then use an extension of the Generalized Linear Model to describe each cross-correlogram and to quantify fluctuations in synaptic efficacy over time. For individual connections, we find that the synaptic

efficacy and presynaptic firing rate often vary substantially over time (both measured on a minute timescale): the mean coefficient of variation of the fluctuations in the presynaptic firing rate is 0.41 (sd = 0.25, n = 9800); the mean coefficient of variation of the fluctuations in the presynaptic firing rate is 0.72 (sd = 0.23, n = 9800). For many connections, the efficacy fluctuations mirror fluctuations in the presynaptic firing rate in patterns consistent with short-term synaptic facilitation or depression. In order to understand the potential mechanisms underlying the relationship between fluctuations in presynaptic firing rate and synaptic efficacy, we fit a statistical model of STP to the observed presynaptic and postsynaptic spike trains - a generalized bilinear model (GBLM). The GBLM describes the postsynaptic spiking with 1) a time-varying baseline rate that is fit using a point process adaptive smoothing, 2) a history term that describes the effect of the recent spiking history of the neuron itself, and 3) a time-varying coupling term that describes how the recent spiking of the presynaptic neuron influences the synaptic strength. We find that, for many connections, the GBLM reproduces the observed efficacy fluctuations, suggesting that these fluctuations can be predicted based on the time-varying presynaptic firing rate and can be, at least partly, explained by a cumulative effect of STP.

Title: Modeling facilitation of asynchronous neurotransmitter release using Monte Carlo simulation of the frog neuromuscular junction active zone

Authors: *R. POAGE[1], G. CHAVIS[1], R. LAGHAEI[2];
[1]Biol., UNC Pembroke, Pembroke, NC; [2]Pittsburgh Supercomputing Ctr., Pittsburgh Supercomputing Ctr., Pittsburgh, PA

Abstract: Computational models allow investigation of presynaptic function in unique ways. Here, we have used a spatially and temporally realistic model of the neuromuscular junction (NMJ) active zone (AZ) that reproduces many *in vivo* experimental findings to investigate molecular events underlying both synchronous and asynchronous fast exocytosis during a short train of action potentials. Some of the critical molecular events believed to underlie neurotransmitter released by an action potential were reproduced in MCell. The resulting model uses spatial and temporal parameters taken from experimental work to assign diffusion and

reaction rates in a Monte Carlo simulation of fast exocytosis at the AZ of the frog NMJ. In prior work by our collaborators, this model showed good agreement with experimental data of synchronous vesicle fusion events that produce endplate potentials at the NMJ. Further. it reproduced the facilitation of synchronous release events seen during and following a short train of physiological stimuli, showing an increased probability of vesicle fusion in the absence of increased calcium influx (Ma et al., 2014; Laghaei et al., 2018). However the ability of the model to recreate the profile of spontaneous (asynchronous) events, presumably those that generate miniature endplate potentials, or mEPPs, have not been fully characterized.Short trains of action potentials applied to the frog NMJ AZ cause the frequency of mEPPS to increase and then to decay to baseline levels with a time course that is best described by a dual exponential (τ_{F1}=47ms ,τ_{F2} =472ms, Zengel & Magleby, 1981). We report that short trains of action potentials applied to this model AZ generate an increase in asynchronous release events. While facilitation of asynchronous vesicle fusion events in response to a single action potential were described well by a single exponential decay, in response to a 100Hz 5-impulse train, the model shows an increase that is better described by a biphasic exponential decay (τ_1=0.44ms, τ_2= 2.3ms) than by any single exponential decay. This decay was more rapid than that observed experimentally.Multiple synaptotagmin 1 and synaptotagmin 7 energy-based rates for calcium ion binding and synaptic vesicle fusion were incorporated into the model, but these modifications of the energy assigned to calcium-binding to these molecules did not greatly improve the model's ability to reproduce asynchronous synaptic activity.

Abstract: Anatomical and physiological compartmentalization of neurons is a mechanism to increase the computational capacity of a circuit, and a major question is what role axonal compartmentalization plays. Axonal compartmentalization may enable localized, presynaptic plasticity to alter neuronal output in a flexible, experience-dependent manner. Here we show that olfactory learning generates compartmentalized, bidirectional plasticity of acetylcholine release that varies across the longitudinal compartments of *Drosophila* mushroom body (MB) axons. The directionality of the learning-induced plasticity depends on the valence of the learning event (aversive vs. appetitive), varies linearly across proximal to distal compartments following appetitive conditioning, and correlates with learning-induced changes in downstream mushroom body output neurons (MBONs) that modulate behavioral action selection. Potentiation of acetylcholine release was dependent on the $Ca_V2.1$ calcium channel subunit *cacophony*. In addition, contrast between the positive conditioned stimulus and other odors required the inositol triphosphate receptor (IP_3R), which was required to maintain responsivity to odors in untrained conditions. These data demonstrate that learning drives valence-correlated, compartmentalized, bidirectional potentiation and depression of synaptic neurotransmitter release, which rely on distinct mechanisms and are distributed across axonal compartments in a learning circuit.

Title: Longitudinal imaging of millions of synapses in vivo reveals that synaptic plasticity in retrosplenial cortex is required for contextual fear learning

Authors: *A. R. GRAVES[1], G. COSTE[1], T. ZHU[1], J. SULAM[2], A. CHARLES[2], R. HUGANIR[1];

Abstract: Synapses are the fundamental unit of the nervous system. They enable rapid communication between neurons and provide a substrate for plasticity that drives adaptive behavior. Synaptic plasticity, the bidirectional control of synapse strength via dynamic regulation of AMPA receptors, is the leading cellular mechanism underlying many cognitive functions, including learning and memory. However, the distribution of memory encoding, storage, and retrieval within vast networks of synapses remains almost completely unknown. Here, we employ longitudinal in vivo imaging of millions of fluorescently tagged AMPA receptors to directly observe the dynamics of endogenous synaptic networks in cortex throughout the entire process of contextual fear learning. We find that synaptic plasticity in retrosplenial cortex is strongly correlated with the strength of fear memory. Further, we show that blocking synaptic plasticity only in retrosplenial cortex—achieved using a conditional NR1 knockout mouse and targeted injections of AAV-Cre into bilateral retrosplenial cortex—significantly impairs fear memory, suggesting that synaptic plasticity in retrosplenial cortex plays an indispensable role in encoding fear learning and memory. Together, these results represent the most detailed spatiotemporal map of learning to date, uncovering the role of synaptic plasticity with brain-region-wide scale at single-synapse resolution in behaving animals.

Title: Serotonin-dependent mechanism of non-associative learning in earthworms

Authors: *Y. KITAMURA, T. NAKAHARA, H. TAKAHASHI;
Kanto Gakuin Univ., Yokohama, Japan

Abstract: We previously reported molecular mechanism of non-associative learning (habituation) in the earthworm. Extracellular recordings from the ventral nerve cord of the earthworm showed that number of action potentials decrease by repeated tactile stimulus to same region of the body wall. It is likely that this habituation is induced due to via serotonin (5-HT) and nitric oxide (NO) signaling, relatively high concentration of 5-HT or NO accelerated habituation. In this study, we further investigated effect of 5-HT receptor antagonists and 5-HT-

related reagent on establishment of habituation. From these results, it is revealed that both 5-HT_2 and 5-HT_3 antagonists inhibit and tryptophan hydroxylase inhibitor delay establishment of habituation. In conclusion, non-associative learning such as habituation in the earthworm by repeated tactile stimulus to the body wall is due to via 5-HT-NO signaling.

Title: Circadian protein TIMELESS regulates cAMP in hippocampus controlling synaptic plasticity and cognitive memory

Authors: *E. BARRIO-ALONSO[1], M. NOTARAS[1], R. ALBERO[3], Y. BOUCHEKIOUA[2], D. P. CALDERON[2], D. COLAK[1];
[1]Brain and Mind Res. Inst., [2]Dept. of Anesthesiol., Weill Med. College, Cornell Univ., New York, NY; [3]Dept. of Systems Biol., Inst. for Cancer Genetics, Columbia Univ., New York, NY

Abstract: Mutations in circadian-rhythm genes are linked to learning and memory deficits. Studies in multiple organisms have revealed that circadian rhythmicity is important for the formation, stability, and recall of memories. This involves the coordinated rhythmic expression of genes, the presence/absence of specific proteins and their active role shaping memory processing. However, the neuronal events underlying the circadian rhythm-mediated regulation of synaptic plasticity and cognitive function is not fully understood.The first set of genes controlling this rhythmicity was described in Drosophila, including TIMELESS, as part of the circadian clock. While mammalian TIMELESS seems to be dispensable in regulating circadian rhythms in the suprachiasmatic nucleus (SCN), TIMELESS does contain a DNA binding domain and has been implicated in DNA damage control. TIMELESS is also indispensable for embryonic development since its embryonic ablation is lethal. Mutations in *Timeless* are associated with numerous cognitive diseases like schizophrenia, autism or familial advanced sleep phase.In this project, we aim to determine, for the first time, the precise role of neuronal TIMELESS in synaptic plasticity and cognitive function in mammals by using conditional TIMELESS mice (*Timeless*$^{fl/fl}$; αCaMKII:CreER^{T2}). TIMELESS deletion led to a poorer performance in short-term spatial memory and contextual fear and tone memory together with significantly increased spine density in TIMELESS CKO hippocampal dendrites compared with

control dendrites *in vivo*. No differences in the sleep phenotype between TIMELESS CKO and control mice could explain these results. In search of the cellular mechanisms, we found that TIMELESS, which follows a circadian regulation in hippocampus, acts as a transcriptional factor that regulates phosphodiesterase 4B (PDE4B) expression. Through PDE4B regulation, we found that TIMELESS regulates cAMP/PKA signaling cascade, leading to a disruption in the AMPA receptor GluA1 phosphorylation activity and therefore affecting the functional properties of the neurons. The results from this study provide insight into the basic principles of how circadian protein TIMELESS participates in the regulation of learning and memory. These results increase our understanding of the etiology of multiple neuropsychiatric/neurodevelopmental diseases.

Title: Immediate early gene induction by trace fear conditioning is preserved in NMDA receptor knockdown mouse hippocampus

Authors: *K. INTSON, R. ISLAM, C. A. MIELNIK, P. ARNOLD, V. MOHN, W. HORSFALL, A. SALAHPOUR, A. J. RAMSEY;
Univ. of Toronto, Toronto, ON, Canada

Abstract: Classical molecular depictions of contextual memory acquisition necessitate NMDA-receptor-mediated induction of immediate early gene (IEG) expression in the hippocampus. Pharmacological NMDA receptor blockade or interference with IEG induction, particularly Arc, greatly impair contextual fear conditioning. Both NMDAR activation and IEG induction are thought to be required for normal contextual fear learning. Here we demonstrate that IEG induction can occur despite dramatic impairments in NMDAR function, and that IEG induction does not correlate with fear learning or memory. Our studies were performed with $Grin1^{KD}$ mice, which have an intron insertion mutation in *Grin1* that causes ~90% knockdown of the gene encoding the obligatory GluN1 subunit for NMDA receptors. Thus, they are a unique model for studying contextual fear memory acquisition in mice with a global hypofunction of NMDA receptors. First, we confirmed using western blot that $Grin1^{KD}$ mice express only 7-15% normal wild-type (WT) protein in the hippocampus. Next, we trained $Grin1^{KD}$ and WT mice to associate a 95dB auditory tone with 0.5mA footshock in a novel context as per typical trace fear

conditioning protocols. Grin1^{KD} mice did not display normal WT freezing behaviour during tone-shock training or when placed in the fear conditioning context 24 hours later. These findings demonstrate expected, profound deficits in contextual fear learning and fear-associated contextual memory in Grin1^{KD} mice. Surprisingly, however, there were no differences in basal or induced IEG expression between WT and Grin1^{KD} mice, including Arc, Fos, Egr1, and Nr4a1. Basal and conditioning-induced CaMKIIa and Dusp1 gene expression also did not differ between WT and Grin1^{KD} mice. Contrary to previous findings, our study suggests that induction of IEG in the hippocampus is not sufficient for contextual memory-related synaptic plasticity, and can occur despite dramatic NMDAR hypofunction. Ongoing experiments are examining whether preservation of the IEG induction pathway in Grin1^{KD}s can be explained by conservation of a subpopulation of NMDARs within their hippocampus, and whether restoration of NMDA receptors to Grin1^{KD} mice in adulthood improves fear conditioning.

Title: Electrophysiological Signature of the Functional Disengagement of the Basolateral Amygdala Over the Course of the Development of a Cocaine Seeking Habit

Authors: *S. STIEBAHL, S. JONES, D. BELIN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The use of cocaine and heroin among young Europeans and Americans has been steadily increasing over the past decade. As such it has never been more important to understand the mechanisms whereby some individuals switch from recreational controlled drug use to habitual and eventually compulsive drug seeking and taking, the hallmark of addiction. In humans, non-human primates, and rodents a shift occurs in the neural locus of control over behaviour from the ventral to the dorsolateral striatum (DLS) over the course of a history of drug use which sets the stage for the development of compulsivity and the tendency to relapse. We have recently shown that this functional shift is driven by a functional transition within the amygdala from the basolateral nucleus (BLA), which is involved in goal-directed behaviour, to

the central amygdala (CeN) which is involved in habits. In rats trained to seek cocaine under the influence of the conditioned reinforcing properties of a cocaine-paired cue, as measured under a second order schedule of reinforcement (SOR), cocaine seeking initially depends on the BLA - Acbc circuit, but when it becomes well-established and habitual, drug seeking relies on dopaminergic mechanisms in the anterior dorsolateral striatum (aDLS), the persistence of which depends on the CeN. The mechanisms underlying these intra-amygdala transitions have not been elucidated. In order to address this progressive shift from early to established cocaine seeking, male Sprague-Dawley rats were trained to seek cocaine under a SOR for 3 or 21 days (N=6 each), time points at which drug seeking is known to be independent of, or mediated by the CeN - aDLS habit system, respectively. Whole cell slice patch-clamp electrophysiology was used to record from pyramidal BLA (N=18) and CeN (N=20) neurons of both groups to determine their intrinsic excitability and spontaneous synaptic activity. While the activity and excitability of CeN neurons did not change between day 3 and day 21, that of BLA neurons was significantly decreased after long-term cue-controlled cocaine seeking. These results show that the switch in neural control over drug seeking when it becomes habitual is accompanied by a decrease in BLA activity which may enable control by the. These findings could indicate an amygdala mechanism by which to re-engage an otherwise downregulated A-O system in addiction.

Title: Self-healing neural codes: Hebbian and homeostatic mechanisms can track evolving neural representations

Authors: *M. E. RULE, T. O'LEARY;
Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Until recently, it was believed that homeostatic processes maintain single-neuron function, stabilizing long-term neural representations in the presence of molecular and synaptic turnover. However, recent experiments have revealed widespread instability not only in the structure of single neurons, but also in their computational function. This "representational drift[1]"

has been found throughout the brain, and occurs even in neural codes for habitual tasks. We examine a type of representational drift observed in the hippocampus[2] and parietal cortex[3]. These areas exhibit population codes with low-dimensional manifold structure that correlates with behavioral variables. However, the relationship between this low-dimensional structure and single-neuron firing rates is unstable, and the neural population code reconfigures over long timescales. Previous works found that such drift is compatible with stable network function in the presence of ongoing supervised[4] or unsupervised[5] learning, and that error correction could stabilize codes that employ discrete, binary neural assemblies[6,7]. We extend these ideas to the case of continuous, low-dimensional manifold representations. We show that drifting codes can be tracked readily via reactivation rather than ongoing relearning. We find that homeostasis and unsupervised Hebbian learning interact to allow neurons to error-correct and track unstable population codes, conferring long-term stability without relying on an external reference. These results suggest that long-term stable learned associations are compatible with continual, and complete, reconfiguration of neural population codes. This highlights a role for Hebbian plasticity in stability as well as learning, and the importance of homeostatic processes in maintaining distributed representations.

Title: Synaptic evidence for the cumulative effects of weak direct current stimulation in spaced learning in rat hippocampus

Authors: *M. SHARMA[1], F. FARAHANI[2], M. BIKSON[3], L. C. PARRA[2];
[2]Biomed. Engin., [3]Dept of Biomed. Engin., [1]City Col. of New York, New York, NY

Abstract: Electric fields generated during direct current stimulation (DCS) are known to modulate activity-dependent synaptic plasticity in-vitro. This provides a mechanistic explanation for the lasting behavioral effects observed with transcranial direct current stimulation (tDCS) in human learning experiments. However, previous in-vitro synaptic plasticity experiments show

relatively small effects despite using strong fields compared to what is expected with conventional tDCS in humans (20 V/m vs. 1 V/m). Leveraging the spaced learning paradigm, we found that DCS applied during repeated bouts of theta burst stimulation (TBS) resulted in an increase of LTP. Weaker TBS and the weakest electric fields of 2.5 V/m resulted in the strongest relative efficacies (12% boost in LTP per 1 V/m applied). These results bridge the gap in terms of efficacy between in-vitro DCS and human tDCS experiments.

Title: Effects of electroacupuncture on post-operative cognitive dysfunction in mice

Authors: *J. Y.-S. HO[1], R. C. CHANG[2];
[1]Sch. of Nursing, The Hong Kong Polytechnic Univ., Hong Kong, China; [2]Lab. of Neurodegenerative Diseases, LKS Fac. of Medicine, Univ. of Hong Kong, Hong Kong, China

Abstract: Postoperative cognitive dysfunction (POCD) is a common complication after surgery which can have a profound impact on the patients. Clinical data suggest that acupuncture before and after surgery may be useful to reduce the cognitive decline. Limited data is available to explain the underlying mechanism. We hypothesize that electroacupuncture (EA) can attenuate inflammation to reduce cognitive dysfunction after surgery. Male C57BL/6N mice (12 weeks old) were divided into four groups: control, laparotomy only, laparotomy + EA, laparotomy + ibuprofen. The EA group mice received EA at Baihui (DU20) and Zusanli (ST36) for 20 minutes each day for 7 or 14 days after surgery. The other groups received physical restriction only. The ibuprofen group served as a positive control. We found that laparotomy caused impairment in recognition memory and associated memory as demonstrated by the novel object recognition test and the Y-maze test. The cognitive decline was attenuated both in the EA and ibuprofen-treated mice. Glial activation was also reduced in EA treated group. Western blot analysis demonstrated that EA could modulate the expression of some synaptic proteins and the phosphorylation of tau

protein. Taken together, our results suggested that EA given after surgery could reduce POCD and the suppression of neuroinflammation may play an important role in its action.

Title: Do we swallow the waste from our brain?

Authors: P. KULKARNI[1], J. LEASTON[1], C. A. GHARAGOUZLOO[2], J. QIAO[1], N. BENS[1], C. F. FERRIS[1];
[1]Ctr. for Translational Neuro-Imaging, Northeastern Univ., Boston, MA; [2]Imaginostics, Inc., Cambridge, MA

Abstract: Ferumoxytol an iron oxide nanoparticle was infused into the lateral cerebroventricle of awake rats to follow its movement and clearance from the brain using MRI. Within minutes the contrast agent could be observed accumulating on the soft palate at the back of the throat (Fig 1). In a subsequent study fluorescent quantum dots were infused into the brain of rats and within 15 min could be observed in the esophagus using microscopy (Fig 2). These imaging studies clearly show the gut is helping to clear waste from the brain.

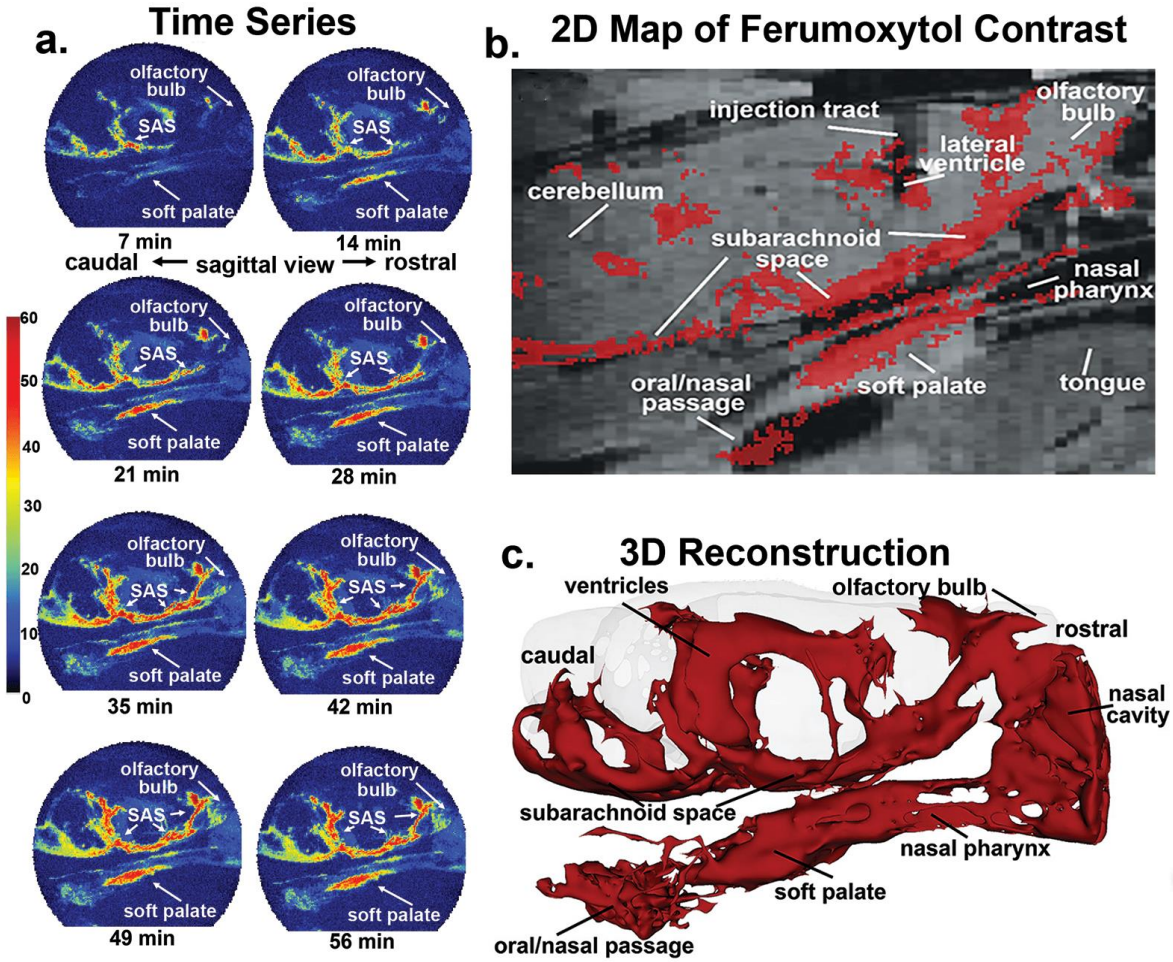

Fig 1. Sagittal reconstructions of ferumoxytol movement and accumulation. The time series (a.) are images from a single rat collected at 7 min intervals over 70 min showing accumulation of CA along the soft palate over time. A summary image (b.) generated as an average of CA signal from six rats is mapped onto the T2 weighted anatomy image of the brain. The 3D reconstruction of CA within and outside the brain was generated from a single rat, postmortem, at the end of the imaging study to eliminate the artifact of blood vessels.

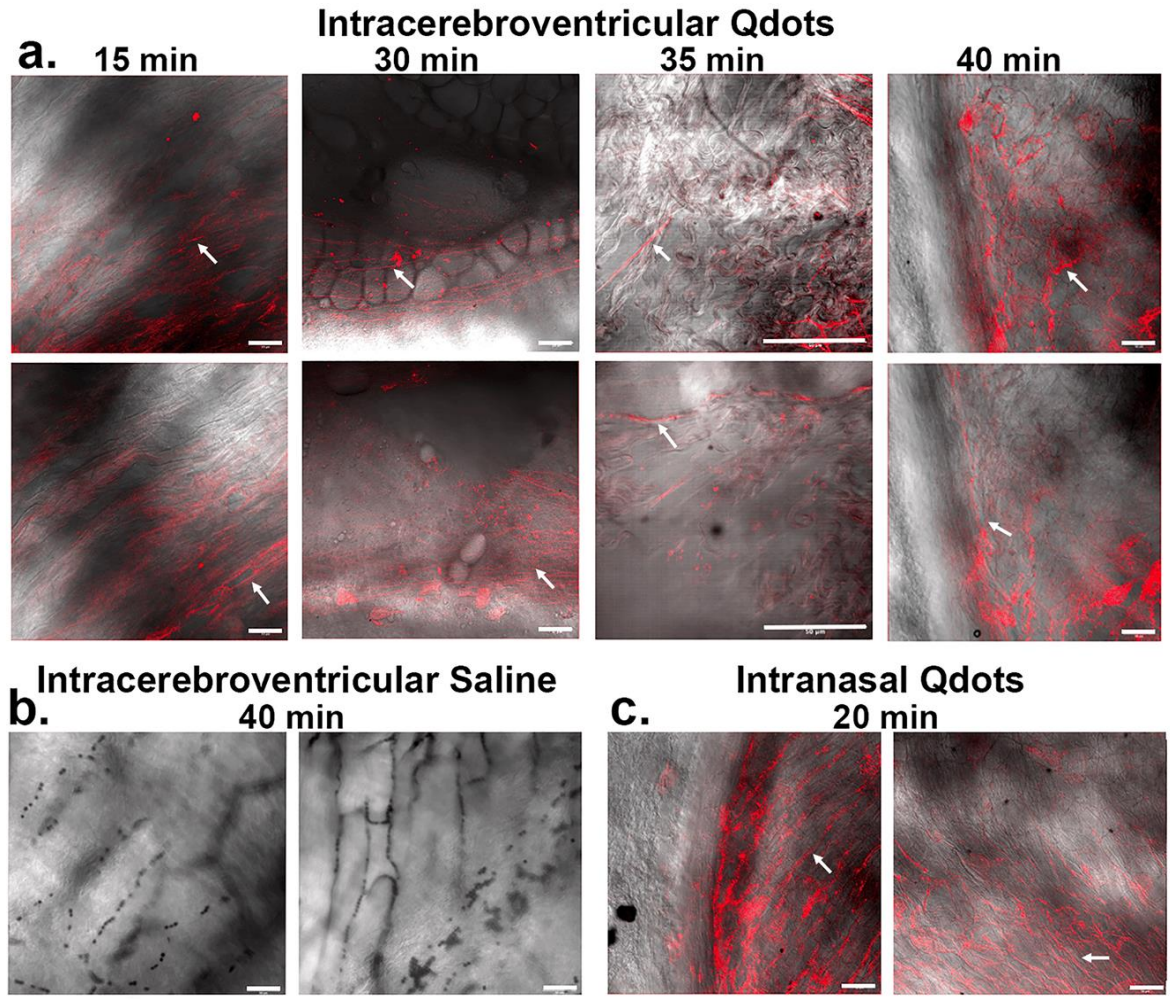

Fig 2. Fluorescent images of the lumen of the upper esophagus. Shown in the upper panel (a.) photomicrographs of the lining of the esophagus from ex-vivo tissue taken at different times following ICV infusion of Qdots. The lower left panel (b.) shows photomicrographs of esophagus from a male rat infused with 10 µl of 0.9% NaCl (saline). The lower right panel (c.) shows the presence of Qdots in the esophagus of a male rat following 1µl injections of Qdots into each nostril.

Title: A resveratrol analog modulates TRH and TRH-like peptide expression throughout the brain and peripheral tissues of male rats

Authors: *A. PEKARY[1], A. SATTIN[2];
[2]Res., [1]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Resveratrol and related polyphenols have therapeutic effects ranging from treatment of depression, Alzheimer's and Parkinson's disease, obesity, neurodegeneration and aging. TRH and TRH-like peptides, with the structure pGlu-X-Pro-NH_2, where "X" can be any amino acid reside, have reproductive, caloric-restriction-like, anti-aging, pancreatic-β cell-enhancing, cardiovascular, and neuroprotective effects. The TRH/TRH-R1 receptor signaling pathway is an important mediator of brain-gut axis communication via the brain medulla. TRH and TRH-like peptides occur not only throughout the CNS but also peripheral tissues, with particularly high levels in rat and human prostate. Female rats were not studied because TRH and TRH-like peptide levels fluctuate 10- to 100-fold in response to the estrus cycle. For these reasons 16 young adult male Sprague-Dawley rats were divided into 4 groups. The control (CON) group remained on ad libitum chow and water for 10 days. The acute (AC) group received ad libitum chow and water for 9 days and then 0.9 g pterostilbene (PT)/250 g rat chow for 24 h. The chronic (CHR) animals received PT in chow for 10 days. The withdrawal (WD) rats received PT chow for 8 days and then normal chow for 2 days. TRH and TRH-like peptide levels were measured in medulla oblongata (MED), frontal cortex (FCX), hypothalamus (HY), amygdala (AY), hippocampus (HC), piriform cortex (PIR), nucleus accumbens (NA), entorhinal cortex (ENT), striatum (STR), cerebellum (CBL), anterior cingulate (ACNG), posterior cingulate (PCNG), prostate (PR), liver (L), testis (T), heart (H), pancreas (PAN), adrenals (AD) and epididymis (EP). Highly significant changes in the levels of TRH and TRH-like peptides occurred throughout the brain and peripheral tissues in response to PT treatment. In brain the number of these changes (in parentheses) declined in the order: PIR(16), HY(15), STR(14), PCNG(12), MED(11), ACNG (10), NA(10), AY(9). In peripheral tissues the corresponding order was: EP(17), PR(13), AD(8), T(4), H(0). We conclude the high responsiveness of PIR, CBL, HY, STR, PCNG, MED, FCX, NA, ACNG and AY in brain and EP and PR is consistent with TRH and TRH-like peptides participating in the therapeutic effects of PT.

Abstract: COMPARATIVE EFFECTS OF AVOCADO (SEED & PULP) ON D-GALACTOSE INDUCED BRAIN AGING IN ALBINO RATS**Saiqa Tabassum[1*], Prashant Tikmani[1], Madiha Shaikh[1], Sameen Fatima Chohan[1], Saara Ahmad[2], Saida Haider[31]**Department of Biosciences, Faculty of Life Science, SZABIST, Karachi[2]Department of Biological and Biomedical Sciences, Agha Khan University, Karachi[3]Neurochemistry and Behavioral Neuropharmacology Research Unit, Department of Biochemistry, University of Karachi, Karachi**Abstract:**Aging is a well-known physiological process of getting older. It has a negative impact on functional abilities of an individual leading to detrimental deficits like cognitive dysfunction. Many factors contribute in brain aging particularly mitochondrial dysfunction characterized by a decrease in the activity of respiratory chain enzymes and ATP production leading to increased free radical generation, mitochondrial deoxyribonucleic acid (DNA) mutations, and impaired mitochondrial structures. D-galactose induced rodent brain aging model, used by previous researchers, is developed by progressive deterioration of brain cells via mitochondrial dysfunction increased oxidative stress, inflammation, and apoptosis contributing to cognitive decline. Persea americana, commonly known as Avocado, is a large berry-shaped fruit which is enriched with lutein and is helpful in improving brain functions. Lutein is a carotenoid which is commonly found in fruits and vegetables that accumulates in the blood, eye and brain. It may act as an antioxidant. So, it can be hypothesized that Persea americana might have neuroprotective properties and it might help in preventing brain aging. For this purpose, aging in rats was induced by D-galactose via oral administration for 6 weeks followed by supplementation of Avocado pulp and seed extract. After induction and treatment, neurobehavioral analysis was conducted followed by decapitation and brain dissection to collect hippocampus and cortex for neurochemical and histological analysis. Results showed that compared to avocado seed extract, avocado pulp is effective in improving spatial memory, muscle strength, anxiety, locomotion, depression and episodic memory and cognitive performance which is further validated by histopathological examination and alteration in levels of GABA and Glutamate. Thus, avocado pulp is found to be effective in preventing D-galactose-induced brain aging and can be suggested as a anti-aging supplement to improve neurological functioning.

Title: Novel adult brain processing method reveals age-, sex-, and species-dependent effects of pharmaceutical compounds on neuron survival and neuritogenesis.

Authors: *A. SEFIANI[1], C. G. GEOFFROY[2];
[1]Texas A&M Univ. Syst. Hlth. Sci. Ctr., College Station, TX; [2]Neurosci. and Exptl. Therapeut., Texas A&M, Bryan, TX

Abstract: Neurodegenerative diseases and neurotraumatic injuries are typically age-associated disorders that can reduce neuron survival, axon and neurite outgrowth, and synaptic plasticity leading to loss of cognitive capacity, executive function, and motor control. In pursuit of reducing the loss of said neurological functions, novel compounds must be identified that augment neuron survival, axon regeneration/neuritogenesis, and synaptic plasticity. However effective high-throughput in-vitro screenings are at finding compounds, most screens use iPSC derived, embryonic, or post-natal neurons. This is a major issue as they are likely to have different characteristics than the targeted neurons in clinical settings. Indeed, the majority of the patients suffering from neurodegenerative diseases and neurotrauma are of middle-age and older. This dichotomy in age between the neurons used in drug screens and patients certainly impedes chances of translational success. It has been historically challenging to culture adult neurons let alone conduct screenings; therefore, age-appropriate drug screenings have previously not been plausible. Thus, we have developed a novel adult neuron processing method and created the first high content morphology-based screening system using adult cortical neurons. This novel method allows for rapid and economical mass processing of large mammalian brains to maximize neuron survival for increased screening capacity. After conducting targeted screens utilizing cortical neurons from 2-year-old sheep (equating to 20-25 years old in humans) and mice of all ages, we have discovered age-, sex-, and species-dependent effects of compounds on neuritogenesis and neuron survival. Demographic-specific screens are expected to 1) prevent the premature dismissal of compounds with no effect in iPSC/embryonic screens yet would be advantageous to adults, 2) reduce the false positivity rate by efficiency vetting compounds with no benefit to adult neurons, and 3) provide quick multi-species validation to better predict success in clinical settings. Therefore, utilizing age-, sex-, and species-appropriate in-vitro models to find novel compounds increasing neuron survival and neurite outgrowth, made possible by our novel neuron processing method, will greatly increase the probability of translational success.

Title: Pharmacologic and non-pharmacologic enhancement avenues targeting the autophagy-lysosomal pathway increase cathepsin B activity, stimulate autophagic flux, and improve synaptic resilience

Authors: *M. F. ALMEIDA, K. M. RENTSCHLER, J. L. NGUYEN, I. GRIJALVA, M. A. DOS SANTOS, M. H. GIANG, K. L. G. FARIZATTO, U. S. IKONNE, B. A. BAHR; William C. Friday Laboratory, Biotech. Res. and Training Ctr., Univ. of North Carolina, Pembroke, Pembroke, NC

Abstract: Exercise and a healthy diet promote cognitive health, influencing the autophagy-lysosomal protein degradation pathway that is also manipulated by synaptic activity and important for memory (Kulkarni et al. 2021 *J Cell Biol* 220:e202002084). The growing incidence of proteinopathies warrants efforts to understand the crosstalk between protein clearance pathways and the targets for modulation (Farizatto et al. 2017 *PLoS ONE* 12:e0182895; Boland et al. 2018 *Nat Rev Drug Discov* 17:660). Interestingly, myokines irisin and cathepsin B (CatB) are elevated in human plasma by exercise of the type that increases BDNF expression and improves memory (Wrann 2015 *Brain Plast* 1:55; Moon et al. 2016 *Cell Metab* 24:332). Irisin was shown to rescue plasticity and memory functions in Alzheimer's disease (AD) mice (Lourenco et al. 2019 *Nature Med.*25:165) and CatB positive modulation increases protein clearance and cognitive measures in models of AD, α-synucleinopathy, and mild cognitive impairment (Mueller-Steiner et al. 2006*Neuron* 51:703; Butler et al. 2011 *PLoS ONE* 6:e20501; Wang et al. 2012 *JBC* 287:39834; Embury et al. 2017 *J Neuroimm Pharm* 12:340; Hwang et al. 2019 *Inter J Mol Sci* 20:4432). Here, we tested whether synapto-protective CatB modulation elicited by peptidyl and non-peptidyl modulators occurs via treatment with plant-derived flavanols, different ginseng extracts, and other plant extracts, to address how diet components influence the autophagy-lysosomal pathway for cognitive maintenance. A select group of the natural products enhanced the 30-kDa active form of the CatB protease (CatB-30) up to 300% in hippocampal explants. Derivatives like BW1002 ([3-(acetyl-benzyl-amino)-1-benzyl-2-hydroxy-propyl]-carbamic acid benzyl ester) typically produced 2-3-fold more CatB modulation than the natural agents. Flavonoid derivatives caused positive effects on the active CatB-30 and synaptic markers. Both pharmacological and non-pharmacological agents were

identified with strong correlations between increased CatB substrate degradation and synaptic resilience indicators. In addition, members of the two groups enhanced the LC3I to LC3II conversion which was confirmed to occur in the presence of the lysosomal inhibitor chloroquine. They also displayed close correspondences between increased levels of CatB-30 and beclin-1, an essential factor for initiation of autophagy, whereas reduced levels were found for p62, a selective autophagy substrate. Thus, the findings indicate that a diverse array of molecules can elicit beneficial effects on the autophagy-lysosomal pathway, perhaps in relation to the role diet plays in supporting brain health and cognition.

Title: Blueberry extract attenuates neuroinflammation and oxidative stress when administered before and/or after lipopolysaccharide in rat microglial cells

Authors: D. S. CAHOON, D. FISHER, *B. SHUKITT-HALE;
USDA-ARS Human Nutr. Res. Ctr. on Aging, Boston, MA

Abstract: Microglia, the primary immune cells of the central nervous system (CNS), are key regulators of inflammation and oxidative stress (OS) in the CNS. In response to stress, activated microglia produce inflammatory cytokines and oxidants to eliminate pathogens and initiate repair. However, overactivation of microglia can be neurotoxic, resulting in reactive microgliosis, a feed-forward amplification of inflammation and neuronal damage. Therefore, microglial activation can continue after removal of the initiating stimulus, leading to chronic inflammation, OS, and neurodegeneration. Blueberries (BB), rich in anti-inflammatory and antioxidant polyphenols, have been shown to reduce inflammation and OS when administered to microglia before stressors such as lipopolysaccharide (LPS), but the therapeutic value of BBs administered after microglial activation has not been examined. This study investigated the differential effects of pre-, post-, and pre-/post-BB on LPS-induced inflammation and OS in microglia.

HAPI rat microglia were pre-treated with freeze-dried BB diluted in media (0.5 mg/mL) or control media (C) for 24h, incubated overnight with LPS (0 or 200 ng/mL), and post-treated with BB or C for 24h. Griess methods, ELISA, and Western blot were used to measure biomarkers of inflammation (nitrite, tumor necrosis factor-α [TNFα], inducible nitric oxide synthase [iNOS], cyclooxygenase-2 [COX-2], phosphorylated IKBα [pIKBα]) and OS (NADPH oxidase [NOX2]). Data were analyzed using two-way ANOVAs with BB treatment period and LPS exposure as experimental factors. Post-hoc testing was performed using Tukey's test.
Results showed that LPS increased nitrite, TNFα, iNOS, COX2, pIKBα, and NOX2 compared to non-stressed control conditions ($P < 0.05$) and BB before and/or after LPS significantly reduced all markers compared to no BB ($P < 0.05$). BB treatment period did not produce significantly different attenuating effects on LPS-induced iNOS, pIKBα, and NOX2. However, pre-BB was more effective than post-BB at reducing nitrite, TNFα, and COX2 ($P < 0.05$). Pre-BB was also more effective than pre/post-BB at attenuating LPS-induced nitrite and TNFα ($P < 0.05$).
Results suggest that BBs can target the downstream effects of microglial activation in addition to preventing stressor-induced neuroinflammation and OS. Therefore, although potentially more effective, BBs may not need to be present prior to microglial activation for beneficial effects. These findings provide evidence to support that dietary interventions may be effective even after initiation of disease processes such as microglial-induced neuroinflammation and OS.

Abstract: The clinical relevance of animal models for diseases, in terms of etiology, symptoms and diagnostic tests, is critical to preclinical efficacy studies. There are as many as ~200 animal models of Alzheimer's Disease (AD) with various symptomatic manifestations. However, the test methods are largely restricted to cognitive behaviors, histopathology and biomarkers, which are either pharmacologically indicative or experimentally terminal.
In an earlier clinical study, it was observed that the phase-amplitude coupling (PAC) of θ and γ oscillations (cross-frequency coupling of brain electrical activities) is impaired in AD patients,

and that the decoupling is progressively associated with dementia (Goodman et al., 2018). We followed the hippocampus local field potential in the 5x FAD mouse model of AD for 12 months, and observed abnormal power and modulation of different oscillations with the progression of disease. In particular, the onset of the aforementioned PAC decoupling was observed as early as in 4 month old model animals, and became almost completely diminished at 12 month. Although histopathological findings (plaque and gliosis) were seen as early as 4 month, cognitive deficiency became significant only at 9-12 month.
Together, our results suggest that PAC decoupling could be used in animal models to monitor the progression of AD. Since the onset of PAC decoupling occurs much earlier in comparison with cognitive behavioral deficiency, it provides a new method to predict the clinical outcome of AD for disease progression and therapeutic efficacy. The clinical relevance of the 5x FAD model and the PAC decoupling further suggests the predictive power of the latter not only in preclinical pharmacological tests but as well clinical tests.

Introduction: The purpose of our study is to determine the protective role of microRNA-455-3p in Alzheimer's disease (AD) progression. MicroRNA-455-3p is one of the highly conserved miRNAs involved in several human diseases but newly explored by our lab in AD. Our past studies unveiled the biomarker and therapeutic potentials of miR-455-3p in AD. Our *in vitro* study exhibited the protective roles of miR-455-3p against AD toxicities in terms of reducing full-length APP and amyloid-β (Aβ) protein levels, inducing defective mitochondrial biogenesis, impaired mitochondrial dynamics and synaptic deficiencies. **Methods:** We sought to determine the essential roles of miR-455-3p in AD using mouse models. Therefore, for the first time, we generated both miR-455-3p (+) transgenic (TG) and miR-455-3p (-) knockout (KO) mouse models. **Results:** We determined the positive and negative effects of miR-455-3p on mice cognitive function, AD proteins, mitochondrial biogenesis, mitochondrial dynamics, mitochondrial quality (number and length), dendritic spine density, synapse numbers and synaptic activity. Morris water maze test showed improved cognitive behavior, spatial learning and memory in miR-455-3p TG mice relative to KO and wild type (WT) mice. AD-related proteins were significantly altered in miR-455-3p TG mice relative to WT and KO mice. Further, mitochondrial biogenesis/dynamics and synaptic activities were enhanced in miR-455-3p TG mice, while these were reduced in KO mice. Overall, miR-455-3p TG mice displayed protective impacts and miR-455-3p KO mice exhibited deleterious effects in relation to AD pathogenesis. **Conclusions:** Both mouse models could be ideal research tools to understand the molecular mechanism of miR-455-3p in other human diseases including AD.

Title: Effect of vanadium pentoxide (V_{2O5}) inhalation on memory and cytoskeleton alterations in brain structures related to Alzheimer disease

Authors: C. DORADO-MARTINEZ[1], E. MONTIEL-FLORES[2], J. ORDOÑEZ-LIBRADO[1], A. GUTIÉRREZ-VALDEZ[2], O. MEJÍA-GARCÍA[1], J. ESPINOSA-VILLANUEVA[2], L. REYNOSO-ERAZO[2], *M. AVILA-COSTA[2];
[1]Neurosci., UNAM, Tlalnepantla, Mexico; [2]Neurosci., UNAM, Neuromorphology Lab., Tlalnepantla, Mexico

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative pathology worldwide; it has been reported that approximately 15 million people suffer from this disease. The incidence annually increases 0.5% in 65 and 8% in 85 years old. However, it was described that more than 100 years ago, and there is a lot of research being done about this pathology, it has been challenging to find an animal model that replicates all the characteristics of the neurodegenerative process of Alzheimer's. Previous experiments in our laboratory have shown that chronic exposure to vanadium pentoxide in rats causes morphological and behavioral changes similar to those seen in AD. To this end, 20 male Wistar rats were randomly divided into control and experimental group (n = 10) with an initial weight of 180-200 gr. The experimental group was exposed to 0.02M V2O5 1 h, 3 times a week, for 6 months. The two groups were trained in the T-maze test to determine behavioral changes that assess spatial behavior and an open-field test for 10 mins. Both groups were evaluated once a month for 6 months. After 6 months of inhalation, the hippocampal CA1 underwent argentic Bielschowsky impregnation and was analyzed to determine histological alterations. The T-maze show memory impairment since three months of V2O5 inhalation. During the open field test, differences were observed in the locomotion patterns of the experimental group. Motor activity decreased while freezing increased. Freezing behavior in control rats is nearly absent, this immobility behavior appears in rats exposed to V2O5 from the first month. Bielschowsky impregnation showed strong argyrophilic and collapsed somas and typical flame-shaped in all V-exposed rats hippocampus CA1 compared to controls. We also observe somatodendritic distortions. Axons and dendrites displayed thick dark bands replaced by noticeable thickening and nodosities and the cytoskeleton fibrillary proteins' linear traces. Our findings suggest that V_2O_5 inhalation induces Alzheimer-like cell death with evident cytoskeletal alterations.

Title: Deep brain theta-burst optogenetic stimulation of the septohippocampal fibers in fornix improves memory performance in an Alzheimer's disease mouse model

Authors: E. CARMICHAEL, E. VICO VARELA, F. MANSEAU, G. ETTER, J. CHOI, ***S. WILLIAMS**;
McGill University, Douglas Res. Center,, Montreal, QC, Canada

Abstract: Electrical stimulation of the Fornix has been proposed to be an effective therapeutic approach to reverse memory loss in Alzheimer's disease. The Fornix is a white matter bundle containing axons connecting the hippocampus to the medial septum (cholinergic, GABAergic and glutamatergic fibers), the anterior thalamic nuclei and the mammillary bodies. While a large body of evidence shows that lesions of the Fornix lead to memory impairments in rodents and humans, there are only a few studies showing that acute or chronic electrical stimulation of the Fornix using theta-frequency related stimulations can improve memory. This study aimed to determine whether 5Hz optogenetic theta fornix stimulation of septohippocampal fibers was sufficient to rescue memory and what mechanisms may underlie the optogenetic improvements in AD mouse models. Using the hAPP-J20 AD mouse model aged 4-6 months, we show that septohippocampal fibers originated primarily from medial septum GABAergic neurons and that 5Hz optogenetic stimulation of the Fornix resulted in a substantial increase in power at that frequency during wake and REM sleep in the hippocampus. We found that a continuous 4 hours theta optogenetic stimulation between the encoding and recall phase of an object-location memory task rescued memory in the J20 mouse. Memory was also recovered in J20 after a 4Hr theta stimulation in the passive avoidance memory task. Interestingly, J20 mice, but not wild-type controls, showed a striking number of large-amplitude 6-9 ms long interictal spikes (IIS) occurring predominantly during REM and slow-wave sleep but not during wake. We observed that the 4hr optogenetic theta stimulation produced a significant reduction of IIs during REM and slow-wave sleep and that the extent of the decline was correlated with memory performance. We are now using calcium imaging to determine the effects of IIS during sleep. Our data suggest that fornix stimulation of septohippocampal GABAergic fibers is sufficient to improve memory in AD mouse models and that some of the underlying causes of the improvement may be related to the reduction of IIS during REM sleep.

Title: Sex differences in age related modulation of synaptic mitochondrial function in the hippocampus and PFC of Wistar rats

Authors: *G. A. SHAW[1], M. M. HYER[1], A. J. WEGENER[1], S. K. DYER[1], G. N. NEIGH[2]; [1]Anat. and Neurobio., [2]Anat. & Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Mitochondrial activity within the neuron, and specifically within the synapse, has been linked to disorders involving altered cognition, including Alzheimer's disease. These disorders are correlated with advanced age and mitochondrial dysfunction, yet the mechanism behind the increased prevalence of these neurocognitive disorders in women when compared to men has yet to be explored. Using male and female rats to assess neuro-mitochondrial activity across the lifespan, we determined the impact of sex and age on the function of synaptic mitochondria (SynMt) in the hippocampus (HPC) and prefrontal cortex (PFC) - regions susceptible to age-related changes in function. Brains were collected from 18 male and 18 female Wistar rats in either young (75 days), middle aged (6 months), or aged (1 year) groups. The HPC and PFC were dissected for isolation of synaptosomes via Percoll gradient. Oxygen consumption rate (OCR) of the SynMt was assessed using Agilent's Cell Mito Stress Test. Samples were examined for relative density of mitochondria within the synaptosomes using a ratio of Hexokinase I to SNAP25 through protein densitometry. OCR within the SynMt from the PFC and HPC was reduced in middle aged males when compared to young or aged males ($p < 0.0001$). Conversely, OCR within PFC SynMt was elevated in middle aged females compared to young ($p = 0.0323$) and aged females ($p < 0.0001$). OCR in HPC SynMt of aged females was also lower than that of young and middle aged females ($p < 0.0001$). A detailed analysis of mitochondrial dynamics reflected patterns seen in middle aged males, with reductions in basal respiration ($p < 0.0001$), maximal respiration ($p = 0.0006$), proton leak ($p = 0.0003$), ATP production ($p < 0.0001$), and spare capacity ($p = 0.0047$) than other male age groups. Middle aged females had higher basal respiration ($p < 0.0001$), maximal respiration ($p < 0.0001$), proton leak ($p < 0.0001$), ATP production ($p < 0.0001$), and spare capacity ($p < 0.0001$) in both the HPC and PFC than other female age groups. Densitometric analysis indicated young and middle aged females had a similar amount of mitochondria within each synaptosomal sample ($p > 0.05$), but aged female SynMt were reduced ($p = 0.0044$). In males, young and middle-aged animals were again parallel ($p > 0.05$) but aged males showed a considerably higher amount of SynMt within each sample ($p < 0.0001$). These findings shed light on a sex-specific mechanism that may contribute to the observed sex differences in age-related cognitive decline. SynMt show considerable changes in dynamics and respiration in the aging brain, suggesting a vulnerability where mitochondrial decline may contribute to the initiation of disease pathology with aging.

Title: Microglia-derived extracellular vesicles carrying Aβ induce progressive memory impairment and cortico-hippocampal network dysfunction.

Authors: *F. TOZZI[1], C. FALCICCHIA[2], M. GABRIELLI[3], O. ARANCIO[4], C. VERDERIO[3], N. ORIGLIA[2];
[1]Scuola Normale Superiore, Pisa, Italy; [2]CNR- Neurosci. Inst., PISA, Italy; [3]CNR- Neurosci. Inst., Milano, Italy; [4]Dept of Pathol, Columbia Univ., New York, NY

Abstract: Synaptic dysfunction is an early mechanism in Alzheimer's Disease (AD) that involves progressively larger areas of the brain over time. However, how it starts and propagates is unknown. We have previously demonstrated that amyloid-beta (Aβ) released by microglia in association with large extracellular vesicles (Aβ-EVs) alters dendritic spine morphology in vitro, and impairs synaptic plasticity both in vitro and in vivo in the entorhinal cortex-dentate gyrus (EC-DG) circuitry. In this work, we recorded EEG in freely-moving mice by means of chronic electrodes implanted both in the cortex (parietal cortex) and hippocampus (DG) and we investigated whether intracerebral Aβ-EVs injection (or control EVs derived from unstimulated microglia) was capable of altering network activity. In particular, we evaluated epileptic-like discharge looking at the clustered activity and the total number of spikes. Mice were recorded for 2h at 24h or 1, 2, 4 weeks post-injection. We observed that the intracerebral injection of Aβ-EVs can induce a significant increase in the number of spikes, and the total time spent in clustered activity, either at the level of the cortex or the hippocampus, when compared to mice injected with EVs alone, without Aβ (n= 6, 3 months old male C57bl/6j mice). Moreover, spectral analysis revealed that Aβ-EVs injection could induce alterations typical of transgenic models and preclinical AD patients, including spike-wave discharges (SWDs), a typical feature of absence epilepsy episodes. Interestingly, the spreading of synaptic dysfunction was also paralleled by progressive memory impairment. In fact, male mice (C57bl/6J, 3/4 months of age, n = 7) injected in the lateral EC (LEC) with Aβ-EVs and tested 1h, 24h, 2 weeks, 1 and 2 months following the injection, showed an early memory impairment (1h) exclusively confined to LEC-dependent memory tasks such as the novel Object-Place-Context Recognition Test (OPCRT) and then a progressive impairment (24h) also in hippocampal-dependent tasks as assessed by the novel

Object Recognition Test (ORT). This progressive spreading of memory impairment to the hippocampus was not observed in mice injected with Aβ alone or in mice injected with Aβ-EVs and Annexin V (inhibitor of EVs movement), suggesting that EVs contribute significantly to the propagation of memory dysfunction to the hippocampus. In conclusion, our results suggest that EVs carrying Aβ and spreading synaptic dysfunction along the Entorhinal-Hippocampal network, could contribute to memory impairment and propose a new neurobiological mechanism for the progression of AD neurodegeneration.

Title: Effects of age on sexually dimorphic food protection behavior associated with hippocampal cholinergic deafferentation.

Authors: J. R. OSTERLUND OLTMANNS[1], E. A. SCHAEFFER[1], A. A. BLACKWELL[1], S. A. PIETRUCHA[1], H. YANG[1], S. TSAI[2], G. L. KARTJE[2], ***D. WALLACE**[1];

Abstract: Loss of hippocampal cholinergic projection originating from basal forebrain structures has been associated with the progression of Dementia of the Alzheimer’s Type. The role of these fibers in information processing deficits has been debated; however, spontaneous behaviors such as food protection have been observed to dissociate the contributions of hippocampal and cortical cholinergic function. Sexual dimorphism and age are critical factors in the progression of neurodegenerative disorders, yet these factors have not been evaluated in food protection behavior. The current study infused the immunotoxin 192-IgG-Saporin bilaterally into the medial septum to produce selective cholinergic deafferentation of the hippocampal formation. Female and male rats received infusion of the immunotoxin at either three or 18 months of age. Testing in the in the food protection paradigm began six weeks after the surgery. During the five days of testing, rats received two food protection sessions. Each of these sessions involved the rat (dodger) being placed in a transparent cylinder with a same sex conspecific (robber). The dodger was given a one-gram food item to consume, while the robber made multiple attempts to obtain the food item. The number, success rate, and type of food protection behaviors were recorded across all food protection sessions. Rats also received a third session each day in which the

latency to consume the food item was recorded in the absence of the conspecific. Preliminary results indicate that sex and age interact with cholinergic hippocampal deafferentation to influence the organization of food protection behaviors. These observations establish a foundation for future work investigating novel therapeutic interventions that target neuroplasticity within spared cholinergic systems.

Title: Involvement of CNS Luteinizing Hormone receptor in Alzheimer’s Disease pathogenesis

Authors: *M. MEY[1], G. CASADESUS SMITH[2];
[1]Kent State Univ., Kent, OH; [2]Pharmacol. and Therapeut., Univ. of Florida, Gainesville, FL

Abstract: CNS Luteinizing hormone and its receptor have been shown to modulate neuronal plasticity and cognition. Importantly, levels of brain LH are inversely related to levels in the periphery, thus low upon menopause-related upregulation of peripheral LH. Previously, we have shown that downregulation of peripheral LH improves function and plasticity in AD mouse models, improvements that are positively correlated with brain LH. However, whether these improvements are driven directly through the activation of central LHR signaling is not known. Therefore, the current study addresses whether central LHR activation was able to rescue cognitive and neuronal plasticity changes previously observed by peripheral LH downregulation. Female APP/PS1 transgenic and wild-type mice underwent ovariectomy or sham surgery and received ICV hCG or aCSF treatment for 8 weeks. Upon completion of cognitive testing, tissue was collected to determine changes in structural plasticity and Abeta pathology. cRISPR/cas9 methodology was used to study LHR in cell culture. Preliminary data demonstrates the ability of hCG treatment to differentially modulate cognition, pathology, and plasticity markers. This work supports the involvement of LHR in CNS function and begets its further study as a contributor linking menopause and increased AD risk.

Title: Characterizing the role of CD63-related tetraspanins, Tsp42Ee and Tsp42Eg, in Alzheimer's disease-associated synaptic dysfunction at the Drosophila neuromuscular junction

Authors: *E. L. HENDRICKS, F. L. W. LIEBL;
Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: The tetraspanin, CD63, is an established regulator of late endosomal trafficking and previous literature has positively correlated reduced CD63 blood serum levels to cognitive decline in Alzheimer’s disease (AD) patients. AD is characterized by the synaptic accumulation of amyloid beta (Abeta) plaques that result from the proteolytic processing of amyloid precursor protein (APP) by beta- (BACE) and gamma-secretases. CD63 physically interacts with the gamma-secretase complex and, thus, may regulate the cleavage of APP. However, CD63’s potential role in the pathogenesis of AD has not been well described. Therefore, we aim to identify a potential mechanism by which disruptions in the *Drosophila* CD63-related tetraspanins, *tsp42Ee* and *tsp42Eg*, lead to alterations in the endocytic pathway and processing of APP in control and AD-model animals. We find that pre- (*tsp42Ee*) and postsynaptic (*tsp42Eg*) knockdown of the CD63-related tetraspanins increases synaptic localization of two key endocytic proteins, Endophilin A and Dynamin. This increase in endocytic protein levels is coupled with a functional increase in synaptic vesicle internalization, indicating an upregulation of the endocytic pathway. Conversely, AD-model animals overexpressing APP and BACE (APP BACE OE) show a reduction in synaptic vesicle internalization. These opposing results suggest that either CD63-related tetraspanin expression, and subsequent endocytic upregulation, is independent of synaptic Abeta levels or APP BACE OE induces downregulation of these tetraspanins as a compensatory response to Abeta overload. These potential mechanisms align with findings that altered CD63 levels are not causative of AD, but rather a correlative indicator of advanced disease states in AD patients. Downregulation of CD63-related tetraspanins may promote endocytosis in states of compromised endocytic function in APP BACE OE animals and may also reduce CD63-directed cleavage of APP by reducing CD63 association with gamma-secretase. To explore these possibilities, we examine synaptic levels of another gamma-secretase interacting protein and endosomal trafficking regulator, Rab11. Rab11 also regulates the localization of BACE at the plasma membrane and, thus, may influence the production of Abeta. We find that *tsp42Ee* and *tsp42Eg* mutants phenocopy the reduced synaptic Rab11 levels and locomotor deficits observed in APP BACE OE animals, indicating that CD63-related tetraspanins may act upstream of Rab11 to regulate endocytosis and APP cleavage by BACE.

Abstract: Alzheimer’s disease (AD) is the most common form of dementia. Current treatments enhance acetylcholine (ACh) levels in the brain, but do not provide long-term amelioration. Patient and animal model data indicate a link between the cholinergic neuro-modulatory system and the amyloid beta (Aβ) peptide in the pathogenesis of AD. *In vivo* behavioral paradigms attempted to dissect the role of α7 nicotinic acetylcholine receptors (nAChRs) by using different AD mouse models crossed with knock-out mice for the α7 receptor (α7KO), but these studies came to opposite conclusions. In addition, previous work *in vitro* indicated either enhancement or blockade of nAChR function by Aβ of the α7 and β2* subtypes. Thus, comprehensive analysis of *in vivo* interactions between Aβ and the different nAChRs subtypes is essential. Here, we studied the early phase of AD pathology in a mouse model that we previously described, expressing soluble forms of the human Aβ peptide using an adeno-associated (AAV-hAPP) vector. We combined *in vivo* two-photon calcium imaging and *in vivo* patch-clamp electrophysiology in the prelimbic cortex (PrLC) of awake mice with synaptic slice electrophysiology and computational modeling. By analyzing the spontaneous activity of layers 2/3 in the mouse PrLC, we found pyramidal cell (PYR) hyperactivity early in the disease progression. However, Aβ peptide did not induce an increase in the PYR cell activity of α7KO mice. Targeted re-expression of α7 nAChRs in layers 2/3 in α7KO mice restored the activity of α7KO-APP mice to the levels of WT-APP, suggesting a key role of α7 subunits early in the disease. We further showed that PYR cell hyperactivity is due to an Aβ-mediated disruption of nAChRs signaling in parvalbumin-expressing interneurons that is accompanied by a differential

disruption of heteropentameric nAChR subtypes expressed by distinct types of GABAergic interneurons. Despite the massive investment in AD drug development, the majority of phase III clinical trials have failed in the past decade. We provide new experimental evidence to explain why clinical trials targeting α7 nAChR subunits with an agonist likely fail, as the drug target is no longer available. In contrast, heteropentameric nAChRs, are only partially inactivated throughout the disease progression, providing a novel drug target for intervention.

Title: The contribution of glia to the onset of Alzheimer's Disease

Authors: *M. KATER, A. B. SMIT, M. H. G. VERHEIJEN;
Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by cognitive decline and the deposition of amyloid beta plaques and tau tangles. Activated glia cells, such as astrocytes and microglia, surround the amyloid plaques. This activation of glia cells, called gliosis, might be neuroprotective in removal of the plaques, while also detrimental by the release of cytokines by both types of glia damaging neuronal structures. The aim of this study is to determine whether gliosis contributes to early cognitive decline in AD, already before the presence of plaques. The commonly used AD mouse model APPswe/PS1dE9 was used to study the disease. Specific markers of astrocytes and microglia, earlier identified as altered during gliosis, were used to study the onset of gliosis. We found that gliosis is present in young AD-mice before the presence of plaques. These experiments will be followed by pharmacological interference with gliosis to study how this affects cognitive behaviour. Consequently, proteomics by mass spectrometry will be used to identify altered expression patterns of proteins that could identify the underlying molecular mechanisms. Taken together, this approach will provide information about early onset gliosis in AD and, ultimately, how early stage interference might be beneficial in treating AD.

Title: Extracellular neuronal activation triggers Tip60 HAT and HDAC2 subcellular dynamics in the brain: implications for cognition and Alzheimer's disease

Authors: *E. ARMOUR, G. GRECO, F. ELEFANT;
Biol., Drexel Univ., Philadelphia, PA

Abstract: Activity dependent gene control serves as the basis for long term memory formation and is driven by epigenetic mechanisms that regulate dynamic gene transcription in response to neuronal stimulation. Our lab has identified the histone acetyltransferase (HAT) Tip60 as a key regulator in the activity-dependent gene control of synaptic plasticity genes, co-regulating these genes with the histone deacetylase 2 (HDAC2). We recently demonstrated that stimulation of hippocampal neurons *in vitro* promotes Tip60 import from the cytoplasm into the nucleus with concomitant genomic reorganization and synaptic gene activation. Strikingly, we also found that Tip60 is largely excluded from the nucleus in hippocampal neurons from Alzheimer's disease (AD) patients. Nevertheless, whether Tip60/HDAC2 extracellular mediated subcellular dynamics functionally impacts activity dependent gene control and cognition *in vivo* and whether this process goes awry in AD remains to be elucidated. Here, we used immunohistochemistry (IHC) to compare the subcellular localization of Tip60 and HDAC2 in the *Drosophila* brain under normal conditions and in response to stimulation of fly brain neurons *in vivo* either by inducibly activating potassium channels using genetic manipulation or by exposure to natural environmental enrichment (EE) living conditions. Remarkably, we found that both methods of neural induction triggered changes in Tip60 and HDAC2 subcellular localization highlighted by a significant increase of both Tip60 and HDAC2 in the nucleus. These results support a model by which neuronal stimulation promotes import of Tip60 and HDAC2 chromatin modulators into the nucleus to activate neuroplasticity genes. To functionally test the impact of neural activation induced Tip60 subcellular changes, we are mutating Tip60's nuclear import and export signal sequences and assessing the consequences of disrupting Tip60 nucleocytoplasmic shuttling in the fly brain on neuroplasticity gene control, synaptic plasticity and cognition. We are also examining potential Tip60/HDAC2 subcellular disruption in the brain of flies modeling AD. Our studies will provide novel insights into the impact of neural induced Tip60 and HDAC2 nucleocytoplasmic shuttling on activity dependent gene control in cognition and AD.

Title: Neural manifold analysis of hippocampal circuit dynamics during behavior in the 5xFAD mouse model of Alzheimer's Disease

Authors: *S. PRADO[1,2], M. GO[1], Y. LI[1], S. R. SCHULTZ[1];
[1]Dept. of Bioengineering, Imperial Col. London, London, United Kingdom; [2]Dept. of Electronics Engin., Univ. of Santo Tomas, Manila, Philippines

Abstract: In mouse models of Alzheimer's Disease (AD), amyloid or tau protein pathologies result in changes in cortical circuitry, which are particularly evident in the hippocampus. Although several treatment approaches that target amyloid-beta (AB) plaques have shown promising results in reducing their levels in the brain, it remains unclear whether reducing AB leads to cognitive improvement. One key issue is that the effect of amyloid pathologies on memory circuit dynamics at the network level is still not well understood, nor is the effect of these therapeutic strategies on the function of hippocampal-cortical circuits. In this study, we aim to characterize the effects of AB on the dynamics of neural circuits involved in spatial memory. We recorded two-photon calcium imaging data from mice running around a circular track floating on an air-pressurized table during a spatial memory task. Two- to ten-month old wildtype (WT) and transgenic 5xFAD mice were injected with hSyn1-GCaMP6f-mRuby in the hippocampal subfield CA1. To separate out memory encoding and recall processes, the mice were imaged after a week of behavioural training while exploring familiar and novel environments respectively. To track cells across multiple imaging sessions, we registered the motion-corrected images from different sessions using an image from a reference session as a template. ROI segmentation was performed on temporally concatenated videos from different sessions. We used Multidimensional Scaling (MDS) and Uniform Manifold Approximation and Projection (UMAP) as neural manifold learning algorithms to characterise the dynamics of CA1 neural population activity during formation, encoding, storage and retrieval of spatial memories. Both methods consistently revealed low-dimensional structures with datapoints clustered on a

manifold representing the spatial trajectory of the mouse and a cyclic pattern of transitions between network states over time across trials (loops). We compared the neural manifolds recovered from the different groups (5xFAD and WT mice of different ages) using the Fréchet distance between average manifold trajectories, finding a significant difference across groups. Neural manifold analysis methods provide a powerful tool for understanding how populations of neurons coordinate in representing task parameters, and here have allowed us to analyse how AB degrades the neural manifolds for spatial memory encoding and recall. By directly assaying the quality of the neural population representations of task-relevant information, they may also provide a sensitive test of whether AB clearance improves cognitive performance during therapeutic trials.

Title: Unanticipated stability of BDNF expression with aging in the hippocampal mossy fibers and resistance of dentate gyrus granule cells to Alzheimer’s disease neuropathology in a mouse model

Authors: *C. CRISCUOLO[1], H. E. SCHARFMAN[2];
[1]Dementia Res., The Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY; [2]Dementia Res., The Nathan Kline Inst. For Psych. Res., Orangeburg, NY

Abstract: It is well known that the neurotrophin brain-derived neurotrophic factor (BDNF) plays an important role in the developing CNS and in adults. In adults, BDNF contributes significantly to several normal functions, and deficits in BDNF have been implicated in disorders such as Alzheimer’s disease (AD). Most studies in mouse models of AD neuropathology show that hippocampal BDNF protein expression is reduced with age but there has been little chance to evaluate specific hippocampal areas because a specific antibody to BDNF has not been available recently. Therefore, we took advantage of a new antibody to develop a protocol for staining and then reexamined the levels of BDNF protein in specific areas of hippocampus at two ages and in a mouse model of AD neuropathology, the Tg2576 mouse.
For the first part of the study, we optimized an immunohistochemical protocol. For example, different fixation times were tested because previous experience suggested BDNF antibodies are sensitive to fixation. Then we compared Tg2576 mice with their littermates, including both

sexes, and focused on two different time points of the progressive neuropathology: 1) 3 months of age when oligomeric amyloid β (Aβ) is present but plaques are still absent, and 2) older than 11 months of age when plaques have started to accumulate.
Similar to past studies, BDNF protein expression in the mossy fiber axons (MF) of dentate gyrus granule cells (GCs) was strong in WT mice compared to other hippocampal layers. As previously shown in normal adult female rats, BDNF protein in female mice correlated with the stages of the estrous cycle. This result was true in both Tg2576 and WT mice. Surprisingly, BDNF protein expression was strong in Tg2576 mice at both young and older ages. Because BDNF expression increases with neuronal activity and Tg2576 mice show hyperexcitability, we also examined a marker of neuronal activity, ΔFosB. We found a correlation between the levels of MF BDNF protein expression and ΔFosB expression in the GCs. Despite the increase of activity in GCs of Tg2576 mice compared to WT, there was relatively little evidence of intracellular Aβ in GCs compared to pyramidal cells, using antibodies to Aβ (McSA1; 6E10). The results show that MF BDNF protein expression is remarkably stable in the Tg2576 mouse model. Furthermore, the reason that MF BDNF may remain stable could be due to the increased neuronal activity of GCs. Finally, we found evidence for a resistance of GCs to intracellular Aβ that is consistent with the resistance of GCs to insults and injury.

Title: Restoring the potassium chloride co-transporter KCC2 rescues functional deficits associated with Alzheimer’s disease-related mutations in mice

Authors: *I. KERAMIDIS[1], B. B. MCALLISTER[2], J. MEHLA[4], J. BOURBONNAIS[1], D. ISABEL[1], R. SANSONETTI[1], P. DEGAGNE[2], A. G. GODIN[1], M. H. MOHAJERANI[3], Y. DE KONINCK[5];

Abstract: Growing evidence indicates that during early stages of Alzheimer's disease (AD) abnormal brain activity occurs due to disruption of $GABA_A$-mediated transmission. While disrupted $GABA_A$ signaling may result from several mechanisms, recent evidence points to deficits in the potassium-chloride cotransporter KCC2, responsible for maintaining low intracellular chloride in neurons to maintain robust inhibition. In this study, we validate whether KCC2 is downregulated in two transgenic mouse lines that develop AD-like amyloid-beta pathology and symptoms. Further, we examine whether by restoring KCC2 function we can alleviate deficits associated with AD. We found a decrease in the global and membrane protein levels of KCC2 in layer II/III of the prefrontal cortex in 4- and 6-months old 5xFAD mice and 6-months old APP^{NL-G-F} mice as compared to their non-transgenic littermates. Global and membrane KCC2 was also decreased in the hippocampus CA1 pyramidal layer of 6 months old 5xFAD mice. In addition, *ex vivo* chloride imaging revealed impaired Cl^- transport in the 5xFAD mice. Moreover, the power of hippocampal gamma oscillations was decreased in the APP^{NL-G-F} mice, as predicted from deficits in KCC2. Consistent with this prediction, treatment with CLP290, a KCC2 activity enhancer developed by our laboratory, restored the power of the higher band gamma oscillations. Finally, short-term administration of CLP290 in the 5xFAD mice improved spatial memory in the Morris Water Maze (MWM) test as compared to vehicle-treated mice. All together, these results indicate that KCC2 may be a viable target for reversing deficits in $GABA_A$-mediated inhibition in AD and attenuating several symptoms associated with AD pathology.

Title: NU-9, a novel inhibitor of amyloid beta oligomer accumulation as an Alzheimer's Disease neurotherapeutic

Authors: *E. A. JOHNSON[1], K. L. VIOLA[2], M. A. BICCA[2], W. ZHU[1], W. HUANG[2], R. B. SILVERMAN[1], W. L. KLEIN[2];
[1]Chem., [2]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Objective and Rationale: Amyloid beta oligomers (AβOs) are a toxic species elevated in the brains of Alzheimer's disease patients. AβO administration in animals induces tau phosphorylation, synapse deterioration, and memory loss; antibodies selective for AβOs can prevent memory loss in Alzheimer's animal models. In this work, we identified a small molecule, NU-9, that prevents AβO buildup along dendrites of hippocampal neurons treated with amyloid beta (Aβ) monomer, which has the potential to be disease-modifying and neuroprotective in Alzheimer's disease, and characterized necessary components in the cell-dependent molecular mechanism of action. **Methods:** We performed immunofluorescence (15-30 images per condition, blind image analysis) and dot blot (3 bio-replicates per condition), using AβO-specific antibodies developed in-house, on primary E18 rat hippocampal neuron cultures at 14-25 days *in vitro*. All results were replicated in multiple cell cultures. For animal behavior studies, we treated 10-month old 5xFAD mice (4-5 per condition) with NU-9 by oral gavage. **Results and Conclusions:** Addition of NU-9 to neurons for 30 minutes prior to Aβ monomer administration significantly prevented the accumulation of AβOs on the dendrites of hippocampal neurons with approximately 60-80% reduction compared to vehicle. Several experiments demonstrate that the mechanism for this effect is cell-based. First, in media without cells, NU-9 did not reduce AβO formation, nor did conditioned media produced by NU-9 treated cells. Further, treatment of neurons with NU-9 prior to application of Aβ monomer did not reduce the number of unbound, extracellular AβOs, suggesting that NU-9 may act by altering the formation of a specific population of neuron-binding AβOs or by removing certain binding targets. Also, effectiveness of NU-9 was abolished in the presence of the lysosome acidification and fusion inhibitor Bafilomycin A, supporting a lysosome-dependent mechanism. The cysteine cathepsin inhibitor E64, additionally, mimicked the effect of NU-9, leading us to hypothesize that a cysteine cathepsin may be the target of NU-9. In a preliminary study with 5xFAD mice, oral administration of NU-9 also prevented memory loss in 75% of treated mice, allowing them to distinguish a novel object, while all vehicle controls failed. In summary, we have identified a small molecule inhibitor of dendritic AβO accumulation which functions via a lysosome-dependent mechanism, with potential to disrupt a key pathogenic process in Alzheimer's disease.

Abstract: The first FDA-approved drug to treat Alzheimer's disease (AD) in nearly two decades, Aduhelm, unfortunately has minimal efficacy and high dosage requirements in clinical trials, likely due to its preferential affinity for the less toxic, aggregated forms of amyloid beta (Aβ), rather than toxic soluble amyloid beta oligomers (AβOs). Here we report evidence further implicating AβOs as the species most germane to instigating AD, showing that a subpopulation of AβOs probed by a humanized AβO-selective monoclonal antibody induces memory dysfunction in the 5xFAD mice. We show that these AβOs first appear in the 5xFAD mice at 3 months of age, just prior to the onset of memory dysfunction, and that they build up with increasing memory dysfunction. In harmony with these results, intra-ventricular injection of AβOs into Wt mice induces hp-dependent memory dysfunction within 24 hours. Strikingly, intranasal inoculation of the AβO-selective antibody into 6 month-old 5xFAD mice rescued memory function 30 days post-inoculation. We also present evidence that probes based on AβO-selective antibodies are capable of distinguishing 5xFAD mice from Wt in MRI and PET imaging, respectively. These tools substantiate target engagement *in vivo* and hold significant diagnostic potential. A new aspect of the AβO mechanism was found in immunofluorescence experiments which showed 5xFAD mice of increasing age manifested concomitant buildup of AβOs and reactive astrocytes (GFAP). At high resolution, reactive astrocytes could be seen surrounding AβO+ cell bodies and micrometer-wide AβO+ puncta along astrocytic processes, strongly suggesting involvement of AβOs in the induction of reactive astrogliosis. These findings are particularly intriguing given recent studies indicating AD's dependence on astrocytes. One especially interesting study showed that when apolipoprotein E (ApoE), a protein which AβOs associate with at synapses, was knocked out in astrocyte-only populations of P301S mice, AD pathology markedly improved [Wang C, et. al, 2021]. Based on these new results, we propose that ApoE-dependent induction of reactive astrogliosis is triggered by the specific subset of AβOs which induces memory dysfunction in 5xFAD mice.

Title: The conformational scFv antibody NUsc1 protects differentiated human neuroblastoma cells against Aß oligomers toxicity

Authors: *N. R. PINHEIRO, A. L. B. BITENCOURT, M. F. CARRARO, I. S. SANTOS, S. CHEDRAOUI-SILVA, A. SEBOLLELA;
Dept. of Biochem. and Immunol., Univ. of Sao Paulo, Ribeirão Preto, Brazil

Abstract: BACKGROUND: Soluble oligomers of the Aß peptide (AßOs) are neurotoxins linked to synaptotoxicity and neurodegeneration in Alzheimer's disease (AD). AßOs are heterogeneous in conformation and toxicity and the extent to which different Aβ species contribute to the pathophysiology of AD remains uncertain. Antibodies sensitive to conformational differences between Aβ aggregates are powerful molecular tools for understanding the structure and function relationship of AßOs. In a previous work, we selected a scFv fragment antibody, named NUsc1, capable of distinguishing AßOs from both monomeric and fibrillar Aß. Different from other conformational anti-Aß antibodies, NUsc1 preferentially targets a subset of AßOs larger than 50kDa present in AD brain tissue. Here, we investigated the potential of NUsc1 in preventing the toxicity instigated by AßOs to differentiated human neuroblastoma cells. **MATERIAL AND METHODS:** SH-SY5Y neuroblastoma cells were differentiated into mature neurons and challenged with AßOs for 24h, either alone or in the presence of purified NUsc1. AßO binding to SH-SY5Y cells was assessed by immunofluorescence. Viability was evaluated by both MTT and Live/ Dead assays. In parallel,

the impact of NUsc1 on the conversion of AßOs into mature amyloid fibrils was evaluated by both Thioflavin T fluorescence emission and transmission electron microscopy. **RESULTS:** AßO binds to differentiated SH-SY5Y cells rendering a punctate binding pattern, as previously shown in primary neurons. Treatment with AßOs caused a decrease in cell viability followed using the MTT assay, although not leading to cell death. Importantly, the MTT reduction capacity was not affected in cells co-treated with AßOs and NUsc1. We have also compared the neuroprotection conferred by NUsc1 with the protection provided by the IgG monoclonal 6E10 (a pan-Aß antibody). Interestingly, AßO species neutralized by NUsc1 seem to be on-pathway to amyloid fibril formation, since a robust inhibition of AßO-to-mature fibril conversion by NUsc1 was observed. **CONCLUSIONS:** The scFv antibody NUsc1 neutralizes AßO-induced toxicity on differentiated SH-SY5Y cells. In the light of the recent advances in therapeutic strategies to AD based on antibodies selective for aggregated Aß, our data encourages a more in-depth investigation on the potential of NUsc1 to prevent AßO neurotoxicity.

Title: Chronic low dose ionizing radiation therapy for Alzheimer’s disease

Authors: *Y. XU[1], G. KUMAR[2], N. P. B. AU[2], R. C. C. CHANG[3], C. H. E. MA[2];
[1]Dept. of Neurosci., City Univ. of Hong Kong, Hong Kong, China; [2]Dept. of Neurosci., City Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Dept. of Anat., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Alzheimer's disease (AD) is characterized by Beta-Amyloid (Aβ) plaques, neurofibrillary tangles, and neuroinflammation leading to cognitive impairment. The primary role of Aβ peptide in the development of AD is well-known. It induces loss of synaptic connections and disrupts the neuronal circuit in the hippocampus, which contributes to memory deficits. Accumulating evidence suggests that reduction of Aβ accumulation could be a possible mechanism for the amelioration of AD symptoms. In our study, we used Streptozotocin (STZ) induced and transgenic (3xTg-AD) mouse of AD to imitate pathology and evaluate the therapeutic potential of low-dose ionizing radiation. Transgenic model (mutations of Swedish APP, MAPT P301L, and PSEN1 M146V) are linked to the early onset of Alzheimer's disease

and develop the extracellular Aβ deposition, hyperphosphorylated tau, gliosis, and cognitive impairment, as seen in AD patients. A sporadic AD mouse model was developed by intracerebroventricular (I.C.V) injection of Streptozotocin, which induces gliosis, neuroinflammation, and cognitive deficits in mice. The efficacy of low-dose ionizing radiation (LDIR) was evaluated in STZ and 3xTg-AD mouse model to assess the beneficial effect by improving learning and memory. Our results showed that the chronic treatment with LDIR improved the long-term and the short-term memory in both the 3xTg-AD mouse model and the STZ mouse model. We also observed a significant reduction of soluble as well as insoluble forms of Aβ in the hippocampus at early (AD mouse model at 9-month-old) and advanced (AD mouse model at 17-month-old 3xTg-AD mice) stages of disease progression. Also, the 17-month-old 3xTg-AD mice with LDIR treatment have shown a reduction of the hyperphosphorylated tau and the intensity of the microglia in the CA1 area of the hippocampus. Next, we used 3D reconstruction of extracellular Aβ plaques and the microglia in the CA1 area of the hippocampus and observed that LDIR treatment enhances the microglial phagocytotic clearance of fibrillar Aβ form. Furthermore, the western blotting results showed that low dose ionizing radiation could protect the neuron against Aβ by inhibiting the mitochondrial pathway of apoptosis in the hippocampus and the cortex of the 9-month-old and 17-month-old 3xTg-AD mice. In conclusion, chronic low dose ionizing radiation improved the memory in the mice model of AD by reducing the Aβ due to increased microglial phagocytotic activity and restored hippocampus neurons by inhibiting the apoptosis of the mitochondrial pathway.

Title: Non-denaturing isolation of neurotoxic oligomers of the β-amyloid peptide using a conformation sensitive fragment antibody-based assay

Authors: *R. M. CAMPOS[1], A. L. B. BITENCOURT[1], E. N. CLINE[2], M. F. CARRARO[1], W. L. KLEIN[2], A. S. SEBOLLELA[1];

Abstract: BACKGROUND: Soluble oligomers of the β-amyloid peptide (AβOs) are currently implicated in the pathogenesis of Alzheimer's disease (AD). Biochemical identity of those oligomers is debated, including their molecular mass and conformation. Importantly, neurotoxicity of AβOs has been shown to be neutralized by the scFv fragment antibody NUsc1, which preferentially targets a subpopulation of AβOs > 50 kDa. NUsc1 is thus a promising candidate to assist in the isolation and subsequent structure-function characterization of AD-relevant AβOs. In this work, we describe a method for the isolation of NUsc1-targeted AβOs under non-denaturing conditions from either *in vitro* prepared or tissue-extracted AβOs, followed by determination of their molecular mass. **MATERIAL AND METHODS**: NUsc1-functionalized magnetic beads were used in the isolation of AβOs. The complex NUsc1-AβOs was successfully released from beads using imidazole, as followed by Western Blot (WB) and liquid chromatography-mass spectrometry (LC-MS). NUsc1-targeted AβO species were stabilized by chemical crosslinking and molecular mass was determined by WB. Alternately, the NUsc1-AβOs complex was crosslinked and also analyzed by WB. In addition, molecular mass of isolated AβOs was investigated by analytical size-exclusion chromatography (SEC). **RESULTS:** The NUsc1-AβO complex was successfully isolated under non-denaturing conditions from a synthetic AβO preparation. Moreover, 5xFAD mouse brain-derived AβOs were efficiently pulled down by NUsc1-functionalized beads, as revealed by LC-MS. Interestingly, cross-linked AβO species targeted by NUsc1 were larger than 100 kDa, in agreement with results obtained with NUsc1-AβO cross-linked after complex isolation. Determination of molecular mass of NUsc1-reactive AβOs by SEC is ongoing, as well as investigations on the molecular shape of these species. **CONCLUSION:** In combination with other data from our group on NUsc1 neuroprotective actions, our findings indicate that NUsc1 preferentially targets AD-relevant AβO species larger than 100 kDa. This strategy may be applied to investigate mass and conformation of AβO assemblies from other complex samples under non-denaturing conditions, enabling the rationale development of more effective therapeutics to treat AD.

Abstract: Alzheimer's disease (AD) is the most common form of dementia, which affects 47 million people worldwide. There are over five million AD patients over the age of 65 in the U.S. which is predicted to increase to 16 million by 2050. There are currently no approved disease-modifying therapies for AD and attempts to prevent or slow the progression of the formation of beta-amyloid plaques by targeting both the beta-secretase 1 (BACE1) and gamma-secretase enzymes have not yet achieved clinical success. Studies suggest that indirect modulation of the function of these enzymes via G-protein coupled receptors (GPCRs) may provide a novel strategy to reduce A-beta peptide production with potentially less side effects. Among GPCRs that influence amyloidogenesis, the delta opioid receptor (DOR), in particular, has been shown to play an important role in the trafficking and function of BACE1 and gamma-secretase and in the production of A-beta peptide. DOR activation increases BACE1 and gamma-secretase activity *in vitro* and in a mouse model of AD, and antagonism of DOR specifically blocks the amyloidogenic pathway and efficaciously prevents AD progression in mice. These effects were demonstrated using a known DOR antagonist, naltrindole. However, the potential of DOR antagonists as therapeutic agents for AD has yet to be explored.
The aim of this project is to create novel DOR antagonists via medicinal chemistry and identify the most promising lead compound based on binding, selectivity, and functional profile *in vitro*. Further, select a small set of the most promising compounds and evaluate the compound's ability to mitigate AD-like pathology *in vivo* using APP/PS double-transgenic mice. We report here the identification of several selective DOR antagonists with low nanomolar affinity/potency that have been shown to block BACE1 activity *in vitro*. Lead compound SRI-22136, showed systemic stability and blood brain barrier penetration using the *in vivo* tail flick assay in CD-1 mice. SRI-22136 also showed efficacy in Novel Object Recognition (NOR) behavioral studies at a dose of 1mg/kg twice daily for 90 days continuous treatment *in vivo* using the APP/PS AD model double-transgenic mice. We further report our progress in testing this compound's effect on histological and biochemical marker evaluation using the cortex and hippocampus regions of the APP/PS AD model double-transgenic mice.

Title: Variants of amyloid beta peptide improve phenotypes related to amyloid toxicity in Caenorhabditis elegans

Authors: *D. P. QUIJANO GUERRERO[1], A. E. ESTRADA RODRÍGUEZ[1], M. GONZÁLEZ GONZÁLEZ[1], J. VALDÉS RODRÍGUEZ[2], R. VIDALTAMAYO[3], V. ZOMOSA SIGNORET[1]; [1]Univ. Autónoma De Nuevo León, Monterrey, Mexico; [2]Univ. Nacional Autónoma de México, Ciudad de México, Mexico; [3]Univ. of Monterrey, San Pedro, Mexico

Abstract: Amyloid beta peptide (Aβ) aggregation is one of the major hallmarks in Alzheimer's disease (AD) pathogenesis and therefore prevention of Aβ deposition is a relevant strategy in the treatment of AD. The development of aggregation inhibitors using Aβ as a starting point allows to create highly specific peptides as possible drugs. Using this approach, we generated three Aβ peptide variants of 42 amino acids (Aβ-42) by introducing the point mutations M35C, A30W or K28A which all lie in key regions that participate during the aggregation process. *In vitro* assays showed the mutant peptides disorganized and prevented *de novo* aggregation of the wild type peptide. For *in vivo* analysis we used the nematode *Caenorhabditis elegans* which is widely use for the screening of Aβ aggregation inhibitors and the evaluation of their associated effects on behavior. Assays done by feeding a small number of worms with the peptides showed some slightly improvement in N2 chemotaxis and CL2006 and CL4173 paralysis phenotype. In this work, to reduce the risk of peptide degradation and to assure its transportation into all body tissues, we standardized a transduction protocol based on the encapsulation of molecules within lipid vesicles. Using a commercial kit consisting of a lipid formulation (BioPORTER), the fluorescent marker FITC-IgG was delivered into worms of a wildtype strain to assess transduction efficiency. Following, peptide toxicity at three different concentrations (15, 25 and 40µM) was evaluated by treating N2 worms using the transduction protocol and tracking lifespan. Next, we used the muscular Aβ-expressing strain CL2006 to monitor the progression of a Aβ-dependent paralysis phenotype and to evaluate the number of amyloid deposits formed after treatment. Additionally, to relate Aβ toxicity with neurological functions, we treated the neuronal Aβ-expressing strain CL2355 and assayed its chemotaxis response to benzaldehyde. All assays were carried out with three groups of 30 synchronized worms for each treatment. Images obtained by fluorescent microscopy showed the transduction protocol allows the protein to reach all body tissues of the worm. Treatment with the mutant peptides caused a significant extension in N2 worm's lifespan, a significant delay in the onset of the paralysis in CL2006 worms, a slightly reduction in size and number of amyloid deposits and a recovery of the chemotactic index of CL2355 worms. Results suggest these mutant peptides could protect *C. elegans* against

Aβ-induced toxicity, probably due to a neuroprotective and antioxidant effect, and therefore could have a potential application in the development of treatments against AD.

Title: A nasal formulation for the treatment of Alzheimer's disease

Authors: *T. ZIENELDIEN, Y. WANG, J. KIM, N. SHEN, X. LIN, M. MOMMER, C. CAO; Pharmaceut. Sci., Univ. of South Florida, Tampa, FL

Abstract: Due to the complexity of the causes of Alzheimer's disease (AD), combination therapy is considered the most effective approach. Furthermore, the adverse effects from long-term applications also represent a major obstacle in anti-AD drug development. The objective of this research was to develop a nasal formulation with nutraceutical molecules for AD prevention and treatment. The MCT oil-based nanoemulsion formulation was prepared with melatonin, insulin, and THC (MIT). In this case, 12-month-old APP/PS1 mice were used as the animal model and were treated with MIT daily via intranasal delivery for 3 months. Radial Arm Water Maze (RAWM) and plasma Aβ levels were used for grouping and treatment benefit evaluation. Post-treatment RAWM results demonstrated that MIT formulation can significantly decrease errors when compared to the no treatment transgenic mice group (N=9 per group). Blood samples were taken when treated for 1.5 months and at the end of treatment. Though plasma Aβ40 and 42 levels showed no difference among the groups at each time interval, both Aβ40 and 42 levels increased with treatment compared to the pre-treatment sample. Furthermore, brain soluble Aβ showed a tendency to increase during treatment, while the insoluble decreased, but there were no statistically significant differences ($P>0.05$). The flow cytometry analysis of the blood samples showed CD3+CD8a+ increased with MIT treatment ($P<0.05$), and this result implied that the MIT formulation not only targets Aβ but also can strengthen impaired immunity in aged mice. Overall, the MIT formulation appears to be a promising combination therapeutic for AD treatment since all the molecules used in this formula are safe and effective molecules for AD.

Title: Irisin reduces Ab pathology by increasing neprilysin from astrocytes in 3D human neural cell culture models of Alzheimer's disease

Authors: *E. KIM[1], H. KIM[2], M. P. JEDRYCHOWSKI[2], G. BAKIASI[1], B. M. SPIEGELMAN[2], R. E. TANZI[1], S. CHOI[1];
[1]Neurol., Massachusetts Gen. Hosp. / Harvard Med. Sch., Boston, MA; [2]Cell Biol., Harvard Med. Sch., Boston, MA

Abstract: Alzheimer's disease (AD) is the most common form of age-related dementia, characterized by progressive memory loss and cognitive disturbance. Two pathological hallmarks that are crucial in the disease are amyloid plaques and neurofibrillary tangles (NFTs). Physical exercise has been shown to counteract various aspects of AD pathology in animal models: it reduces amyloid-β (Aβ) levels and amyloid deposition in the brain, mitigates tau pathology, attenuates neuroinflammation, and ameliorates cognitive dysfunction. Irisin, a myokine that is cleaved from its precursor protein, fibronectin type III domain containing protein 5 (FNDC5), is a novel exercise-induced myokine which regulates energy metabolism in adipose and is recently considered to be a critical mediator for the beneficial effects of exercise in the brain. Using our three-dimensional (3D) human neural cell culture models of AD (3D-AD cultures) with Aβ-driven NFTs, we recently found that irisin significantly reduced Aβ pathology by increasing the activity/levels of the Aβ-degrading enzyme neprilysin (NEP) potentially secreted from astrocytes. We also identified that integrin αV/β5 acts as an irisin receptor on astrocytes, which was previously reported in bone and fat, and is required for the effects of irisin to enhance NEP-mediated Aβ clearance. Irisin reduced GFAP and S100β protein expression and inhibited STAT3 signaling via integrin αV/β5 in the 3D-AD cultures. Inhibition of IL-6/ERK-STAT3, a key modulator of astrocyte reactivity, was found to contribute to enhancement of NEP-induced Aβ clearance. Our findings suggest that irisin is a potential mechanism of exercise that acts on Aβ pathology which could emerge as a potential therapeutic target for AD.

Title: Alzheimer's disease alters oligodendrocytic glycolytic and ketolytic gene expression

Authors: *E. R. SAITO[1], J. B. MILLER[2], O. HARARI[3], C. CRUCHAGA[3,4,5,6], K. A. MIHINDUKULASURIYA[7], J. S. K. KAUWE[2], B. T. BIKMAN[1];

Abstract: Sporadic Alzheimer's disease (AD) is the most common form of senescence-related dementia, characterized by neurodegeneration that progressively compromises memory and behavior. A growing body of evidence has demonstrated that AD is strongly correlated with impaired glucose metabolism and implicates metabolic dysfunction in disease onset and progression. However, the degree to which glia contribute to glucose hypometabolism and whether ketone metabolism is also impaired in AD is unknown. Because glucose metabolism is altered in AD, ketolysis has been suggested as an alternative pathway to fuel the brain. In the present study, RNA-seq data from postmortem AD brains were used to determine whether dysfunctional AD brain metabolism can be determined by impairments in glycolytic and ketolytic gene expression. Data were obtained from the Knight Alzheimer's Disease Research Center (62 cases; 13 controls), Mount Sinai Brain Bank (110 cases; 44 controls), and the Mayo Clinic Brain Bank (80 cases; 76 controls). These data were normalized to cell type – astrocytes,

microglia, neurons, oligodendrocytes – using cell-specific markers. In oligodendrocytes, both glycolytic and ketolytic pathways were significantly impaired in regions of the brain relevant to memory and cognition. However, ketolytic gene expression was not significantly altered in neurons, astrocytes, and microglia. Generally, these data indicate that oligodendrocytes may be larger contributors to brain hypometabolism and AD pathophysiology than previously thought. These demonstrate a potential link between AD hypometabolism and dysmyelination, and suggest that ketones may be therapeutic in AD due to their ability to fuel neurons despite widespread impairments in glycolytic brain metabolism.

Dis., Gladstone Inst., San Francisco, CA; [4]Inserm UMR1106, Inst. De Neurosciences Des Syst, Marseille, France

Abstract: A paramount driver of sporadic Alzheimer's disease (AD) is the synergy of oxidative stress and glucose hypometabolism in the brain. Oxidative stress damages macromolecules such as DNA, lipids and proteins, whereas glucose hypometabolism impairs cellular energy supply and antioxidant defense; Together, these cellular and functional alterations may be primary triggers of AD. However, the exact basis of AD-associated glucose hypometabolism as well as its causes and consequences has remained unknown. We utilized electrophysiology together with live imaging of NAD(P)H & FAD autofluorescence and metabolic sensors (glucose, lactate, oxygen) in activated hippocampal network. We report acute inhibition of brain glucose utilization by $A\beta_{1-42}$ and identify oxidative stress resulting from $A\beta_{1-42}$ -induced activation of NADPH oxidase 2 (NOX2) as the trigger of brain glucose hypometabolism with resulting network hyperactivity and behavioral disruptions. In hippocampal brain slices, $A\beta_{1-42}$ application

reduced network activity-driven glucose consumption and glycolysis by half, while NOX2 antagonism prevented this effect. *In vivo*, intracerebroventricular injection of $A\beta_{1-42}$ exerted a profound inhibitory effect on brain glucose consumption, resulting in long-lasting network hyperactivity and changes in animal behavioral profile. Critically, the novel bioavailable NOX2 antagonist GSK2795039 prevented all of the observed Aβ-related detrimental effects. These data provide the first experimental evidence behind AD-related brain glucose hypometabolism and its consequences, and suggest that targeting NOX2-induced oxidative stress is a promising approach to both the prevention and treatment of AD.

Title: Examining the effects of a blood glucose rescue on alzheimer's disease-related pathology in young vs. aged hyperglycemic mice

Authors: *A. A. ORTIZ[1], A. R. PLATT[2], A. M. OSSE-LEISGANG[1], J. W. WANG[1], K. C. ALCAZAR[1], E. MIRELES[1], A. M. SALAZAR[1], J. W. KINNEY[1];

Abstract: Abstract
Alzheimer’s disease (AD) is an irreversible neurodegenerative disease that is characterized by progressive synaptic and neuronal loss, learning and memory deficits, and cognitive/behavioral decline. The pathological hallmarks of AD include senile plaques composed of amyloid-beta (Aβ); intracellular neurofibrillary tangles, composed of accumulated hyperphosphorylated tau protein (ptau); and chronic neuroinflammation that can promote and accelerate both Aβ and tau pathologies. AD affects approximately 6.2 million Americans and is the 6th leading cause of death in the US. AD is classified as familial (fAD) or late onset (LOAD). fAD (early onset) is associated with genetic mutations in several genes (i.e., amyloid precursor protein, presenilin 1, presenilin 2, etc.) and accounts for 3-5% of all AD cases. In contrast, LOAD accounts for 95-97% of all AD cases with no genetic etiology, however, several genetic and/or other comorbidities confer increased risk for LOAD.
A major risk factor for developing LOAD is diabetes mellitus (DM). DM confers up to a 4-fold

increased risk for developing AD, and approximately 80% of individuals with AD have type II diabetes (T2DM) or impaired fasting glucose levels. Furthermore, over 25% of the population over the age of 65 are diabetic. As age is also a risk factor for developing LOAD, DM and age may combine to impact AD onset and progression.
Hyperglycemia - abnormal elevated blood glucose level - is the primary characteristic of diabetes and is observed in T2DM. We have previously demonstrated that chronic hyperglycemia can initiate and promote neuroinflammation, resulting in significant increases in ptau and learning and memory deficits that are consistent with other AD models. To determine if hyperglycemia or the ensuing inflammatory response is the mechanism driving AD related changes, we evaluated if lowering blood glucose in our hyperglycemia model would rescue ptau and inflammation. We induced hyperglycemia via a staggered and low dose of streptozotocin (STZ) in young (7 months) and aged (18 months) wild-type male mice. Following 6 weeks of sustained hyperglycemia, we treated animals with Phloridzin (PZ) to lower blood glucose levels. Following PZ treatment, we evaluated if the AD relevant changes were rescued.
Briefly, STZ induced a sustained hyperglycemic state and PZ decreased blood glucose levels. However, in both the young and aged cohorts, PZ did not rescue the ptau or inflammatory changes consistent with AD. Our data demonstrate that even when hyperglycemia is controlled, AD relevant changes persist, and the underlying mechanism of how DM confers increased risk for AD is more than just a hyperglycemic state.

Title: Metabolic and cognitive effects of altering core body temperature in APP/PS1 mice

Authors: S. A. MCFADDEN[1], M. F. COX[1], C. A. FINDLEY[1], M. R. PECK[1], L. A. ALEWELT[1], K. QUINN[1], Y. FANG[1], A. BARTKE[2], E. R. HASCUP[1], ***K. N. HASCUP**[1]; [1]Neurol. / CARE, [2]Intrnl. Med., Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: Aging is the predominant risk factor for developing Alzheimer's disease (AD), so lifespan extending therapies may be effective treatments to ameliorate cognitive decline. Reducing core body temperature (Tc) promotes healthy aging through mechanisms associated with insulin signaling and glucose homeostasis. However, Tc declines with age, perturbs memory formation, and drives aggregation of both amyloid plaques and tau tangles. This paradox led us to hypothesize that increasing, rather than lowering Tc may improve cognitive performance in mouse models of Alzheimer's disease (AD). Starting at 6 months of age (mild amyloid pathology and cognitive impairment), male and female APP/PS1 and C57BL/6 (littermate controls) were chronically housed at either 16, 23, or 30°C for 6 months. At 12 months of age (advanced amyloid pathology and cognitive decline), their metabolic profile was assessed using an insulin and glucose tolerance test followed by cognitive performance on the Morris water maze (MWM) spatial navigation task. Plasma, hippocampal, and peripheral (adipose and hepatic) samples were procured postmortem and tissue-specific markers of amyloid accumulation and metabolism were assayed. Male and female APP/PS1 mice housed at 16°C for 6 months had similar insulin sensitivity, but significantly worse glucose tolerance and cognitive performance compared to temperature-matched littermate controls. Hepatic mRNA expression levels of INSR, PI3K, GCK, G6PC were significantly reduced in male, but unchanged in female APP/PS1 mice compared to temperature-matched littermate controls. In contrast, chronically housing mice at 30°C showed significant cognitive and metabolic improvements over genotype-matched mice housed at 23°C. Male C57BL/6 mice were more insulin sensitive while male APP/PS1 mice had improved glucose tolerance. Memory recall in male APP/PS1 mice chronically housed at 30°C was significantly improved compared to genotype-matched 23°C controls and were similar to littermate controls housed at 30°C. Chronically housing female mice at 30°C improved the insulin sensitivity and glucose tolerance in C57BL/6 and made APP/PS1 mice more insulin sensitive compared to 23°C genotype-matched controls. Despite an enhanced metabolic profile after housing at 30°C, this did not lead to improved cognitive performance in female APP/PS1 mice. Hepatic mRNA expression of GCK and G6PC was reduced in female, but not male APP/PS1 mice. Although reducing Tc is beneficial for successful aging, our data supports this exacerbates cognitive deficits in a model of AD. Rather, increasing Tc may provide therapeutic benefits in males experiencing dementia.

Title: Loss of nuclear estrogen-related receptor alpha activity impairs metabolic plasticity and mitochondrial OXPHOS in neurons: Implications of sex differences observed in Late-onset Alzheimer's disease

Authors: *H.-M. CHOW[1], J. SUN[1], M. LAU[1], R. P. HART[2];
[1]Sch. of Life Sci., The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Rutgers Univ., Piscataway, NJ

Abstract: Late onset Alzheimer's disease (LOAD) is the most common form of age-related dementia, causing memory loss, cognitive deficits and behavioural changes. Currently, LOAD remains untreatable and the high failure rate of clinical trials over the past decade has increased the urgency to better understand the heterogeneity of the disease in order to facilitate more personalised therapies. Females are at the epicentre of the LOAD epidemic, and that better longevity found in women over men alone is insufficient to explain such phenomenon. Previous studies indicated that neurons located within LOAD-relevant brain regions are estrogen sensitive, and that they are also one of the extra-gonadal sites of estrogen synthesis. Here we report that loss of neuronal estrogen signalling transforms a sex-biased benefit to an increased risk of pathological changes associated with LOAD in older women. Supported by our unsupervised transcriptomic meta-analyses using multiple public datasets, various nuclear-encoded genes for oxidative phosphorylation (OXPHOS) components were consistently reduced specifically in neurons of LOAD brains. When the same analysis was further stratified based on the sex of the patients, such losses were observed only in female subjects. Mechanistically, systems analyses indicated that the loss in activity of estrogen-related receptor alpha (ERRa) is the most likely link behind such changes in gene expression observed in LOAD. ERRa is an orphan receptor; our integrated ChIP-seq analysis as well as in vitro mitochondrial bioenergetic studies revealed it is an under-appreciated trans-activator of nuclear-encoded respiratory and metabolic genes in neurons. Further analyses revealed that ERRa expression was not reduced in LOAD, but insufficient cholesterol ligand availability due to reduced cellular uptake mechanism may render ERRa inactive, particularly in female subjects. Taken together, our study suggested an unexpected link between the infidelity of estrogen-mediated cholesterol homeostasis and mitochondrial dysfunction in female neurons. This situation may be further exacerbated in the presence of apolipoprotein E4 allele—the greatest genetic risk factor of LOAD, offering a new explanation to the sex-dimorphic distribution occurred in the disease pathogenesis.

Title: Mild deficiency of mitochondrial Complex III in a mouse model of Alzheimer's disease decreases amyloid beta plaque formation

Authors: *M. PINTO[1], N. NISSANKA[1], C. GUASTUCCI[2], P. ILLIANO[2], R. BRAMBILLA[2], C. T. MORAES[1];

Abstract: For decades, mitochondrial dysfunctions and the generation of reactive oxygen species have been proposed to promote the development and progression of the amyloid pathology in Alzheimer's disease, but this association is still debated. In particular, it is still unclear if mitochondrial dysfunctions are a trigger or rather a consequence of the formation of amyloid aggregates, and in particular, the role of the different mitochondrial oxidative phosphorylation complexes in Alzheimer's patients' brain remains poorly understood. To study how mitochondrial Complex III defects affect amyloid beta pathology *in vivo,* we partially knocked out mitochondrial Complex III ($CIII^{KO}$) in mature forebrain neurons of an Alzheimer's mouse model that develops plaque pathology (APP/PS1). We found that Complex III dysfunction in adult neurons induced mild oxidative stress which did not correlate with increased amyloid beta accumulation. In fact, $CIII^{KO}$-AD mice showed decreased plaque number, decreased Ab-42 toxic fragment and altered amyloid precursor protein cleavage pathway. Our results support a model in which mitochondrial dysfunction is not the cause of amyloid oligomer accumulation but rather a consequence of amyloid beta toxicity.

Title: Apolipoprotein CIII may link metabolic diseases and brain disorders

Authors: *P. RECIO-LÓPEZ, I. VALLADOLID-ACEBES, P.-O. BERGGREN, L. JUNTTI-BERGGREN;
Karolinska Inst., Stockholm, Sweden

Abstract: Apolipoprotein CIII (apoCIII) is a pro-inflammatory factor that increases in obesity and diabetes mellitus (DM). Extensive research has been done to link different apolipoproteins with neurodegenerative diseases. However, the presence of apoCIII in the central nervous system (CNS) and its relationship to metabolic disorders have never been investigated. We used leptin-deficient obese diabetic (*ob/ob*) mice and lean wild type controls, to investigate whether apoCIII is present in CNS and if it is an inducible factor that can be modulated by RNA-based therapy. Expression of apoCIII was analyzed in fresh frozen brains, microdissected *in loco* from five *ob/ob* mice and five controls, by quantitative Real-Time polymerase chain reaction. We found that apoCIII was up-regulated in the frontal cortex, hypothalamus, hippocampus, thalamus, substantia nigra, pons and cerebellar cortex in *ob/ob* compared to control mice. Thereafter *ob/ob* mice were injected intravenously with a mix of two apoCIII-specific siRNAs, or an inactive siRNA as control. There were five mice in each group and injection doses of siRNAs and inactive siRNA were 1mg/kg for three consecutive days. When *ob/ob* mice were given the apoCIII siRNA mix, apoCIII levels were reduced in hypothalamus and thalamus. Importantly, we have now demonstrated the presence of apoCIII in mouse brain. We provide evidences that apoCIII can be produced locally in the brain under conditions of obesity and DM and that its expression can be effectively modulated by siRNA. Hence, our findings not only suggest that brain apoCIII might have a role linking metabolic diseases with neuronal dysfunction but also a tentative way for therapeutic intervention.

Title: Effects of Visceral Fat Removal on Insulin Sensitivity and Cognition in $APP^{NL-F/NL-F}$ Mice

Authors: *S. A. MCFADDEN[1], C. A. FINDLEY[2], A. BARKE[3], K. N. HASCUP[4], E. R. HASCUP[4];
[1]Southern Illinois Univ., SPRINGFIELD, IL; [2]Pharmacol., SIU Sch. of Med., Springfield, IL; [3]Intrnl. Med., Southern Illinois Univ. Sch. of Med., Springfiled, IL; [4]Neurology, Neurosci. Institute, Ctr. for Alzheimer's Dis., Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: Background: Visceral fat (VF) contributes to the development of insulin resistance, type 2 diabetes, and dyslipidemia that are risk factors for developing Alzheimer's disease (AD). Previous work from our laboratories demonstrates that VF pad removal (VFR) improves insulin sensitivity and glucose tolerance in the growth hormone receptor knockout mouse model of successful aging. We hypothesized that VFR would improve metabolic signaling and slow disease progression in an AD mouse model. **Methods:** At 4-5 months of age, prior to cognitive decline, male and female $APP^{NL-F/NL-F}$ (knock-in) and C57BL/6 (genetic background controls) underwent either VFR or sham surgery. In the VFR group, perigonadal and perinephric adipose tissue was removed in both sexes. For the sham operation, similar incisions were made and the same adipose depots were mobilized but not removed. Insulin and glucose tolerance tests (ITT, GTT) were conducted at 18 months of age to examine metabolic function followed by cognitive assessment using novel object recognition (NOR). **Results:** Preliminary metabolic data support an increase in insulin sensitivity in the C57BL/6 male VFR group (n=5) when compared to their sham control mice (n=2). However, this trend was not seen between the male $APP^{NL-F/NL-F}$ VFR (n=7) and sham (n=13) groups. VFR in female $APP^{NL-F/NL-F}$ mice (n=7) significantly impaired insulin sensitivity compared to the sham group (n=5; $p<0.01$). This difference was not observed in the female C57BL/6 sham group. No change in glucose tolerance was observed in either sex in any of the genotypes. VFR negatively impacted NOR performance in female VFR mice ($p<0.03$) when compared to their sham littermates. A similar trend was seen in the male $APP^{NL-F/NL-F}$ VFR mice. **Conclusions:** Prodromal VFR significantly affected insulin signaling in male control mice, but this improvement was not seen in male $APP^{NL-F/NL-F}$. This, coupled with the absence of changes to glucose tolerance, support that VFR does not significantly alter metabolic signaling in male $APP^{NL-F/NL-F}$ mice. However, the significant reduction of insulin sensitivity observed in female $APP^{NL-F/NL-F}$ mice after VFR, but not C57BL/6 controls, points to sex-dependent VF function in insulin signaling in AD. Reduced cognitive performance in both sexes of $APP^{NL-F/NL-F}$ VFR mice demonstrates that changes in peripheral insulin signaling may not contribute to VFR-related cognitive decline. Future studies investigating VFR at 16 months of age could help elucidate the influence of VF on insulin signaling and cognition during later stages of disease progression in these mice.

Title: Cholesterol diet promotes improvement of cognitive decline in mice models of Alzheimer's disease.

Authors: *S. KOERICH, G. L. MARTINS, M. L. N. BRANT, G. G. FREITAS, W. F. BRAGA, H. J. REIS, A. C. P. DE OLIVEIRA;
UFMG: Univ. Federal de Minas Gerais, Belo Horizonte, Brazil

Abstract: Introduction: Alzheimer's disease (AD) is the main cause of dementia in the world, in which behavioral changes, cognitive impairment and progressive memory loss are observed. Despite its high social impact, the pathophysiological mechanisms involved in the disease need further elucidation. It has recently been suggested that cholesterol homeostasis is involved in the pathophysiology of AD. In addition, recent studies demonstrated the influence of a cholesterol diet on cognition of mice models of AD. However, the effects of cholesterol diet on AD pathology are still controversial. To explore this issue, we investigated the effect of a cholesterol diet in a memory paradigm in different models of AD. Aim: The present study aimed to investigate the effects of cholesterol on cognitive impairment and hepatic lipid profile in models of neurotoxicity induced by Aβ and in the transgenic mouse model for AD. Methods: For this, male C57Bl/6 mice, aged 8 weeks, were treated with 1.25% of cholesterol or control diet for four months, then received intrahippocampal microinjection of Aβ (400 pmol) or saline. Additionally, we evaluated the effects of the cholesterol diet in the APP/PS1 transgenic model. For this purpose, male and female APP/PS1, aged 10 months, were treated for four months with a 1.25% cholesterol or control diet. For cognitive evaluation, we performed the novel object recognition test (NORT). In addition, hepatic lipids (triglycerides and cholesterol) were measured in the liver. All the experiments followed the principles of animal experimentation adopted by the Animal Use Ethics Committee of the Federal University of Minas Gerais (UFMG), approved under the number 374/2018. This is an exploratory research. Results: Even considering the higher hepatic cholesterol and triglycerides in the group that received cholesterol diet, in both

APP/PS1 and Aβ models, we observed that the cholesterol diet reversed cognitive deficit in NORT in male and female APP/PS1 mice and prevented cognitive deficit induced by Aβ 1-42. Conclusion: These results indicate that a cholesterol diet induces beneficial cognitive effects, despite appearing to induce systemic alterations, such as those observed in the liver. This data enhances the knowledge about the complexity of the pathogenesis of AD.Financial Support: FAPEMIG; CNPq (Process number: 310347/2018-1); CAPES; Congresswoman Beatriz Cerqueira (PT-MG) provide financial support directly from the House of Representatives.

Abstract: Neuronal loss of NCLX-dependent mitochondrial calcium efflux contributes to cognitive decline
Pooja Jadiya[1], Devin W. Kolmetzky[1], Dhanendra Tomar[1], and John W. Elrod[1*]
1 Center for Translational Medicine, Lewis Katz School of Medicine at Temple University, Philadelphia, PA 19140
Abstract:
Alzheimer's disease (AD) is characterized by memory loss, neuronal dysfunction, and the deposition of amyloid β plaques and tau neurofibrillary tangles. These AD-phenotypes are associated with mitochondrial dysfunction and impaired intracellular calcium homeostasis. We recently reported that mitochondrial calcium ($_{m}Ca^{2+}$) overload, due to remodeling of the mitochondrial calcium uniporter channel (mtCU) and by early neuronal loss of the mitochondrial Na^{+}/Ca^{2+} exchanger (NCLX), occurs before the appearance of AD-associated phenotypes. The loss or re-expression of NCLX in an AD mouse aggravates or reduces AD-associated memory decline and pathology, respectively. However, whether disrupted $_{m}Ca^{2+}$ signaling causally contributes to AD development or progression independent of amyloid-beta remains enigmatic. In the present study, we generated wild-type mice with neuronal-specific deletion (Camk2a-Cre)

of NCLX and evaluated age-associated changes in cognitive function and neurohistology. We found that neuronal-specific loss of $_{m}Ca^{2+}$ efflux in aged mice (12-15 months) impaired spatial and cued recall memory, elicited minor amyloidosis and tau hyperphosphorylation, and caused synaptic remodeling. Our findings suggest that loss of NCLX-dependent $_{m}Ca^{2+}$ efflux alone is sufficient to induce AD-like pathology in aged mice. These findings further advocate for modulating $_{m}Ca^{2+}$ exchange as a therapeutic strategy in AD.

Abstract: Methamphetamine (meth) abuse increases the risk to develop Parkinson's disease (PD) later in life. To decipher neurobiological links between meth abuse and PD, we use meth self-administering (SA) rats undergoing protracted abstinence to study prodromal and early stages of PD. Hyposmia is a prodromal symptom of PD. We hypothesized that olfactory brain circuits will exhibit pathogenic markers in rats with a history of meth SA. The mitochondrial toxin rotenone, which produces PD, synergizes with meth to dysregulate mitochondria and produce PD-like brain and behavior pathology (see Calma Persons Napier, this meeting). Pathological α-synuclein can interfere with mitochondrial ATP production. Accordingly, we conducted immunohistochemical evaluations of α-synuclein in the olfactory bulb (OB) and output structures, the anterior olfactory nucleus (AON) and piriform cortex (PIR) in meth SA (male, Sprague-Dawley) rats with and without subthreshold doses of rotenone. Meth was provided as 0.1mg/kg per 0.1mL infusion in daily 3h sessions for 2 weeks; controls were saline-yoked. Rotenone was delivered as 1mg/kg/day for 6 days *via* subcutaneous osmotic minipumps starting on day 14 of meth abstinence; controls received vehicle only. Brains were harvested 60 days after meth (n=5-9 per treatment). Meth SA rats exhibited progressive deficits in postural

instability, and there was an increase in synuclein-stained cell bodies in the nigra, which were both enhanced by rotenone, validating the relevance of this model to PD. Also as reported for PD, AON area was reduced by meth ($p<0.05$). α-Synuclein staining was not changed in the OB, AON or PIR layer 1 by meth or rotenone. In PIR layer 2, α-synuclein was decreased by 50% in meth SA rats and by 48% with rotenone ($p<0.05$); however, meth+rotenone was not different from either treatment alone. To ascertain if similar results were obtained in a nigral output, we measured striatal α-synuclein. Meth reduced striatal staining by 43% ($p<0.05$), but no changes were observed for rotenone alone or meth+rotenone. These outcomes illustrate regional differences in synuclein regulation. As α-synuclein was measured 60 days after meth exposure and 40 days after rotenone, results may reflect compensation to initial exposure, or incubation, a phenomenon well-described for meth-induced seeking behaviors. α-Synuclein is degraded by a ubiquitin pathway, and ubiquitin is increased in humans with fatal meth overdose (Quan *et al, Legal Med*, 2005). Increased metabolism would explain the observed meth-induced reductions in α-synuclein and mitochondrial dysregulation. Ongoing studies are determining if such mechanism link meth abuse to PD.

Title: Differential mitochondrial dysfunction in striatum of HD depending on astrocyte population

Authors: *L. LOPEZ-MOLINA[1,2,3], A. PEREDA-VELARDE[1,2,3], S. GINES[1,2,3];
[1]Univ. of Barcelona, Barcelona, Spain; [2]Inst. d'Investigacions Biomèdiques August Pi i Sunyer, Barcelona, Spain; [3]Ctr. de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas (CIBERNED), Madrid, Spain

Abstract: Huntington's Disease (HD) is a neurodegenerative disorder characterized by the selective loss of striatal medium spiny neurons. Although the molecular mechanisms of this striatal vulnerability remain unclear, compelling evidences point out that mitochondrial dysfunction could play a major role. However, much of what we know regarding the mechanisms underlying mitochondrial disturbances in HD has been gained from studies

conducted in neurons. Less is known about the role and regulation of mitochondrial dynamics in glia, particularly in astrocytes, the predominant type of glia cell in the brain. Indeed, relatively unexplored is whether mitochondrial dynamics in astrocytes may also contribute to neuron disturbances and therefore, to pathology in HD. Hence, we aimed to define the specific contribution of astrocytic mitochondria as well as the intercellular mitochondria communication between neuronal and astrocytes to HD pathology. In this work, we used the transgenic R6/1 mouse model of HD to either isolate adult astrocytes at different stages of the disease and to culture primary striatal astrocytes. Since astrocytes is a complex and heterogeneous population, we evaluated several astrocyte markers at the striatum of R6/1 mouse throughout the disease using biochemical and immunofluorescence assays. Then, we studied how mitochondria could be affected in HD striatal astrocytes depending on specific population. We could observe that mitochondrial abnormalities in HD astrocytes differed whether it occurs in GLAST+ or GFAP+ astrocytes. Finally, preliminary results showed that mitochondria could be a crosstalk mechanism between astrocytes and neurons and HD condition could hamper this cell-to-cell communication.

Title: Changes in Striatal Mitochondria in a Rat Model of Methamphetamine-Induced Increased Risk for Parkinson's disease

Authors: *I. CALMA[1], A. L. PERSONS[2], T. NAPIER[3];
[1]Rush Univ., Chicago, IL; [2]Psychiatry, [3]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Parkinson's disease (PD) is a progressive degeneration of nigrostriatal dopaminergic neurons resulting in motor disturbances and the emergence of α-synuclein rich protein aggregates in several brain regions, including the substantia nigra. Methamphetamine (meth) abuse increases the risk for developing PD. We revealed that meth self-administering (SA) rats have a force abstinence (FA) time-dependent loss of nigrostriatal tyrosine hydroxylase (TH), a marker for dopamine neurons (Kousik et al., JPET 351:432, 2014), and that this loss in TH is parallel by the emergence of PD-like postural instability (Persons et al., DAD 225:108746, 2021). Mitochondrial health is important for proper energy production and normal cell function, and mitochondrial dysfunction is implicated in meth toxicity and the pathogenesis of PD. We

hypothesized that meth-induced trajectory towards PD is associated with striatal mitochondrial dysfunction. Male Sprague Dawley rats were trained for meth SA (0.1mg/kg/0.1mL/infusion) 3h daily for 2 weeks or were saline-yoked. We administered subthreshold (behaviorally ineffective) doses of the mitochondrial toxin, rotenone, or vehicle *via* subcutaneous osmotic minipumps during FA days 14-20. Meth SA rats exhibited progressively worsening motor deficits and reductions in striatal TH that were exacerbated by rotenone ($p<0.05$). The rats were killed on FA day 62, and brain harvested. In the substantia nigra, the number of α-synuclein+ cells was increased by meth and the effect was enhanced by rotenone ($p<0.01$). Several markers of mitochondrial dysfunction were discovered in the striatum. Cytochrome c translocation to the cytosol was increased by meth and further enhanced by rotenone ($p<0.01$). Rotenone reduced levels of electron transport chain Complex I and II protein ($p<0.05$) and Complex I activity ($p<0.01$). Meth reduced Complex II protein levels ($p<0.05$), and meth-induced reductions in Complex I and Complex II activity were potentiated by rotenone ($p<0.01$). These findings reveal that mitochondrial dysfunction occurs with SA meth, these effects were observed months after terminating meth and were potentiated by subthreshold doses of rotenone, and the brain pathology parallels with motor deficits seen in early stages of PD. Thus, protracted dysregulation of mitochondria may underpin the link between meth-abuse and PD.

Abstract: Parkinson's disease (PD) is a progressive movement disorder characterized by the loss of midbrain dopaminergic (DAergic) neurons and widespread accumulation of intracellular aggregates containing misfolded α-synuclein (Lewy bodies; LB). LB pathology is observed across multiple brain regions in PD, however, hallmark motor symptoms are attributed to the selective loss of DAergic terminals and neurons in the basal ganglia. Despite the identification of risk genes for inherited forms of PD, the etiological contributors to the vulnerability of DAergic neurons in idiopathic PD are not known. While genetic risk variants for PD provide starting points for exploring mechanistic contributors to disease etiology, it has been challenging to determine ways to use this information to uncover convergent mechanisms of disease. Here, single-cell transcriptomic data from mouse brain were leveraged to identify enrichment patterns of PD-implicated genes. Gene lists were derived from statistical clustering based on region- and cell-specific enrichment patterns, with empirical confirmation of top prototypical genes in mouse and human brain. Additionally, the top DAergic prototypical gene was modified in a *C. elegans* model of synucleinopathy; modification of this gene was shown to affect DAergic neuronal viability in this model. Single-cell data was further utilized to identify a subpopulation of midbrain DAergic neurons vulnerable to loss in a mouse model of synucleinopathy. Altogether, these results provide a strategy to prioritize and contextualize PD-linked risk genes for biological studies, highlighting the value of cell-type-specific resolution.

Title: excitotoxic commitment to die in dopaminergic neurons is associated with changes in mrna expression consistent with failure of the mechanism of internalization of ampa receptors. p { margin-bottom: 0.1in; line-height: 115%; background: transparent }

Authors: O. MALDONADO[1], L. PADILLA[2], *G. A. DE ERAUSQUIN[1];
[1]Glenn Biggs Inst. for Alzheimer and Neurodegenerative Dis., [2]Glenn Biggs Institute for Alzheimer and Neurodegenerative Dis., Univ. of Texas Hlth. San Antonio, San Antonio, TX

Abstract: Mesencephalic dopaminergic neurons (DN) in primary culture are selectively susceptible to excitotoxic injury mediated by activation of the α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamate receptors, through a pathway requiring loss of intracellular calcium homeostasis, opening a mitochondrial permeability transition, nuclear translocation of nuclear factor kappa B (NFkB) and phosphorylation of the transcription factor p53 leading to programmed neuronal death. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) acts as a stimulator of programmed cell death, and forms protein complexes with glutamate receptor AMPA type-2 subunit (GluA2) leading to its internalizion during excitotoxicity in hippocampal neurons in culture. Further, nuclear accumulation of GluA2, GAPDH, and p53 were observed in the substantia nigra of Parkinson's disease post-mortem. We evaluated the expression of GAPDH and GluA2 mRNA in single dopaminergic neurons during an excitotoxicity challenge. Primary mesencephalic mouse cultures were exposed to conditioned medium alone, or containing 30 or 100 μM AMPA for 1, 3, or 6 h (the latter known to result in commitment to die in this model). DN were labeled with 5,7, dihydroxytrptamine (DHT) and manually picked live under fluorescent microscopy, and the dopaminergic phenotype was confirmed by expression of Tyrosine Hydroxylase (TH) and Paired-Like Homeodomain Transcription Factor 3 (pitx3) mRNA. Single DN were then processed for multiplex microfluidic PCR gene expression for genes included in the molecular pathway of AMPA induced excitototoxicity in DN. We found that commitment to die is correlated with dose-dependent significant increases in GluA2 expression, as well as decreses in GAPDH and p53. These results suggest a failure of the mechanism of internalization of AMPA receptors at the time of commitment to die in DN. p { margin-bottom: 0.1in; line-height: 115%; background: transparent }

Title: Enhanced transcriptional drive through estrogen related receptor gamma (Esrrg) for mitochondrial and synaptic gene programs protects dopaminergic terminals from synuclein-mediated toxicity

Authors: *S. FOX[1], L. MCMEEKIN[2], C. SAVAGE[1], K. JOYCE[1], G. HAGGARD[1], S. BOAS[1], M. SIMMONS[2], J. PAUL[1], C. FARMER[1], J. AUWERX[3], S. SUDARSHAN[1], J. MA[4], K. GAMBLE[1], R. ROBERTS[1], D. CROSSMAN[1], A. KRALLI[5], R. COWELL[2];

Abstract: Many studies implicate mitochondrial dysfunction as a key contributor to age-related neurodegenerative diseases, including Parkinson Disease (PD). Previously published gene expression analyses from laser captured dopaminergic (DAergic) neurons from the substantia nigra of patients with Lewy-body pathology revealed a deficiency in nuclear-encoded genes for mitochondrial respiration. The functional consequences of these changes and their role in disease progression and pathology are still unknown. The coordinated downregulation of a large number of nuclear-encoded mitochondrial genes suggests the disruption of a central regulator for mitochondrial gene expression. In fact, most affected genes are putative targets for the transcription factor estrogen-related receptor gamma (*Esrrg*/*ESRRG*), and several recent studies indicate that in addition to regulating mitochondrial genes, *Esrrg* can modulate dopaminergic phenotype and neuritogenesis. Here, we determine the dependence of DAergic neurons on *Esrrg* for gene expression, survival, and regulation of motor function and explore how cell type-specific manipulation of *Esrrg* expression influences DAergic neuron vulnerability in the pre-formed fibril model of synucleinopathy. We demonstrate that, while knockdown is well-tolerated in normal adult mice, it leads to a reduction in the number of mitochondria in DAergic neurons and renders DAergic terminals and neurons more susceptible to synuclein toxicity. Remarkably, overexpression of *Esrrg* provides neuroprotection from alpha-synuclein-induced toxicity at the terminals. Translating ribosome affinity purification-mediated transcriptional profiling of DAergic neurons revealed that *Esrrg* is required for the expression of genes related to synaptic vesicle cycling, vesicle-mediated transport, and tricarboxylic acid metabolic processes; however, overexpression was associated with a robust induction of non-*Esrrg*-dependent genes involved in mitochondrial respiration. In contrast to adulthood deletion, developmental deletion caused a reduction in classic transcriptional markers for DAergic neurons without causing overt cell loss. Interestingly, differences in behavioral sensitivity to amphetamine across the various mouse lines revealed a positive association between DA availability and eventual neuron loss. Altogether, these findings indicate that *Esrrg* is required for normal transcription and function of DAergic neurons and that overactivation of *Esrrg*-dependent transcriptional programs should be considered as a strategy for maintaining DAergic innervation in PD.

Title: Multiple roles for estrogen-related receptor-gamma in gene regulation in neurons

Authors: K. L. JOYCE[1], S. N. FOX[1], J. A. MOBLEY[1], L. PEREBOEVA[1], ***R. M. COWELL**[2]; [1]Univ. of Alabama at Birmingham, Birmingham, AL; [2]Dept. of Neurosci., Southern Res., Birmingham, AL

Abstract: The dysregulation of mitochondrial and synaptic genes occurs with neurodegeneration. Recently, members of the estrogen-related receptor (ERR) transcription factor family have been implicated in the regulation of mitochondrial and synaptic genes in the brain. Previous and ongoing studies indicate that ERRγ is involved in the regulation of cellular identity and neuritogenesis-related genes in dopaminergic neurons, yet little is known about its putative gene targets or interacting proteins in these cells. Here, we performed RNA-Seq and BioID proximity assays in an SH-SY5Y neuroblastoma line to identify putative ERRγ targets and interacting factors in dopaminergic neuron-like cells. In doing so, we discovered that 800 genes are upregulated and 3000 genes downregulated by ERRγ overexpression. Among these genes is ADARB2, an enzyme involved in RNA editing, and NEAT1_2, a long non-coding RNA which forms a scaffold for nuclear paraspeckles. Interestingly, BioID studies determined that overexpressed ERRγ resides in close proximity to proteins enriched in paraspeckles, such as SFPQ and FUS. Accordingly, ERRγ overexpression increases, and shRNA-mediated knockdown decreases, the abundance of paraspeckle foci in SH-SY5Y cells. Other putative ERRγ-interacting proteins of interest included proteins involved in RNA editing, splicing and trafficking, suggesting a more complex role for ERRγ in gene regulation beyond its role as a DNA-binding transcription factor. Furthermore, it is interesting to note that ERRγ was in close proximity to both transcriptional coactivators and repressors, suggesting that it can be recruited into both transcriptionally active and repressed transcriptional complexes, depending on the locus. Neuroanatomical localization of a subset of altered genes and co-factors to cell types in the mouse brain guided studies to test for ERRγ-responsive gene expression in mice lacking ERRγ in different cell types, demonstrating the utility of these studies for understanding ERRγ's roles *in*

vivo. Future experiments will explore whether alterations in ERRγ and its targets are associated with dopaminergic vulnerability in Parkinson's Disease.

Title: Targeted activation of midbrain neurons restores locomotor function in mouse models of parkinsonism

Authors: *D. MASINI, O. KIEHN;
Dept. of Neurosci., Copenhagen Univ., Copenhagen, Denmark

Abstract: The pedunculopontine nucleus (PPN) is a locomotor command area in the midbrain that contains glutamatergic neurons directly involved in the control of locomotor initiation and maintenance, especially slower explorative locomotion. Motor output is suppressed in Parkinson’s disease (PD), where dopaminergic neurodegeneration alters basal ganglia activity leading to strong inhibition of its targets. The PPN is a subregion of the MLR that is under direct inhibitory control from the basal ganglia. Activating the PPN to release it from the excessive basal ganglia inhibition in PD is, therefore, a logical step to ameliorate Parkinsonian locomotor deficit. However, when deep brain stimulation targeting the MLR is applied in the clinics, it exhibits variable and sometimes no locomotor improvement. In the present study we hypothesize that the lack of consistent clinical results is caused by the variable and/or nonspecific activation of the MLR. We therefore use cell-type-specific chemogenetic and optogenetic approaches to activate localized MLR subpopulations in two distinct mouse models of parkinsonism. To induce an acute parkinsonian-state we pharmacologically interfere with dopaminergic signaling by antagonizing D1- or D2-type dopamine receptors. We show that excitation of caudal glutamatergic PPN neurons can alone, normalize the otherwise severe locomotor deficit in PD, whereas targeting the GABAergic PPN population is not sufficient to support full locomotor recovery. Moreover, we compare the motor recovery driven by glutamatergic PPN stimulation to

that of the Cuneiform nucleus. Our observations pinpoint caudal glutamatergic PPN neurons as an optimal target for neuromodulatory restoration of locomotor function in Parkinson's disease.

Title: The microtubule-protecting drug candidate SKIP modifies Parkinson's disease deficits: rotenone and 6-hydroxydopamine neurotoxicity models

Authors: Y. IVASHKO-PACHIMA[1], K. B. SEROOGY[2], Y. SHARABI[3], ***I. GOZES**[1]; [1]Sch. Med/Tel Aviv Univ., Tel Aviv, Israel; [2]Dept Neurol, Univ. of Cincinnati, Cincinnati, OH; [3]Sheba & Sch. Med/Tel Aviv Univ., Tel Aviv, Israel

Abstract: Parkinson's disease (PD) poses a significant challenge to public health, requiring disease-modifying therapies. The Gozes laboratory discovered activity-dependent neuroprotective protein (ADNP), which is deregulated (decreased) in PD (Chu et al., J. Parkinsons Dis., 2016; Hadar et al., Mol. Psychiatry, 2021). ADNP contains a NAPVSIPQ (NAP) domain, including the SxIP motif, which interacts with microtubule (MT) end-binding proteins (EB1, EB3) enhancing/replacing ADNP-MT interactions, thereby regulating axonal transport and synapse formation. The laboratory further designed SKIP (based on the SxIP MT-interacting motif in NAP). SKIP interacts with NAP in ADNP to protect MTs, presenting a potential drug candidate for PD disease modification. Here, we used both cell culture and animal models to determine if SKIP provides in vitro protection against rotenone and in vivo attenuation of nigrostriatal 6-hydroxydopamine (6-OHDA) neurotoxicity. Rotenone, a well-known pesticide/insecticide, inhibits mitochondrial complex I and depolymerizes MTs, combining catecholamines and MTs in PD toxicity. Using live cell imaging and morphometrics at the microscopical level, we found significant protection of neuronal-like cells (neuroblastoma SH-

SY5Y and N1E-115 cells) by SKIP against rotenone challenge. Mechanistically, rotenone disrupted MT dynamics, which SKIP partially repaired through EB1/EB3, coupled with increasing neurite branch length. We chose the established rat model of nigrostriatal 6-OHDA neurotoxicity to initially evaluate SKIP in vivo in a pilot study. Using the intrastriatal 6-OHDA partial lesion model in adult Sprague Dawley rats, we found that supranigral SKIP pretreatment (2 weeks prior to 6-OHDA lesion) improved motor behavior in the forelimb asymmetry test and protected against nigral dopaminergic cell degeneration (as determined by tyrosine hydroxylase immunohistochemistry and stereological cell counts) at 4-weeks post-lesion (Ivashko-Pachima et al., J. Mol. Neurosci., 2021, in press). These findings are the first to demonstrate the neuroprotective potential of SKIP against neurotoxin-induced neuronal impairment and dopaminergic neurotoxicity. With PD afflicting millions of people globally, and with disease modification challenges, SKIP holds promise for future therapeutic development.

Title: Effect of subthalamic high frequency stimulation on exploratory behaviors in a parkinsonian animal model

Authors: *S. G. HILLAN[1], C. B. MULDER[2], J. L. SILVERNAIL[3], W. D. LUJAN[3], S. L. BOSCHEN DE SOUZA[3], J. L. LUJAN[3];
[1]Mayo Clin. Grad. Sch. of Biomed. Sci., Rochester, MN; [2]Minnesota State Univ., Mankato, MN; [3]Neurologic Surgery, Mayo Clin., Rochester, MN

Abstract: A well-established treatment for the motor symptoms of Parkinson's disease (PD) is high frequency deep brain stimulation (DBS) of the subthalamic nucleus (STN). Despite the effectiveness of DBS in treating the motor symptoms of PD, a subset of patients experience side effects from stimulation, including psychiatric side effects like anxiety. Stimulation-evoked anxiety commonly manifests in these patients six months or more following the onset of stimulation, though anxiety has also been identified as a transient side effect immediately

following surgery. Given the proximity of the stimulation target to the limbic region of the STN, anxiety may be the result of stimulation spread. However, the mechanisms responsible for stimulation-induced psychiatric side-effects are not well understood. A complicating factor is that psychiatric disorders have a high comorbidity with PD, with psychiatric symptoms presenting earlier than motor symptoms. Interestingly, psychiatric disorders are an exclusion criterion for DBS for PD. Thus, there is a need to better understand how STN DBS induces anxiety and other psychiatric side-effects. The goal of this study is to better understand the effects of DBS on anxiety-like symptoms by investigating changes in exploratory behaviors in a pre-motor rodent model of PD undergoing chronic and acute DBS. This study uses a partial 6 hydroxydopamine lesion to preserve motor function and reduce movement deficits that can affect behavior, while still exhibiting psychiatric symptoms associated with PD. The small size of the rodent STN relative to the size of the simulating electrode (both in the order of 1 mm) prevents selective targeting of the motor region. As such, stimulation spread to the entire STN can be expected. However, we expect larger increases in anxiety-like behaviors in the chronically stimulated cohort due to long-term stimulation-induced changes in neuroplasticity. Next steps include characterizing changes in neural activity in brain regions associated with anxiety-like behaviors to better understand the pathways responsible for inducing anxiety in response to DBS.

Title: Improving the forced running wheel as a neuroprotective treatment in mouse models of Parkinson's disease

Authors: *H. SKELTON[1], D. GROGAN[2], J. RUBIANO[3], K. BERGLUND[4], C.-A. N. GUTEKUNST[4], R. E. GROSS[5];
[1]Biomed. Engin., Emory University/Georgia Inst. of Technol., Atlanta, GA; [2]Med. Col. of Georgia, Augusta, GA; [3]Emory Univ., Atlanta, GA; [4]Neurosurg., Emory Univ. Sch. of Med., Atlanta, GA; [5]Dept Neurosurg., Emory Univ. Sch. Med., Atlanta, GA

Abstract: Exercise is associated with lower risk for and slower progression of Parkinson's disease (PD) and is demonstrably neuroprotective in animal models. If the underlying mechanisms were better understood, they could provide an avenue towards disease-course

modifying treatment with neuromodulation. However, exploring that physiology requires an exercise modality that is repeatably neuroprotective and conducive to the relevant assays, particularly tethered electrophysiologic recording. We settled on forced wheel running as an ideal solution to this problem, but were not convinced that existing commercial wheels were suitable. We developed a new forced running wheel platform designed to be comfortable to run on and difficult to grab onto. It also allowed high quality video recording and can be used with tethered mice. We then tested whether exercise on this new platform could provide neuroprotection in mice lesioned with 6-hydroxydopamine (6-OHDA). For that study, exercise was conducted according to a fixed, 9-week schedule with 30-minutes of wheel running per day at up to 12 m/min. Eight-week old, male C57Bl/6J mice were trained to run for 5 weeks. After training, they received a unilateral 6-OHDA injection in the striatum, after which they were exercised for 4 weeks followed by tissue collection. Exercise consisted of daily 30-minute wheel running at up to 12 m/min. We ran mice in either a commercial wheel or the one we developed and compared their neurodegenerative outcome to that of a sedentary group of mice. To assess neurodegeneration, tyrosine hydroxylase immunoreactive (TH+) cell counts in the substantia nigra on the lesioned side were compared to the non-lesioned side using stereology. Though it was difficult to rigorously quantify running performance on the commercial wheel, it was quite poor, with most mice refusing to run when it got above 8 m/min. These mice had a mean TH+ cell deficit of 58%, which was not significantly different from the mean of the sedentary control group, 74% (p=.010, independent t-test). Mice ran much more consistently on the new wheel, which also allowed for quantification of running via precise markerless, video pose tracking. These mice had a mean 41% loss of TH+ cells, significantly less than the sedentary control group (p=0.0021). In conclusion, our new forced wheel platform provided an effective intervention and can be used to test hypotheses about the underlying neurophysiologic mechanisms of exercise-based neuroprotection. Future work should also examine the effect of different exercise parameters, such as speed and duration, on neuroprotection in PD.

Title: Impact of sex and advancing age on genetic silencing of striatal CaV1.3 for amelioration of levodopa-induced dyskinesias in a rat model of Parkinson's disease

Authors: M. E. CAULFIELD[1], F. P. MANFREDSSON[2], J. A. STANCATI[1], C. E. SORTWELL[1], S. A. BOEZWINKLE[3], M. J. VANDER WERP[1], I. M. SANDOVAL[2], M. DAVIDSSON[4], T. J. COLLIER[1], *K. STEECE-COLLIER[1];
[1]Translational Neurosci., Michigan State Univ., Grand Rapids, MI; [2]Barrow Neurolog. Inst., Phoenix, AZ; [3]Col. of Literature, Science, and the Arts, Univ. of Michigan, Ann Arbor, MI; [4]Mol. Neuromodular, Lund Univ., Lund, Sweden

Abstract: The loss of striatal dopamine (DA) in Parkinson's disease (PD) results in dysregulation of CaV1.3 calcium channels leading to synaptic pathology that appears to underlie levodopa-induced dyskinesias (LID). We previously demonstrated* that silencing of striatal CaV1.3 with rAAV9-CaV1.3-shRNA in young (3 mo at lesioning), male parkinsonian rats can: 1) provide uniform and near complete protection against induction of LID even with sustained high dose levodopa, and 2) significantly reduce severity of already established LID. This gene therapy approach of CaV1.3 silencing provides some of the most profound antidyskinetic benefit reported to date. As a next step in understanding the utility of this novel therapeutic approach for LID in individuals with PD, acknowledging the strong link between aging and PD, we examined the ability of striatal CaV1.3 silencing to impact LID in middle-aged (15 mo at lesioning) male and female parkinsonian rats. To examine 'LID reversibility' in middle-age rats, subjects were unilaterally lesioned with 6OHDA and lesion status confirmed with amphetamine rotational asymmetry 2 wks later. Rats were then primed with low dose levodopa (3mg/kg) for 3 wks resulting in low level LID at which time they received intrastriatal CaV1.3-shRNA or scrambled (Scr) vector. LID remained low for 30 days post-vector in both groups with the 3mg/kg dose, which was escalated to 6 mg/kg and then to12 mg/kg; 2 wks/dose. At the higher doses, there was significant amelioration LID severity in aged male, but not female rats receiving rAAV-CaV1.3 compared to Scr-shRNA. Despite evidence that aged female rats may be more resistant to reversal of LID, a subpopulation (~40%) of subjects showed therapeutic efficacy comparable to aged male rats. To examine 'LID prevention' in middle-age rats, subjects received CaV1.3-shRNA or Scr-shRNA, one week later rats were unilaterally lesioned with 6OHDA and 3 weeks later began receiving escalating doses of levodopa (6, 9, 12, 18 mg/kg, 2 wks/dose; per *PMID:31002755). Unlike the 'LID reversibility' study, data from the 'LID prevention' study suggests that viral vectored silencing of striatal CaV1.3 channels maintains potency in preventing development of LID in both middle-aged male and female parkinsonian rats. However, in contrast to young subjects where all parkinsonian rats receiving CaV1.3-shRNA showed near complete amelioration of LID, middle-aged rats showed more variability, especially in female subjects. The source of the apparent sex difference in functional efficacy of CaV1.3 silencing to reverse LID and the therapeutic variability in preventing LID induction are currently under investigation.

Abstract: Parkinson's disease (PD) is a progressive disease that affects dopaminergic and non-dopaminergic pathways which contributes to the development and maintenance of motor and non-motor symptoms in PD. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been used to treat symptoms in advanced PD patients; however, the mechanisms involved in the analgesic response are yet to be determined. Considering the importance of serotonergic circuitry in the control of the nociceptive response, in this study we investigate the effect of STN-DBS treatment on the nociceptive response and the serotonergic system of hemiparkinsonian rats. Male Wistar rats were evaluated at the basal nociceptive threshold. After that, animals were injected with 6-hydroxydopamine (6-OHDA) neurotoxin or saline in the left striatum. In the same surgical procedure, the animals were implanted or not with stainless steel electrodes in the left STN. Seven days after the surgery, animals were evaluated in the apomorphine-induced rotation and re-evaluated in the paw pressure test. On the 8th day, the animals were divided into four groups: saline (control), 6-OHDA (not implanted), 6-OHDA + DBS OFF (implanted but not stimulated) and 6-OHDA + DBS ON. Six-OHDA + DBS ON animals were stimulated for five consecutive days (8th to 12th day after the surgical procedure) during 2 h (130 Hz, 60μs, 0,1 mA). In the next day, animals were re-evaluated in the nociceptive test, and euthanized by transcardial perfusion. Brains were collected and immunolabeled for tyrosine hydroxylase (TH) in the substantia nigra (SN), and for 5-hydroxytryptophan (5-HT) in the magnus raphe nucleus (MRN) and dorsal raphe nucleus (DRN). Six-OHDA animals presented increased contralateral rotation and decreased TH immunoreactivity (IR) in the SN, confirming the nigrostriatal lesion. The PD model decreased the nociceptive threshold in both paws of the lesioned animals compared to control animals and the STN electrode implantation per se did not interfere with this response. However, the STN-DBS treatment was able to bilaterally reverse the mechanical hyperalgesia induced by neurotoxin. Six-OHDA animals showed a decrease of 5-TH-IR in the MRN and DRN when compared with controls. The 6-OHDA + DBS ON animals showed a reversal of the 5-HT deficit in both raphe nuclei when compared to the saline and 6-OHDA

groups. Our data lead us to suggest that STN-DBS treatment inhibits nigrostriatal injury-induced hyperalgesia due, at least in part, to restoration of serotonergic circuitry in the raphe nuclei, which allowed the reorganization of the descending analgesic pathway and thus the inhibition of persistent pain transmission.

Title: Closed-loop spinal cord stimulation creates a pro-locomotion brain state in rats with Parkinson's disease

Authors: B. REES[1], E. BORDA[2], M. A. NICOLELIS[3], ***A. P. YADAV**[1];
[1]Neurolog. Surgery, Indiana Univ., Indianapolis, IN; [2]Swiss Federal Inst. of Technol. Lausanne, Geneva, Switzerland; [3]Neurobio., Duke Univ., Durham, NC

Abstract: Enhanced oscillatory activity is a dynamic neuropathological hallmark of Parkinson's disease (PD), and excessive synchronization in the beta frequency band (10-25 Hz) has been linked to motor impairments seen in the disease. Previously, we've shown that epidural dorsal column stimulation (DCS)-an emerging semi-invasive technique improves locomotion in animal models of PD. Here, we incorporated a closed-loop DCS (CLDCS) paradigm and investigated the mechanisms by which CLDCS facilitates locomotion in PD animal models. Through an analysis of the spiking behavior of neurons in the motor cortex and striatum, we hypothesize that CLDCS promotes motor functioning by disrupting beta activity in the brain and restoring neural functioning to a more pro-locomotion state. We implanted six Parkinsonian rats with epidural electrodes in thoracic spinal cord and microelectrode arrays in the primary motor cortex and dorsolateral striatum. CLDCS was delivered in response to periods of elevated beta activity in the striatum. Spiking activity of single units was recorded during off-stimulation and CLDCS periods and analyzed offline. Spectral power for each neuron was computed during periods of on- and off-stimulation and averaged for each recording session. Across all rats our results indicated a significant reduction in beta activity during periods of CLDCS compared to periods of no stimulation. To understand how CLDCS facilitates locomotion we identified bouts of locomotion and studied the firing rate of each unit before and during the locomotion bout. Principal component analysis was performed to reduce dimensionality and to represent the population activity in a three-dimensional neural state-space that evolved over time. We were able to capture a representative view of ensemble activity as the behavior evolved from a state of

pre-locomotion akinesia to pro-locomotion movement. The neural trajectory represented in the 3D state-space during CLDCS was compared to that during off-stimulation and a control pre-disease condition. We calculated the mean distance of all points to the centroid as well as the three-dimensional path distance of the neural trajectory across conditions. We found that the spread and path distance of neural trajectory during CLDCS was more identical to the pre-disease condition as compared to the off-stimulation condition. This suggested that CLDCS facilitated the transition from a pre-locomotion to locomotion state. Overall, our results suggest that CLDCS mitigates motor impairments in PD animal models by reducing beta activity within individual units and restoring the neural state closer to a more healthy, pro-locomotion condition.

Title: A novel target of deep brain stimulation restored Parkinson's disease symptoms in mice

Authors: *G. KUMAR[1], P. ASTHANA[1], C. H. E. MA[1,2];
[1]1 Dept. of Neurosci., City Univ. of Hong Kong, Tat Chee Avenue, Kowloon Tong, Hong Kong;
[2]City Univ. of Hong Kong Shenzhen Res. Inst., Shenzhen, Hong Kong

Abstract: Parkinson's disease (PD) is common chronic neurodegenerative disorder with unknown etiology affecting more than 1% of the world population. Levodopa treatment is frequently used to control PD symptoms. However, it is effective only in the early stages of the disease and develops resistance in majority of patient at later stages as disease progresses. Deep brain stimulation (DBS) has become vital therapeutic option for the resistance PD. Stimulation of subthalamic nucleus (STN), globus pallidus pars interna (GPi) or ventral intermediate nucleus (VIM) of the thalamus has been used for two decades for PD treatment. It modulates either direct or indirect pathway of thalamo-cortical-striatal loop. The imbalance between direct and indirect pathways results in abnormal activation of output nuclei and over-inhibition of thalamus and motor cortex, leading to undesirable side effects such as cognition, depression and anxiety. The relatively small STN and GPi stimulation site is potential limiting factor in surgical implantation of DBS electrode that high surgical precision is required. These limitations could be overcome by validating a new target site proposed in our current study, which offers (a) larger size for easy electrode implantation and increases the area of stimulation; (b) stimulates both direct and

indirect pathways of locomotion to mimics the normal physiology state in healthy people that send normal output signals to motor cortex; (c) prevents direct stimulation of STN or GPi to reduce adverse side effects. Our novel target is located in strategic positions and acts as integrating centre for motor control by activation of both direct and indirect pathways. We explored the DBS efficacy of our proposed novel target in rotenone and 6-OHDA induced PD in mice. Mice received DBS stimulation at 130Hz frequency, 100μA pulse amplitude, 80μs pulse width for 1 hour on a daily basis for 7 days. Strikingly, novel target-DBS showed significant increase in recovery of general locomotion test, beam walking test, pole climbing test in rotenone model and decreased apomorphine induced rotation in 6-OHDA model as compared to GPi-DBS. We further examine the electrophysiological properties on day after the last stimulation. Consistent with the animal behavior test results, novel target-DBS significantly reduced abnormal neuronal firing and restored neuronal bursts and interspike interval to nearly baseline levels in PD mice as compared to GPi-DBS. In conclusion, our novel target-DBS showed better efficacy than GPi-DBS in improvement of PD symptoms by restoring abnormal firing pattern in PD mice.

Title: Burst DBS induces persistent motor rescue in parkinsonian mice

Authors: *S. NANIVADEKAR[1], T. A. SPIX[1], A. H. GITTIS[2];
[2]Biol. Sci., [1]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Deep brain stimulation (DBS) is a highly effective, but invasive treatment for patients with medication-resistant Parkinson's disease (PD). The neural mechanisms underlying its effectiveness remain unknown. This has limited the ability to optimize the stimulation parameters to allow resolution of the underlying dysfunction. Issues related to continuous stimulation protocols like battery replacement, appropriate onset of therapy, and adverse clinical side effects have motivated a study of patterns of stimulation that can prolong the therapeutic duration beyond the time of active stimulation, an outcome currently unexplored in clinical practice. Our lab has demonstrated that optogenetic manipulation that differentially modulates cell types - namely excites the PV neurons while inhibiting the Lhx6 neurons in the GPe can generate long-lasting motor recovery in a parkinsonian mouse model. However, optogenetic stimulation is currently not feasible in humans. Our lab also identified in an in-vitro model that synaptic differences can be leveraged to differentially drive these cell types by using bursts of

electrical stimulation. In this study we test whether an electrical DBS protocol, tailored to drive population-specific neuromodulation could produce such persistent recovery in parkinsonian mice after stimulation has stopped. Using an in-vivo mouse model of electrical DBS in mice rendered parkinsonian by bilateral injections of the toxin 6-OHDA into the medial forebrain bundle, we compared the therapeutic efficacy of conventional continuous delivery of electrical stimulation vs. delivery of 200 ms/second bursts of electrical stimulation at a 175Hz frequency. Our DBS platform was modeled after Schor et al. and used six-lead DBS electrodes implanted in the entopeduncular nucleus, an area where fibers from the STN and D1-SPNs are coactivated. Both conventional and burst DBS were comparable in reducing immobility during stimulation measured as the percent time the animal did not move in the open-field. After stimulation, mice who received conventional DBS quickly returned to the immobile state (pre vs. 90' post-stim = 0.195), whereas those that received burst DBS continued to move around the arena for up to 2.5 hours after stimulation had stopped (pre vs. 90' post-stim =0.016*). On average, the therapeutic effects of DBS persisted about 4.5-fold longer than those of conventional DBS (p=0.008, n = 8 mice). These results demonstrate the ability to prolong the therapeutic benefits of DBS beyond conventional methods, by translating principles of basal ganglia cell-type specific neuromodulation to an in-vivo parkinsonian mouse model.

Abstract: The adeno-associated viral vector variant known as true type (AAV-TT) is a novel capsid engineered to improve CNS tropism and retrograde transport through brain circuits. This retrogradely-spreading AAV-TT capsid was designed for enabling neuronal transduction in multiple brain regions innervating the injected area (e.g. multiple targeting to be achieved with one single AAV-TT intraparenchymal delivery). Here we have performed a single injection of a GFP-coding AAV-TT (5 uL; 1 x 10E13 vg/mL) into the left post-commissural putamen of two

adult juvenile *Macaca fascicularis*, together with a similar strategy conducted with AAV9-GFP in two more animals for comparison purposes. All animals were sacrificed 4 weeks post-AAV deliveries. GFP+ neurons were consistently found throughout the layer V of the cerebral cortex (ipsi- and contralateral to the injected side), the caudal intralaminar nuclei and the substantia nigra pars compacta. Within the cerebral cortex, cortical areas showing the highest neuronal transduction were the superior frontal gyrus, the precentral gyrus, the cingulate cortex and the postcentral gyrus. Although both AAV-TT-GFP and AAV9-GFP showed a roughly similar pattern of retrograde transduction, AAV-TT capsid, in the present study, exhibited a slight enhanced transduction when compared to AAV9, as shown by its ability to transport and transduce the dorsal raphe nucleus. Moreover, uptake of viral vectors through fibers of passage was only observed for AAV9 and not for AAV-TT capsid (e.g. the latter lacking false positive results). These data represent a powerful ability of AAV-TT for transducing projection neurons in multiple brain areas located far away from the injection site, thus opening unprecedented possibilities when using retrogradely-spreading AAV-TT capsids for both disease modeling as well as for therapeutic approaches in the field of neurodegenerative disorders

Copenhagen, Copenhagen, Denmark; [3]Dept of Neurol., Univ. Rochester Med. Ctr., Rochester, NY

Abstract: Parkinson's Disease (PD) is a neurodegenerative disorder, which is associated with focal loss of dopaminergic neurons in the substantia nigra. The therapeutic prospective of cell replacement therapy for treating PD has been established through clinical trials transplanting human fetal tissue and stem cell therapies are under development. Direct reprogramming of resident glia cells *in situ* into therapeutic neurons represents a strategy based on cell replacement but circumvents the need for cell transplantation. Proof-of-concept experiments has been performed in rodent models using genetic overexpression of lineage-specifying transcription factors or downregulation of key barriers such as *Ptbp1*, but it remains an open question if human glia can be converted *in situ* into clinically relevant neurons with the ability to restore function in the damaged brain. For studies of direct neural reprogramming of human glia, we have established a stem cell-based *in vitro* conversion model (Nolbrant et al., 2020) as well as a pre-clinical humanized glial chimeric rodent model for *in vivo* conversion. In this model, human glia progenitor cells (GPCs) derived from induced pluripotent stem cells are transplanted into neonatal immunodeficient rats. The GPCs engraft and proliferate, and upon maturation the rodent brain contains large numbers of human GPCs and astrocytes. We have also engineered human GPCs to express CRE recombinase, which allows us to specifically target the human cells *in vivo* upon stereotactic injection of CRE-dependent neural conversion factors. Using these two models, we are currently exploring both transcription factor-mediated conversion and *PTBP1* knockdown-mediated conversion *in vitro* and *in vivo*, with the goal to select neural conversion factors that specify the reprogramming of dopaminergic neurons from human glia directly in the brain.

Title: Deep brain stimulation reveals high-precision temporal coding in basal ganglia and thalamus in pediatric patients with movement disorders

Authors: *J. S. L. VIDMARK[1], E. HERNANDEZ-MARTIN[2], T. D. SANGER[1,2,3];
[1]Dept. of Biomed. Engin., [2]Dept. of Electrical Engin. and Computer Sci., Univ. of California, Irvine, CA; [3]Children's Hlth. Orange County, Orange, CA

Abstract: Deep brain stimulation (DBS) is a common treatment of movement disorders. While the mechanisms of DBS remain largely unexplained, recordings from implanted electrodes provide valuable insight into the brain's response to the electrical stimulations. We here present novel findings of complex and high-frequency evoked potentials (EPs) in basal ganglia and thalamus from DBS in 7 pediatric patients with movement disorders.
Externalized DBS leads in thalamic nuclei and basal ganglia were used to concurrently stimulate and record. Stimulations were performed through one bipolar pair of conventional contacts at a time, while recordings were acquired from all high-impedance contacts with a sampling frequency of 24 kHz, allowing us to detect high-frequency neural responses. Complex EPs were recorded in every subject, in regions including ventral oralis (VO), ventral intermediate (VIM), globus pallidus interna (GPi), and the subthalamic nucleus (STN). These responses consisted of multiple high-frequency oscillations up to and above 6 kHz, standing in stark contrast to the more commonly observed ~1-kHz single-oscillation DBS EP shape.
To ensure that these complex responses were not merely artifacts of the electrical stimulation, multiple analytical tests were run. First, phase reversal of each stimulation contact pair was performed, which successfully reversed the stimulus artifact, while leaving the EP intact (as expected for a neural response). Second, the response shape could be seen consistently in individual recordings, ruling out the possibility that the stimulation averaged EP shape was merely generated by noisy samples. Finally, stimulations in different contacts and at different frequencies generated similar but slightly varying responses, conforming to the inherent neural variability expected, while differing from the anticipated replicability of artificial electrical stimulus artifacts.
While further analysis is needed to determine the origin of these complex responses, it is possible that local resonant circuits or multiple axons firing with different delays are key mechanisms of this high-precision temporal coding. These recordings also emphasize that high-impedance contacts are vital to detect the complex, high-frequency neural activity that conventional low-impedance contacts would inherently filter out. Such precision may prove to be vital for successful applications of e.g. closed-loop DBS and brain-machine interfaces.
The observed high-frequency, high-precision EPs highlight the complexity of the brain's response to DBS, and will help shed light on the mechanisms of DBS as a treatment for movement disorders.

Title: Dynamic causal modelling predicts the cortico-basal ganglia-thalamo-cortical loop neurotransmission in children with secondary dystonia undergoing deep brain stimulation

Authors: *M. KASIRI[1], E. HERNANDEZ-MARTIN[2], T. D. SANGER[1,2,3];
[1]Dept. of Biomed. Engin., [2]Dept. of Electrical Engin. and Computer Sci., Univ. of California, Irvine, Irvine, CA; [3]Children's Hlth. Orange County (CHOC), Irvine, CA

Abstract: Dystonia is a movement disorder in which excessive or abnormal deep brain activity causes involuntary muscle contractions and abnormal postures, however its neurophysiology remains unknown. An effective method to reduce its symptoms in children is deep brain stimulation (DBS). DBS target may differ in different patients, including ventralis oralis anterior/posterior (VoaVop) in thalamus, internal globus pallidus (GPi) and subthalamic nucleus (STN) in basal ganglia. Knowledge about the brain network and dynamics helps us better understand the mechanism of dystonia and DBS. Therefore, we aim to model the cortico-basal ganglia-thalamo-cortical loop in children with dystonia to explore the coupling and connection strength between deep brain structures, using dynamic causal modeling (DCM) from Statistical Parametric Mapping (SPM12). We recorded GPi, VoaVop, and STN oscillations through externalized DBS electrode implants in five dystonic children, executing a voluntary reaching with their upper limbs. The data was preprocessed and divided into “active” and “rest” segments, and their cross spectral densities were used to fit the models. Seven neuronal architectures were tested on five subjects’ data where the movement acts as an external effect on the connections between the brain deep structures. We assumed a Mean Field Neural Model (MFM) for each structure. Bayesian model inference provided strong evidence in favor of a model corresponding to the ‘standard architecture’; GPi receives excitatory input from STN, and its connection gain strengthens during movement ($p < .001$). Moreover, GPi inhibits VoaVop and this connection gain also increases during movement ($p < .001$), however the later gain is significantly smaller ($p < .001$) than the former, which shows the dominant effect of STN-GPi connection over GPi-Vo connection. Besides, VoaVop and STN excite each other bidirectionally. We suggest that it could be through cortex. Our results confirm current hypotheses of cortico-basal ganglia-thalamus connectivity and signal flow, and they show that DCM with MFM can potentially be used with intracranial recordings to test different hypotheses about brain networks. Even when the intracranial neural models are not specified in detail, the current models suffice to predict the direction and type of connections, and how they differ during movement. Furthermore, the effect of DBS can be better understood by implementing a detailed neural model into DCM models and making more accurate predictions about how connectivity parameters change with stimulation.

Nacional de Ciencias Neurológicas, Lima, Peru

Abstract: Spinocerebellar ataxia type 3 (SCA3) or Machado-Joseph disease (MJD) is an autosomal-dominantly inherited, neurodegenerative disorder caused by the expansion of a CAG repeat within the *ATXN3* gene resulting in an expanded polyglutamine repeat in the encoded ataxin-3 protein. SCA3/MJD, therefore, belongs to the group of polyglutamine diseases comprised of nine neurodegenerative diseases including Huntington's disease. Statistically, a correlation between the number of CAG repeats and the age at onset of SCA3 patients exists and patients with more CAG repeats have an earlier onset of symptoms. However, this statistical correlation is not perfect and the number of CAG repeats contributes only about 55% to the age at onset. Therefore, the remaining 45% are influenced by other factors, which we aim to identify in this study. In order to identify modifiers of the disease progression, we genotyped in a combined European and South American approach more than 500 SCA3/MJD patients for promising polymorphisms in candidate genes. Candidate genes included ataxin-3 itself and known interaction partners of ataxin-3, functional modifiers identified in previous studies as well as genes with known relevance for the pathophysiology of SCA3/MJD including genes involved in the nucleocytoplasmic transport. We selected polymorphisms with a high likelihood of having a functional relevance i.e. polymorphisms in the promoter regions as well as polymorphisms leading to amino acid changes. While controlling for ethnic origin we assessed the contribution of the respective polymorphism to the age at onset in addition to the already known modifying factor, the length of the expanded CAG repeat within *ATXN3*. We indeed identified interesting

polymorphisms contributing to the age at onset including certain haplotypes within *ATXN3* itself. Subsequent functional characterizations will reveal the impact of these polymorphisms on pathogenic mechanisms in SCA3/MJD. We hope that our results will improve the prediction of clinical symptoms and contribute to the understanding of pathogenic processes in SCA3/MJD.

Title: Aberrant structural and functional brain differences in spinocerebellar ataxia subtypes 3 and 6

Authors: *A. BARRY, P. C. NOPOULOS, T. R. KOSCIK;
Psychiatry, Univ. of Iowa Hlth. Care, Iowa City, IA

Abstract: Aberrant structural and functional brain differences in spinocerebellar ataxia subtypes 3 and 6
Spinocerebellar ataxias (SCA) are a heterogeneous group of over 40 autosomal dominant, neurogenerative disorders often caused by CAG trinucleotide repeats. Patients with SCA subtype 3 (SCA3) often present with ataxia, pyramidal, and extrapyramidal symptoms, while patients diagnosed with SCA subtype 6 (SCA6) frequently report ataxia, tremors, and dysarthria. Previous literature suggests cerebellar atrophy in SCA3 and SCA6 brains, though SCA3 atrophy continues through the brainstem and portions of the cortex. SCA3 and SCA6 functional connectivity (FC) studies are rare, though one study found within-network FC differences for SCA6. The current project examines the relationship between structural brain abnormalities and functional connectivity among SCA3 and SCA6 patients.
Participants completed MRI scans at University of Iowa Psychiatry Department. Healthy controls (CTRL; 18 total, 11 males, mean age: 53.07) were age- and sex-matched with SCA3 (9 total, 3 males, mean age: 46.40) and SCA6 patients (5 total, 4 males, mean age: 61.05). Structural T1w and resting-state fMRI (rs-fMRI) scans were preprocessed to obtain jacobian determinants (JD) images and Schaefer 7-network parcellation. JDs, which measure the difference in shape and volume of the cortex, cerebellum, and brainstem, were compared across participant groups. Regions of significantly different clusters were individually correlated to

Schaefer networks to assess how structurally abnormal regions functionally connect to major networks.
Initial linear mixed-effects (LME) models revealed that multiple JD clusters across the cortex, brainstem, and cerebellum differed significantly between groups. Further, LME models controlling for age, sex, and hemisphere successfully predicted FC between these JD clusters and Schaefer networks. Specifically, the control, default mode, dorsal attention, and limbic networks were abnormally connected to JD clusters across both SCA subtypes compared to CTRLs.
This study demonstrates that structural differences throughout the brain are related to abnormal functional connectivity among SCA patient groups. While previous literature has suggested limited atrophy for SCA6, this study demonstrates both SCA subtypes have varied atrophy across the cortex, brainstem, and cerebellum, as well as aberrant functional connectivity among multiple networks when comparing SCA patients and CTRLs. Because SCA subtypes affect patient brains differently, it will be important to consider these subtypes separately for potential behavioral and clinical phenotypes.

Title: Open loop training in Spinocerebellar Ataxia 6 (SCA6)

Authors: B. YACOUBI[1], A. CASAMENTO-MORAN[1], Y. CHOI[1], S. DELMAS[1], S. H. SUBRAMONY[2], D. E. VAILLANCOURT[1], E. A. CHRISTOU[1];
[1]Applied Physiol. and Kinesiology, [2]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Approximately 150,000 people are affected by hereditary ataxia in the US. Common features of ataxias are cerebellar degeneration and significant loss of function and mobility. Ataxia is notoriously difficult to treat, and rehabilitation, the mainstay of care, has had limited success. Individuals with cerebellar ataxia are impaired in open-loop control; yet there have been no efforts specifically targeting its rehabilitation. We have devised a training based on open-loop control and hypothesized that this form of training will have generalized effects and benefit functional movements. Here we examined the effects of this novel training intervention on endpoint control, ataxic gait severity, postural balance and BOLD activity in the cerebellum and motor cortex in individuals with Spinocerebellar Ataxia 6 (SCA6), an autosomal dominant

mostly pure cerebellar ataxia. Participants with SCA6 (n = 14) were randomly assigned into a SCA-training group and a SCA-control group. Both groups visited the lab twice 6 weeks apart to perform baseline (pre) and return (post) measures. Only the SCA-training group performed in-home error-reducing training with ballistic goal directed leg movements (4 times a week for 1 hr.). We found that the SCA-training group exhibited greater pre-post improvements in endpoint control of ankle ballistic goal-directed contractions relative to the SCA-control group (35% vs. 15%; $p = 0.001$). We found that ataxic gait (Scale for the Assessment and Rating of Ataxia; SARA gait) improved for the SCA-training ($p = 0.03$) but not for the SCA-control group. Similarly, we found significant training-specific improvements in biomechanical variables associated with balance and gait; including significant reduction in sway path-length during a postural balance test ($p = 0.03$) and significant increase in stride length, during 14 m overground walking ($p = 0.03$). Overall, these improvements suggest that our open-loop error-reducing intervention has the potential to successfully mitigate functional deficits in SCA6. Also, our results provide preliminary evidence of transfer (generalization) of open loop goal-directed training to balance and locomotion. This is further supported by our preliminary finding that activation (change in BOLD fMRI) of the cerebellum and the motor cortex increased for the training group only ($p < 0.001$).

Title: Spinocerebellar ataxia type 10: Memory and executive impairments and their relation with cortical thickness

Authors: *A. CHIRINO-PÉREZ[1], I. VACA-PALOMARES[1], D. L. TORRES[1], C. R. HERNANDEZ-CASTILLO[2,3], R. DÍAZ[1], G. RAMIREZ-GARCIA[1], J. FERNANDEZ-RUIZ[1,2]; [1]Univ. Nacional Autónoma De México, Mexico City, Mexico; [2]Univ. Veracruzana, Xalapa, Mexico; [3]Consejo Nacional de Ciencia y Tecnología, Mexico City, Mexico

Abstract: Spinocerebellar Ataxia Type 10 (SCA10) is a neurodegenerative disorder caused by the expansion of an ATTCT pentanucleotide repeat. Its clinical features include ataxia and, in

some cases, epileptic seizures. To date, little is known about SCA10 cognitive impairments and there is no information yet about the neural bases underpinning them. The aim of this study was to explore SCA10 patients' performance in two cognitive domains typically affected in SCAs: memory and executive functions. Our second objective was to correlate the cognitive impairments of SCA10 patients with their clinical features and cortical thickness, as quantified by Magnetic Resonance Imaging (MRI). To this end, we administered memory and executive functions tests to 17 genetically confirmed SCA10 patients and 17 healthy matched volunteers. SCA10 patients showed deficits in the durability of visual memory traces, storage volume of verbal memory, error detection (monitoring), planning and cognitive flexibility. Patients with seizures (n=9) and without seizures (n=8) did not show significant differences in cognitive performance. Cognitive deficits in SCA10 patients were independent of the cerebellar motor impairments and the age at onset of disease. Based on MRI performed in 16 patients, we found associations between short-term visual memory impairments and cortical thickness in the bilateral posterior lobe of the cerebellum (bilateral lobule VI, IX and right X). Cognitive flexibility deficiencies correlated with cortical thickness in left dorsolateral prefrontal cortex, cingulate gyrus and middle temporal regions. Motor impairments were correlated with cortical thickness in several bilateral cerebellar regions. In conclusion, this study offers novel information about the SCA10 cognitive profile, showing significant memory and executive deficits that correlated with atrophy in specific cerebral/cerebellar regions.

Abstract: While *ATM* loss-of-function has long been identified as the genetic cause of Ataxia Telangiectasia (AT), how this genetic mutation leads to selective and progressive cerebellar degeneration of Purkinje and granule cells remains poorly understood. We performed single-nucleus RNA-sequencing of the human cerebellum and prefrontal cortex from individuals with AT and matched unaffected controls to identify AT-associated transcriptomic changes in a cell-type- and brain-region-specific manner. We provide the largest single-nucleus transcriptomic atlas of the adult human cerebellum in health and degeneration to-date (126,356 nuclei), annotate major cell types in the human cerebellum and prefrontal cortex, and identify cell type proportion changes between AT and controls. We demonstrate cell-type-specific expression of cerebellar ataxia-associated disease genes, with remarkably enriched expression of *ATM* in microglia from human cerebellum and prefrontal cortex, suggesting a particularly important role of *ATM* in microglia. We analyze the cell-type-specific molecular pathways perturbed in AT, revealing prominent and widespread inflammation of microglia in AT cerebellum with transcriptional signatures similar to aged and neurodegenerative microglia. Our analyses suggest that microglia activation precedes Purkinje and granule neuron death in disease progression, consistent with a cell-intrinsic mechanism of activation. The CGAS-STING pathway was upregulated specifically in AT microglia, implicating cytosolic DNA as a potential cell-intrinsic trigger of microglial activation. In addition, apoptotic and ER stress pathways were upregulated in AT Purkinje and granule neurons, while genes involved in calcium ion homeostasis were downregulated in AT Purkinje neurons, including calcium genes implicated in other hereditary ataxias. Overall, our data implicates a novel role of microglial activation underlying cerebellar degeneration and a convergence of disease pathophysiology underlying hereditary ataxias.

Title: Hematological Parameters in Friedreich's Ataxia Patients: Evidence for Subtle Features of Iron Deficiency

Authors: S. BHAGWAGAR[1], C. RUMMEY[2], R. WILSON[3], *D. LYNCH[4];
[1]State Univ. of New York Upstate Med. Univ., Syracuse, NY; [2]Clin. Data Sci. GmbH, Basel, Switzerland; [3]Perelman Sch. of Med., Philadelphia, PA; [4]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Introduction: Friedreich's Ataxia (FRDA) is a neurodegenerative disorder affecting 1 in every 50-100000 individuals in the United States. The most common mutation in FRDA is an expansion of guanine-adenine-adenine (GAA) trinucleotide repeats within the gene encoding mitochondrial protein frataxin, leading to its genetic deficiency. Mitochondrial dysfunction resulting from frataxin deficiency is a component of the underlying pathophysiology of FRDA. Recently, a new isoform of frataxin was discovered in erythrocytes; its role and impact on extramitochondrial processes such as hematologic iron stores and hemoglobin production remain unknown at a clinical level. This study aimed to elucidate the features of erythrocytes and other hematological parameters in FRDA patients. **Methodology**: Specific clinical parameters associated with iron disposition and hemoglobin synthesis were examined in a cohort of 114 FRDA patients in order to ascertain the effect of deficiency of erythrocyte frataxin on such parameters. The effect of FRDA on ferritin, a systemic intracellular iron reservoir proposed to serve as a biomarker in FRDA, was also analyzed in an overlapping cohort of 221 FRDA patients. Linear regression and unpaired, two-tailed t-tests were performed with a significant p-value < 0.05. **Results**: This study demonstrated that in spite of the low levels of frataxin in erythrocytes, its absence leads to no major abnormalities in clinical parameters of hemoglobin synthesis or red blood cell parameters. Hemoglobin levels were normal in FRDA patients, however, a small decrease in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and ferritin suggested that patients with FRDA manifest subtle features of iron deficiency. When hematological data were ranked by tertiles according to disease biomarkers, MCV values decreased significantly as a function of guanine-adenine-adenine (GAA) repeats but increased as a function of age of onset, while MCH values significantly increased as a function of age of onset. This study also demonstrated that ferritin levels are sex-dependent, correlate with hemoglobin levels, and are predicted by age. **Conclusion**: Collectively, the present results demonstrate a subtle level of hematological abnormalities in FRDA and suggest that ferritin may serve as a biomarker in FRDA. As MCV and MCH were more associated with age of onset and genetic severity than disease duration, such changes suggest that these differences are part of the FRDA phenotype. Further studies are required to understand whether other compensatory iron homeostasis mechanisms might increase in response to reduced frataxin levels in erythrocytes.

Title: Discrimination of idiopathic REM sleep behavior disorder patients by single-trial event-related potential during visuospatial attention based on deep neural networks

Authors: *H. KIM[1], P. SEO[1], M. KIM[1], J. HUH[1], K. CHA[2], J.-S. SUNWOO[2], J.-I. BYUN[3], K.-Y. JUNG[2], K. KIM[1];

Abstract: Introduction: Idiopathic REM sleep behavior disorder (iRBD) is a sleep disorder characterized by loss of muscle atonia during REM (rapid eye movement) sleep. An early detection of neurodegeneration in iRBD is essential to cure or slow down the progression of the disease since the majority of patients develop neurodegenerative diseases. We try to develop an efficient algorithm for the discrimination of iRBD patients by single-trial event-related potential (ERP) during visuospatial attention task based on deep neural networks.**Methods**: Nineteen healthy subjects (63.47 ± 7.37 years) and 16 drug-naive iRBD patients (64.94 ± 6.92 years) participated in this study. 60-channel electroencephalograms (EEGs) were recorded while performing Posner cueing task. Cortical source activities were reconstructed using weighted minimum norm estimation. The single-trial ERPs were averaged within every 100 ms time-interval from target onset to 800 ms for all subjects. The cortical activities were projected onto 2D image using Mollweide projection. Finally, the 120x120x12 three-dimensional volumes were constructed and used as input for the pattern classifiers based on a number of deep neural network architectures. The structure of the proposed classification algorithms is illustrated in Fig 1.**Results**: Four pattern classification algorithms were developed and successfully discriminated iRBD patients from normal controls (deep multilayer perceptron (MLP), long short-term memory (LSTM), two- and three-dimensional convolutional neural networks (2DCNN and 3DCNN)). The accuracies achieved by each algorithms were as follows: MLP: 92.19 ± 0.79 %, LSTM: 90.96 ± 0.69 %, 2DCNN: 97.66 ± 0.48 %, 3DCNN: 97.2 ± 2.15 %.**Discussion**: The iRBD patients could be successfully discriminated based on single-trial cortical activities with high accuracy based on deep neural network classifiers. The CNN-based architectures showed best test performance by 97 %. Our results suggest that the spatial characteristics of cortical activities are crucial to discriminate iRBD patients.

Title: Selective inhibition of mPGES-1 mitigates cerebral ischemia-induced neuronal injuries and functional deficits

Authors: *L. LI, R. HOU, Y. YU, J. JIANG;
Dept. of Pharmaceut. Sciences, Col. of Pharm., The Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Ischemic stroke is one of the leading causes of death and disability among adults. It involves microglia-mediated neuroinflammation in its pathophysiology. Microsomal prostaglandin E synthase-1 (mPGES-1)-derived prostaglandin E2 (PGE2) is a key mediator of inflammation. We herein investigate whether targeting mPGES-1 with a selective inhibitor MPO-0063 (N-phenyl-N'-(4-benzyloxyphenoxycarbonyl)-4-chlorophenylsulfonyl hydrazide) may improve functional outcomes after experimental cerebral ischemia. We first found that the

release of PGE2 and pro-inflammatory cytokines from mouse primary microglia was considerably increased upon lipopolysaccharide (LPS) stimulation. The pretreatment with mPGES-1 inhibitor MPO-0063 and its analogs significantly attenuated these microglial responses in a dose-dependent manner (n=4). Meanwhile, 11-week old C57BL/6 male mice were subjected to a 45-min episode of transient middle cerebral artery occlusion (tMCAO) and were intraperitoneally administrated with MPO-0063 over 24 hours after stroke onset (n=13-15). At the acute stage (over 72 hours), the inhibition of mPGES-1 was associated with a better survival, milder neurological deficits, transient improvement of weight loss, and a notable reduction in infarction. The ischemia induced an extensive upregulation of inflammation-associated genes, which was largely mitigated by treatment with MPO-0063. Moreover, a batteries of behavior tests were performed throughout the sub-acute stage and long-term recovery. In open field test, the maximal instantaneous locomotor velocity was notably compromised at day 7, whereas this deficit was undetectable in MPO-0063-treated cohort. The progressive anxiety of mice was indicated by the ever-increasing presence at corners, and MPO-0063 provided a significant alleviation in this regard. In light/dark box, MPO-0063 conferred a shorter presence in the dark and an extended latency under the light, further highlighting its anxiolytic potential. Among the vehicle cohort, the failure of recognizing novel objects was still ongoing at day 30, and the spontaneous cognitive recovery was not seen until day 60. By contrast, the cognitive restoration appeared as early as day 30 and was maintained at day 60 upon MPO-0063 administration. Our findings suggest that the mPGES-1 inhibition might represent a novel strategy to mitigate neurological and neuropsychological dysfunctions caused by ischemic stroke.

Title: Adeno-associated virus mediated expression of CIB2 restores the mechanosensory transduction & auditory function in mouse model of hearing loss

Authors: *S. REHMAN[1,2], A. P. J. GIESE[1], Z. M. AHMED[1], S. RIAZUDDIN[1];
[1]Univ. of Maryland, Baltimore, MD; [2]Ctr. of Excellence in Mol. Biol., Univ. of the Punjab, Lahore, Pakistan

Abstract: Background: Hearing loss is the most common sensorineural deficit occurring in approximately 1 in 1000 newborns. Hearing loss can be classified into acquired and congenital forms. Out of all congenital forms of hearing loss 50% cases are due to genetic mutations. Variations in *CIB2* are reported globally and it accounts 8.6% of all known genetic causes of hearing loss in Pakistani population. CIB2 localizes at the tip of stereociliary bundle and is essential for mechanosensory transduction function. *Cib2*$^{tm1a/tm1a}$ mouse models exhibit profound hearing deficits and replicate the human phenotype. Therefore, they are good model to execute preclinical evaluation of potential therapeutic strategy to restore hearing function. **Approach:** Here we investigated, Adeno-associated virus (AAV) mediated *Cib2* gene delivery to inner ear hair cells and evaluated impact on hearing restoration. To execute this study, First *Cib2*$^{tm1a/tm1a}$ cochlear explant cultures were infected with AAV vector and mechanosensory transduction function was assessed through FM1-43 uptake. Secondly, AAV Capsid harboring full length *Cib2* was injected into posterior semicircular canal at P0. Auditory function was assessed through auditory brainstem response(ABR) measurements and expression of CIB2 was examined through Immunolabeling. **Results:** In vitro infection of AAV into HEK293T cells led to significant expression of *Cib2* mRNA and protein when examined through RT-qPCR and Western blot analysis respectively. Mechanosensory transduction in *Cib2* $^{tm1a/tm1a}$ cochlear explant cultures was restored due to infection of *Cib2* containing AAV vector. A single in vivo delivery of AAV vector into inner ear of *Cib2*$^{tm1a/tm1a}$ mice resulted in restoration of the Auditory brainstem responses (ABR) within two weeks. Further, CIB2 specific immunolabelling confirmed the localized expression of CIB2 at the tips of stereocilia of inner ear hair cells. **Conclusion:** In summary, this study suggests that AAV mediated gene transfer into inner ear is a potential biological strategy to treat deficits that affect sensory hair cells and auditory function. The success of this translational study can help in targeting the larger animal models as well as a better understanding of the therapeutic approach in humans.

Title: Evaluation of miR20a-3p in alleviating stroke-induced cognitive impairment in reproductively senescent female rats.

Authors: *D. SAMPATH[1], K. G. MARKOWSKY[2], T. BRANYAN[3], C. MYERS[4], F. SOHRABJI[5];

[1]Neurosci. and Exptl. Therapeut., Texas A&M Univ. Syst. Hlth. Scien Neurosci. and Exptl. Therapeut., College Station, TX; [2]Sch. of Publ. Hlth., Texas A&M Univ., college station, TX; [4]Neurosciences and Exptl. Therapeut., [3]Texas A&M Univ., College Station, TX; [5]Neurosci. and Exp Therapeut., Texas A and M Univ. Syst., Bryan, TX

Abstract: Stroke is the major cause of death and disability worldwide. Our previous work has shown that epigenetic modifications in astrocytes of middle-aged rats resulted in reduced expression of microRNA (miR)20a-3p after stroke.
Additionally, mir20a-3p mimics injected 4h after stroke improved acute stroke outcomes including infarct volume and sensory motor performance. We hypothesized that this treatment will also improve chronic stroke outcomes such as cognitive impairment.
Middle-aged acyclic female (Sprague-Dawley, 12-15 months of age) were injected stereotaxically with endothelin- 1 in the left MCA region to create an ischemic stroke. Mir20a-3p mimics or scrambled oligo were administered i.v. at 4, 24 hours, and at 70 days after the induction of MCAo. Animals were evaluated for sensory-motor function pre-stroke and 2d and 5d after MCAo.
Cognitive assessments were performed using the Novel Object recognition task at 30- and 100-days post stroke and cued fear memory retrieval at 30, 60 and 100 days after stroke. Fear conditioning was performed using the tone-shock trace fear conditioning protocol prior to the induction of the stroke.
MCAo resulted in significant deficits on the right-side forelimb placement, and adhesive removal test ($p<0.003$) in comparison to sham and miR 20 treated female groups ($p<0.01$), and ($p< 0.002$) among the male group.The middle-aged female group that received MCAo+ scrambled oligos were resistant to fear extinction to conditioned fear at 100 days after MCAo ($p<0.01$), displaying a sustained freezing response even after 3 days of fear extinction.
Additionally, the retrieval of fear memory was impaired in the scrambled treated stroke rats ($p<0.05$) but was retained by the miR20 treated group of rats even at 30-, 60- and 100-days post stroke (multi dose cohorts). The declarative memory, which is tested with the novel object recognition task, was also found to be significantly affected in the scrambled treated stroke rats compared to the miR20 treated group of rats at 100 days after stroke ($p<0.05$).
Overall, this data show that mir20a-3p treatment during the acute period improved short-term outcomes related to sensory motor performance, long-term improvement of fear, and declarative memory related to cognitive impairments. This data suggest that stroke therapies that improve acute stroke outcomes will also ameliorate chronic stroke outcomes.

Title: Nicotine exposure alters lipid metabolism and exacerbates ischemic brain injury in female rats

Authors: *S. H. PATEL, J. SIEGAL, A. P. RAVAL;
Neurol., Univ. of Miami, Miami, FL

Abstract: While it is known that smoking-derived nicotine (N) and oral contraceptives (OC) synergistically exacerbate global and focal ischemia, the underlying mechanisms by which this occurs remains elusive. Our previously published study has demonstrated that OC exacerbation of N toxicity occurred via altered oxidative phosphorylation, in particular the dysfunction of mitochondrial complex IV in the electron transport chain [1, 2]. Due to the essential role mitochondria play in cellular respiration, we analyzed the metabolomic fingerprint in the brains of adolescent and adult female rats exposed to N +/- OC. In our study, 6-week-old adolescent and 12-week-old adult female Sprague-Dawley rats were randomly (n = 8/group) exposed to either saline or nicotine (4.5 mg/kg) +/- OC for 16-21 days. Following this exposure, the rats were sacrificed, and brain tissue was collected and Metabolon Inc performed unbiased metabolomic analysis. This metabolomic data was complemented with enzyme activity and western blot analysis. Pathway enrichment analysis revealed significant alterations in lipid metabolism. Adolescent female rats treated with N or N +/- OC showed significant increases in carnitine conjugated fatty acid metabolites when compared to saline treated rats. However, this difference was not observed in the adult female rats. Along with these changes, an increase in a subset of free fatty acids was also observed, implying elevated β-oxidation of fatty acids in the mitochondria in order to meet energy demands. Additionally, the presence of the ketone body 3-hydroxybutyrate (BHBA) was significantly lower in OC and N+OC treated adolescent rats, suggesting a total shunting of acetyl CoA for energy production via the TCA cycle. The concentration of BHBA increases in a direct relationship with the rate of lipid oxidation as acetyl CoA accumulates. Diminished BHBA levels may also point to OC and N+OC treatment initiated mitochondrial disfunction. These altered metabolomic profiles in conjunction with altered fatty acid metabolism suggests a general disfunction in energy metabolism specifically in young female animals treated with N. Furthermore, these alterations were heightened with N+OC treatment. Exploring the molecular mechanisms that dictate mitochondrial function at different ages, as well as the exact effects N +/- OC has on general brain metabolism, will open a new avenue for therapeutic interventions in the future. Title: Post-stroke low frequency whole body vibration improves cognition in middle-aged rats of both sexes

Authors: N. KERR[1], J. SANCHEZ[1], W. MORENO[1], O. E. FURONES-ALONSO[1], W. DIETRICH[1], H. M. BRAMLETT[1], ***A. P. RAVAL**[2];
[1]Neurolog. Surgery, Univ. of Miami, MIAMI, FL; [2]Neurol., Univ. of Miami, Miami, FL

Abstract: Low frequency whole body vibration (WBV; 40 Hz), a low impact form of exercise, intervention for a month following mild transient middle-cerebral artery occlusion (tMCAO) reduces infarct volume and improves motor function in reproductively senescent, middle-aged female rats [1]. Since post-stroke cognitive decline remains a significant problem, the current study aims to investigate the efficacy of WBV in ameliorating post-tMCAO cognitive deficits and to determine underlying putative mechanism(s) conferring benefits of WBV in middle-aged rats. Middle-aged rats of both sexes were randomly assigned to tMCAO (90 min) or sham surgery followed by exposure to either WBV (twice a day for 15 min each for 5 days a week over a month) or no WBV treatment groups. Following the last WBV treatment, rats were tested for hippocampus-dependent learning and memory using a water maze followed harvesting brain and blood samples for histopathological and inflammatory marker analyses, respectively. Results show that post-tMCAO WBV significantly lessens cognitive deficits in rats of both sexes. Post-tMCAO WBV significantly decreased circulating pro-inflammatory cytokines and increased serum levels of irisin, a muscle-derived hormone that may play a role in brain metabolism and inflammation regulation, which suggests putative beneficial mechanisms of WBV. Title: Effect of endogenous estrogen fluctuations on stroke outcomes in young rats

Authors: *V. REDDY, B. MANKALIYE, S. H. PATEL, A. P. RAVAL;
Neurol., Univ. of Miami, Miami, FL

Abstract: One out of five women suffer stroke after menopause in the United States. Menopause is characterized by decline in endogenous estradiol-17 beta (E2). Estrogen is neuroprotective against ischemia; however, concern regarding the safety of E2 therapy in menopausal women has inhibited translation of this treatment to the clinic. Despite these findings, women appear to be naturally protected against ischemic neuronal damage during pre-menopausal life, suggesting some estrogen-influenced neuroprotective mechanism. Thus, a better understanding of the cellular and molecular mechanisms by which endogenous estrogen fluctuations govern the female brain is required. In a published study, we demonstrated that increasing titers of E2 during the transition from the diestrus to proestrus stage of the estrous cycle protected neurons against global cerebral ischemia in young rats (Raval et al., 2009). The goal of the current study is to investigate the effects of endogenous E2 on stroke outcome and its impact on synaptic function. We hypothesized that higher levels of prevailing estrogen would lead to an increase in synaptic vesicle release. The proposed hypothesis was tested using young cyclic female (4-6 months) rats. Animals were randomly exposed to transient middle cerebral artery occlusion (tMCAO; 90 min) or sham surgery. Twenty-four hours after tMCAO, brains were collected to quantify infarct volume. The area of infarction was visualized using the TTC (triphenyltetrazolium chloride) technique and measured using ImageJ software. In a separate cohort of rats, brain tissue was collected for western blot analysis 24h after tMCAO/sham surgeries. The brain tissue was incubated with primary antibodies against synaptic proteins including syntaxin, synapsin, synaptotagmin, synaptophysin, Munc-18, SNAP 25, Complexin-1, and PSD-95. We observed a significant ($p<0.05$) reduction in infarct volume in young female rats, which underwent tMCAO during the estrus stage (higher levels endogenous E2) as compared to diestrus (lower levels of circulating E2). Results also showed that the brain of young rats in the estrus stage had an increased expression of syntaxin, synapsin, and synaptotagmin compared to diestrus stage. Our study demonstrates that higher levels of endogenous E2 regulate synaptic vesicle release after stroke thus reducing ischemic brain damage in young female rats.Reference: Raval, A. P., et al., 2009. Pretreatment with a single estradiol-17beta bolus activates cyclic-AMP response element binding protein and protects CA1 neurons against global cerebral ischemia. Title: Serum/glucocorticoid-regulated kinase 1 in cardiac arrest-induced brain injury

Authors: C. Y.-C. WU[1], G. CLEMONS[2], C. H. ACOSTA[2], W. C. CARR[1], C. T. CITADIN[2], H. LIN[1], ***R. H. LEE**[1];
[1]Neurol., [2]Cell. Biol. and Anat., LSU Hlth. Sci. Ctr., Shreveport, LA

Abstract: Cardiopulmonary arrest (CA) is a major cause of death/disability in the U.S. with poor prognosis and survival rates. The current CA therapeutic challenges are physiologically complex because they involved hypoperfusion [decreased cerebral blood flow, (CBF)], neuroinflammation, and mitochondrial dysfunction. Therefore, identify these complex regulatory elements that ultimately control neuronal viability can lead to novel therapies against CA. We previously discovered that novel serum/glucocorticoid-regulated kinase 1 (SGK1, a serine/threonine kinase) is highly expressed in brain neurons that are susceptible to ischemia (e.g., hippocampus and cortex). SGK1 plays a critical role for numerous cellular processes, including regulating homeostasis, inflammation, and apoptosis in various organs. However, the role of SGK1 in the brain is understudied. To explore the potential role of SGK1 in CA-induced brain injury, we inhibited SGK1 following CA using pharmacological (specific SGK1 inhibitor) and cell type (neuron)-specific genetic approaches (e.g., shRNA) in our well-established rodent models of CA (asphyxia- and potassium chloride-induced cardiac arrest). Intra-vital two-photon laser scanning microscopy and laser speckle contrast imaging revealed that pre-treatment with GSK 650394 (1.2 μg/kg, intracerebroventricular injection) or SGK1-shRNA ($1x10^{11}$ viral particles, retro-orbital injection) attenuated cortical hypoperfusion after CA. Interestingly, neuroinflammation (via astrogliosis and M1 microglia polarization) and mitochondrial dysfunction (via Seahorse respirometry) were reduced, while neuronal survival was enhanced in the CA1 region of the hippocampus after pre-treatment with GSK 650394 or SGK1-shRNA. Finally, rodents' functional learning and memory after CA were evaluated using Y-maze and novel object recognition test. Rodents pre-treated with GSK 650394 or SGK1-shRNA exhibited better neurological outcomes following CA as compared to untreated animals. In conclusion, SGK is one of the major contributors to CA-induced brain injury, while pre-treatment with GSK 650394 or SGK1-shRNA to diminish SGK1 expression provides neuroprotection against CA-induced hypoperfusion, neuroinflammation, mitochondrial dysfunction, neuronal cell death, and neurological deficits. Since the FDA has approved over 46 kinase-related drugs for the treatment of various diseases, our study will be promptly translated into human clinical trials for the patients suffering from CA.

Title: Safety and efficacy of intra-arterial mesenchymal stem cell therapy following ischemic stroke

Authors: *R. THAKKAR[1], M. WATANABE[2], P. BHATTACHARYA[3], S. CHAKRAVARTY[4], C. DONG[5], A. P. RAVAL[5], J. HARE[6], A. KHAN[4], T. RUNDEK[5], D. YAVAGAL[5];

Abstract: Introduction: Stroke is the leading cause of disability and the 5th leading cause of death in the USA. Despite recent advances in the standard of care for ischemic stroke, over 50% of stroke survivors are chronically disabled. To overcome this, novel treatment strategies need to be developed, particularly ones that help patients regain their functional abilities. Research in the past 2.5 decades has shown great promise in the use of cell-based therapies for ischemic stroke. Intra-arterial (IA) delivery directs the cells to the injured brain, is minimally invasive and widely available, making it attractive for clinical translation. Our group and others have shown the safety and efficacy of IA Mesenchymal Stem Cell (MSC) treatment in a rodent stroke model at 24 hours post-reperfusion. The optimal timing of a single dose of IA MSC is unknown. Also, whether an additional dose will lead to greater benefit and the optimal timing of the second dose need to be determined for successful translation of IA MSC to clinic. Here, we hypothesize that dual dose IA-MSC treatment leads to enhanced improvement after stroke as compared to a single dose and the controls. **Methods:** For this study, we used a reversible middle cerebral artery occlusion (rMCAO) model for stroke in rats. IA-MSCs (10^5 cells) or control PBS were administered in dual doses first at 1 day and then at 4, 6- or 15-days post-stroke. Behavioral analysis, stroke volume and neuronal counting were determined at 30 days after treatment. **Results:** Significant improvement in behavior, reduction in stroke volume, and increased neuronal survival with improved brain tissue integrity were reported in the 1-6D group.

Conclusion: The results of our study indicate that dual dose IA-MSCs at 1-6days after stroke is safe and leads to enhanced symptomatic recovery, reduced stroke lesion, and increased neuronal survival. In summary, our findings contribute to the understanding of the benefit of dual dose of IA MSC and aid effective translation to stroke patients.

Abstract: Uncovering sex-specific differentially regulated molecular changes in chronic hypoxia-induced learning and memory impairments using zebrafish model Kalyani Soren[1,3], Tapatee Das[1,3], Kodi Gnaneshwari[1], Pankaj Malakar[1], Arvind Kumar[2], Srinivas Kantevari[3,4], Sumana Chakravarty*[1,3] [1]Applied Biology, CSIR- Indian Institute of Chemical Technology , Hyderabad. [2]CSIR-Centre for Cellular and Molecular Biology, Hyderabad [3]Academy of Scientific and Innovative Research (AcSIR), Ghaziabad-201002, U.P, India. [4]Fluoro & Agrochemicals Division, CSIR- Indian Institute of Chemical Technology, Hyderabad. *Email: sumanachak@iict.res.in Chronic hypoxic (CH) episodes often lead to problems in the brain, which in turn lead to cognitive impairments such as decline in memory & inability to learn, besides other behavioral deficits. Many of the neurological disorders have sex-specific characteristics. We have recently reported sex differences in systemic responses in zebrafish (zf) at the cellular & molecular level during the post-hypoxia (PH) recovery. However, studies on sex differences in CH induced cognitive impairment are not reported yet. To address this, we have used zf of 6-7 months old in this study. We have examined the effects of hypoxic stress (HS) on the behavior of zf using the novel tank test following their exposure to CH. Our results showed PH behavioral deficits in most of the tests, which are thought to be known as the hallmarks of

HS in both sexes. We evaluated cognition of zf, using T-Maze test after training them to recognize reward/punishment zone. We observed a PH cognitive impairment with an indication of sex difference in choosing the reward zone. Further study showed significant increase in the levels of inflammatory markers found in male zf brain compared to that in female. Keeping in mind, restoration between protective & degenerative neuroinflammation is of great interest in therapeutic approaches, we have used a novel inhibitor compound of inflammasomes molecule NLRP3 screened through in-vitro assays. There was significant decrease in inflammation associated with an increase in glial markers & cognitive improvements, irrespective of sexes; the compound was injected at the dose 5mg/kg body weight. A noticeable increase in neurogenesis in females as compared to their male was also observed suggesting the beginning of neural repair mechanism. Revealing the sex specificity in HS response, this study emphasizes not only the importance of sex difference in behavioral & pharmacological analyses but also in modeling sex differences in clinical responses to anti-inflammatory drugs in developing CNS therapeutics, using an alternate animal model.

Title: Age-related differences in inflammatory and behavioral responses following spinal cord contusion in rats

Authors: *B. T. DAVID, S. Y. OH, Q. SHEN, Y. LOPEZ-RAMIREZ, D. TUCKER, N. WROBEL, B. AVONTS, J. ALBERTS, J. MOSS, K. RAUE, R. G. FESSLER;
Neurosurg., Rush Univ. Med. Ctr., Chicago, IL

Abstract: The damage that results from spinal cord injury (SCI) is caused by both the initial mechanical trauma and the secondary injury that exacerbates the inflammatory reaction at the lesion site. As the average age at which an individual suffers an SCI has increased over the past decades, it has become increasingly relevant to determine what role age has on that inflammatory response. The aging process has been thought to be coincident with a state of nonresolving activation of inflammatory pathways, but many studies that have investigated the role of aging and SCI have found mixed results. Here, using the Infinite Horizon Impactor, we administered moderate contusive injuries to rats at a variety of ages between 3 and 12 months. We found that the older animals had a trend towards a worse recovery of both hindlimb locomotion and bladder function, despite having a lower microglia/macrophage population at the injury epicenter. Moreover, the reduced inflammatory response in older rats was not detected during the acute

phase. This inflammation data is contrary to what some have reported in significantly older animals (18 months), suggesting a possible shift in the inflammatory response with age, as opposed to a gradual increase in overall systemic inflammation.

Title: Transplantation of tauroursodeoxycholic acid-inducing M2-phenotype macrophages promotes an anti-neuroinflammatory effect and functional recovery after spinal cord injury in rats

Authors: *S. SOHN, W.-K. KO, S. KIM, G. HAN, D. LEE, S. SHEEN;
CHA University, CHA Bundang Med. Ctr., Gyeonggi-do, Korea, Republic of

Abstract: In this study, we study the transplantation of tauroursodeoxycholic acid (TUDCA)-induced M2-phenotype (M2) macrophages and their ability to promote anti-neuroinflammatory effects and functional recovery in a spinal cord injury (SCI) model. To this end, compared to the granulocyte-macrophage colony-stimulating factor (GM-CSF), we evaluated whether TUDCA effectively differentiates bone marrow-derived macrophages (BMDMs) into M2 macrophages. The M2 expression markers in the TUDCA-treated BMDM group were increased more than those in the GM-CSF-treated BMDM group. After the SCI and transplantation steps, pro-inflammatory cytokine levels and the mitogen-activated protein kinase (MAPK) pathway were significantly decreased in the TUDCA-induced M2 group more than they were in the GM-CSF-induced M1 group and in the TUDCA group. Moreover, the TUDCA-induced M2 group showed significantly enhanced tissue volumes and improved motor functions compared to the GM-CSF-induced M1 group and the TUDCA group. In addition, biotinylated dextran amine (BDA)-labeled corticospinal tract (CST) axons and neuronal nuclei marker (NeuN) levels were increased in the TUDCA-induced M2 group more than those in the GM-CSF-induced M1 group and the TUDCA group. This study demonstrates that the transplantation of TUDCA-induced M2 macrophages promotes an anti-neuroinflammatory effect and motor function recovery in SCI.

Therefore, we suggest that the transplantation of TUDCA-induced M2 macrophages represents a possible alternative cell therapy for SCI.

Title: No monocyte-derived macrophages in the anterior cingulate cortex of mice with SCI-induced affective pain

Authors: *J. H. RICHARDS, M. R. DETLOFF;
Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) is a neuroimmune disorder that results in chronic pain development. The pain experience is multidimensional, involving sensory, cognitive, and affective components. While most basic science research focuses on sensory discriminative alterations in SCI pain, the prevalence of affective disorders, like major depressive disorder is high in the SCI community. Affective pain is defined as the negative emotion ascribed to the perception or anticipation of noxious sensations that motivates behavior. Importantly, both chronic pain and affective disorders have been correlated with aberrant inflammation generated by resident or infiltrating immune cells throughout the nervous system. The anterior cingulate cortex (ACC) contributes to both decision-making and emotional regulation and its activity is associated with both pain and affective disorders. Thus, we hypothesize that SCI-induced neuroinflammation in the ACC causes alterations in affective pain in the mouse model. We completed moderate unilateral C5 contusions on LysM-eGFP reporter mice in order to visualize macrophages that infiltrate the ACC after injury. Alterations in affective behavior, like anhedonia, learned-helplessness, and social withdrawal were measured with sucrose preference, forced swim, and social interaction tests. von Frey and Hargreaves' testing measured sensory discriminative aspects of pain. At 6 weeks following SCI, both male and female mice exhibit sensory and affective dysfunction compared to naïve, uninjured mice. Immunohistochemistry performed on ACC tissue did not reveal any evidence of infiltrating macrophages at 7- or 28-days post injury. However, we identified increased IBA-1+ staining in the ACC at 7-day post-SCI, which suggests that SCI causes activation of microglia. We are currently utilizing qPCR to

measure changes in gene expression of cytokines that may be associated with affective pain. These findings indicate that supraspinal inflammation may be a potential target for future interventions that reduce affective pain.

Title: Perturbations of the immune response after spinal cord injury in aged mice revealed by single-cell profiling

Authors: *A. SALVADOR[1,2], T. DYKSTRA[2], J. RUSTENHOVEN[2], S. BLACKBURN[2], I. SMIRNOV[2], J. HERZ[2], J. KIPNIS[2];
[1]Neurosci. Grad. Program, Univ. of Virginia, Charlottesville, VA; [2]Dept. of Pathology and Immunol., Washington Univ. of St. Louis, St. Louis, MO

Abstract: Traumatic CNS injuries such as spinal cord injury (SCI) affect millions of people worldwide. More aging individuals experience SCI which lead to more devastating consequences. While treatment modalities are limited, one promising strategy is to harness the power of the immune system as previous studies have demonstrated its beneficial function after CNS injury. In this study, we investigated the temporal changes of the immune (CD45+) cell response in the injured mouse spinal cord using single-cell profiling. We observe dramatic changes in the immune cell composition of the spinal cord characterized by a massive infiltration of myeloid cells in the acute phases of injury (3 dpi) followed by the recruitment of lymphocytes in the more chronic phase of injury (14 dpi). These changes were also accompanied by shifts in the transcriptional state of the resident immune cells of the spinal cord, microglia. We observed the emergence of activated and interferon-responding microglia states, which may have diversified functions in the injured spinal cord. Peripheral myeloid cells recruited to the injury site were also investigated, and our analysis reveals populations that may contribute to distinct function and ontogeny. Putative ligand-receptor interactions were also analyzed to predict signaling pathways between immune cells that can perpetuate inflammation to worsen damage and those that can support repair. We also studied the temporal changes in the immune response of aged mice after spinal cord injury, which remain unexplored. The aged naive spinal cord already harbors a striking proportion of activated microglia and T cells representing heightened inflammation. Moreover, injury in aged mice leads to an upregulated expression of cytokine and

chemokine genes in macrophages compared to injury in young mice. These results may indicate that there is exacerbated inflammation in aging that worsens recovery. Overall, the cellular atlas we generated in this study serves as a rich, comprehensive resource that can shed light on our mechanistic understanding on the role of the immune system and of aging in CNS injury, which may help identify critical targets that enhance repair.

Title: Foamy macrophages induce fibrosis via IL1R1 after spinal cord injury

Authors: *K. MADDY[1], C. RYAN[1], L. MILICH[1], J. CHOI[1], J. K. LEE[2];
[1]Univ. of Miami Miller Sch. of Med., Miami, FL; [2]The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Background: Following spinal cord injury (SCI), inflammation and fibrosis at the lesion reduces the regenerative capacity of neural tissue. Myeloid cells play a key role in modulating inflammatory responses and thus are an important target in limiting tissue damage and maintaining tissue integrity at the injury site. A subset of these cells are lipid-droplet filled proinflammatory macrophages, termed “foamy macrophages.” In order to develop more effective therapeutic interventions, a better understanding of these myeloid cellular interactions is necessary. Our previous single-cell RNA sequencing (sc-RNAseq) study using of virtually all cell types comprising the mouse SCI site identified a novel interaction between IL1R1+ fibroblasts and IL1a+ macrophages. However, the functional role of this receptor-ligand signaling pathway in SCI pathobiology remains poorly understood.**Methods:** scRNA-seq data from mouse SCI tissue was used to assess expression of IL1a and IL1R1 at the injury site. Immunohistochemistry and in situ hybridization was used for validation studies. Using in vitro models to further probe the mechanism of fibrosis after SCI, primary fibroblasts from wild-type (WT) and IL1R1 knockout (KO) mice were cultured and treated with foamy macrophage

conditioned media as a source of IL1a, to measure the expression of extracellular matrix (ECM) molecule fibronectin. For in vivo analysis, IL1R1 KO mice received a mid-thoracic contusive SCI and the injury site was assessed histologically.**Results:** scRNA-seq data showed IL1a expression in macrophages and IL1R1 expression specifically in fibroblasts and endothelial cells, which was validated using immunohistochemistry and in situ hybridization.. Injury sites in IL1R1 KO mice showed reduced fibrosis after SCI.**Conclusion:** Our results suggest an important role played by IL1R1+ fibroblasts and their interactions with IL1α+ macrophages in inflammation and fibrosis after SCI. Genetic deletion of IL1R1 results in reduced fibrotic scar formation after SCI. Understanding these receptor-ligand interactions and their role in SCI pathogenesis at the injury site can present new opportunities for targeted therapeutic interventions.

Title: Pi3k/mtor inhibition reduces foamy macrophages after spinal cord injury

Authors: *C. B. RYAN, J. S. CHOI, H. A. ALI, J. K. LEE;
Dept. of Neurosurgery, The Miami Project to Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: After spinal cord injury (SCI), macrophages infiltrate the injury site and phagocytose lipid debris, forming lipid-laden “foamy” macrophages. Foamy macrophages contribute to the propagation of inflammation at the injury site and remain in the lesion chronically. To better understand the mechanisms of foamy macrophage formation, we developed a novel in vitro foamy macrophage assay. The assay uses primary bone-marrow-derived macrophages isolated from wildtype 6-8 week old male mice treated with wildtype spinal cord homogenate to represent all lipid sources at the spinal cord injury site. Using this assay, we found increased expression of inflammatory cytokines and mitochondrial dysfunction in foamy macrophages, accompanied by increased production of ROS. Pharmacological inhibition of PI3K/mTOR resulted in decreased lipid content in foamy macrophages, which was associated with reduction

in ROS production and inflammatory cytokine production. RNA-sequencing of foamy macrophages following PI3K/mTOR inhibition identified induction of lipid transporters as a potential mechanism. Macrophage-specific inhibition of PI3K/mTOR using liposomes showed significant decrease in foamy macrophages at the injury site after a mid-thoracic contusive SCI in 8-10 weeks old female mice (7 dpi: n=9 PBS, n=9 Inhibitor; 28 dpi: n=8 PBS, n=8 Inhibitor). Together, our data suggests that foamy macrophages are important contributors to inflammation after injury and identify PI3K/mTOR pathway in foamy macrophages as a potential therapeutic target for SCI.

Title: Microbiome alterations lead to impaired enteric neuronal status following spinal cord injury

Authors: *A. M. HAMILTON, J. CHANG, S. M. GARRAWAY, S. SRINIVASAN, T. R. SAMPSON;
Emory Univ., Atlanta, GA

Abstract: Research Objective & Rationale: Neurogenic bowel dysfunction is one of the most cited detriments to quality of life in persons with spinal cord injury (SCI). In addition to the loss of supraspinal control over spinal defecation centers, SCI results in significant alterations to enteric neuromusculature, including enteric neuron loss. The gut microbiome changes significantly post-SCI and directly affects injury outcomes and recovery, likely through metabolic and inflammatory pathways. Interactions between host and microbiome modulate overlapping functions including enteric neurogenesis, endocrine signaling, and inflammation, all of which impact intestinal motility. We therefore sought to determine if post-SCI dysbiosis directly contributes to changes in enteric neuromusculature and gastrointestinal (GI) motility and if targeting the post-injury microbiome could improve GI outcomes associated with SCI.
Methods: Adult Mice were subjected to a midthoracic (T9) spinal cord injury or a midthoracic laminectomy (sham-surgery controls). GI motility was assessed, and molecular analysis of enteric neuronal status and colonic inflammation performed. Fecal microbiomes derived from mice with SCI or from sham controls were used to colonize germ-free mice to assess the impact

of the injury-induced microbiome on GI physiology in mice naive to injury. Following colonization, GI motility was assessed, colonic tissues collected, and molecular markers of neuronal and inflammatory status analyzed. **Results:** We observed that mice with SCI had significantly impaired intestinal transit, as compared to sham controls. Colonic tissues revealed decreased neuronal markers in injured mice, as well as evidence of increased inflammation. We noted alterations to serum serotonin metabolism, indicative of dysfunction present in intestinal endocrine cells. Colonization of injury naïve mice with microbiomes derived from injured donors recapitulated colonic dysmotility of their donors. Intriguingly, molecular analysis of mice colonized with SCI-derived microbiomes revealed increased intestinal inflammation and significant alterations to the status of the ENS and circulating intestinal neuropeptide hormones. **Conclusions:** Our data demonstrate a direct effect of the gut microbiome on post-SCI GI dysmotility and pathophysiology, suggesting that dysbiosis appearing after injury contributes to reduced enteric neurons, GI inflammation, and an altered serum metabolic status. These novel findings provide a clear rationale for the advancement of targeted dietary or probiotic therapies to ameliorate GI dysfunction in persons with SCI.

Title: Il-12 contributes to secondary damage and functional impairment after spinal cord injury.

Authors: *J. ROSAS[1], N. PELISCH[1], B. APERI[1], K. STEHLIK[2], M. D. BUDDE[2], K. SWARTZ[1], **A. KRONER-MILSCH**[2];

Abstract: Traumatic spinal cord injury (SCI) is a relatively frequent event that imposes a massive burden on the health, quality of life and socioeconomic situation of affected persons. Tissue damage after SCI occurs in two phases: primary and secondary damage. Primary damage refers to the initial mechanical trauma causing cell death and tissue disruption while secondary damage includes multiple processes that can promote further damage. One critical secondary process is inflammation or the recruitment and activation of immune cells. A more complete understanding of individual contributors to inflammatory damage is necessary to specifically target and modify detrimental factors. Inflammation after SCI is exacerbated, with activated

microglia and monocyte-derived macrophages being the main immune cell populations in the injured tissue. Pro-inflammatory cytokines IL-12 and IL-23 share the p40 subunit which is strongly upregulated after phagocytosis of red blood cells. IL-12 and IL-23 can be expressed by a multitude of cell types and mediate multiple functions on different target cells. Here, we assess the functional effect of IL-12 and IL-23 via IL-12p40 on SCI, using a low thoracic (T11) moderate contusion injury (50 kDyne) in mice. First, we quantified protein expression using Western blot to find IL-12 factors upregulated compared to laminectomy controls. Furthermore, we observed a concurrent upregulation of IL-12p70 with hemoglobin, a biomarker for magnetic resonance imaging (MRI) spinal cord hemorrhage. We have identified IL-12p40 to be expressed primarily by astrocytes early after injury and by microglia by 28 days after injury. Both receptors are robustly expressed in astrocytes. To test the functional impact of IL-12 and IL-23 on SCI, we utilized IL-12p40 knockout mice and wildtype controls to quantify locomotor recovery after SCI using the Basso Mouse Scale (BMS). We observed improved recovery in IL-12p40 deficient mice compared to wildtype mice. IL-12p40 KO mice also demonstrate significantly more spared tissue 28 days after injury. In summary, these results suggest that the absence of IL-12p40, but not IL-23p19, mediates a neuroprotective effect after contusion SCI, serving as a new potential therapeutic target to ameliorate secondary damage and promote better functional recovery.

Title: Neutrophil Extracellular Traps in Spinal Cord Injury

Authors: *S. K. REID[1,2], M. E. LEAL[2], M. A. KIRCHHOFF[2], S. J. LEE[2], S. W. MIN[2], M. E. PLATT[2], D. A. MCCREEDY[1,2];

Abstract: Spinal cord injury (SCI) is a severely debilitating event that results in extensive tissue loss and long-term neurological deficits. Neutrophils are the first peripheral immune cell to infiltrate the spinal cord in large numbers following injury; however, their role in secondary tissue damage is not well characterized. Neutrophils employ numerous cytotoxic effector functions in response to injury that are important for eliminating potential pathogens, but may

result in collateral tissue damage. Neutrophil extracellular traps (NETs) are a recently identified effector function wherein decondensed chromatin decorated with granule proteins is expelled from the cell body as a mechanism to trap and destroy bacteria and other pathogens. Beyond their bactericidal role, NETs have been implicated in a variety of sterile pathologies as damaging to the host. The contribution of NETs towards secondary tissue damage in the context of SCI, however, remains unexplored. To determine if NET formation occurs acutely after SCI, we performed an ELISA for citrullinated histone 3 (CitH3) and DNA complexes in peripheral blood and spinal cord samples at 0, 4, 8, 12, 18, and 24 hrs post-SCI. We found that CitH3/DNA levels, which are indicative of NETs, markedly increased over the first 12 hours post-SCI and remained elevated through 48 hours post-SCI. Similar trends were observed in blood samples, albeit at lower levels. To confirm NET formation in neutrophils, we also performed flow cytometry to assess the presence of CitH3 in neutrophils from in blood and spinal cord samples at 24 hrs post-SCI. We observed a nearly 7-fold increase in CitH3+/Ly6G+ cells in the acutely injured spinal cord relative to the blood, further indicating that NET formation is occurring in response to SCI. Collectively, our data demonstrate the first evidence of NETs in the injured murine spinal cord, peaking by 24 hrs following injury. Our results suggest that pharmacological treatment to eliminate NETs, such as with the DNase I, may represent a therapeutic strategy to limit tissue loss and improve functional recovery after SCI.

Title: Oncomodulin derived from pro-regenerative macrophages following preconditioning injury promotes sensory axon regeneration

Authors: *M. J. KWON[1], Y. SEO[2], H. CHO[3], H. C. KANG[3], B. G. KIM[1];

Abstract: We have previously reported the neuron-macrophage interaction mediating perineuronal activation of pro-regenerative macrophages in dorsal root ganglia (DRGs) following preconditioning peripheral nerve injury. Oncomodulin (ONCM) is a macrophage-derived factor previously identified to exert pro-regenerative activities for retinal ganglion axons. The current study found that ONCM expression was markedly increased in DRGs at 3 and 7 days following preconditioning injury. Preconditioning-induced enhancement of neurite outgrowth activities was abolished in ONCM-deficient mice. We determined whether the ONCM is involved in our neuron-macrophage interaction model, in which conditioned medium (CM) obtained from the neuron-macrophage cocultures treated with cAMP exhibits robust neurite outgrowth activities for DRG sensory neurons. The neurite-outgrowth activities were abolished when ONCM-deficient macrophages, but not ONCM-deficient neurons, were used for the cocultures, indicating that macrophage-derived ONCM play a critical role. Our previous study demonstrated that sensory neuron-derived chemokine CCL2 drives activation of pro-regenerative macrophage phenotype. Preconditioning injury in CCR2-deficient mice increased ONCM level to a much smaller extent. CCL2 overexpression in DRG neurons exhibited a dramatic increase in the extent of neurite outgrowth mimicking conditioning effects, while it failed to promote neurite outgrowth in ONCM-deficient mice. We further demonstrated that certain regenerative-associated genes, such as Neuropeptide Y, Sprr1a and Vip were upregulated in ONCM treated DRGs sensory neuron. We sought to examine whether ONCM can be therapeutically used to enhance intrinsic regenerative capacity for DRG sensory axons following spinal cord injury. When ONCM was injected into DRGs, sensory neurons showed very little, if any, improvement in neurite outgrowth. However, injection of ONCM conjugated to a reducible epsilon-poly(L-lysine)-nanogel (REPL-NG) dramatically increased neurite outgrowth. Furthermore, intraganglionic injection of REPL-NG/ONCM complex increased the extent of axon regeneration beyond the dorsal hemisection injury site. Thus, our study demonstrated that ONCM is a critical proregenerative factor derived from macrophages to enhance intrinsic regenerative capacity of sensory axons. We also suggest a possibility that the nanogel-mediated ONCM delivery can be exploited as a therapeutic agent for promoting sensory axon regeneration following spinal cord injury.

Title: Association of metabolic markers and microbiota populations in a rat model of thoracic spinal contusion

Authors: *A. M. SMITH[1], B. A. WELCH[2], K. K. HARRIS[2], M. GARRETT[3], B. E. GRAYSON[4];
[1]Neurobio., Univ. Of Mississippi Med. Ctr., Jackson, MS; [2]Neurobio., [3]Pharmacol., [4]Dept of Neurobio. and Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Spinal cord injury (SCI) results in chronic changes to multiple body systems, including the digestive system. The gut microbiota exist symbiotically within the organism and are readily influenced by diet, health status, and physical activity. The relationship between metabolic markers and the microbial populations following SCI remains unknown. We performed thoracic level 10 contusions or sham injuries on male Long-Evans rats. After 4 weeks of recovery, the rats were exposed to either low-fat (9%, LF) or high-fat (40%, HF) diet for 12 weeks. Following euthanasia at 16 weeks, caecal samples were harvested. Microbial DNA was isolated and sequenced using the Illumina Iseq100 platform, and data processed using Microbiome Analyst software. Overall, sham rats weighed significantly more than the SCI rats ($p < 0.01$), but HF-fed rats were heavier than LF-fed rats ($p < 0.05$). HF rats also had elevated body fat composition ($p < 0.05$), with no difference in lean body mass in comparison to LF. Leptin levels were significantly reduced in SCI animals compared to sham ($p <0.05$). Leptin levels were also higher in the HF group compared to LF, independent of injury ($p < 0.05$). Triglyceride levels were significantly increased in HF compared to LF. With respect to the microbiome analysis, significantly increased richness in read diversity existed in SCI animals when compared to sham ($p < 0.01$). Beta diversity analyses showed significant differences in the four groups; LF-fed rats were found to have more diversity overall. There were abundant changes at all taxonomic levels when comparing LF vs. HF, independent of injury ($p < 0.05$). Simple linear regression analyses were performed in sham animals alone to determine the association between body fat; strong association existed at multiple taxonomic levels, including *Lautropia, Rhodobacteraceae,* and *Bacilli.* This relationship was abolished in SCI animals, who only demonstrated a strong relationship in four taxa, (e.g., *Olivibacter* and *Roseburia),* which were alternately not significantly correlated in sham animals. Similarly, analyses in sham animals to determine the relationship with leptin levels showed that there were strong associations with certain bacteria (i.e., *Firmicutes, Clostridia,* and *Enterobacteriales).* Again, this relationship was eliminated in SCI animals, whose leptin levels only had an association with the genus *Olivibacter.* These data suggest that the unique relationship that exists between markers of adiposity and microbiota in healthy, able-bodied rats are mitigated following SCI. More studies are required to understand the reason behind this altered relationship.

Title: Role of Hemopexin in secondary damage following spinal cord injury

Authors: N. PELISCH[1,3], J. ROSAS ALMANZA[4,2], K. STEHLIK[3,2], B. APERI[4,2], ***A. KRONER**[4,2,5];
[1]Neurosurg., [2]Clement J Zablocki VA Med. Ctr., Milwaukee, WI; [3]Neurosurg., [5]Microbiology and Immunol., [4]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Tissue damage in spinal cord injury (SCI) occurs in two phases, with the primary damage being caused by the mechanical insult and the secondary damage mediated by a multifactorial cascade of events. Inflammation and hemorrhage from sheared blood vessels significantly contribute to secondary damage after SCI. Blood breakdown products such as hemoglobin, heme and iron are pro-inflammatory and highly cytotoxic through lipid peroxidation, DNA oxidation and iron deposition. In the vasculature, breakdown products are sequestered by designated capture proteins: Haptoglobin (Hp) and Hemopexin (Hx) bind free hemoglobin and heme, respectively, $Hx^{-/-}$ mice until the complexes are taken up by macrophages, thereby preventing its toxic effects. Despite low expression levels of Hp and Hx within the CNS, limiting the potential to reduce tissue damage and enhance functional recovery following hemorrhagic insults and trauma, the absence of Hp and Hx under such conditions resulted in further functional impairment. Here, we investigate the role of Hx on injury progression, axonal damage and functional outcome in male and female mice following thoracic contusion SCI. After SCI, Hx is expressed predominantly in astrocytes, while its receptor LRP is expressed mainly by macrophages. At the gene expression level, Hx was upregulated at day 1 post SCI, while LRP expression was increased at day 7 post SCI compared to the laminectomy control group. $Hx^{-/-}$ mice showed reduced locomotor recovery compared to wildtype mice, combined with an increase of axonal damage and reduced neuronal survival distal to lesion. These results indicate a detrimental effect of the lack of Hx and that boosting Hx availability could result in improved functional recovery and reduced secondary damage after SCI.

Title: Distinct effects of arousal and movement on visual spatial selectivity across network, cellular and subthreshold levels in mouse visual cortex

Authors: S. COLETTA[1], J. DEL ROSARIO[2], A. DEL CASTILLO VALERIO[1], B. HAIDER[3]; [1]Georgia Tech., Atlanta, Georgia; [2]Georgia Inst. of Technology/Emory Univ., Atlanta, AL; [3]Biomed. Engin., Georgia Tech. and Emory Univ., Atlanta, GA

Abstract: Sensory processing depends strongly upon factors such as arousal, movement, and task engagement. Several studies in primary visual cortex (V1) of head-fixed mice have revealed that locomotion increases arousal and this leads to membrane potential (Vm) depolarization, desynchronization, and elevated firing rates in excitatory neurons (Neske et al., 2019; Vinck et al., 2015). There remain open questions regarding the influences of arousal and motor action upon vision. First, most studies examine response amplitude without assessing changes to spatial selectivity. Second, most studies rely on one signal modality in isolation from others, providing an incomplete picture of potential effects of arousal and movement on spatial selectivity in V1 across multiple scales. Here, we performed multisite silicon probe and whole-cell patch-clamp recordings in awake, head-fixed, stationary mice (n = 23) while monitoring pupil and periorbital facial movements with high-speed video. We computed pupil size and facial motion energy to explore the impact of arousal versus movement on V1 receptive field (RF) properties. We showed small (9° wide) full contrast vertical bars throughout the visual field (>150°) to assess changes to spatial selectivity. In some probe recordings, we identified parvalbumin (PV) and somatostatin (SOM) interneurons via optogenetic stimulation, and identified putative excitatory and inhibitory neurons based on regular spiking (RS) or fast spiking (FS) waveforms. Even in stationary mice, we found that arousal and movement exerted clear and non-overlapping effects on visual responses and spatial selectivity. With increasing arousal, RS neurons (n = 1150) and local field potential (LFP) responses showed modest and potentially non-monotonic changes in RF amplitude. These effects of increased arousal were mirrored in Vm of excitatory neurons (n=35), where subthreshold response amplitude and spikes decreased while spatial selectivity increased; these trends were distinct from effects of movement, which generally evoked greater depolarization and firing. The effects were clearer and distinct among different inhibitory cell-types: in PV (n=25) and fast-spiking (FS) neurons (n=290), responses increased with arousal and especially movement, but both factors suppressed SOM neurons (n=20). We are examining timing between movement and pupil, and if inhibitory neuron responses explain those in excitatory neurons. These preliminary results suggest a complex interplay of arousal and

movement even in non-locomoting mice, with distinct contributions from cortical cell-types to visual spatial selectivity.

Title: Local field potential signatures of context-specific processing in the mouse cortical column during visual oddball

Authors: *C. G. GALLIMORE, J. P. HAMM;
Neurosci., Georgia State Univ., Atlanta, GA

Abstract: Attentional demands shift on a moment-to-moment basis. Top-down attentional control, the ability to maintain focus on the task at-hand by filtering out irrelevant information, is in constant competition with bottom-up attentional capture, the propensity of non-goal related, but otherwise potentially salient, stimuli to evoke an orienting response in cortex. The oddball paradigm is a classic psychological assay to measure this interplay in cortical circuits, which manifests in the form of event-related potentials (ERPs) collected from the scalp. Human studies using this paradigm have shown that people in neuropsychiatric disease-states, such as schizophrenia, display reductions in prediction-error signaling to “oddball” stimuli. However, the cortical circuitry supporting this computation needs further characterization. Here, we used linear microelectrode arrays to measure intracranial local field potentials and current source density profiles across laminae 1-5b of the primary visual cortex (V1) of mice (n=7, male and female) while they viewed full-field oriented square-wave grating stimuli in visual oddball sequences and a “many-standards” control sequence. This allowed us to compare cortical responses to the same visual grating stimuli when they were predictable (i.e. redundant in the oddball run, p=.875), rare and unexpected (i.e. deviants, p=.125), and rare but not-deviant (i.e. in the control run, p=.125). We performed dimensionality reduction techniques on trial-wise time-frequency spectral to identify relevant frequency bands for analysis. We identified a superficial (layer 1) and deep (layer 4, ≈400 μm deep) increase in low-frequency (2-10 Hz) oscillatory power to contextually deviant stimuli, suggesting anatomical and frequency-specific signatures of sensory prediction error. Further analysis of current source density (an estimate of local synaptic current flux)

demonstrated deviant stimulus-specific sources and sinks in supragranular regions of V1, consistent with previous *in vivo* two-photon microscopy recordings from our lab which showed excitatory cell firing selective to contextually deviant stimuli in L2/3, but to negligible degrees in deeper layers. We also identified increased alpha (10-15Hz) desynchronization to deviant stimuli across layers 2-5 at the immediate onset of deviant stimuli, but decreased alpha desynchronization in the late stimulus period (300-500ms). These results suggest that bottom-up processing of contextually unexpected stimuli engages low-frequency oscillations and alpha-band dynamics in a layer-specific pattern in V1.

Inst., Princeton Univ., Princeton, NJ

Abstract: The nervous system needs to dynamically adapt to changing environments. A well-known form of visual adaptation is the reduction of neuronal spiking to prolonged exposure of sensory stimuli. This adaptation had long been thought to be not a feature in LGN neurons but one for cortical neurons. However, this view has been challenged by evidence of visual adaptation in the lateral geniculate nucleus of the thalamus (LGN) (Solomon et al., 2004). LGN adaptation in that study was limited to a specific class of neurons in anesthetized animals stimulated over prolonged periods of time (> 10 secs). However, under normal viewing

conditions, eye movements limit uninterrupted stimulation to durations of a few hundred milliseconds. This difference in time scales raises the question whether LGN adaptation occurs on time scales relevant to typical visual function. Here, we show that adaptation in the LGN occurs for short stimulus presentations in awake macaque monkeys. We recorded the visual responses of LGN neurons to one second presentations of 4Hz drifting sinusoidal luminance gratings. We then examined the relative change of each neuron's response across successive grating cycles. This analysis revealed significant decreases in the responsiveness of neurons from all cell classes (parvocellular, magnocellular, and koniocellular). However, only magnocellular neurons showed significant adaptation on the population level. Adaptation also increased response variability between neurons while the Fano factor of individual neurons remained largely constant. Lastly, we examined whether adaptation differed between binocular and monocular stimulation. We found that response reduction was equally pronounced when stimuli were shown to one or both eyes, suggesting a monocular (possibly retinal) origin. Taken together, these results demonstrate significant pre-cortical adaptation during active vision.

Title: Temporal context in visual encoding and readout across species

Authors: *T. SHEEHAN[1], J. SERENCES[2];
[1]UC San Diego, La Jolla, CA; [2]Psychology, UCSD, La Jolla, CA

Abstract: How does stimulus history shape the encoding of incoming visual information and eventual perception? These questions have been explored in the context of adaptation studies which typically present inducing stimuli for unnaturally long periods, and examine the relative influence on neural coding (Patterson, et al., 2013) or perceptual reports (He & MacLeod, 2001). Recently, we found that changes in sensory coding do not directly shape perception but require a readout process that accounts for changes at encoding due to adaptation (Sheehan & Serences, 2021). We further noted that sensory effects were observable up to three stimuli (and over 50s) following the inducing item (presented for only 500ms), suggesting history effects may be robust

even under natural stimulus conditions.
To shed light on this further, we analyzed data from mice and non-human primates passively viewing stimuli and examined how sensory history shapes neural coding (Pachitariu & Stringer, 2019). We found that repulsive biases were pervasive across paradigms, recording technique, and model organisms with significant repulsive biases observable from items as many as 9 stimulus presentations back (12s). This is notable because at such short presentation times perceptual reports are not found to be repelled and are often attracted to past stimuli. As stimuli are naturally correlated across time (Felson et al., 2005), we propose that sensory readout 'expects' a certain amount of adaptation in the encoding population and adjusts its interpretation of incoming sensory signals accordingly. Such an account allows both perceptual attraction and repulsion from past stimuli depending on the strength and duration of stimulus presentations. We test this model on human observers while examining sensory representations in visual areas with BOLD fMRI decoding.

Title: Unaltered divisive normalization in V1 of a mouse model with altered short-term plasticity in thalamocortical synapses

Authors: *J. L. CAZEMIER[1], L. N. CORNELISSE[2], J. A. HEIMEL[1];
[1]Dept. Cortical Structure and Function, Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands; [2]Dept. Functional Genomics & Dept. Human Genet., Ctr. for Neurogenomics and Cognitive Res. (CNCR), Amsterdam UMC - Location VUmc, Amsterdam, Netherlands

Abstract: Divisive normalization is a model that describes how much the response of a neuron to a set of combined stimuli is lower than would be expected by a linear summation of the responses to the individual stimuli. This type of normalization describes the interaction of stimuli on responses in V1 very well and has been suggested to serve the maximizing of sensitivity and reduction of redundancy (Carandini and Heeger, 2011). The source of this normalization is still unclear. One hypothesis is that divisive normalization in the early visual system is caused by short-term depression of afferent excitatory synapses (Carandini et al., 2002). In order to test this hypothesis, we used a mouse model with altered short-term plasticity in the thalamocortical synapse. This was achieved by knocking out one allele of the Stxbp1 gene in thalamic relay neurons. Heterozygous knockout of Stxbp1 (a.k.a. Munc18-1) has been shown to cause increased short-term depression (Toonen et al., 2006). We recorded visual responses from V1 of the anesthetized mice. Indeed, these mice show a decreased half-life of visual responses. However, contrast tuning and cross orientation suppression, in which the effects of divisive normalization can be shown, were unaffected. This suggests that divisive normalization is not caused by short-term depression of thalamocortical synapses. Based on our data, a cortical source of divisive normalization seems more likely.

Title: Schizophrenia-relevant mutation in Kalrn yields neurooscillatory aberrations in mouse sensory cortices

Authors: *A. D. FERRELL[1], A. M. RADER[1,2], Z. NISSEAU-BEY[1], R. A. SWEET[3,4], M. J. GRUBISHA[3,4], J. P. HAMM[1,2];
[1]Neurosci. Inst., [2]Ctr. for Neuroinflam. and Cardiometabolic Dis., Georgia State Univ., Atlanta, GA; [3]Psychiatry, [4]Neurol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Many neuropsychiatric disorders involve disruptions in basic sensory processing. Using standardized sensory stimulation paradigms, such as the auditory steady-state (aSSR) and oddball sequences, such disruptions can be reliably quantified with scalp electrophysiology (i.e. EEG) in human patient samples. From a translational standpoint, these passive stimulation

sequences present a strategic inroad for studying the underlying neurobiological basis of sensory pathology utilizing animal models. To this end, we have recently developed a mouse model of a naturally occurring mutation in Kalrn, initially described in a re-sequencing analysis of a schizophrenia cohort. These mice (Kalrn-PT) exhibit reductions in auditory cortical dendritic length, branching, and spine density and impaired silent gap detection in auditory testing that develops across adolescence. In order to gain insight into disease-relevant pathology at the circuit level, we recorded local field potentials (LFPs) in awake mice, employing two sensory stimulation paradigms used in human clinical research: aSSR and a visual oddball sequence. In the aSSR, we presented 1-second long pure-tone auditory stimuli (70 dB), from 2kHz to 21kHz, where sinusoidally modulated at 40-Hz (gamma-band), and stimulus induced power at 40-Hz was quantified in the LFP. In the visual oddball, full field moving grating stimuli were presented at 1-Hz (.5 sec ISI), with one orientation (e.g. 45-deg) serving as the redundant (p=.875) and the opposite orientation as the oddball stimulus (p=.125). Adult male and female mice (P84-154) were used with the following genotypes: homo-(n=6) or heterozygous (n=3) Kalrn-PT mutants; littermate wildtype controls (WT; n=8). Bipolar electrodes were stereotaxically implanted ≈300 µm deep into primary sensory cortex (auditory-A1 or visual-V1). For mice in the visual stimulus paradigm, bipolar electrodes were also inserted into ACa, a region of prefrontal cortex (PFC) which projects to V1. In A1, mutants displayed increased background noise across all frequencies. 40-Hz entrainment was altered as a function of A1 tonotopy; mutants showed decreased power to locally preferred pitches, but increased power to side-bands, relative to WT. In the dual recordings from V1 and PFC, the Kalrn-PT mice exhibited diminished fronto-visual synchrony across all frequencies. Collectively, these results suggest that Kalrn-PT mutations likely affect inter -regional/-columnar circuitry. This is consistent with known deficits in apical dendrites in Kalrn-PT mutants and suggests a deficiency in dendrite-targeted inhibition, potentially mediated by somatostatin-positive interneurons.

Title: Task-dependent routing of visual information

Authors: *L. POLLINA[1,2], K. BENDTZ[2], G. KREIMAN[2];
[1]École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland; [2]Children's Hospital, Harvard Med. Sch., Boston, MA

Abstract: Current computational models of visual processing focus on the bottom-up cascade of sequential operations along the visual cortex. However, feedback in the brain is abundant and its role is crucial, especially for goal-directed behaviors. In this exploratory research, we investigated how information is routed in a task-dependent manner by recording intracranial field potentials during two tasks in 21 epilepsy subjects implanted with electrodes. We propose a computational model whereby top-down signals modulate activations in a convolutional neural network. In experiment 1, subjects indicated the presence of a given object category (Bansal et al, 2014). Out of 776 electrodes, 101 electrodes (13 %) showed target-dependent response modulation. These electrodes were mainly located in the inferior and middle temporal gyri and the fusiform gyrus. Experiment 2 consisted of synthetic face images generated by the software FaceGen that varied along the male/female dimension or the young/old dimension and subjects classified images according to either dimension. The instructions about whether to discriminate according to one or the other dimension were provided either before stimulus presentation (*pre* condition) or after stimulus presentation (*post* condition). Focusing on the *pre* condition, out of 1201 electrodes, 25 electrodes (2 %) showed modulation by either one of the two tasks. These electrodes were mainly in the middle occipital gyrus, the lingual gyrus, and the middle temporal gyrus. We divided the temporal dynamics of the responses into two phases: an object recognition phase [0-t_i] ms after stimulus onset and a top-down modulation phase [t_i-t_f] ms after stimulus onset, where t_i and t_f represent the first and the last time point of significant divergence (t-test, $p < 0.01$) between the two conditions compared, respectively. To understand the mechanisms of target modulation we propose a computational model that starts with a deep convolutional neural network (VGG19) pre-trained on ImageNet. A top-down modulation signal is implemented in the top two layers of the model (from the classification layer to the topmost fully connected layer and from the topmost fully connected layer to the prior fully connected layer). This top-down signal was dependent on the inputs and on the current task. The same model was used for both experiments. The proposed model qualitatively approximated the task-dependent modulation effect observed in the two experiments. These results provide a proof-of-principle account for how task-dependent goals can be incorporated by the cortex to route information and achieve different goals with the same sensory inputs.

Title: Stimulus invariant population statistics in response to natural movies

Authors: *B. HOSHAL[1], C. M. HOLMES[3], J. M. SALISBURY[2], M. J. BERRY, II[4], O. MARRE[5], S. E. PALMER[2];

Abstract: Over the course of the lifetime of an organism, its sensory organs must encode stimuli described by different statistics; we expect that neural mechanisms exist to support stimulus dependent adaptation. In the absence of adaptation, cells doing the same computation should have different statistics in response to different stimuli. Stationarity in the signal can therefore be a signature of adaptation. To investigate this, we simultaneously recorded the responses of 93 tiger salamander retina ganglion cells presented with multiple natural scene movies. A variety of maximum entropy-based analysis techniques revealed a consistent, stimulus invariant structure to the population codes. We believe that this invariance may be useful for downstream decoding, and may be an indicator of adaptation in response to natural scenes.

Title: Adaptation to synthesized naturalistic textures in macaque V1 and V2

Authors: *A. DAVILA, A. KOHN;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Adaptation alters neuronal responsivity and tuning, in a manner that depends on the cortical area and the stimulus used. However, previous adaptation work has largely used stimuli tailored to each targeted area. This approach has left unclear how adaptation with a given image affects neuronal encoding distributed across different stages of the visual hierarchy. To

understand the hierarchical effects of adaptation, we measured responses to synthetic, naturalistic textures in primary visual cortex (V1) and area V2 of anesthetized macaque monkeys using Neuropixel probes. V1 and V2 neurons have been shown to encode different texture statistics: V1 is sensitive to the spectral content of textures, whereas V2 is sensitive additionally to higher-order texture statistics. We presented 5 different textures and their spectrally-matched noise images, either under control conditions (no adaptation) or after exposure to an adapter (600-ms duration). Adapters were synthesized samples of one of the test textures or its corresponding noise image. Both V1 and V2 showed robust adaptation to textures and noise images. V1 responsivity was reduced more strongly by adaptation than V2 responsivity, for both texture and noise adapters. The reduction in responsivity was broadly shared across test textures and noise images, in both areas. In V1, responses to test stimuli matched to the adapter were not reduced more strongly than responses to novel textures or noise images. In V2, there was only weak evidence of stimulus specificity: responses to textures matched to the adapter were reduced slightly more than responses to novel textures. We also evaluated neuronal population information by training a classifier to discriminate among texture families, based on responses measured before and after adaptation. Adaptation either had little effect on discriminability, or led to slightly worse performance, consistent with its broad tuning. We conclude that adaptation with naturalistic textures induces broadly-tuned response suppression across early stages of the visual system.

Title: Perceptual adaptation to continuous versus intermittent spatial distortions

Authors: *I. R. MCLEAN[1], T. S. MANNING[1], E. A. COOPER[1,2];
[1]Sch. of Optometry, [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: The visual system adapts to changing environmental demands. Adaptation during continuous exposure to a novel stimulus has been well studied and involves a range of neural mechanisms. However, little is known about how repeated exposure to a stimulus might change the dynamics and mechanisms of adaptation. In a psychophysical experiment, we compared perceptual adaptation in humans who were either continuously or intermittently exposed to an adapting stimulus for the same cumulative amount of time. We measured adaptation to spatial distortions caused by small changes in the retinal image size in one eye. These distortions change the apparent shape and orientation of objects due to altered binocular disparities. Two groups of

participants wore glasses with a 3.8% monocular horizontal magnifier for five hours in one day. Upon initially putting the glasses on, participants experienced distortions in the perceived shape and 3D slant of objects. The continuous group (n = 14, 10 females, mean age = 25 years) wore the glasses continuously for five hours, while the intermittent group (n = 14, 10 females, mean age = 26 years) wore the glasses for five one-hour periods with 20-30 minute breaks in between. To measure adaptation to the shape distortion, participants adjusted two corners of a quadrilateral until it appeared square. To measure adaptation to the slant distortion and changes in the weight given to binocular disparity, participants adjusted the slant of stereoscopic stimuli until they appeared frontoparallel. Stimuli isolating binocular disparity were randomly interleaved with stimuli that contained multiple slant cues. Measurements were taken immediately before and after the glasses were put on, and before and after the glasses were taken off at the end of the day. Adaptation was quantified by the difference in the judgments from the beginning to the end of the day. The magnitude of shape and slant adaptation in the two groups were descriptively similar, suggesting that intermittent exposure did not substantially alter perceptual adaptation. However, our results suggest a difference in the adaptation mechanisms between groups. Specifically, in the slant judgment task, the continuous group showed an increase in the weight given to binocular disparity and the intermittent group did not. These findings suggest that adaptation is present after one day of exposure to spatial distortions and that the number of hours exposed to the distortion may be more important than the continuity. Finally, the visual system may employ different adaptation mechanisms, such as cue weighting strategies, depending on whether an adapting stimulus is present continuously or intermittently.

Title: Contribution of individual features to repetition suppression in macaque inferotemporal cortex

Authors: *N. P. WILLIAMS, C. R. OLSON;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: When an image is presented twice in succession, first as adapter and then as test, neurons in area TE of macaque inferotemporal cortex exhibit repetition suppression, responding

less strongly to the second presentation than to the first. Suppression is known to occur if the adapter and the test image are subtly different from each other. However, it is not known whether cross-suppression occurs between images that are radically different from each other but that share a subset of features. To explore this issue, we measured repetition suppression using colored shapes as stimuli. On interleaved trials, the test image might be identical to the adapter, might share its shape alone, might share its color alone or might differ from it totally. When an image was repeated precisely, the population response was strongly suppressed and also was altered in dynamic, taking the form of a trough during which suppression was especially deep followed by a rebound. This represented an accentuation of the tendency previously described in our laboratory for visual responses in TE to take the form of a damped 5 Hz oscillation. Suppression was of intermediate depth when the images shared only one attribute and was minimal when they shared neither attribute. At the level of the individual neuron, the degree of suppression depended not only on the properties of the two images but also on the preferences of the neuron. Suppression was deeper when the repeated color or shape was preferred by the neuron than when it was not. This effect could arise either from feature-specific adaptation or from adapter-induced fatigue. We favor an interpretation based on feature-specific suppression because neither we nor others have been able to obtain independent evidence for neuronal fatigue. The fact that response suppression occurs even when the test image differs from the adapter in shape or color tends to undercut the notion that suppression is a useful cue for recognition of the test image as recent or familiar. Further undercutting this notion, we have demonstrated that TE neurons, as a population, are unable to distinguish between an image that elicits a relatively weak response because it is intrinsically ineffective and one that does so because it is repeated. On these grounds, we argue that repetition suppression is more akin to classical adaptation rather than to a memory signal.

Title: Characterizing the development of sensory prediction error in cortical circuits

Authors: *J. M. ROSS, J. P. HAMM;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: In naturally complex environments, organisms are inundated with sensory information. The ability to dynamically process this information to perceive salient changes is crucial to survival. One theoretical framework for explaining this computationally complex task is predictive coding, in which brain networks continuously generate and test predictive models about future sensory information, based on past experience. With simple "oddball" sequences and concurrent recordings in primary sensory cortices, past work shows that neurons exhibit reduced responses to repetitive stimuli (i.e. redundants) known as "stimulus specific adaptation" (SSA); rare stimuli (i.e. deviants) evoke augmented neuronal responses, referred to as "deviance detection" (DD), a putative type of sensory prediction error. While DD is robust in adult mammalian brains, whether and how such prediction error signals emerge postnatally, across adolescence, is unknown. This could hold clues to the underlying neurobiology of predictive coding in cortical networks, as well as its significance for cognitive development.
To assess how DD develops across adolescent development, we employed two-photon calcium imaging of excitatory pyramidal cells (PYRs) in L2/3 of primary visual cortex (V1). We presented visual stimuli (full-field oriented squarewave gratings) to awake mice while imaging neural responses during three different postnatal periods relevant to postnatal brain development: early adolescence (P28), late adolescence (P42), and adulthood (P84). We assessed the stimulus evoked activity of PYRs during two classic visual oddball sequences and a many standards control sequence. This paradigm allows the direct comparison of responses to the same stimuli (e.g. 45° grating) in different contexts - when the stimulus is expected (redundant), when it deviates from expectation (deviant), and when it is neither expected nor deviates from expectations (control). In general, we find that adapted responses to redundant stimuli are present in both sexes (SSA) well before adulthood, but that DD develops and changes over adolescence in V1. Further, this trajectory differs between males and females. Males do not demonstrate DD in V1 until adulthood, whereas females appear to generate the largest DD signals in early adolescence.
Ongoing work is aimed at further characterizing the underlying mechanisms that contribute to differential DD development between males and females, as well as its relevance for learning and behavior. Altogether, this work may inform our understanding of how postnatal brain development and biological sex contribute to aspects of predictive coding, such as SSA and DD.

Title: Divisive normalization is an efficient code for multivariate Pareto-distributed environments

Authors: *S. F. BUCHER[1,2], A. M. BRANDENBURGER[3];
[1]Eberhard Karls Univ. of Tübingen, Tübingen, Germany; [2]Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany; [3]NYU Stern Sch. of Business, New York, NY

Abstract: Divisive normalization (DN) is a canonical computation (Carandini & Heeger 2012) reputed to solve the brain's problem of representing potentially unbounded stimuli via bounded firing rates. Originally discovered in the primary visual cortex, DN has since been observed in many other sensory domains as well as in decision-making. It is often considered to be an implementation of the ***efficient coding principle***, as it has been shown empirically to reduce redundancy in natural stimulus statistics (Schwartz & Simoncelli 2001). To date, however, the sense in which divisive normalization is efficient has not been made analytically precise. We close this gap with a theoretical result that states the conditions under which divisive normalization is an optimal encoding system, and specify a class of input distributions that DN encodes efficiently. Our approach differs from previous ones in that we ask what class of input distributions DN represents efficiently, rather than analyzing the properties of the DN computation for a given empirical input distribution. We show that in a low-noise environment DN maximizes the mutual information between an *n*-dimensional stimulus and its representation if and only if the stimulus' prevalence in the environment is described by a multivariate Pareto distribution. Divisive normalization transforms (only) this particular distribution into an entropy-maximizing distribution, which amounts to a multivariate analog of histogram equalization. We extend this result to allow for an arbitrary metabolic cost of the representation, and show how this impacts the optimally encoded distributions. Our result suggests that divisive normalization may have evolved to efficiently represent stimuli with Pareto distributions, consistent with empirical observations on naturalistic stimulus distributions such as the conditional variance dependence of filter responses to natural images. Beyond formalizing the sense in which this important computation adheres to the efficient coding principle, our theoretical result also yields empirically testable predictions across sensory domains on how the divisive normalization parameters should be tuned to features of the input distribution.

Title: Haptic cue combination for size discrimination

Authors: *K. ALLEN, D. GOLDREICH;
McMaster Univ., Hamilton, ON, Canada

Abstract: Our senses provide noisy inputs (cues) which we interpret to perceive the world. Many studies have investigated multisensory cue combination: the integration of cues that arise through different senses. Fewer studies have investigated cue combination within a single modality. The haptic modality has been particularly under-investigated in this regard. Here, we investigated whether haptic cutaneous and hand configuration cues are combined optimally to discriminate between coin-sized discs of different sizes. When the hand is open such that the thumb and index fingers span the diameter of a disc to contact its perimeter, cutaneous cues occur from the indentation of the skin caused by the curvature of the disc (smaller discs cause greater indentation). Simultaneously, the hand configuration cue (proprioceptive), provides an additional cue to size. We considered three hypotheses for how humans may use these cues: humans rely solely on the least noisy cue (Winner-Take-All Model), humans combine cues based on a simple average (Average Model), or humans combine cues via an optimal weighted average (Optimal Model). Each experiment tested participants using a two-interval forced-choice (2IFC) paradigm with 3D printed disc stimuli. On each trial, under occluded vision, participants felt two discs sequentially and responded which felt larger. Participants were tested under four counterbalanced conditions to test performance with each finger's cutaneous cue alone, the hand configuration cue without the cutaneous cue, and all cues together. We applied Bayesian parameter estimation to fit cumulative normal psychometric functions to these data and Bayesian model comparison to determine a winning model for each participant. Results from Experiment 1 (12 participants) were ambiguous due to the poor reliability of the cutaneous cues. A new set of discs was 3D printed to enhance the cutaneous cues and used for Experiment 2 (11 participants). Results indicated optimal cue combination for 9 of the 11 participants. We conclude that humans may combine haptic cutaneous and hand configuration cues optimally to judge the size of held objects.

Title: Multisensory representation of object location in mouse barrel cortex and posterior parietal cortex

Authors: *A. HOFFMANN[1,2], F. HELMCHEN[1,2];
[1]Brain Res. Institute, Univ. of Zurich, Zurich, Switzerland; [2]Neurosci. Ctr. Zurich, Zurich, Switzerland

Abstract: For a stable and coherent perception of the world, the brain combines sensory information from different modalities using distinct reference frames. In the mouse brain, tactile input is organized somatotopically in the primary whisker somatosensory cortex (wS1) while the primary visual cortex (V1) contains a retinotopic map of the visual field. For nearby objects, these two sensory streams likely converge in the rostro-lateral (RL) area of the posterior parietal cortex (PPC). However, how the integration of multisensory information happens for naturalistic stimuli on a single-cell level remains unclear. Here, we investigated how neurons across mouse wS1, V1, and RL integrate visuotactile information about a pole that is in reach of the whiskers and can be seen and/or felt. Using two-photon calcium imaging, we recorded several 10,000 excitatory neurons expressing GCaMP6f in L2/3 of head-fixed mice (n=5, male triple transgenic Rasgrf2-2A-dCre;CamK2a-tTA;TITL-GCaMP6f mice) that were free to run on a disk. We presented a pole that was moved to different locations in reach of the whiskers, either under nearly dark conditions or during illumination of the pole. We recorded the interactions of the whiskers (only C-row) with the pole with a high-speed camera and tracked their kinematics offline with the deep learning pose estimation algorithm DeepLabCut. For reproducible and flexible data analysis, we organized the analysis workflow as a DataJoint pipeline and created interactive user interfaces to explore the raw and processed data. We find that around one third of neurons across wS1, V1 and RL are significantly more active when the pole is in reach of the whiskers, whereas around 15% of neurons reduce their activity. A higher fraction of neurons in V1 and RL were more modulated by light (significantly more active) compared to wS1 (~20% vs. ~5%). By comparing average activities at different pole locations, we find that subsets of neurons in RL and wS1 show selectivity for specific locations in the near space based on tactile and/or visual input. To test whether location selectivity was a result of altered whisker kinematics, we predicted neural activity using Generalized Linear Models (GLMs) based on different sets of regressors. We find that object locations predict neural activity in RL better than whisker kinematics, whereas the opposite holds for wS1. Together, these findings corroborate the notion of RL representing object locations based on visual and tactile information, potentially in a more modality-invariant manner.

Title: Neural computations underlying tactile texture constancy

Authors: *A. F. TORTOLANI, E. OKOROKOVA, R. NGACHOKO, S. J. BENSMAIA; Univ. of Chicago, Chicago, IL

Abstract: A major function of sensory processing is to achieve neural representations of objects that are stable across changes in context and perspective. Small changes in exploratory behavior can lead to large changes in the neural signals at the sensory periphery, thus resulting in ambiguous neural representations of objects. Overcoming this ambiguity is a hallmark of human object recognition across sensory modalities. Our ability to achieve a stable perception of texture regardless of the way we explore a surface constitutes an instance of this process. Indeed, the responses of tactile nerve fibers to textured surfaces depend critically on the speed at which the surface moves across the skin. In contrast, texture responses of neurons in somatosensory cortex are less susceptible to changes in scanning speed and the resulting representation of texture is far more stable across changes in speed. The resulting texture percept is highly independent of scanning speed. The nature of the transformation from periphery to cortex that gives rise to texture constancy is not entirely understood. One hypothesis is that two computations -- spatial and temporal differentiation --, which have been shown to be implemented along the somatosensory neuraxis, are sufficient to give rise to a speed-invariant texture representation. To test this hypothesis, we simulated the responses of all the nerve fibers that innervate the glabrous skin of the hand to a large set of natural and artificial textures scanned across the fingertip using exploratory trajectories measured in human subjects. First, we found that the (stimulated) population response in the nerve provides ambiguous information about texture. Next, we simulated cortical responses by applying a set of temporal and spatial filters -- inspired by the known response properties of cortical neurons -- to the simulated afferent input. We then assessed the degree to which the simulated cortical responses yielded a texture representation that was more robust to changes in scanning speed than was its peripheral counterpart. We found that filters improved texture classification performance when textures were scanned with variable speed and force, demonstrating that temporal and spatial differentiation of peripheral input is sufficient to give rise to an invariant representation of texture.

Abstract: Much effort has been focused on understanding how the brain processes the information from individual senses. Yet, the neural mechanisms that allow the effortless integration of unisensory inputs into multisensory objects are less well understood. To study how neural circuits integrate visual and tactile information, we developed a multisensory discrimination task for head-fixed mice. Here, two sequences of visual, tactile or visuotactile stimuli are presented on both sides of the mouse which has to respond to the higher-rate target side to obtain a water reward. To ensure integration of sensory information over the entire stimulus period, a short delay was added before the response. Mice achieved high accuracy in all conditions, with improved performance in the multisensory condition. In line with the principle of inverse effectiveness, improvements were highest in the most difficult trials. We then used widefield imaging to measure cortexwide activity in transgenic mice, expressing the Ca^{2+}-indicator GCaMP6s in all excitatory neurons. Multisensory stimuli evoked higher neuronal activity compared to unisensory stimulation. This was most evident in the rostrolateral association area RL and parts of medial frontal cortex (mFC), which reliably responded to both visual and tactile stimulation. These responses, as well as activity in the primary visual (V1) and somatosensory barrel cortex (S1), evolved over the course of learning and increased in magnitude and the duration of sensory responses. To better isolate multi- from unisensory responses we then used a linear encoding model. Including a multisensory interaction term explained significantly more information as with unisensory regressors alone, especially in parietal and frontal areas. This suggests that cortical multisensory responses are not easily explained as a linear summation of unisensory responses.To causally test the relation between cortical activity and perceptual decisions, we then used the inhibitory opsin stGtACR2 to silence excitatory neurons in either V1, S1, RL and mFC at different times during the task. Inhibiting V1 or S1 strongly impaired task performance during the stimulus while inactivating mFC had the strongest effect during the delay period. Surprisingly, inactivating RL had a minor impact on performance, despite its robust multisensory activation.Our results demonstrate that multisensory stimulation leads to improved task performance and widespread cortical activation in mice. However, only sensory and frontal cortices were causally required, raising the question of the function of multisensory activity in expendable areas such as area RL.

Title: Sensory modality modulates neural coding ofresponse side:comparison of visual and somatosensory cortices, perirhinal cortex andhippocampus

Authors: *J. FIORILLI, P. MARCHESI, T. R. RUIKES, G. HUIS IN ‘T VELD, M. QUINTERO, R. BUCKTON, C. M. PENNARTZ;
Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Studies on rodent hippocampus present evidence for an increasing level of invariance in object and spatial representations along the sensory-cortical to hippocampal hierarchy. However, neural coding of object recognition and motor variation effects has not been compared directly between cortical and hippocampal areas. We conducted simultaneous ensemble recordings in primary somatosensory cortex (S1BF, N units= 119), secondary visual cortex (V2L, N units = 366), perirhinal cortex (PRH, N units = 210), and the hippocampal subfields (CA1, CA3, DG, N units = 221) from 4 rats that performed an object discrimination task using vision, touch, or both senses combined. This enabled us to quantify both the sensory evoked (tactile and visual) responses during active sampling, as well as illumination-invariant coding during object sampling and self-motion for individual cells.
We first explored the relative prominence of object- and motor-related neural coding when ascending the cortico-hippocampal hierarchy. All four areas showed a predominant coding of the response side, with surprisingly little evidence for coding of object-specific information. Whereas V2L, PRH and CA1 contained information on the response side starting from self-motion initiation, PRH choice-side encoding peaked around the nose-poke ports. Secondly, we asked how the neural coding of the response side is modulated by illumination, and if neural representations become more independent to photic changes when ascending the hierarchy. We found light-dark modulation of response side in all four areas, but with a stronger independence in area CA1 as compared to V2L and S1BF. Surprisingly, despite the illumination invariant coding of the response side in CA1, a significant proportion of cells in this area was modulated by the light onset. Different from the three other areas, PRH neurons revealed a sparse but highly selective coding of reward information that was specific to the combination of object and response side.

Altogether, under naturalistic movement conditions we demonstrate a dominant neural coding of spatial motor choice in sensory cortical and hippocampal areas, with increasingly light independent response side coding when ascending the hierarchy. The perirhinal cortex forms a rather exceptional entity, selectively and sparsely coding information on reward contingencies.

Title: The impacts of audiovisual spatial congruency on pupil dilation

Authors: *Z. PARK, H. LEE, C.-Y. KIM;
Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: Pupillometry is a reliable measurement for investigating bisensory integration. Recent studies have reported faster and greater pupil dilation for audiovisual conditions compared to auditory and visual conditions (Rigato et al., 2016; Wang et al., 2017). However, little is known about the impacts of bimodal stimulus congruency on pupil dilation. As spatio-temporal congruency is a substantial factor in modulating the extent of bisensory integration, we investigated whether spatial congruency of audiovisual stimuli influences pupil dilation by adopting the ventriloquist illusion paradigm. Participants maintained fixation on a small dot at the center of a computer monitor with their heads fixed on a chin rest. On each trial, an auditory or visual stimulus was presented alone as A or V conditions, or a pair of auditory and visual stimuli were presented simultaneously (AV condition). A simple beep sound and a small dot were respectively used for the A and V stimuli, presented for 100ms following 1-1.5s of fixation. We manipulated spatial congruency of audiovisual stimuli by presenting the aforementioned auditory stimulus from the left, right, or center of each participant accompanied by a visual stimulus on the left or right. Here, we defined an AV condition as "spatially incongruent" (SI) if the visual and auditory stimuli were presented on different sides, while "spatially congruent" (SC) AV conditions featured collocated stimuli. Participants' eye responses were recorded using an eye tracker (Eyelink-1000, SR Research) for 2000ms following the onset of the stimuli. Afterward, participants performed a sound localization task by clicking their perceived location of the auditory stimulus. Behavioral results exhibited the ventriloquist effect (VE), which is the degree of bias towards a visual stimulus, for the SI condition. For the pupillometry results, transient pupil dilation was evoked for conditions featuring stimuli compared to those that did not, and greater pupil dilation was observed for the AV condition rather than the A and V

conditions, which replicates previous studies. In addition, we found that pupil dilation for the SI condition was greater than that for the SC condition: this effect remained persistent throughout the entire 2000ms, but was statistically significant for 950ms to 1200ms after the onset of the stimuli. These results indicate that spatial congruency modulates pupil dilation reflecting bisensory integration. We are now attempting to extend our current findings into another important eye measurement, microsaccades.

Title: Multimodal Proprioceptive Integration in the Sensorimotor Network of an Insect Leg

Authors: *C. GEBEHART, A. BÜSCHGES;
Univ. of Cologne, Cologne, Germany

Abstract: To generate the internal representation of the limbs that is an essential aspect of stable motor control, an animal's nervous system integrates proprioceptive sensory input from multiple sense organs. Distinct proprioceptive modalities are monitored by separate sense organs. In insects, campaniform sensilla (CS) and the femoral chordotonal organ (fCO) provide information about leg loading and joint movement. Both sensory modalities are able to alter motor output, and must therefore converge along the sensorimotor pathways. Understanding the network computations and architecture underlying proprioceptive signal convergence thus requires knowledge about spatial and temporal summation of multimodal signals and their interaction. We combined the mechanical stimulation of trochanterofemoral and tibial CS (tr/fCS, tiCS) and the fCO with intra- and extracellular electrophysiological recordings of sensory afferents, premotor nonspiking interneurons (NSI), and motor neurons (MN) to analyze proprioceptive signal integration in the stick insect leg. Spatial summation - Load signals from tr/fCS and tiCS and movement feedback from the fCO was distributed into one common network of premotor NSIs. Signal processing for both sensory modalities was antagonistic, i.e. each individual NSI's responses could support or oppose the ensuing motor output. Temporal summation - Movement signal transmission along sensorimotor pathways was faster than load signaling, resulting in temporally shifted effects on motor output and muscle force. Using signal timing to establish network connectivity, we demonstrate that functional connectivity between NSIs was determined

by temporal aspects, i.e. to which NSI the sensory signal was transmitted first. Signal integration - During combined load and movement stimuli, fCO afferents were presynaptically inhibited by tiCS afferents. In postsynaptic NSIs, the interaction between both modalities led to nonlinear summation of sensory signals. The gain of NSIs opposing the resistance reflex of extensor tibiae (ExtTi) MNs increased. Consistently, the gain of the slow ExtTi MN to movement stimuli decreased in the presence of load, an effect that was abolished when presynaptic inhibition was blocked. In summary, load and movement were spatially summed by premotor NSIs, while being separated in time. The temporal delay of load signals predestines them for a role in tuning ongoing movement processing, which we verified by their effect on movement signal gain. Taken together, these results provide a framework for multimodal proprioceptive integration in which load feedback contextualizes movement signal processing.

Title: Neural representations in larval zebrafish navigating different sensory-modality gradients

Authors: *V. PALIERI[1], E. PAOLI[1], I. C. GRUNWALD KADOW[2], R. PORTUGUES[1]; [1]TUM Sch. of Med., Technische Univ. München, Munich, Germany; [2]Sch. of Life Sci., Tech. Univ. of Munich, Freising, Germany

Abstract: Animal survival depends on the ability to find environments where chances of survival are maximized. Achieving this goal often requires navigating spatial gradients successfully. For example, animals can use odor gradients to locate food and they can exploit temperature gradients for thermoregulation. It has been shown, in larval zebrafish, *C. elegans* and *D. melanogaster*, that a temporal sampling strategy is used to probe the stimulus landscape and to detect the rate of change of stimulus intensity. As a consequence, animals increase their turning as they either move away from a favorable condition or come closer to a negative one. The majority of existing studies on gradient navigation focus on single sensory modalities to show how sensory neurons detect stimulus characteristics or how the behavioral output is modulated. However, an understanding of how sensory and motor components are linked in the brain and whether the representation of the rate of change of different sensory modalities converges onto the same circuit is still missing. In the present study, we took advantage of the optical accessibility and the well-defined behavioral repertoire of larval zebrafish to investigate

how and where the temporal derivative of stimulus intensity across different modalities is processed in the fish brain. We first developed an open-loop virtual gradient navigation assay in head-restrained larvae used in combination with lightsheet microscopy for whole-brain calcium imaging. Then, we used three different aversive stimuli while recording fish behavior to screen for areas representing the change of stimulus irrespective of its identity. These representations may convey information about improving or worsening conditions and could be a hub for the collection of relevant stimulus information used by the animal to successfully perform gradient navigation.

Title: The Behavioral Benefits of Multisensory Integration Require Multisensory Experience

Authors: *N. BEAN, S. SMYRE, B. STEIN, B. ROWLAND;
Neurobio. and Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Concordant visual-auditory stimuli enhance the responses of superior colliculus (SC) neurons and the detection and localization functions they mediate. However, this capacity for multisensory integration is not an innate capability. Animals reared in omnidirectional noise ("noise-rearing") lack the needed visual-auditory experience required to instantiate this physiological capability. Here we tested the presumption that the multisensory enhancements in detection and localization in such animals would also be compromised. A cohort of cats reared in omnidirectional noise (n=3) and a cohort (n=2) of normally-reared animals were trained to detect, localize, and approach brief visual cues (50 ms) presented randomly at any of 8 locations (±60◦, 15◦ increments, excluding 0◦). They were also trained to remain at the start location ("No-Go") for stimulus absent ("catch") trials. After training, stimulus intensities were lowered so that performance did not exceed 25-40% correct approaches to the visual targets. Target stimuli were presented at random locations and consisted of either a visual stimulus, a clearly audible (but novel) auditory stimulus, or their spatiotemporally combination. The performance of normally-reared animals was enhanced by the cross-modal stimulus combination. They approached it more reliably (63±1.4%) than the visual target alone (38±1.2%). In contrast, noise-reared animals

showed no greater ability to respond to the visual-auditory stimulus (35±1.3%) than the visual stimulus alone (33±1.0%). Yet, they had no severe hearing deficits, and a second series of tests thereafter confirmed that even when trained that both the visual and auditory stimuli were targets, they failed to show enhanced performance to their combination. Normally-reared animals performance on multisensory trials far exceeded that to the best unisensory performance selected in a statistical facilitation model (80±1.1% vs 59.±4.6%); whereas the multisensory performance of noise-reared animals were impaired relative to statistical facilitation 47±1.3 vs 59±3.9%. Error analysis revealed defects in both detection and localization in the noise-reared cohort in both conditions. The data suggest that simultaneous activation of visual and auditory neural ensembles in noise-reared animals does not translate into better performance in these simple behavioral tests. Their behavioral defects resemble those noted physiologically in SC neurons and are consistent with a model in which these neurons are primary decoders for cross-modal information. Title: Visual and auditory predictions independently affect superior colliculus responses

Authors: *S. A. SMYRE, N. L. BEAN, B. E. STEIN, B. A. ROWLAND;
Neurobio. & Anat., Wake Forest Baptist Hlth., Winston-Salem, NC

Abstract: The brain possesses multiple senses that transduce different energies, a feature that increases the amount of information available for decision-making and enhances adaptability in a greater variety of environments. Multisensory circuits like the superior colliculus (SC) simultaneously process signals derived from multiple senses, and cross-modal (e.g., visual-auditory) signals aligned in space and time are integrated into novel neural products. SC neurons use sensory context to enhance their efficiency: repeated stimulus presentations generate predictive signals that can either potentiate or attenuate (habituate) future responses depending on the presentation rate and sensitivities of individual neurons. The present study sought to better understand the origin of these predictive signals. The first objective was to determine whether they were modality-specific or cross-modal. SC neurons (n=50) of anesthetized cats were tested with stimulus trains containing three repetitions of either a visual (50ms flash) or auditory (50ms

broadband burst) stimulus followed by a fourth stimulus of either the same or the opposite modality presented at the same location at the same temporal interval. A presentation rate (2 Hz) was selected in which almost all (92%) of the neurons showed robust, significant attenuation in the auditory modality, but either potentiation or attenuation (46%/34% respectively, 20% no change) in the visual modality. We found that the predictive signals for almost all neurons (90%) failed to cross sensory modalities, suggesting that they were modality-specific. The second objective was to determine if the predictions were generated and applied to each modality independent of the other modalities in the immediate context, or if they would be different in multisensory vs. unisensory contexts. The same neurons were tested with stimulus trains containing three repetitions of a modality-specific (visual or auditory) or cross-modal (visual-auditory) stimulus followed by a fourth stimulus of the same or the opposite configuration. The cross-modal stimulus configuration reliably elicited enhance neural responses. The influence of the predictions crossed between modality-specific and cross-modal configurations, suggesting the predictions for each modality were generated and applied independently. Collectively, these findings are consistent with a model in which predictive modality-specific signals independently alter the modality-specific inputs to the SC, which are rapidly integrated by multisensory neurons into enhanced neural products. Supported by NIH/REI RO1 EY031532 and T32 NS73553.

Title: Input and output specific microcircuits of the insular cortex

Authors: *Y. CHEN, B. C. JONGBLOETS, M. A. MUNIAK, I. GINGERICH, T. MAO; Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The insular cortex (IC) is an information-integration hub that mediates diverse functions such as taste perception, decision making, and aversive state processing. While great progress has been made in the field using in vivo optogenetics, pharmacology, and calcium imaging to establish diverse functional roles of the anterior and posterior subregions of the IC, their underlying circuit mechanisms remain elusive. To better understand how local signal processing within the IC contributes to its diverse functions, our study aimed to decipher IC microcircuits that are associated with specific input sources and output targets. To

comprehensively identify local inputs to IC output neurons, we utilized laser scanning photostimulation (LSPS) of caged glutamate, coupled with patch-clamp recordings of neurons labeled with retrograde bead injections in either the basolateral or central amygdala (BLA, CEA), mediodorsal (MD) or perifascicular (PF) thalamus, or the contralateral IC, five of the known major projection targets of the IC. We found that IC output neurons exhibit stereotypical distribution patterns across cortical depths. Also, their local input patterns—often differing from the canonical microcircuits observed in primary cortices—are unique based on their projection target. Further, by recording postsynaptic responses to optogenetically stimulated long-range axons, we showed that long-range inputs to the IC that originate from different thalamic nuclei preferentially target distinct subsets of IC neurons, and that local circuits are required to connect these input-receiving neurons with output-projection neurons both across cortical layers and along the anterior-posterior axis of the IC. Notably, we uncovered an information pathway from the posterior to anterior IC. Although the two subregions have been reported to mediate distinct functions, our results suggest that they may be synergistically recruited during certain behaviors, thereby providing a new perspective on how functional diversity within the IC can be achieved. Together, our findings show that local circuits unique to the insular cortex are specifically tailored to integrate unique neuronal signals for different output pathways. Our work also elucidates the neuronal substrates responsible for information-integration within the IC, and sets the foundation for future studies on input- and output-specific insular functions.

Title: Origin-specific dendritic integration of long-range cortical inputs to agranular insular pyramidal neurons

Authors: *I. GINGERICH, M. A. MUNIAK, Y. CHEN, B. C. JONGBLOETS, T. MAO; Vollum Institute/Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Origin-specific dendritic integration of long-range cortical inputs to agranular insular pyramidal neurons

Ian K Gingerich, Michael A Muniak, Yang Chen, Bart C Jongbloets, Tianyi Mao Vollum Institute, Oregon Health & Science University, Portland, OR 97239 USA

The insular cortex receives inputs from many cortical and subcortical structures and integrates these inputs to mediate diverse functions. These include proprioception, visceral sensation, taste perception, and aversive state processing. The agranular insula (AI) receives inputs from cortical areas associated with disparate sensory processes, including regions associated with olfactory, taste, and proprioceptive processing, as well as higher order cortical functions including memory and navigation. However, how these inputs integrate in the AI and facilitate AI function remain elusive. Here, we used subcellular ChannelRhodopsin-2 Assisted Circuit Mapping (sCRACM) to investigate the functional connectivity and the subcellular organization of these input patterns to the AI. sCRACM allows us to map the spatial distribution of synaptic inputs to the dendritic arbors of recorded neurons by expressing ChR2 in presynaptic neurons. Presynaptic axon terminals are excited via laser patterns, triggering local neurotransmitter release which, in combination with extracellular application of Na^+- and K^+- channel blockers, results in robust excitatory postsynaptic currents ($EPSC_{sCRACM}$). This technique is well suited to the investigation of long-range inputs, in which the presynaptic somata may reside in a different brain region than that of the recorded neuron.
To investigate cortical input organization, we systematically injected ChR2 in the known cortical regions that send projections to the AI. We performed sCRACM experiments by recording from pyramidal cells located in all layers of the AI. Using cluster analysis and pattern recognition algorithms, we identified insular region-specific, layer-specific, and dendritic-compartment-specific input patterns. In conjunction with morphologic analysis of the recorded pyramidal neurons, we conclude that the unique patterns associated with each input source is one of the ways by which the insular cortex may mediate its diverse functions within the same anatomical region.

Title: Neural implementation of causal inference during multisensory processing in the Macaque brain

Authors: *G. QI, W. FANG, S. LI, J. LI, L. WANG;
Inst. of Neuroscience, Key Lab. of Primate Neurobiology, CAS Ctr. for Excellence in Brain Sci. and Intelligence Technology, Chinese Acad. of Sciences, Shanghai, China, Shanghai, China

Abstract: Natural perception relies inherently on inferring causal structure in the environment. However, the neural mechanisms and functional circuits that are essential for representing and updating the hidden causal structure during multisensory processing are unknown. To address this, monkeys were trained to infer the probability of a potential common source from visual and proprioceptive signals on the basis of their spatial disparity in a virtual reality system. The proprioceptive drift reported by monkeys demonstrated that they combined historical information and current multisensory signals to estimate the hidden common source and subsequently updated both the causal structure and sensory representation. Single-unit recordings in premotor and parietal cortices revealed that neural activity in premotor cortex represents the core computation of causal inference, characterizing the estimation and update of the likelihood of integrating multiple sensory inputs at a trial-by-trial level. In response to signals from premotor cortex, neural activity in parietal cortex also represents the causal structure and further dynamically updates the sensory representation to maintain consistency with the causal inference structure. Thus, our results indicate how premotor cortex integrates historical information and sensory inputs to infer hidden variables and selectively updates sensory representations in parietal cortex to support behavior. This dynamic loop of frontal-parietal interactions in the causal inference framework may provide the neural mechanism to answer long-standing questions regarding how neural circuits represent hidden structures for body-awareness and agency.

Sci. and Technol., ETH Zürich, Zuerich Eth-Zentrum, Switzerland

Abstract: Restoration of somatic sensations from the missing limb of amputees through sensory neuroprosthetics improves the functionality and embodiment of prosthetic devices. Yet, while it is possible to generate touch percepts, proprioception restoration remains elusive. Theoretically, large-diameter proprioceptive afferents should have the lowest threshold for electrical stimulation of the peripheral nerves and should thus be the easiest sensory afferents to recruit with neural interfaces. Why, after decades of research in independent clinical trials, reports of controlled proprioceptive sensations have been so scarce? We hypothesized that sensory regulation mechanisms, such as presynaptic inhibition, may play a major role during non-selective recruitment of afferents classes. To unveil these mechanisms, we recorded signals in the gray matter of the spinal cord, while simultaneously stimulating muscle and cutaneous branches of the radial nerve. Multi-channel spinal neural signals are projected into a low-dimensional neural space. Proprioceptive inputs elicited robust trajectories and showed that processed proprioceptive information was reduced when the cutaneous nerve was concurrently stimulated. Our results suggest that interference of sensory modalities may pose an electrophysiological limit to sensory restoration and set a base for overcoming the current and defining the future neurotechnology challenges.

Title: Neuronal responses of different types of neurons are modulated by arousal state in mouse sensory cortices

Authors: *S. JO[1], D. MCCORMICK[2];
[1]Univ. of Oregon, Eugene, OR; [2]Univ. of Oregon, EUGENE, OR

Abstract: Identifying meaningful sensory stimuli is required to survive, and the ability to detect sensory stimuli is significantly affected by ongoing brain activities. Recent works have shown that spontaneous brain activities were various in different brain areas. However, these studies used 1-photon widefield calcium imaging to observe brain-wide activities, or small parts of the brain were examined in 2-photon calcium imaging or electrophysiology. Therefore, it is important to understand how different types of neurons in different sensory cortices are related to arousal state. For a better understanding of neural network dynamics by arousal state, we performed calcium imaging of excitatory neurons (EXC), as well as vasoactive intestinal peptide (VIP), somatostatin (SST), and parvalbumin (PV) interneurons in three sensory cortices, auditory, visual, and somatosensory cortex, using a 2-photon mesoscope. We crossed VIP, SST, and PV mouse CRE lines with reporter line Ai162 which is expressing GCamp6s. To define each sensory cortex, we performed 1-photon widefield calcium imaging while tone clouds, visual stimuli, or whisker deflections were delivered to a mouse. To measure arousal state, running speed, whisker motion energy, and pupil size were recorded. We also delivered tone clouds as auditory stimuli in a subset of VIP and SST imaging sessions. Different types of neurons showed various response directionality to arousal state in different sensory cortices. In the visual cortex, all types of neurons, VIP, SST, PV, and EXC were activated with whisking and running. However, in the auditory cortex, the majority of VIP neurons were inactivated and SST neurons were activated, and PV and EXC neurons showed more heterogeneous responses to the arousal states. In the somatosensory cortex, VIP neurons showed heterogeneity with whisking, but were inactivated with running. SST, PV, and EXC neuronal activities were activated with both whisking and running. VIP was inactivated, but SST was activated by tone clouds during stillness, whisking, and running. In a subset of auditory stimuli sessions of VIP mouse, narrower band tone clouds were presented, and VIP neurons were activated, which is the opposite to the responses to the broader band tone clouds. Our results show that different types of neurons in different areas show different relationships to arousal, and their responses to sensory stimuli could be different to the characteristics of the stimuli. Our research contributes to a better understanding of neural network dynamics by revealing characteristics of four different types of neurons in three sensory cortices.

Title: Effects of experience on multisensory processing in primary somatosensory cortex

Authors: *D. KATO[1], R. M. BRUNO[2];
[1]Columbia University, Dept. of Neurosci., New York, NY; [2]Neurosci., Columbia Univ., New York, NY

Abstract: Several studies over the past few years have found that activity even in primary sensory cortical areas is modulated by multiple sensory modalities. However, the functional and computational roles of these responses remain unclear. To test whether these cross-sensory effects encode stimulus-specific information, we measured responses to different auditory stimuli in primary somatosensory cortex (S1) of C57 mice using in vivo 2-photon calcium imaging. We found that very few cells were preferentially driven by one auditory stimulus over the other, and a linear decoder could not distinguish between population responses to different auditory stimuli once the effect of whisking had been taken into account. Moreover, we found very few cells whose responses to tactile stimuli were specifically modulated by concurrent presentation of one tone versus another, and a linear decoder was unable to distinguish between different conjunctive audio-tactile stimuli. Repeatedly pairing one auditory stimulus but not the other with a tactile stimulus did not seem to have any effect on decoder performance, nor did pairing reward with the presentation of conjunctive audio-tactile stimuli. However, we also found attenuated auditory brainstem responses in these mice, suggesting that these results may be at least in part due to a general hearing deficit. We are currently repeating these experiments in CBA mice, which do not exhibit the same hearing deficits.

Title: Multisensory integration and social behavior in Drosophila

Authors: *E. NORMAND, D. DEUTSCH, T. D. PEREIRA, N. RANGARAJAN, M. WANG, M. MURTHY;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Social behaviors rely on multisensory integration. How multisensory responses are generated from unimodal inputs and how they are read out to inform behaviors remain open questions. Here, we dissect the cellular mechanisms underlying multisensory integration in the

fruit fly Drosophila, focusing on neurons involved in mated female rejection behavior (ovipositor extrusion) during courtship. We utilize this female behavior because it is driven by a specific cell type (DNp13 (Wang et al. Current Biology, 2020)). Using two available Drosophila female brain connectomic resources, FlyWire (Dorkenwald et al. bioRxiv, 2020) and the hemibrain (Scheffer et al. eLife, 2020), we have mapped sites of audiovisual integration onto DNp13 as well as its presynaptic partners. Auditory neurons in this circuit are selective for male courtship song, while visual neurons are uncharacterized. Through high resolution behavioral tracking technology (SLEAP; Pereira et al. bioRxiv, 2020) we trained a machine learning model to track male and female pose, including ovipositor extrusion. We tracked both pose and male song throughout courtship in over 45 pairs of virgin males with previously mated females. These data are used to build a model of audiovisual integration that predicts female rejection behavior. Via neuronal silencing and calcium imaging experiments, we are testing the role of specific neurons in this circuit in audiovisual integration. Taken together, this study expands our understanding of how cells and circuits process multisensory signals and transforms them into dynamic motor responses.

Title: Lack of sensorimotor contingency deters visuo-haptic interaction of realistic stimuli

Authors: *H. SHIN, C.-Y. KIM;
Korea Univ., Seoul, Korea, Republic of

Abstract: Sensory information from modalities other than vision is known to alleviate visual ambiguity. In a previous experiment, we explored the influence of visuo-haptic shape congruence on perceptual selection during binocular rivalry using 3D shape objects (Shin et al., VSS 2021). Spiky, round, and a neutral shape neither spiky nor round was created using Superformula (Gielis, 2003). Rotating 3D rendered spiky and round shape objects were presented dichoptically and participants simultaneously explored with their hand either spiky, round, or neutral haptic object by rotating it in a direction congruent or incongruent with the presented visual target. Results revealed that shape congruence between visual and haptic stimuli influenced visual selection by boosting the dominance duration of the shape congruent visual

target for both spiky and round shapes. The present experiment was conducted using ecologically valid stimuli to examine the same shape congruence effect in a setting with tighter visuo-haptic interactions. By changing the visual targets to a pre-recorded video of a hand exploring a spiky or round 3D shape object in a rotating motion, the influence of sensorimotor contingencies involved in dynamic visuo-haptic interactions was expected to be observed. Participants dichoptically viewed videos exploring a round or spiky shape and reported the consciously perceived visual target via keyboard key press using their left hand while exploring the given haptic object with their right hand. However, the pattern of results was largely different from the previous experiment - previously the interaction between visual and haptic shapes was significant, with no main effects of either visual or haptic shape. In the present experiment, visuo-haptic shape interactions were not statistically significant, and there existed a main effect of visual shape. We deduce that even with shape congruence between visual and haptic stimuli, the reality of the visual stimuli highly resembling (but not identical to) participants' hand movements bolstered the significance of sensorimotor contingency between what was being seen and what was being haptically explored. This suggests that visuo-haptic interactions underlying shape congruence effects in perceptual selection is dependent upon sensorimotor contingency, especially when the stimuli closely resemble perceptual experience in real life.

Title: Tactile Motion Coordinate Transforms in the Somatosensory Cortex

Authors: *H. AHUJA[1], S. SHIVKUMAR[1], C. FEISTRITZER[2], R. M. HAEFNER[1], G. C. DEANGELIS[1], M. GOMEZ-RAMIREZ[1];
[1]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY; [2]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Our ability to perceive motion information on the skin is key to manipulating dynamic objects in the environment. Previous studies show that the brain derives tactile motion representations by integrating cues of the object that impinge on the skin (e.g., speed, intensity, direction), a mechanism known as the Full Vector Average model. This model was derived from studies that placed the hand in the same posture. Yet, object perception and manipulation with the hand (i.e., haptics) is a highly dynamic function. Thus, it is key to study whether motion inputs on the skin are transformed by hand position, and whether these transformations depend on the reference frame of the motion discrimination judgement. Here, we asked human

participants to discriminate motion stimuli on the index finger in a hand-centric or sternum-centric reference frame, while the stimulated hand was placed in different postures. Humans sat on a chair wearing a virtual reality headset, wherein a visual cue instructed participants to judge whether stimuli moved to the left- or right-side (relative to their sternum) or towards vs. away from their thumb (i.e., hand-centric task). The data revealed that humans flexibly represent tactile motion information according to the instructed reference frame, with motion judgements relative to the sternum perceived with higher sensitivity. We also developed a Bayesian generative model that accounts for the motion percepts in different reference frames and postural configurations. These data show that perceptual representations of tactile motion are generated by neural circuits that integrate cutaneous and proprioceptive inputs from the hand, and are under the control of goal-directed cortical signals.

Title: Compensatory changes follow somatosensory feedback loss in a dexterous manual task

Authors: *K. UNG[1], P. F. NORDMARK[2], J. YAU[1];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Integrative Med. Biol., Umeå Univ., Umeå, Sweden

Abstract: The role of sensory feedback is well established in current models of motor control, evidenced by severe deficits in movement coordination resulting from impaired sensory function. Goal-oriented motor behaviors involve extracting and integrating somatosensory and visual information about the action goal before the movement, and outcomes during and after the movement. How these sensory cues interact to contribute to dexterous motor behavior and how these interactions change following acute sensory loss have not been well studied. Here, we collect a large multimodal dataset from subjects performing a dexterous unimanual behavior (pegboard task) in order to address how behavior is impacted by loss of somatosensory feedback. Subjects retrieved, transported, and placed pegs under normal sensory conditions. They repeated the task with local anesthesia that removed somatosensory feedback at the fingers. During the performance of the task, we performed eye and hand tracking while also recording forces applied to the pegboard during the retrieval and placement of pegs. We hypothesized that impaired

tactile feedback disrupts the ability to finely tune dexterous motor behavior, leading to exaggerated movements and a greater reliance on visual feedback.
We found that loss of tactile feedback impairs performance of our manual dexterous motor task, leading to increased time to complete the task. Successful peg retrieval and placement required more time. Without tactile feedback, subjects also applied more force on the pegboard, implying impaired fine motor control. In some subjects somatosensory loss was accompanied by a shift in visual behavior marked by a closer alignment between eye and hand positions during all task stages. Together, these data support the important roles of sensory feedback on force control in service of dexterous object manipulation. Uncovering novel functional roles for sensory integration in dexterous motor tasks may not only better inform us of how the brain supports multimodal sensory integration, but may also help develop novel therapeutic approaches towards sensory feedback-based recovery of motor control.

Title: Multisensory integration of dynamic stimuli and the role of active touch

Authors: *M. CASADO PALACIOS[1,2], C. CAMPUS[1], *A. TONELLI[1], M. GORI[1];
[1]Italian Inst. of Technol., Genova, Italy; [2]Univ. of Genoa, Genova, Italy

Abstract: Multisensory integration of dynamic stimuli and the role of active touch. M. Casado, C. Campus, A.Tonelli, M. Gori.
Multisensory integration is a topic that has been extensively studied. However, the mechanism underlying visual and audio integration with touch and especially the impact that active touch, defined as voluntary movements, might have in this integration has been neglected. Some studies have found the specific effect of the active movement at the behavioral level, such as better recognition of objects (Morton, 1984), or a more accurate perceived duration of tactile stimuli after adaptation (Tomassini et al., 2012). We wanted to shed some light into the role of active touch on the multisensory integration process with this work. In the framework of the project MCSA MULTITOUCH, we designed two different experiments that compare the velocity discrimination threshold using tactile and audio information during active and passive tactile perception. 15 healthy participants have performed the experiments.The participant had to perceive a sequence of two stimuli with different speeds and discriminate the faster one. Two

standard speeds were used as the first stimulus (3 and 7 cm/s), while the second was determined by the adaptive QUEST algorithm (Watson and Pelli 1983). Three experimental conditions were considered: unimodal tactile condition, in which the participant had to feel the movement of a wheel embedded on a tactile frequency greeting with the index finger; Unimodal audio condition, in which the information was produced by a device attached to the wheel; and a bimodal audio-tactile condition, where audio and tactile stimulation were provided. In experiment one, the finger was fixed in a certain position, while in experiment two, the participant had to move the finger in the opposite direction of the wheel's movement. Our results show that for the 3cm/sec standard velocity, the multisensory information is integrated into a Bayesian optimal fashion when tactile information is perceived during passive touch but not during dynamic touch. Interestingly, for the 7cm/sec standard velocity, the reverse is true. The audio and tactile information is integrated into a Bayesian fashion when active movements are involved but not for the passive touch.These results might indicate two different mechanisms of multisensory integration for active and passive multisensory speed perception. The passive touch could be more adapted to integrate multisensory signals that are slower, while the active touch could be more adapted to integrate multisensory signals faster.

Title: Multisensory interaction of visual and proprioceptive cues in tactile motion perception

Authors: *C. FEISTRITZER[1,2], H. AHUJA[3], A. FULLER[3], M. GOMEZ-RAMIREZ[3]; [1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for Visual Sci., [3]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: The ability to perceive motion on the skin is crucial for manipulating objects with our hands. Recent work from our lab shows that tactile motion representations are derived by integrating motion cues impinging on the skin with the proprioceptive signals from the arm. We further showed that these representations are under control of goal-directed cognitive signals encoding the reference frame of the motion judgement. However, previous reach-to-grasp studies show that visual cues can modulate perceptual representations of the body's position. Here, we investigated whether visual signals relaying the proprioceptive state of the arm bias perceptual representations of tactile motion on the hand, and whether these effects depend on the reference

frame used to make the motion judgement. Human participants were asked to discriminate the motion direction presented on their index finger while the arm was placed in different postures. Participants wore a virtual reality headset that provided a visual representation of the arm's location. On certain trials we modulated the disparity between the visually-displayed arm and the physical position of the arm. Participants were asked to make motion judgements left vs. right relative to their sternum, or towards the tip vs. the base of the finger. Preliminary data showed that visual inputs modulated motion percepts according to a causal inference mechanism, wherein perceptual biases increased when visual and proprioceptive cues were closely aligned, and then decreased (and eventually disappeared) as visual and proprioceptive as disparity increased. These causal inference effects were observed in both reference frames. These data indicate that the brain integrates visual cues conveying proprioceptive state to derive tactile motion representations regardless of the reference frame used to make the motion judgements.

Abstract: Multisensory integration is the process by which we integrate stimuli from different sensory modalities which generates a facilitatory effect on perception and action, namely *multisensory enhancement effect*. This requires absence of unisensory imbalance and appropriate exposure to cross-modal cues. Following spinal cord injury (SCI), multisensory integration may be altered by sensorimotor deficits, altered GABAergic inhibition and reorganization of multisensory areas, causing unisensory imbalance and altered responsiveness to cross-modal cues. The aim of this study was to determine if SCI causes deficits in multisensory integration, and where in the processing stream this would occur. We used a detection task in which

redundant unimodal (visual, auditory, and tactile) and bimodal (audio-visual, visuo-tactile, and audio-tactile) targets were delivered. Participants (17 controls and 15 individuals with SCI) were instructed to rapidly detect any of the stimuli and respond vocally by saying “yes”. We recorded vocal reaction times. To quantify the multisensory enhancement effect, we used the independent race model that dissociates multisensory integration from bimodal facilitation lead by redundant stimuli. The multisensory enhancement effect is expressed as a “violation of the race model”, in which bimodal stimuli are faster than the summed unimodal probabilities. We hypothesized a reduced multisensory enhancement effect in SCI participants compared with control subjects. We found evidence of reduced race model violations in SCI participants. This result involved all tested sensory modalities.In addition, we investigated whether independent processing or competition mechanisms would occur at the stimulus and/or perceptual level in the SCI group by using a computational model approach. We tested two model parameters (i.e., stimulus strength and multisensory competition). We hypothesized that multisensory integration deficits could either involve one of the model parameters in a specific processing stream (stimulus or perceptual level), or involve more than one parameter, suggesting that after an SCI both independent processing and competition mechanism may arise at multiple perceptual stages. The computational model results indicate that SCI participants exhibit a higher perceptual multisensory competition at the neural representation level.Our results indicate that SCI reduces multisensory integration due to competition mechanisms occurring at the neural representation level. This suggests that a reorganization of multisensory areas after an SCI may play a role in multisensory integration deficits.

Title: Vision and artificial touch through intracortical microstimulation integrate optimally in humans

Authors: *V. KARAPETYAN[1], M. L. BONINGER[2], J. L. COLLINGER[2], A. P. BATISTA[1], P. LOUGHLIN[1], R. A. GAUNT[2];
[1]Bioengineering, [2]Physical Med. and Rehabil., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Sensory feedback rarely operates in isolation. For instance, skillful object manipulation relies on the interplay between somatosensation and vision. Brain computer interface (BCI) based prostheses can implement intracortical microstimulation (ICMS) of the somatosensory cortex to augment vision with localized sensory feedback. However, it remains to be determined whether, or to what extent such artificial somatosensation can integrate with natural vision. We used a two-alternative forced choice task to study the interaction of ICMS with vision in a human participant with tetraplegia and compared our results with a well-established Bayes' optimal integration model.
ICMS was delivered using microelectrode arrays implanted in Area 1 of the somatosensory cortex. It consisted of a constant frequency pulse train with a sinusoidally modulated amplitude to simulate the tactile sensation of running a finger across a corrugated surface. The visual stimulus consisted of random dots coalescing into vertical light and dark patches, matching the sinusoidal ICMS signal. The amount of dot coherence permitted control over noise in the visual signal. These modalities were presented together over two intervals, each interval with a different sinusoidal frequency, and our participant reported which had the faster oscillation. By delivering vision and ICMS incongruently (at different frequencies) we were able to determine the extent to which one modality was preferred over the other at different degrees of visual noise. Single modality performance was used to generate predictions under a Bayes' optimality model, and multi-modal observations were compared with these predictions.
We found that ICMS and vision do not operate in isolation but indeed do integrate in a manner consistent with minimal-variance optimality. As visual feedback noise decreased, participant preference became significantly biased towards the visual modality, in accordance with model predictions. This effect was replicated on two electrodes, projecting to different somatotopic locations and having different sensory profiles. Our results show that direct cortical stimulation can engage similar multisensory integration mechanisms as visuo-haptic exploration in able-bodied individuals. These results help interpret the manner in which somatosensory ICMS feedback operates in conjunction with other sensory modalities and guide its use in neuroprostheses.

Title: Mirror Neuron Therapy for Central Pain Syndrome

Authors: *E. ALTSCHULER;
Metropolitan Hosp., New York, NY

Abstract: A 63 year old female presented with six years of a severe central pain syndrome from presumed medication toxicity. The pain started in the left arm, leg and face and then spread to the right leg as well. Even after eventually tapering the medication thought to have initiated the pain syndrome, severe pain remained. Pain was exacerbated by warm temperature, vibration and even wind against the limbs. The patient found icing the limbs to be useful, but still had to have the limbs covered at most times to avoid wind or other light touch sensations setting off a pain exacerbation. The topic of mirror neurons--neurons that respond not only when one moves, but when one watches another move--was discussed with the patient as a possible therapeutic avenue: The patient is a yoga instructor and she noticed that when doing yoga wearing socks and leggings, he pain was lessened when she watched her student performing yoga in bare feet without experiencing any pain. The patient then started for limited times working without socks while still watching her students perform yoga. Gradually, the patient was able to go an entire teaching session without socks. Concomitant with this improvement the patient's pain at other times improved as well. Over the course of three months the patient's pain decreased to only a minimal level. The patient is now able to well tolerate vibration, e.g., long drives, without significant pain, and the patient does not need to cover up to avoid a pain exacerbation caused by wind. This case suggests that a mirror neuron inspired approach may be a useful treatment for central pain syndromes. Controlled studies of this approach may be warranted.

Weill Inst. for Neurosciences, Anesthesiology, Neurolog. Surgery, Neurology, Physiol., Univ. of California San Francisco, San Francisco, CA; [6]Dept. of Speech, Language, and Hearing Sci., Univ. of Texas at Austin, Austin, TX

Abstract: The anterior cingulate cortex (ACC) and orbitofrontal cortex (OFC) have been extensively implicated in the functional brain network underlying chronic pain. Electrical stimulation of the ACC and OFC have been proposed as therapies for refractory chronic pain, although, mechanisms of therapeutic action are still unclear. While the OFC is commonly associated with the valuation and cognitive manipulation of pain, the ACC plays a varied role in sensory and emotional integration of pain, as well as modulating internally generated perceptual states. In the context of perception, ACC activation has been commonly associated with audition, including detection of music, while the OFC has been described in the perception of taste, vision, and olfaction. In this case series, we report the emergence of subjective musical hallucinations (MH) after electrical stimulation of the ACC in two patients with refractory chronic pain. In an N-of-1 analysis from one patient, we identified neural activity (local field potentials, LFP) that distinguish MH from both the non-MH condition and during a task involving music listening. In contrast to an absence of notable LFP changes in the OFC, activity in the ACC (particularly in gamma and alpha bands), was associated with musical hallucinations and musical listening, respectively, extending prior results that internally-generated perceptual phenomena are supported by circuits in the ACC. We discuss these findings in the context of phantom perceptual phenomena and posit a framework whereby chronic pain may be interpreted as a persistent internally-generated percept.

Title: Chemotherapy induces proprioceptive deficits in the proximal limbs of cancer survivors

Authors: *A. B. WANG[1], S. N. HOUSLEY[3], A. M. FLORES[2,5], T. C. COPE[4], E. J. PERREAULT[1];
[1]Biomed. Engin., Northwestern Univ., Evanston, IL; [2]Dept. of Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL; [3]Sch. of Biol. Sci., [4]Applied Physiol. and Engin., Georgia Inst. of Technol., Atlanta, GA; [5]Robert H. Lurie Comprehensive Cancer Ctr., Chicago, IL

Abstract: The neurotoxic side effects of oxaliplatin (OX) chemotherapy contribute to movement deficits such as dexterity loss, imbalance, and falls in cancer survivors. It is often thought that OX-induced sensory nerve degeneration in the distal limbs, commonly termed sensory neuropathy, causes these movement deficits. However, recent animal studies have identified dysfunction in the muscle proprioceptors as an alternative mechanism. Muscle proprioceptors encode the muscle and limb motions and forces needed for accurate interactions with the physical world. Unlike distal sensory neuropathy, proprioceptive dysfunction could lead to more extensive motor deficits, including in the proximal limbs, where neuropathies are typically not reported. It is unclear whether chemotherapy leads to proprioceptive dysfunction independent of sensory nerve degeneration in humans. This study fills this gap by evaluating the functional use of proprioception in the shoulder and elbow joints of cancer survivors treated with OX. Thirteen cancer survivors and thirteen control subjects were tested. We implemented three sensorimotor tasks that assessed the use of proprioception in the horizontal plane: isometric force matching, unloaded reaching, and postural stability while countering external loads. Subjects were attached to a HapticMaster robot that measured endpoint displacements and forces and created the virtual environment required for each task. All subjects completed the tasks with and without visual feedback to separate the role of proprioception and vision. Cancer survivors had the greatest deficits in force matching. They were 62% less accurate ($p = 0.003$) and 37% less precise ($p = 0.03$) than controls when completing the task without vision. The group differences were small in the postural stability task (accuracy: 35%, $p = 0.05$) and minimal in the reaching task (accuracy: 22%, $p = 0.11$), suggesting that tasks involving force sensing and generation might be more affected in cancer survivors than those related to kinesthesia. The severity of the observed force deficits was correlated with cancer survivors perceived motor deficits, assessed using the clinical QLQ-CIPN20 questionnaire ($p < 0.001$). The most severely impaired cancer survivors had the poorest force-matching in directions that required significant use of shoulder muscles, indicating proximal involvement. While distal symptoms are routinely assessed in the clinical setting, our results suggest proximal assessments are also needed. Force tasks like those tested could be a starting point towards a more thorough and objective assessment of movement function in patients treated with chemotherapy.

Title: Multiple groups of neurons in superior colliculus control gaze and saccade based on object values

Authors: *A. GOPAL, O. HIKOSAKA;
NIH, Bethesda, MD

Abstract: Specialized networks in the basal ganglia (BG) assess the value of objects in the visual field. The neural activity in the caudate nucleus and substantia nigra reticulata distinguishes high-valued good objects from low-valued bad objects. This value signal from BG is then transmitted to the superior colliculus (SC), which contains at least three subtypes of neurons based on their functional role in generating saccades. This value signal must interface with these neuronal subtypes to modulate behavior, but the detailed connectivity is not well understood. To test this, we studied the response properties of different subtypes of SC neurons when monkeys directed saccades to objects of high and low value presented in their contralateral visual field. We identified four subtypes of SC neurons using a linear array that recorded cells across the different layers. Consistent with the previous findings, we found the four classes of SC neurons have distinct response profiles. Despite this, we found some common features in three groups: visual, visuomotor, and motor neurons. The early transient activity (0-80ms after target onset) did not differentiate between the value of objects. In the time interval 80-160ms, there was significantly higher activation in these neurons in response to good objects in the receptive field than bad objects. This suggests that the descending value inputs from the BG connect with these three classes of neurons. In addition, we found that the activity in the same interval has a systematic relationship with the latency of the upcoming saccade. The highest activation resulted in the fastest reaction time (RT), and the average activity progressively reduced for slower RTs. This systematic relationship between firing rate and RT was most prevalent in the visuomotor and motor neurons and to a lesser extent in the visual neurons. We also found a novel class of neurons (i.e., Inhibited) that are tonically active but decreased their activity in response to object onset in the receptive field. When the decrease was larger, the saccade tended to be faster, suggesting that these neurons may control saccades by their inhibitory connections to the other three groups: tonic inhibition (before object) and disinhibition (after object). However, these neurons are not sensitive to the value of objects as a population, hence unlikely to receive BG inputs. These data suggest that control of gaze/saccade based on object value involves the interplay of several mechanisms 1) Inputs from BG to visual, visuomotor, and motor neurons, 2) Interactions between visual, visuomotor, and motor neurons, 3) Inputs from Inhibited neurons to visual, visuomotor, and motor neurons.

Abstract: Motor control can be divided into automatic and voluntary processes. These processes require planning and preparation in order to deciding in advance to perform one action and not another when a particular sensory event occurs. It is known that the primary motor, the premotor, and the dorsolateral prefrontal cortices are linked to motor preparation. The cerebellum is recognized as an important structure in motor control, however, we do not know its precise role in voluntary motor preparation. To delve into this problem, 18 healthy right-handed volunteers, 9 females and mean age 23.8 years ± 3.44 performed the Pro/Anti-saccade Task while undergoing a fMRI scan with concurrent aye tracking. A randomly interleaved design was used including full prosaccade (PS), antisaccade (AS); and preparatory-only (PO) trials aimed at examined both the preparatory an execution components of saccade. Participants fixated on a central white circle for 1000 ms (neutral fixation stimulus) to start each trial. The neutral fixation stimulus changed to an instructional cue indicating that a PS (green circle) (look toward the target location) or an AS (red circle) (look away from the target in the opposite direction) was required. After 1300 ms presentation of the instructional cue, a 200 ms black screen gap period was introduced. On saccade trials, a peripheral target was flashed for 100 ms to the left or right of the neutral fixation to signal a saccade. Participants had 1400 ms to execute the appropriate PS or AS. Once a trial was finished, the neutral fixation stimulus reappeared at the center of the screen for 500 ms. On PO trials, the instructional cue was briefly presented, but the peripheral target never appeared to signal the saccade. Participants did not know whether or not the peripheral

target would appear on any given trial; thus the instruction cue would always elicit preparation for PS or AS. There were statistical differences between correct PS Saccade Reaction Time (SRT) and AS-SRT (p=0.003), and differences between correct and error PS-SRT cumulative distributions (p=0.01). Our fMRI analysis identified the main oculomotor network previously reported for PS and AS. More importantly, on PP trials we showed significant activation in the cerebellar lobules VI, VIII A and B; and Cruz I – II (p=0.05). These findings suggest that the cerebellum is important not only in the execution but also in the motor preparation. This activity pattern can be explained by the functional link between cerebellar and frontal-motor areas controlling the preparation and inhibition of the motor commands, which involves attentional processes.

Title: Peripheral signatures of sequential saccade planning

Authors: *D. BASU[1], N. SENDHILNATHAN[2], A. MURTHY[1];
[1]Ctr. for Neurosci., Indian Inst. of Sci., Bengaluru, India; [2]Columbia Univ., New York, NY

Abstract: The conversion of neural motor plans into muscle activity at the periphery underlie all targeted behavior. Planning of single saccades in oculomotor centers like the frontal eye field (FEF) have been shown to rapidly engage neck muscle motor units involved in head movements, suggesting that a tight link exists between the eye movement and head movement machinery. However, it is not known if a similar motor unit recruitment pattern occurs during sequential saccade planning, or if the downstream leakage of sequential signals is blocked by inhibitory control centers like the basal ganglia. To determine the relationship between neural and peripheral firing patterns during sequential movement planning, we undertook simultaneous single-unit recordings from the FEF (neural activity) and the dorsal neck muscle (electromyographic or EMG activity) of two macaque monkeys performing a sequential saccade task. In our study, the monkeys were head-restrained and only execution of saccadic eye movements was required in the task.We have previously shown that when a sequence of two saccades is concurrently planned, a processing cost is imposed on both the motor plans and FEF

activity ramping up towards threshold slows down. Neural signatures of processing bottlenecks seen in the FEF were preserved in neck motor unit activity: the shorter the gap between two saccade plans, the higher is the processing cost, and slower is the rate of growth in both neural (FEF) and peripheral activity (neck muscle). Mimicking neural activity patterns, evidence of parallel programming of saccades was also found at the level of the neck muscle: motor unit activity for the second plan was initiated before the first plan reached completion, although the onsets of neck muscle activity was delayed when compared to the onsets of FEF activity. Thus, the correspondence of the results between the FEF and the muscle periphery suggests that a common gaze command originates in the FEF and is relayed down to the neck muscle for executing eye-head gaze sequences. Our results indicate that inhibitory control centers like the basal ganglia, which has been shown to limit the processing of concurrent motor plans, restricts the downstream flow of signals encoding the second saccade in the FEF-neck muscle circuit only to a limited extent. We posit that sequential oculomotor plans in the FEF are indexed by the motor units in the dorsal neck muscle to bring about coordinated sequential gaze shifts.

Title: A new model of binocular eye movement control

Authors: *S. HEINEN[1], A. CHANDNA[1], D. SINGH[1], S. WATAMANIUK[1,2];
[1]Smith-Kettlewell Eye Res. Inst., San Francisco, CA; [2]Psychology, Wright State Univ., Dayton, OH

Abstract: Oculomotor physiologists usually record one eye, assuming that the other rotates identically (or oppositely). This methodology is reflected in the structure of virtually all oculomotor models, since these models describe pure conjugate or pure vergence eye movements. However, many eye movements acquire targets that lie off of the horopter or midline, requiring asymmetric eye rotations. How are asymmetric eye movements controlled? According to Hering's (1868) theories, a unitary vergence command is simply added to a unitary conjugate command to drive gaze shifts to any location, and most models assume this occurs. Our recent results during monocular viewing show asynchronous rotation of an occluded eye making it unlikely that a unitary vergence command drives gaze shifts to objects in depth (Chandna et al., 2021). Theoretical independent control of each eye could substitute for vergence

and solve the problem, but pure independent control does not account for sluggish midline vergence or inappropriate conjugate rotations during gaze shifts to targets aligned on an eye (Müller paradigm). Here we introduce a new theoretical model of binocular control. The core of the model is a rapid conjugate system that outputs a unitary command, and it is modulated by slow independent controllers. Like other oculomotor models, ours uses feedback and generates eye movement profiles with realistic temporal dynamics. Our model generates rapid saccades, as well as asymmetric eye movements, slow midline vergence and inappropriate conjugate rotations in the Müller paradigm. An additional endogenous component that interprets target motion when sensory evidence is lacking explains our covered eye results.

Title: Saccade amplitude, among other age-related differences in eye movements, is related to Archimedes spiral tracing performance in older adults

Authors: *B. HEINTZ WALTERS[1], W. E. HUDDLESTON[2], K. G. KEENAN[3];
[1]Kinesiology, Seattle Univ., Seattle, WA; [2]Kinesiology, Integrative Hlth. Care & Performance, [3]Kinesiology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Introduction. Archimedes spiral tracing is a common, clinical assessment sensitive to age-associated impairments in hand function. When performed on a touchscreen, tracing with the relatively larger diameter index finger versus stylus preferentially impaired performance in older adults, suggesting that decreased visual information of the spiral may contribute to age-associated spiral tracing impairments. However, no comprehensive analysis to date has evaluated the effect of eye movements on spiral tracing performance. The purpose of this study was to determine the association between eye movements and Archimedes spiral tracing performance in older adults. **Methods.** Eye movements were recorded from 21 young (age 20 - 38 yrs; 12 f, 9 m) and 20 older (age 65 - 85 yrs; 10 f, 10 m) adults during a spiral tracing task. Participants traced an Archimedes spiral template displayed on a touchscreen as accurately as possible using their index finger and a stylus. Live feedback of the participant's trace was superimposed onto the template. RMSE was calculated to quantify proximity of the participant's trace to the template. **Results.** RMSE was approximately 30% greater in older versus young adults when tracing with

the finger ($p < .001$) though there was no difference in RMSE when tracing with the stylus ($p = .130$). All participants used a series of saccades and fixations while tracing the template. Older adults made fewer saccades than young adults ($p = .029$). Saccade amplitude ($p = .029$) and saccade amplitude variability ($p = .011$) were greater in older versus young adults. Increased saccade amplitude was associated to increased RMSE in older adults ($r = .741$). Due to the nature of the task, the hand may have obstructed more visual information of the spiral depending on the part being traced. Participants made more saccades when tracing parts of the spiral where vision of the upcoming spiral template was likely less obstructed by the hand ($p < .001$) though there were no differences in RMSE ($p = .065$). **Conclusions**. Because saccades are used to orient gaze with areas of interest in the visual field, a greater number of saccades likely reflects a visual strategy that would allow for more up to date visual information of the spiral; however, this had no effect on spiral tracing performance. Results provide evidence of age-related changes in eye movements during the spiral tracing task and suggest that decreased visual information may not be the main contributing factor associated with impaired spiral tracing performance when tracing with the finger in older adults. Future work could continue to investigate other factors associated with the ability to perform the touchscreen spiral tracing task.

Title: Neuronal computations associated with saccades in a widely distributed prefrontal cortex

Authors: *E. CONTRERAS-HERNANDEZ, G. M. JEANPIERRE, S. S. KOUKUNTLA, H. M. STEALEY, S. R. SANTACRUZ;
Dept. of Biomed. Engin., Univ. of Texas at Austin, Austin, TX

Abstract: The role of different cortical prefrontal areas in the preparation of voluntary visual- and memory- guided saccades is well studied. In particular, the anterior cingulate cortex (ACC) and dorsolateral prefrontal cortex (dlPFC) play important roles in the control of intentional saccades and visuospatial working-memory, respectively. Studies that have analyzed neuronal computations associated with saccade movements at the level of single neurons have been primarily conducted in individual prefrontal regions. We analyzed the tuning of single neurons simultaneously recorded from the ACC, dlPFC and orbitofrontal cortex (OFC) while non-human primates (macaca mulatta) performed a center-out saccade task. After a center-fixation period,

visual cues appeared simultaneously in four quadrants, and then the subjects made a saccade at a free chosen direction. The employed data in this analysis were obtained by other authors and made openly available (CNCRS.org-PFC7). By using a linear discrimination-based neural classifier we find that the firing rate of the neurons recorded from each of these three areas are tuned at different extents to the direction of the saccades. Interestingly, we observe that the accuracy of the prediction of the saccades direction is proportional to the number of analyzed neurons regardless if they were recording simultaneously from the three regions (ACC, dlPFC and OFC) or from subgroups of regions (e.g. ACC and dlPFC). We also show that the firing rate of a modest fraction of single neurons are tuned with the amplitude, speed and onset time of the ocular movement. Additionally, all the correlates between neuronal activity and the features of the saccades appear after the presentation of the visual cues, and before, during and after of the saccades. These observations suggest that the dlPFC, OFC, and ACC form part of an integrative prefrontal network involved on the preparation and execution of voluntary saccades. Additionally, it supports the inclusion of the OFC in such network in non-human primates, whose participation has remained on debate.

Title: Head tilt influences saccade directions during free viewing

Authors: *S. M. REEVES[1], E. A. COOPER[1,2], R. RODRIGUEZ[1], J. OTERO-MILLAN[1,3]; [1]Sch. of Optometry & Vision Sci. Program, Univ. of California Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Institute, Univ. of California Berkeley, Berkeley, CA; [3]Dept. of Neurology, Johns Hopkins Univ., Baltimore, MD

Abstract: When humans freely explore visual scenes they can make saccades in any direction, but it turns out that not all directions are equally likely. A bias toward horizontal and vertical saccade directions is well documented, though the reason for the bias is unknown. In addition to biases in oculomotor anatomy, scene structure, or past experience, it is possible that vestibular signals indicating head orientation play a role in the saccade direction biases. Thus, in the present study, we asked whether roll tilting the head influenced saccade direction distributions during free viewing. Study participants (n = 14) viewed natural scenes (outdoor and indoor) and abstract

scenes (radially symmetric patterns) using the FOVE virtual reality headset. We recorded eye movements with the integrated FOVE eye tracking system (120Hz, binocular). Participants sat in a chair with their heads stabilized and tilted at -30, 0, or 30 degrees while viewing scenes that could also be tilted by -30, 0, and 30 degrees relative to the head. All participants were exposed to all head tilt and scene tilt conditions. Head tilt angle was blocked, and scene type and tilt angle were randomized. To determine if the biases in saccade direction changed with head tilt (i.e., if the directions with the most saccades rotated) we calculated polar histograms of saccade directions in head-referenced coordinates for both natural scenes and abstract scenes for each head tilt block, and then cross correlated the distributions for -30 and 30 degree head tilts to find the angular displacement that resulted in the maximum correlation. A single sample t-test revealed that saccade distributions for abstract scenes were significantly rotated by a mean angle of 5.29 degrees ($SD = 5.41$; $t(13) = 3.65$, $p = 0.003$). Saccade distributions for natural scenes were also significantly rotated by a mean angle of 2.2 degrees ($SD = 2.36$; $t(13) = 3.51$, $p = 0.004$). These results suggest that the saccade direction biases can be affected by head tilt, and that non-visual information about head orientation, such as information from vestibular signals, likely plays a role in saccade generation.

Title: Translational and rotational eye movements during blinks measured using real-time MRI

Authors: J. KIRCHNER[1], T. WATSON[2], *M. LAPPE[1];
[1]Inst. for Psychology, Univ. of Muenster, Muenster, Germany; [2]Western Sydney Univ., Penrith, Australia

Abstract: Blinks occur frequently in normal life and have increasingly been linked to perceptual and cognitive effects. However, some aspects of the oculomotor mechanics of blink-related eye movements remain unclear. Blink-related retraction of the eyeball has been observed when forcibly holding the eyelid open, but the full extent of the blink-related eye movement has not been measured so far due to technical limitations. Here we use real-time Magnetic Resonance Imaging (MRI) to image the eye in motion during blinks and developed a fully-automated segmentation method allowing to analyse eye movements in terms of both translation and

rotation. For our MR-based Eye Tracking (MREyeTrack) procedure we used a balanced steady-state free precession (bSSFP) MR sequence with a temporal resolution of 35 ms in the axial or 38 ms in the sagittal plane. Motion estimation was optimised by obtaining precise knowledge of the geometric shape of the eyeball from a 3D anatomical scan before undertaking kinematic estimation using the high temporal resolution single-slice data. For comparison, a video-based eye tracker (Eyelink 1000) simultaneously recorded gaze direction and pupil size of the right eye of the participants. We recorded various horizontal eye movements, blinks and longer periods of eye closure. Linear regression analysis of the MREyeTrack data and the horizontal gaze data from the video-based eye tracker yielded highly significant agreement between both data sources. We were able to measured the full extent of the blink-related eye movement, further demonstrating that the eye approaches a holding position during lid closure moving by as much as 35° in rotation and 2 mm in translation. Apart from the previously reported retraction, we additionally observed that the eyeball lifts during blinks. We also investigated the coordination of gaze shifts with blinks. We found that the gaze shift is tightly coupled in time to the translational blink movement and that blinks can induce significant temporal shifts of the gaze trajectory between left and right eye. We have demonstrated the application of real-time MR sequences to eye tracking and established MREyeTrack, an automated analysis method based directly on anatomical eye orientation. It is capable of establishing translational eye movements and those that occur when the eyelid is closed. We used this method to show novel aspects of the blink-related eye movement and think that these may provide useful insights into the biomechanics of the oculomotor system.

Title: Role of the frontal eye field in human pupil and saccade orienting responses

Authors: *C.-A. WANG[1], T.-Y. HSU[2];
[1]Inst. of Cognitive Neurosci., Natl. Central Univ., Taoyuan City, Taiwan; [2]Grad. Inst. of Mind, Brain and Consciousnes, Taipei Med. Univ., Taipei City, Taiwan

Abstract: The appearance of a salient stimulus evokes a series of orienting responses including saccades and pupil size to prepare the body for appropriate action. The midbrain superior colliculus (SC) that receives critical control signals from the frontal eye field (FEF) is hypothesized to coordinate all components of orienting. It has shown that the FEF, together with the SC, is also importantly involved in the control of pupil size, in addition to its well-documented role in eye movements. Although the role of the FEF in pupil size is demonstrated in monkeys, its role in human pupil responses and the coordination between pupil size and saccades remains to be established. Through applying continuous theta-burst stimulation (cTBS) over the right FEF and vertex using magnetic resonance imaging-guided TMS in twenty-eight human participants, we investigated the role of the FEF in human pupil and saccade responses evoked by a salient stimulus, and the coordination between pupil size and saccades. Each cTBS session delivered a 40 seconds train of uninterrupted biphasic theta-bursts pulses. This consisted of 3 pulses, at 50 Hz, given in 200 ms intervals, comprising a total of 600 pulses for 40 seconds at 80% intensity stimulation for active motor threshold. The active motor threshold was defined as the lowest stimulator output in percentage that elicited 5 out of 10 twitches of more than 200 μV peak-to-peak amplitude in the contralateral hand, while the participant maintained 20% of a finger-thumb contraction, with the mean being 41.03% ± 6.15 (mean ± standard deviation) of maximum stimulator output. The participants came in twice (one week apart) for the same experiment with a different stimulation (the sequence of stimulation sites was counterbalanced across participants). All participants underwent the identical experimental procedure and conducted the behavioral task 1 minute after the completion of cTBS. Our results showed that neither saccade reaction times (SRT) nor pupil responses evoked by salient stimuli were modulated by FEF stimulation. Contrarily, the correlation between pupil size and SRTs in the contralateral stimulus condition (stimulus appeared in the contralateral field of stimulation) was diminished with FEF stimulation, but intact with vertex stimulation. Moreover, FEF stimulation effects between saccade and pupil responses associated to salient stimuli correlated across participants. This is the first TMS study on the pupil orienting response, and our findings suggest that human FEF was involved in coordinating pupil size and saccades, but not involved in the control of pupil orienting responses.

Title: Hpa axis and cognitive function: circadian cortisol pattern and oculomotor task performance

Authors: *T. KARANTINOS[1], F. ATHANASOPOULOS[1,2], A. MEGALOKONOMOU[1], C. MITROU[1], A. MANTZOU[3], P. PERVANIDOU[4], N. SMYRNIS[1,2];
[1]Lab. of Cognitive Neurosci. and Sensorimotor Control, Univ. Mental Health, Neurosciences and Precision Med. Res. Inst. "COSTAS STEFANIS", Athens, Greece; [2]2nd Dept. of Psychiatry, Natl. and Kapodistrian Univ. of Athens, Sch. of Medicine, Univ. Gen. Hosp. "ATTIKON", Athens, Greece; [3]First Dept. of Pediatrics, Unit of Clin. and Translational Res. in Endocrinol., Natl. and Kapodistrian Univ. of Athens, Sch. of Med., Athens, Greece; [4]Lab. of Developmental Psychophysiology and Stress Res., Natl. and Kapodistrian Univ. of Athens, Sch. of Medicine, "Aghia Sophia" Children's Hosp., Athens, Greece

Abstract: The Hypothalamic-Pituitary-Adrenal (HPA) axis is a basic neuroendocrine system that regulates Circadian Cortisol Rhythm. Findings indicate that cortisol affects multiple aspects of cognitive function. In this study we attempted to explore the relationship between the diurnal variation of cortisol, measured by saliva samples collected five times a day, and cognitive function, by employing four experimental tasks that assess eye movements and inhibition, in two distinctive experimental paradigms. We compared the performance of 21 healthy young adults, aged between 18-33, in the Prosaccade (STP), GAP, Antisaccade (ANS) and in two task conditions of the Countermanding (CMN) task (CMN 40 and CMN 100), in three different time points (Morning, Afternoon, Evening) during one day. Participants presented a general improvement in their performance in the evening condition compared to the morning one, as measured by reaction time (main effect of time for: STP & GAP: $F_{2,40} = 8.16$, $p<.001$, ANS: $F_{2,40}= 4.88$, $p=.013$, CMN 40 & 100: $F_{2,38} =7.17$, $p =.002$), reaction variability (ANS: $F_{2,40}= 5.68$, $p =.007$, CMN 40 & 100: $F_{2,38} = 16.44$, $p <.001$) and percentage of correct responses (ANS: $F_{1.25, 25.01}= 7.88$, $p=.006$, CMN 40 & 100: $F_{2,38} =12.26$, $p <.001$). However, the diurnal variation of all oculomotor tasks' performance was not correlated to the expected and observed diurnal variation of cortisol. Results suggest that normal variability of cortisol levels in healthy young adults does not affect oculomotor performance and inhibition. We, also, compared the performance of 9 healthy young adults in the aforementioned oculomotor tasks during the morning of two consecutive days. Participants presented an improvement in their performance on the second day as measured by reaction time (main effect of day for: STP & GAP: $F_{1,8} = 17.84$, $p = .003$, ANS: $F_{1,7} = 39.26$, $p <.001$, CMN 40 & 100: $F_{1,8} = 5.62$, $p = .045$), reaction variability (STP & GAP: $F_{1,8} = 39.42$, $p <.001$, ANS: $F_{1,7} = 29.7$, $p <.001$) and percentage of correct responses (ANS: $F_{1,7} = 10.96$, $p = .013$, CMN 40 & 100: $F_{1,8} = 11.45$, $p = .009$) suggesting that the improvement observed in the first experimental paradigm, as well as in the second one, is due to learning effects.

Title: Cortical contributions to transsaccadic discrimination of object orientation vs. shape changes: An fMRI study

Authors: *B. R. BALTARETU, W. D. STEVENS, E. FREUD, J. CRAWFORD;
Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Recently, Dunkley et al. (2016) showed modulations in parietal cortex (i.e., supramarginal gyrus, SMG) for transsaccadic changes in object orientation. However, this result did not generalize to other features, such as spatial frequency (Baltaretu et al., 2021). We hypothesized that the fundamental difference between these results was the detection of transsaccadic changes in object orientation (inferior parietal regions) vs. shape (medial occipital regions). Moreover, we anticipated that transsaccadic perception would occur through a unique functional network comprising saccade and object perception regions. Here, we used a double-dissociation fMRI task to determine the cortical correlates for transsaccadic change detection of multiple object features. 21 participants fixated a cross ±15.4° of centre, where an object was subsequently presented (rectangle, barrel, or hourglass) oriented at ±45° from vertical. The fixation cross remained in the same position (Fixation condition) or shifted (Saccade condition), followed by the same object re-presented at the orthogonal orientation (Orientation change) or another object at the initial orientation (Shape change). Change in object orientation or shape in each trial was indicated via button press. After excluding 4 participants, a region-of-interest analysis on two regions (supramarginal gyrus and cuneus) showed that only cuneus presented significant eye movement and feature sensitivity. A similar whole-brain univariate analysis was used to localize the optimal seed region for network analysis, which showed connections between *left medial occipital cuneus* and early-to-mid-level visual (e.g., lingual gyrus, superior occipital gyrus), object-relevant (e.g., medial occipitotemporal sulcus, transverse occipital sulcus), and oculo/sensorimotor (i.e., superior parieto-occipital cortex) regions. These results implicate medial occipital cortex in the transsaccadic memory and discrimination of multiple object features, with additional recruitment of regions in parietal and temporal cortex.

Title: Dynamic visual processing coverage predicts observed differences in natural oculomotor behavior across mammals

Authors: *J. SAMONDS[1], M. SZINTE[2], C. BARR[1], A. MONTAGNINI[2], G. MASSON[2], N. J. PRIEBE[1];
[1]Univ. of Texas at Austin, Austin, TX; [2]Inst. De Neurosciences De La Timone, Marseille, France

Abstract: Most vertebrates use saccadic eye movements to quickly change gaze and sample different portions of the environment. Several hypotheses have been proposed to explain saccadic dynamics, from low-level automatic image analysis (e.g. decorrelating receptive field responses) to cognitive scanpaths (e.g. directing gaze towards new objects). The adaptive properties of visual neurons require that saccades should be large enough to sample local information that are uncorrelated with the previous fixation in order to maximize responsiveness. Using this rationale, we previously were able to predict average saccade sizes from the combination of receptive field sizes and natural scene statistics. This prediction applies not only to small fixational saccades, but to all saccades when free viewing natural scenes for both foveate and afoveate mammals. Adaptation recovery times can also explain saccade rate distributions in these different animal species. Here, we examine what general principles would drive the differences for both saccade sizes and rates across three species (mice, marmosets, humans) scanning the same set of natural images. We report that in order to achieve similar coverage over time, animals with larger receptive field sizes require slower rates. For all three animals, saccade rates and sizes decrease with smaller images and over time. Differences in the number of photoreceptors and V1 cells available to process the sampled visual information also appear to play a substantial role in determining saccade rate. We conclude that a diverse set of mammals share a common strategy of maintaining sufficient sampling coverage of their environment over time, under the constraint of conserving energy.

Title: Dopamine and control of memory-guided saccades in Parkinson's disease

Authors: *L. JIANG, A. KHIBOVSKA, H.-C. LEUNG;
SUNY Stony Brook, Stony Brook, NY

Abstract: Voluntary eye movement control has long been associated with dopaminergic modulation in the cortico-basal ganglia (BG) circuitry, yet its underlying neurocognitive mechanisms remain unclear. Using Parkinson's disease (PD) as a model, we examined how cortico-BG dopamine deficiency may influence selective memory- and visually-guided saccades (MGS and VGS). A group of early-stage PD patients (N = 12, both *on* and *off* dopaminergic medication) and age-matched healthy controls (HC, N = 14) completed an MGS and VGS task requiring selective processing. During the VGS task, participants were instructed to shift their gaze to one of two displayed items and ignore the other item. The paradigm was similar for the MGS task, except there was a delay period (1.7 or 4.3 s) between stimulus presentation and saccade response. We compared a wide range of saccade metrics between the two subject groups (PD vs. HC) and PD medication status (*on* vs. *off*), including saccade latency, gain, and peak velocity, number of corrective saccades, as well as systematic and unsystematic errors of the saccade endpoint with and without statistical modeling. Performance accuracy was comparable between PD and HC (MGS: 80.5% vs. 85.8%; VGS: 92.9% vs 93.6%) and between *on* and *off* (MGS: 77.1% vs. 83.8%; VGS: 92.5% vs 92.9%). As expected, individuals with PD showed reduced saccade velocity, prolonged latency, and more corrective saccades during the tasks, indicating impaired voluntary saccade generation in the early stage of the disease. In addition, individuals with PD showed significantly greater unsystematic errors, not systematic errors or mean saccade gain, in saccade endpoints of both tasks. These findings suggest an increased response variability, not a shift in the mean endpoint responses in PD relative to HC in the face of distraction. However, the dopaminergic medication did not show clear behavioral benefits. Compared to off medication, the same individuals with PD seemed to show prolonged saccade latency and were less accurate when they are on medication. These preliminary data suggest that dopaminergic medication impairs the ability to select the target or ignore the distractor in MGS and VGS in early-stage PD, potentially due to excessive upregulation of the indirect basal ganglia pathway dopamine or downregulation of the prefrontal dopamine. Taken together, these results revealed deficits in both visually and memory-guided saccadic responses in PD while dopaminergic medication did not seem to restore but may exacerbate these deficits, suggesting a complex role of cortico-BG dopamine in regulating voluntary control of eye movements during cognitive tasks.

Title: Effects of ischemic injury on the organization of complex forelimb movements in mouse motor cortex

Authors: *C. C. WOLSH, A. R. BROWN, S. MITRA, R. M. BROWN, M. M. LOPEZ, J. A. BOYCHUK;
Cell. and Integrative Physiol., Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Stroke is a predominant source of disability and there is a need to understand the neuronal processes underlying its pathophysiology and recovery. In this study, motor cortex was tested (using electric brain stimulation) as this structure is often damaged by stroke and motor impairments of the upper extremities are common post-stroke sequelae. Stroke was modeled by permanent ischemic injury using photothrombotic occlusion of the distal middle cerebral artery (MCAo-injury group). Control animals received sham-injury except one animal was non-surgerized (Uninjured group). Skilled motor behavior was assessed pre- and post-injury using the single pellet reaching task. Following completion of behavioral testing, long duration intracortical microstimulation (LD-ICMS; 500ms pulse trains) was applied to motor cortex to determine the location and proportion of complex forelimb movements of this structure. LD-ICMS was used here to study the resulting complex (multi-joint) movements since these responses may represent fundamental components of active motor behaviors. We detected four distinct complex forelimb movement regions of motor cortex in mice by determining the most consistent and robust movement at individual test sites during LD-ICMS; ‘advance’ (anterior forelimb displacement with flexion of the shoulder, and wrist extension), ‘elevate’ (dorsal forelimb displacement involving elbow flexion and wrist extension), ‘retract’ (posterior forelimb displacement involving flexion of the elbow and extension of the wrist) and ‘Dig/Push’ (posteroventral forelimb displacement involving extension of the shoulder and elbow). Comparison between the MCAo-injury group and Uninjured group detected a significant overall effect on reaching accuracy on the single pellet reaching task, with the MCAo-injury group being 56% less successful across the last 4 sessions. MCAo-injury also reduced the overall area of motor cortex capable of producing complex forelimb movements whereas the cortical area capable of producing simple movements (during LD-ICMS) was not reduced. The regions of most complex movement types (advance, retract, dig/push) were significantly decreased by MCAo (relative to the Uninjured group). Surprisingly, the cortical region of Elevate was not decreased by MCAo (relative to the Uninjured group). Kinematic testing of evoked LD-ICMS movements is ongoing. Future experiments will test for mechanisms that account for this

difference between Elevate and the other zones of complex forelimb movement in order to test parameters of intervention to improve motor outcomes after stroke injury.

Title: Physical Effort and Reward Value Representation in Sensorimotor (PMd, M1 And S1) Cortical Local Field Potentials

Authors: *T. YADAV, O. MAGAÑA-TELLEZ, J. T. FRANCIS;
Biomed. Engin., Univ. of Houston, Houston, TX

Abstract: Reward expectation in humans and animals is known to modulate behavior and its valuation is discounted by the physical effort associated with the movement. Our previous work has shown reward encoding within the macaque premotor (PMd), motor (M1), and somatosensory (S1) cortices. However, the involvement of these regions in concurrent processing of reward and effort information is not clearly understood. To address this gap, we asked how the reward representation in local field potentials (LFPs), recorded from the PMd, M1, and S1 are influenced by physical effort requirements. We trained a non-human primate (female, Macaca Mulatta) to perform three variations of a planar center-out reaching task: reward-only, effort-only, and reward-effort tasks. A visual cue (color and shape) presented at the beginning of each trial indicated the expected reward (3 levels of juice amount) and effort (4 levels of hand velocity dependent resistive force field) respectively. Cued amount of juice reward was delivered only for successful trials. While no viscous field was active for the reward-only task, a fixed reward (1 drop) was delivered in the effort-only task, whereas both reward and effort levels were varied in the reward-effort task. We assessed binned LFP during the post-cue period, before the target information was known, using generalized linear model (predictors: reward level, time bin for reward-only task; effort level, time bin for effort-only task; and reward level, effort level, and time bin for reward-effort task). In the reward-only task, we have previously shown that the post-cue amplitude of alpha and beta band LFPs encode reward value in PMd, M1 and S1. The effort-only task showed no significant effect of effort level or effort-bin

interaction, indicating negligible modulation in LFP amplitude with effort level (F-test, $p>0.05$). Interestingly, the reward-effort task showed a significant effect of reward-bin interaction, as well as reward-effort interaction (F-test, $p<0.05$), indicating effort-dependent reward representation in the alpha and beta oscillations. Taken together, our preliminary findings suggest subjective influence of effort information on the reward value encoded by the LFP amplitude from PMd, M1 and S1 regions. In addition to highlighting the neural processing of reward and effort information, results from this study could be critical to develop autonomous brain computer interfaces (BCIs) for clinical applications.

Title: Mouse sensorimotor cortex reflects complex kinematic details during reaching and grasping

Authors: *H. A. GRIER[1], M. T. KAUFMAN[2];
[1]Committee on Computat. Neurosci., [2]Organismal Biol. and Anat., The Univ. of Chicago, Chicago, IL

Abstract: Neural recordings in non-human primates have shown that activity in sensorimotor cortex correlates with the kinematic and postural details of reach to grasp movements. We characterized this relationship in the mouse. To obtain a diverse set of forelimb postures and movements, 5 head-fixed mice performed unimanual reaches to grasp water rewards from two spout targets cued by sound (based on Galinanes et al. 2018). We collected high speed camera data and tracked 15 points on the proximal and distal limb using DeepLabCut and DeepGraphPose. 3D triangulation allowed extraction of 25 angular degrees of freedom (DoFs) from skeletal relationships between markers. These variables showed that our task evoked complex kinematics: cross-validated dimensionality reduction (PCA) performed on single-trial joint angle time series revealed dimensionalities in the range of 6-11 across mice. To relate these variables to neural activity, we recorded from layer 2/3 excitatory cells of contralateral forelimb

S1 (S1-fl) and M1 (Caudal Forelimb Area, CFA) using 31 Hz two-photon calcium imaging in GCaMP6f transgenic mice (337-635 cells/dataset). Deconvolved calcium events showed that a substantial fraction of cells in both areas were significantly modulated over time or across spout targets: 61-66% in S1-fl and 38-80% in CFA. To determine how these responses reflected forelimb kinematics, we used cross-validated ridge regression encoding and decoding models. We found that 40-47% of significantly modulated neurons in S1-fl and 50-55% in CFA encoded 3D marker position, velocity or acceleration, and 40-44% / 51-54% encoded joint angles, velocities or accelerations. Position information was more accurately decoded than velocity or acceleration from both S1-fl and CFA, with a median of 73% variance explained (VE) across all markers and sessions. Multiple angular DoFs could be decoded from both areas, with wrist rotation, elbow flexion, and shoulder rotation decoded best (71-73%, 60-65%, 68-78%, VE). These results suggest that detailed cortical representations of reaching and grasping in the mouse are highly distributed across sensory and motor areas, and that activity strongly reflects the forelimb and digit positions across many angular DoFs.

Title: Effect of Intracortical Microstimulation on Motor Learning in Macaques Manual Interception

Authors: *C. ZHENG[1], H. CUI[1,2];
[1]Lab. of Neural Mechanism of Motor Control, Ctr. for Excellence in Brain Sci. and Intelligence Technol. (Institute of Neuroscience), CAS, Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: Recent progress in intracortical microstimulation (ICMS) has shown the promise of bi-directional brain-machine interface (BMI) for restoring sensorimotor function. However, the

artificial sensations evoked by ICMS in primary somatosensory cortex (S1) are still far from naturalistic. Despite that motor cortex is mainly responsible for motor generation, it has been recently shown that subthreshold ICMS in the motor cortex can evoke distinguishable sensations to guide specific movements. In contrast, a previous study claimed that subthreshold ICMS disrupted the activities in motor cortex and delayed the movements. To examine the effect of subthreshold ICMS in motor cortex in a stricter behavioral context, we delivered ICMS to monkey when doing the delayed manual interception task. One monkey (*Macaca mulatta*) was trained to manually intercept a target that moved circularly around a center on a vertical screen in his front. Subthreshold ICMS (100 ms of 0.2-ms biphasic pulses at 300 Hz) were delivered via single electrodes inserted into the primary motor cortex (M1) or dorsal premotor cortex (PMd) acutely. ICMS was delivered randomly in 30% trials, with a random onset time during the delay period. Arm kinematics was recorded using optical motion capture systems (vicon). Although subthreshold ICMS in M1 delayed the movements with endpoint error unaltered in the first eight sessions, reaction times (RTs) were gradually accelerated later in both non-stimulated (NS) and stimulated (ST) trials, while RT reduced more in ST trials without increasing endpoint error. The subsequent PMd ICMS no longer evoked RT increase, instead manifested a similar effect to M1 after the transformation of RT: shortened RT + movement time (MT), reduced RT/(RT+MT), and elevated peak hand velocity. Moreover, M1 ICMS made hand trajectory more curved without changing the error, whereas PMd ICMS induced an insignificant but modest increase in error and a straighter hand trajectory. Furthermore, we gradually dimmed the GO cue and found that the monkey learned to used subthreshold ICMS in PMd, M1, or S1 in place of visual GO cue to conduct delay-intercept task. Our study reveals that subthreshold ICMS in motor cortex induced a motor adaption with kinematic change in manual interception. Short-train subthreshold ICMS in motor cortex probably mainly evokes sensation rather than motor perturbation, which can be utilized by the monkey to improve action execution. In summary, in addition to S1, motor cortex is a candidate for feeding information into the brain which may help the development of more integrated bi-directional BMIs in the future.

Title: Largely shared neural codes for biological and nonbiological observed movements but not for executed actions in monkey premotor areas

Authors: *D. ALBERTINI[1], M. LANZILOTTO[2], M. MARANESI[1], L. BONINI[1];
[1]Dept. of Med. and Surgery, Univ. of Parma, Parma, Italy; [2]Dept. of Pyschology, Univ. of Turin, Turin, Italy

Abstract: The neural processing of others' observed actions recruits a large network of brain regions (the action observation network, AON), in which frontal motor areas are thought to play a crucial role. Since the discovery of mirror neurons (MNs) in the ventral premotor cortex, it has been assumed that their activation was conditional upon the presentation of biological rather than nonbiological motion stimuli, supporting a form of direct visuomotor matching. Nonetheless, nonbiological observed movements have rarely been used as control stimuli to evaluate visual specificity, thereby leaving the issue of representational similarity among executed actions and biological or nonbiological observed movements unresolved. Here, we addressed this issue by recording from two nodes of the AON that are attracting increasing interest, namely the dorsal premotor area F2 and the mesial pre-supplementary motor area F6 of macaques while they 1) executed a reaching-grasping task, 2) observed an experimenter performing the task, and 3) observed a nonbiological effector moving in the same context. Our findings revealed stronger neuronal responses to the observation of biological than nonbiological movement, but biological and nonbiological visual stimuli produced highly similar neural dynamics and relied on largely shared neural codes, which in turn remarkably differed from those associated with executed actions. These results indicate that, in highly familiar contexts, visuo-motor remapping processes in premotor areas hosting MNs are more complex and flexible than predicted by a direct visuomotor matching hypothesis.

Title: Local and long-range action selection mechanisms across a cortico-collicular circuit

Authors: *A. THOMAS[1], S. LAASYA TIPPARAJU[1], G. CHEN[1], W. YANG[1], K. SWIEKATOWSKI[1], M. TATAM[1], C. GERFEN[2], N. LI[1];
[1]Baylor Col. of Med., Houston, TX; [2]NIH, Bethesda, MD

Abstract: Prior to movement, competing motor representations are intermingled and distributed across a multi-regional circuit, including frontal cortex and superior colliculus (SC). Preparatory activity in these regions is considered a correlate of action selection, yet the circuit mechanisms mediating this process remain poorly understood. Traditional models posit that cortex selects upcoming behaviors, then sends a motor command to SC. However, recent data implicate SC feedback in action selection. We employed anatomical tracing, optogenetic manipulation and electrophysiological recordings to investigate action selection mechanisms in mice. Our anatomical tracing experiments reveal that the lateral SC receives direct input from ipsilateral frontal cortex (anterior lateral motor cortex, ALM) and projects back to ALM through medio-dorsal and ventral-medial thalamus, forming a loop. To define SC contributions to behavior, we performed optogenetic manipulation during a delayed response task. Animals used their whiskers to discriminate the position of an object during a sample period. After a delay period (1.3 s), the animals reported their choice via directional licking (left or right). Unilateral activation of SC evoked contralateral licking, and bilateral inactivation blocked licking altogether. Unilateral inactivation of the SC during the delay and response periods (but not the sample period) produced ipsilateral choice biases. Even transient inactivation of SC during the early delay was sufficient to bias upcoming licking, suggesting that the SC participates in the selection of future movements. Electrophysiological recordings revealed topographically organized action representations where SC preparatory activity is localized to the ALM projection zone. Intermingled neurons in both SC and ALM encoded competing representations for ipsilateral and contralateral licking prior to movement. Combined SC inactivation and ALM recording reveal that a local SC mechanism was sufficient to drive action selection dynamics across the ALM-SC loop prior to movement. Optrode tagging experiments within SC show that SC GABA neurons preferentially encoded ipsilateral licking and locally inhibited contralateral licking representations. Stimulating SC GABA neurons was sufficient to mediate competition between motor representations and bias upcoming behavior. Our findings argue against action selection models that relegate SC function to a motor relay. Instead, the SC is implicated as a locus for behavioral competition and a driver of cortical action selection dynamics.

Title: Speed Prediction and Temporal Relationship Across Multiple Motor Association Areas During a Precision Reaching Task

Authors: *K. S. CHATLEY[1], A. G. ROUSE[2];
[1]Neurosurg., Univ. of Kansas Med. Ctr., Kansas City, KS; [2]Neurosurg., Univ. of Kansas Med. Ctr., Kansas CIty, KS

Abstract: While many studies have examined how the cortex encodes movement by recording directly from neurons, most have recorded from only one or two cortical areas simultaneously and during similar magnitude movements. Less is known about how neural activity is coordinated across multiple motor-related areas during a wide range of movement speeds including low speed, precise movements. We recorded from four different cortical areas and used a linear regression model to predict speed from neural activity to assess their time preceding movement as well as in their information about the specific timing and magnitude of speed peaks.

Two *Rhesus Macaques* were trained on a precision center out reaching task that often required corrective movements. The animals were implanted with electrode arrays in primary motor (M1), dorsal premotor (PMd), ventral premotor (PMv), and Parietal Reach Region (PRR) to simultaneously record the neural activity as they performed the task. The timing and magnitude for neurally predicted speed was compared to the actual movement. A linear regression model was used to separately analyze the initial reach period on each trial and any subsequent corrective submovements.

First, the time lag with the best R-squared between movement speed and speed predicted from neural activity was identified. For all regions analyzed, corrective movements had a shorter time lag than initial movements. For corrective movements, the longest time lag was in PMd at 94ms-121ms, then M1 at 80ms-87ms, then PRR at 63ms-42ms while initial movements tended to have a lag of 10-30ms longer in each area. The timing of speed peaks was generally well predicted with a standard deviation of 50-75ms for all individual areas. The peak magnitude, however, was considerably smaller with predicted amplitude being only 40-85% of the true magnitude.

Linear regression models for speed prediction provide valuable information about neural activity across cortical areas. In this analysis, an important temporal relationship between multiple motor-associated areas is demonstrated with a progression from premotor to M1 then, surprisingly, to PRR. When comparing initial to corrective movements, a shorter time lag is observed with corrective movements. Additionally, this analysis demonstrates that the timing of peaks can be well predicted via a simple linear regression model, especially in initial peaks. Linear models fall short, however, in accurately predicting the magnitude of these peaks. Further refinement in these models and potentially machine learning algorithms may better delineate these relationships, especially with low speed corrective movements.

Title: Complexity and high-dimensionality of motor cortex activity during a simple task

Authors: *E. AMEMATSRO, N. MARSHALL, E. TRAUTMANN, L. ABBOTT, M. M. CHURCHLAND;
Neurosci., Columbia Univ., New York, NY

Abstract: Single-neuron responses in motor cortex (M1) are complex and heterogeneous, yet the nature and implications of that complexity have yet to be fully characterized. For a limited set of behaviors, a handful of dimensions is typically sufficient to capture most response variance. But are the smaller signals in higher dimensions effectively noise, or are they computationally relevant? Are the dimensions that contain large signals consistent across behaviors? How does cortical heterogeneity compare with that of the motoneurons?
We trained rhesus macaques to generate one-dimensional isometric forces with diverse temporal profiles. We recorded from 1257 M1 neurons using Plexon S-probes and primate-optimized Neuropixels. We recorded the activity of 134 motor units, allowing direct comparisons between two populations of spiking neurons (M1 and motoneuron). Consistent with prior findings, M1 responses were highly heterogeneous. Although motor output was simple (a 1D force), almost no neurons had activity resembling force or its derivative. While force could still be reliably decoded, the decoding dimension captured <5% of the response variance. Those dimensions that did capture considerable variance were behavior specific - e.g., they differed for slowly versus rapidly changing forces. Consequently, it took ~80 dimensions to capture 90% of the variance across all force profiles. Even dimensions past those 80 contained structure that was reliable across trials. Using a novel method, we estimated that the M1 population contained >300 independent signals. Decoding of simultaneously recorded motor units confirmed that low-

variance dimensions contained useful signals. Despite this complexity, M1 trajectory tangling remained low (far lower than for the motor units) due to structure in the higher-variance dimensions.
Thus, even when controlling a one-dimensional force, the motor cortex population response was remarkably complex and high-dimensional. This finding does not invalidate the use of low-dimensional projections, which often discriminate amongst model predictions. Yet our results argue that it is equally important for candidate models to account for the behavioral specificity of the high-variance features, and for the large number of reliable but low-variance features.

Title: Network information flow in macaque motor cortex during manual interception

Authors: *Q. WANG[1,2], C. LI[1,2], Y. ZHANG[1,2], T. WANG[1,2], R. ZHENG[1,2], H. CUI[1,2];
[1]Lab. of Neural Mechanism of Motor Control, Ctr. for Excellence in Brain Sci. and Intelligence Technol. (Institute of Neuroscience), CAS, Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: Interaction with the evolving world largely relies on dynamic interplay between sensory inflow and motor outflow in central nervous system, but network mechanism underlying dynamic sensorimotor control is still unclear. In the present study, we aim to reveal information flow between premotor cortex (PMd) and primary motor cortex (M1) from a network perspective. We calculated functional connectivity of neuronal networks in monkeys performing a manual interception task. The Utah microelectrode arrays were implanted in PMd and M1 of two macaques. Cross-correlation histograms (CCHs) between pairwise spike trains in task epochs were computed. Then, a cluster-based surrogate test was used to find significant peaks or troughs. Based on this analysis, functional connectivity matrices were calculated. Consistent with

previous studies, we found the small-world and scale-free (power-law distribution) characteristics of functional networks under our task. Since the complexity of computing the CCHs between the pairwise neurons is $O(n^2)$ and surrogate CCHs are 1000 times, a point process and GPU-based algorithm was developed and tremendously reduced calculation cost, allowing us to calculate dynamic functional networks under different task epochs. By comparing the directed functional network in the pre- and peri-movement periods, we found a significant increase in connectivity from PMd to M1, indicating a rise in information flow from PMd to M1 and a temporal hierarchy between the two areas. Furthermore, the connectivity from PMd to M1 during intercepting moving target is stronger than the reaching to the static target. Finally, calculations of the network entropy show a significant drop in PMd from pre- to peri-movement period for the static target condition, while M1 does not. In contrast, the network entropy of both brain regions was consistently maintained at a high level for moving targets. This indicates that the local functional network in PMd demands an enriched intrinsic information processing in dynamic environment.

Abstract: Even simple reaching movements require sophisticated cortical computations that give rise to complex, spatiotemporally patterned muscle activity. Current theories of motor cortex suggest that these computations are carried out by a neural dynamical system that, once initialized during motor preparation, uses self-propagating dynamics to generate patterns of motor output. While this theory is attractive, it cannot yet explain a fundamental property of motor control: how sensory feedback is seamlessly integrated throughout a movement to correct unexpected errors (i.e., "feedback control"). Here, we combine the computation-through-dynamics perspective with a feedback control approach to propose a new model of how motor cortex controls movement. Critically, this model was enabled by new methods for training and dissecting high-fidelity neural network models that control simulated musculoskeletal arms. We identify three dynamical motifs that consistently emerged in neural networks trained to control arms: (1) integration dynamics that are used to counteract persistent visual and haptic perturbations, (2) oscillating dynamics that compensate for long feedback delays, and (3) gating dynamics that prevent goal information from reaching the feedback control subsystem when movement must be inhibited. In our model, preparatory neural dimensions serve as dynamically gated 'input' dimensions through which goal information flows into a low-level feedback control subsystem. This model reproduces many neural phenomena of recent interest, such as the existence of preparatory activity, the appearance of rotatory neural dynamics after the go cue, and small reaction time penalties when preparatory activity is disrupted - but it does so through neural mechanisms that are shaped by the need to perform robust feedback control in the presence of unpredictable perturbations and long feedback delays. Moving forward, we envision that high-fidelity neural network models of feedback control will play a key role in generating new hypotheses about neural mechanisms, understanding whether there are alternate explanations for observed neural phenomena, and designing experiments that are capable of distinguishing certain models from others based on neural recordings.

Title: Continuous and difficult cognitive tasks do not improve gait control compared to a discrete and easier task in healthy young adults

Authors: *L. MICHAUD, J. DENNIS, C. LEBEAU, M. PELLETIER, A. ZEVNIK, Y. LAJOIE;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Background**:** It is believed that gait is not purely automatic since multiple studies found a decrease in gait performance (slower, more variable, etc.) under dual task conditions which might indicate a competition for attentional resources (Yogev et al., 2005). However, based on the constrained action theory (Wulf, 2013), dual task conditions could in fact enhance motor performance due to a shift of attention away from the primary task (e.g. walking) that promotes a more automatic and efficient control. In a recent study on quiet standing, it was observed that continuous and more difficult cognitive tasks as secondary tasks were better at improving postural control compared to discrete and easier cognitive tasks since more engaging secondary tasks might favor a shift of attention and, thus, automaticity (Lajoie et al., 2016). The objective of this study was to assess if automaticity could be promoted for walking using continuous and more difficult cognitive tasks as secondary tasks.
Method**:** Twenty healthy young adults (25.3 ± 2.8 years) were recruited. The experiment involved walking in a straight line for eight meters while performing different cognitive tasks or no secondary task (Baseline). The tasks were: a serial reaction time (SRT), counting backward by seven (7down) and identifying the total number of times that two predetermined digits occurred during a sequence of three-digit numbers (Recall). Each conditions was performed five times. Gait speed and stride variability and length were recorded using 3-D kinematic data from markers on the right and left foot with the Vicon512^{TM} System at 200 Hz. Two-way repeated ANOVAs were computed to assess changes between leg side (left and right) and the four conditions (Baseline, SRT, 7down and Recall).
Results**:** Statistical analysis revealed a main effect of condition for gait speed and stride length. Gait speed was reduced during 7down and Recall compared to SRT and Baseline. Stride length was also reduced during 7down compared to all other conditions and during Recall compared to Baseline and SRT.
Conclusion**:** The absence of changes for stride variability and a decrease in gait speed and stride length for 7down and Recall suggest that more difficult and continuous secondary tasks interfered with the primary task of walking. Thus, our results do not support that more engaging tasks promote a more automatic gait control.

Title: Prefrontal cortex activity during gait in the recently concussed adults

Authors: *D. MARTINI[1], M. MANCINI[2], R. VITORIO[3], L. A. KING[2];
[1]Univ. of Massachusetts Amherst, Amherst, MA; [2]Neurol., Oregon Hlth. and Sci. Univ., Portland, OR; [3]Northumbria Univ., Newcastle, United Kingdom

Abstract: A concussion results in transient symptoms (e.g. cognitive, somatic, effective) that are tied to the metabolic energy crisis stemming from the need to reestablish neurophysiological homeostasis. This post-concussion symptomatic period is associated with gait dysfunction, the cortical underpinnings of which are poorly understood. Assessing prefrontal cortex activity during gait may provide insight into the altered neurophysiology during gait in the concussion recovery phase. The purpose of this preliminary study is to quantify gait and prefrontal cortical activity in symptomatic individuals with a recent concussion. We hypothesize that worse symptoms will relate to increased cortical activity, and that increased cortical activity will correlate with worse gait performance. We present data from 7 symptomatic, recently concussed (32 years old; 5 female; 36 days from concussion (min = 12; max = 66)). The Neurobehavior Symptom Inventory (NSI) was used to characterize the self-reported number and severity of concussion symptoms. The NSI provides a somatic, affective, and cognitive symptom sub-score, with a total possible score of 88; higher scores are worse. Prefrontal cortex activity was quantified using a portable functional near-infrared spectroscopy system, which uses near-infrared light to determine changes in concentration of oxygenated (HbO2) and deoxygenated hemoglobin. Gait was quantified using 6 inertial sensors (2 feet, 1 lumbar, 1 sternum, 2 wrists), which provide spatiotemporal and turning variables of gait. Participants walked for 80 seconds, back and forth over a 9-m straight path with a 180° turn at each end. The average NSI total score was 19.1 (s.d. = 11.1). The HbO2 during gait significantly correlated with the NSI total symptom score ($r = 0.93$; $p = 0.002$), NSI somatic score ($r = 0.80$; $p = 0.03$), NSI affective score ($r = 0.86$; $p = 0.01$), and NSI cognitive score ($r = 0.94$; $p = 0.002$). Further, the HbO2 during gait significantly related to the medial-lateral lumbar range of motion ($r = 0.83$; $p = 0.02$), anterior-posterior lumbar range of motion ($r = 0.79$; $p = 0.03$), and turn velocity ($r = 0.89$; $p = 0.007$). These preliminary data provide the first evidence of prefrontal cortex activity being related to symptom severity and gait performance in the recently concussed. Quantifying cortical activity during gait in this population may provide greater insight into identifying individuals more likely to have a prolonged recovery timeline. Future work needs to replicate these preliminary results in a larger group of recently concussed and compare gait related changes in HbO2 to a control group to verify the changes in HbO2 observed herein are concussion-specific.

Title: Synergic relations between eye and postural movements in searching to locate objects in room inside houses

Authors: *C. T. BONNET[1], J. A. BARELA[2], T. SINGH[3];
[1]SCALab, Villeneuve d'Ascq, France; [2]Inst. of Biosci., São Paulo State Univ., Sao Paulo, Brazil; [3]Dept. of Kinesiology, The Pennsylvania State Univ., University Park, PA

Abstract: Although people continuously sway in the standing position, they still succeed in visually exploring their environment and performing precise visual tasks efficiently. Based on this knowledge, our team published a synergic model of postural control in 2016 suggesting that the brain should continuously adapt postural control to the precision and difficulty of performed gaze shifts. In the present study, our objective was to test the existence of behavioural synergic relations between eye and postural movements in a goal-directed, precise, visual search task (locate target objects in large images). Twenty young participants performed a search task and a control free-viewing task. The method was rigorous with calculation of the sample size and the use of a validated, already published, methodology to analyse data; this was a confirmatory study. Negative correlations between the recorded eye and postural movements were assumed to show synergic, stabilizing, relations. In fact, they showed that postural sway was better reduced to perform and succeed in longer, more difficult, gaze shifts. In other words, they showed that the further the eyes moved, the less people swayed. In contrast, positive correlations were assumed to show destabilizing relations for the opposite reason. Our results showed that young adults exhibited significant negative correlations between eye and postural (head and upper back) movements in the precise visual task. They also did not exhibit any significant correlation in the free-viewing task. In conclusion, these results confirmed that the brain adjusts postural control online to succeed in subtle and continuous precise gaze shifts.

Title: The impact of attention on sensory integration for postural control as characterized by behavioral and cortical changes.

Authors: *L. MA[1], P. J. MARSHALL[2], W. G. WRIGHT[1];
[1]Hlth. and Rehabil. Sci., [2]Psychology, Temple Univ., Philadelphia, PA

Abstract: Postural control requires accurate integration of multiple senses to maintain body orientation and equilibrium. However, it is unclear how changes in focus of attention and instruction may influence the underlying sensorimotor mechanisms for postural control. By studying how directing attention can influence sensory processes and postural control, we can better understand how to improve balance and prevent falls. The present study investigates how different types of attentional focus specifically affect visual integration in maintaining posture. Fifteen healthy adults (>20 years old) underwent an experimental paradigm where they balanced on a rocker board while wearing a virtual reality head-mounted display (HMD) and a 32-channel electroencephalography (EEG) cap. The HMD displayed a virtual world of standing on a boat that tilted from side to side in the mediolateral direction at a frequency of 0.2Hz and amplitudes of 2 ± 0.2 degrees. All participants were first given the instruction of looking straight ahead and keeping their body as still as possible (control condition). Using random assignment, participants were then either instructed to focus on keeping the rocker board flat to help them keep still (external focus condition; n=8) or instructed to focus on keeping both feet leveled to each other to help them keep still (internal focus condition; n=7). The dependent variables were the EEG alpha power response (9-13Hz) of independent components clustered in the occipital cortex and the gain response of the participant's postural sway relative to the 0.2Hz visual stimulus. Results revealed a significant ($p<0.05$) increase in alpha power over the occipital cortex during both external and internal focus conditions when compared to control condition, with external focus showing a trend towards higher alpha power than internal focus. This suggests that both types of focus may influence brain responses to visual input during postural control. Interestingly, participants instructed to focus externally showed a significant decrease in visual influence on postural sway relative to the control condition, while participants instructed to focus internally showed no change. This suggests that external focus may be better than internal focus at resolving sensory mismatches for postural control. Findings from this study may help guide clinicians and researchers on how best to provide instructions to direct attention during balance control and explain why external focus has been shown to be more effective for balance performance in prior studies.

Title: Visual shift in normal standing affects the direction of loss of balance during perturbation.

Authors: *B. TAHAYORI[1], D. M. KOCEJA[2], B. TAHAYORI[3];
[1]Univ. of St. Augustine, Coral Gables, FL; [2]Indiana Univ., Bloomington, IN; [3]Florey Dept. of Neurosci. and Mental Hlth., The Univ. of Melbourne, Melbourne, Australia

Abstract: Controlling upright posture entails acute adjustments by the neuromuscular system to keep the center of mass (COM) within the limits of a relatively small base of support. Several sensory systems interact with each other to provide accurate information for maintaining upright posture. In this experiment we shifted the visual field of 15 healthy, young individuals by using a 25 diopter prism goggle, and recorded their Centre of Pressure (COP) movement. While subjects were standing, we stimulated the posterior tibial nerve by a constant current stimulator and thereby, simulated a perturbation or loss of balance. We therefore, tested the balance reaction of our subjects in 4 different conditions of normal vison (NMV), no vision (NOV), visual shift to the right (VSR) and visual shift to the left (VSL). With each nerve stimulation, the COP would follow a relatively consistent pattern of immediate frontward displacement followed by backward movement and several oscillations to bring the body back to stability. When stimulating the right leg, COP would deviate to the right and vice versa, when stimulating the left leg, COP would move toward the left. This was manifested by calculating a vector for each COP displacement (Vector origin as the location of COP just before stimulation and endpoint as the deflection in COP trajectory).COP deviation during normal vision, caused on average 16.7±2.9 degrees relative to midline. In the VSL condition, left side stimulation caused 20.12±1.5 degrees of deviation. In VSR condition, stimulating the right leg caused 15.8±2.1 shift to the right. Visual information is a major sensory source for maintaining balance during quiet standing. However, these findings suggest that during loss of balance, visual sensory input plays an important role in the recovery mechanism of regaining balance. It was shown that a change in the directional change of visual information proportionally affects the direction of COP trajectory displacement. Understanding the neural and mechanical events occurring during loss of balance (LOB) are helpful to understand the underlying mechanisms of balance control, loss of balance and regaining balance after a perturbation.

Title: Uncovering hidden organization of apparent random fluctuations in human gait

Authors: J. MAZZEO[1], F. WAGNER[1], G. CAMPIGLIO[1], *V. DELLA-MAGGIORE[2]; [1]Inst. de Ingeniería Biomédica, Univ. de Buenos Aires, Buenos Aires, Argentina; [2]IFIBIO Houssay, Sch. of Medicine, UBA, Buenos Aires, Argentina

Abstract: The classical model of gait describes it as a quasi periodic process based on “cycles”. In this framework, differences between cycles or "fluctuations" are considered to lack information and, thus, are often disregarded. The present study focused on the analysis of these apparently random fluctuations under the hypothesis that they can characterize operating modes of the motor control system that remain hidden under the classical view. From the theoretical framework of stochastic processes, here we analyzed the variability of step times (ST) obtained experimentally under four different conditions: free gait, treadmill, metronome, and obstacles. Based on ST, we estimated the Hurst index (H) or "scaling index", a metric of long-term memory in time series, which reflects the statistical dependence of steps as the lag between them increases from short (3-10 steps) to long (300-400 steps) time scales. An H index of 0.5 would be consistent with the occurrence of random fluctuations in ST, whereas H> 0.5 would reflect the presence of positive autocorrelation between ST, and H<0.5 would reflect the presence of negative autocorrelation. We obtained continuous 40 min recordings of foot pressure under the heel from normal subjects, while they walked in a gym under the four conditions described above. Preliminary data yielded differences in the H index depending on the experimental condition ($p = 0.01$). Free gait, obstacle gait and treadmill gait were characterized by positive autocorrelation (mean = 0.79, SD = 0.049, $p < 0.01$) both at short and long time scales. This finding is consistent with a long-term memory process. In contrast, metronome gait was also characterized by positive autocorrelation at short-time scales (mean = 0.68, SD = 0.01), but by negative autocorrelation at long time scales (mean = 0.29, SD = 0.02). The latter may reflect the fact that as subjects adjust their gait to the pace of the metronome they produce ST that fall either above or below its period. Interestingly, however, the operation at the lowest temporal scales remained similar to that of the free gait. Our preliminary findings may reflect the existence of two different endogenous mechanisms controlling gait at the short-and long time scales.

Title: Step length synergy is reduced with increasing demands on foot placement during adaptive gait

Authors: *A. KULKARNI, C. CUI, S. RIETDYK, S. AMBIKE;
Purdue Univ., West Lafayette, IN

Abstract: During community ambulation, forward motion and stability are maintained while gait is adapted to navigate hazards. In order to maintain stability, foot placement is modified to control the center of mass (COM) motion. However, foot placement must also be modified to avoid tripping on a hazard. Previously, we have shown that the step length around an obstacle is stabilized (i.e., *step length synergy* exists), indicating that foot placement is controlled not only with reference to the obstacle but also to stabilize the step length, which in turn controls the COM motion. In the current work, we increased the foot placement demands by adding step targets while approaching the obstacle. These targets allow us to determine how foot placement demands affect the step length synergy, indicating priorities of the nervous system in challenging environments. Fifteen healthy participants (24$\pm$3 yrs) walked on a 6 m walkway and stepped over an obstacle (25% of leg length, about 24 cm high). Conditions included baseline (no target) and five target locations projected onto the walkway (1, 2, 3, 4, or 5 steps before obstacle). When a target was present, participants stepped on the target and continued walking. The across-trial variance in the horizontal distances between trail and lead heel from the obstacle for the crossing step was analyzed using the uncontrolled manifold analysis to determine step length synergy. We hypothesized that (1) foot targets will reduce the step length synergy, and (2) targets closer to the obstacle will lead to greater reduction in synergy. A weaker synergy indicates greater priority for foot placement relative to external cues, compared to step length stability. We observed that the step length was stabilized for all target locations ($p < .01$). That is, the front and back heel distances relative to the obstacle's edge co-varied synergistically for all target locations. However, the strength of the step length synergy was affected by target location ($p = .01$). Synergies were up to 66% lower when the step target was closer to the obstacle, as hypothesized with an exception: when the target was two steps before the obstacle, the step length synergy was not different from baseline. This exception may be related to the observation that people visually fixate on the obstacle to gather obstacle position information when they are two steps away from the obstacle; this will be examined further in the future. Overall, young adults responded to increased challenges by prioritizing foot placement relative to external cues over stabilizing step length. Yet, they maintained step length synergies, demonstrating the relevance of this strategy during adaptive gait.

Title: The rat hindlimb sensorimotor cortex encodes for postural perturbations after complete spinal cord injury

Authors: *G. DISSE[1], J. B. DOUGHERTY[2], N. R. BRIDGES[3], K. A. MOXON[4];
[1]Univ. of California Davis, Sacramento, CA; [2]Biomed. Engin., [3]Sch. of Biomed. Engin. Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA; [4]UC Davis, Davis, CA

Abstract: While descending cortical signals are not critical for maintaining postural control in the normal animal, the role of the cortex after spinal cord injury is unknown. To assess how the cortex responds to unexpected postural perturbations, adult rats were placed on a tilting platform, and the firing patterns of single neurons in the hindlimb sensorimotor cortex were recorded with microelectrode arrays as the platform rotated with different tilt profiles (e.g. varying velocities, maximum angles, directions, and durations). For a subset of animals, limb ground reaction forces were recorded as well throughout the tilts. This procedure was repeated 1-3 weeks after animals underwent a complete mid-thoracic spinal cord transection. Confirming previous studies, neurons in the hindlimb sensorimotor cortex of pre-injury animals fired in response to tilts and the magnitude and timing of the response was modulated with different tilt profiles. Additionally, significant mutual information existed between cortical neuron firing patterns and tilt types, suggesting that the cortex conveys significant information about postural perturbations. After an injury severing all ascending and descending tracts at the mid-thoracic spinal cord, clear behavioral deficits were observed in the limb ground reaction forces. However, the cortex continued to display a similar pattern of response modulation to different tilts -albeit with a slight increase in latency. Additionally, there was a decrease in mutual information after injury. Despite this, it remained significantly above random information as estimated through bootstrapping. These results suggest that the cortex not only continues to respond to and encode for postural perturbations after SCI, but that it conveys enough information to discriminate tilt types from both stance (tilt sensitivity) and other tilts (tilt specificity). This is likely due to remaining forelimb and trunk afferents from above the lesion, and suggests that the cortex is an viable target for restoring independent, functional movements after spinal cord injury.

Title: Stride-by-stride analyses of anterior cingulate cortex activity during perturbed recumbent stepping

Authors: *L. RICHARDSON[1], S. SHIRAZI[2], H. J. HUANG[2];
[1]Biomed. Sci., [2]Mechanical and Aerospace Engin. Dept., Univ. of Central Florida, Orlando, FL

Abstract: Theta band (3-8 Hz) synchronization in the anterior cingulate cortex is commonly associated with error monitoring during motor learning. During seated recumbent stepping, applying brief increases in stepping resistance during each stride perturbs the stepping motion, generating an error. In healthy young adults, these perturbations elicited increased anterior cingulate theta spectral power around the onset of the perturbation. In this study, we performed stride-by-stride analyses on the motor error and anterior cingulate cortex responses from our previous perturbed recumbent stepping study with young adults (n=17). In our experimental protocol, there were 4 tasks based on the perturbations being applied, which was either at right/left either leg extension onset or mid-extension (4 tasks = 2 legs x 2 timings). There were also “catch” trials where no perturbation was applied. These catch trials occurred randomly once within every 5 strides. The stride-by-stride approach allowed us to explore whether increasing predictability influenced anterior cingulate responses. We hypothesized that the maximum anterior cingulate theta power and motor errors (pacing errors and stepping errors) would decrease as perturbations became more predictable. We computed the theta-band event related spectral power (ERSP) for each stride and binned each stride relative to a preceding catch stride as catch+1, catch+2, catch+3, etc. Perturbations more distant from the catch are more predictable as they are preceded by more perturbations. For the group averaged theta-band ERSPs for left and right mid-extension and left extension onset perturbations, the perturbed stride immediately after the catch, catch+1, the unexpected and less predictable stride had the largest peaks. Individual subject linear fits of the average maximum theta-band ERSP on bin positions, however, showed that only 6 out of 14 subjects had a negative slope in each perturbation, suggesting that more predictable perturbations did not correlate with less anterior cingulate theta power in most subjects. Individual subject linear fits of the average stepping error on bin positions showed that most of the subjects had a negative slope, suggesting that stepping errors decreased as perturbations became more predictable. These preliminary results suggest that anterior cingulate activity does not reliably correlate with perturbation predictability, even though stepping errors decreased with increasing perturbation predictability.

Title: Vision and walking: how reliance on feedback and feedforward visual information changes during locomotor learning

Authors: *A. CATES[1], J. DEMBSKY[1], K. E. GORDON[1,2];
[1]Northwestern Univ., Chicago, IL; [2]Edward Hines Jr. VA Hosp., Hines, IL

Abstract: Vision plays a vital role in executing controlled walking. Feedforward fixations (i.e. fixations greater than 1.5 steps ahead) are used to make feedforward motor plans while feedback fixations (i.e. fixations less than 1.5 steps ahead) are used to make corrective actions to the current step. The present study examined how healthy young adults (n=9) change their reliance on feedback and feedforward visual information during a locomotor learning task. Participants completed a treadmill-based target stepping task in which they were asked to accurately step on small moving targets projected onto the treadmill surface. To determine an individual's reliance on feedforward and feedback visual information, we compared stepping performance across 3 different visual conditions: full vision, no feedback vision where the targets were not visible within 1.5 steps of the individual, and no feedforward vision where the targets were not visible greater than 1.5 steps away from the individual. Visual reliance was defined as the decrease in step accuracy when the targets related to feedforward or feedback visual information were removed. We hypothesized that participants would rely more on feedback information during their initial exposure to the novel walking task and shift to a greater reliance on feedforward information as they learned the task. Our results do not support our hypothesis. Instead, we found that participants increased reliance on feedback information as they improved at the task while their reliance on feedforward visual information remained unchanged. One possible explanation may be an increased emphasis on the temporal coordination between vision and locomotor execution. Specifically, previous research has shown better target stepping performance by fixating on the target until heel strike. Participants may have adopted a similar strategy as their performance improved in the present study. Future research should focus on the interplay of spatial and temporal relationships between gaze and walking.

Title: Changes in Cortical Activity during Preferred and Fast Speed Walking under Single and Dual Task in the Young-old and Old-old

Authors: *J. KIM[1,3], J. KIM[3], E. KIM[3,2], S.-H. LEE[3], G. LEE[3], J. LEE[3], S. SHIN[3], W. CHANG[3], Y.-H. KIM[1,3,2];

Abstract: In the elderly, walking performance starts to decline with aging. Furthermore, walking while simultaneously engaging in other activities become more and more difficult with severe aging. This study aimed to examine the changes in cortical activity during walking with aging. We especially try to reveal differences of cortical activities during the dual task walking between the young-old and old-old persons. Fifty elderly participants without history of neurological or psychiatric symptoms participated in this cross-sectional study. Prior to the experiment, evaluations such as the short physical performance battery (SPPB), the four-square step test (FSST), the timed up and go test (TUG), the 10-meter walking test (10MWT) were performed to assess function. Each subject completed four walking tasks on the treadmill, 2x2 design; two normal walking conditions with self-selected walking speed (NW-SSWS) and fast walking speed (NW-FSW), and two dual task walking conditions with self-selected walking speed (DTW-SSWS) and fast walking speed (DTW-FWS). The fast speed was set to 130% of the self-selected speed and for the dual task, the phonemic verbal fluency task was given. Functional near-infrared spectroscopy (fNIRS) was applied for the measurement of regional cerebral oxyhemoglobin (oxyHb) concentration during each walking condition. The fNIRS data were analyzed using the statistical parametric mapping (SPM) software and time-series analysis. Region of interests were the primary leg motor cortex (M1-leg), the pre-motor area (PM), the supplementary motor area (SMA), the posterior parietal cortex (PPC), and the dorsolateral prefrontal cortex (dlPFC). Twenty-seven participants were divided into the young-old (under 75-yrs old; 70.2 ± 3.0 years) and 23 into the old-old (over 75 yrs old; 78.0 ± 2.3 years) groups. There were significant functional differences between the two groups in the SPPB, the FSST, the 10MWT, and the TUG. In the SPM analysis, cortical activities were increased during the two DTW conditions than the NW conditions, but decreased during the two FWS conditions than the SSWS conditions on the bilateral M1-leg, the SMA, and the dlPFC in both old groups. These oxyHb

concentration changes were significantly less prominent in the old-old group than in the young-old group, which reflected diminished adaptive plasticity of cortical activity with severe aging. This study demonstrated that degree of cortical activity changes during the dual task walking was decreased in the old-old than the young-old group. These different profiles between the two groups of elderly people can explain impaired compensation strategies and increased fall risk with aging.

Abstract: Walking is a complex task, especially in an environment that constrains a person to where they can step. Constant active control must be modulated to maintain an upright and balanced position. We do not have a comprehensive theory for how humans regulate balance during walking especially when there is awareness of a known navigational restraint. We have previously identified three balance mechanisms utilized by healthy young adults to maintain bipedal locomotion: 1) The ankle roll mechanism, a modulation of ankle inversion/eversion; (2) The foot placement mechanism, a shift of the swing foot placement; and (3) The push-off mechanism, a modulation of the ankle plantarflexion angle during double stance. This study seeks to observe changes in this neural control paradigm when presented with an environmental constraint. Twenty healthy young subjects walked on a self-paced treadmill while immersed in a virtual environment displayed via an Oculus Rift. The virtual scene provided three different

colored pathways. Subjects were instructed not to step in the No-Step Zone, which appeared either on the right or left side of the subject. While walking, subjects received balance perturbations in the form of galvanic vestibular stimulation, providing the sensation of falling sideways, either toward the No-Step zone or toward the Neutral zone on the other side. The results indicate that the use of the balance mechanisms are altered depending on whether the perceived fall is toward the No-Step or the Neutral zone. Participants increased the use of the lateral ankle mechanism and foot placement mechanisms for No-Step stimuli resulting in an overall larger shift of the center of mass (CoM) compared to the Neutral stimuli. This difference proposes a supraspinal tuning bias of the balance response imposed by the external constraint. Although a stronger CoM shift is expected for a response away from a perceived constraint, we expected this shift to be generated by the ankle and push-off mechanisms. We hypothesized that perceived falls in the direction of the No-Step zone would constrain the foot placement mechanism, resulting in a decoupling of the balance mechanisms. Instead, this non-intuitive increase in foot placement suggests that an overall balance response is driven via supraspinal mechanisms, which is coordinated throughout the gait cycle.

Title: Cortical brain dynamics associated with gait adaptation to an active ankle exoskeleton

Authors: *J. BRADFORD[1], S. SONG[1,2], C. HAYNES[1];
[1]US DEVCOM Army Res. Lab., Aberdeen Proving Ground, MD; [2]Texas A&M Univ., College Station, TX

Abstract: Adaptive exoskeletons have been shown to reduce the metabolic cost of walking in some individuals. While this is an important metric for exoskeleton performance, little research has been performed to understand how the human brain and body respond and adapt to these devices. The goal of this study was to uncover cortical brain signals related to the user's adaptation to an autonomous, bilateral ankle exoskeleton. 22 subjects walked on a treadmill while wearing a powered bilateral ankle exoskeleton that assisted with plantarflexion at toe off. We measured EEG, EMG, kinematics, and ground reaction forces during early and late adaptation periods. We found reduced alpha and beta band power in sensorimotor brain areas

during late adaptation. We found that these changes in brain dynamics corresponded with reduced EMG activity and reduced step width during late adaptation.

Title: A neuromuscular model of human locomotion that combines flexibility and stability

Authors: *R. RAMADAN[1], G. SCHONER[2], J. J. JEKA[3], H. REIMANN[4];
[1]Ruhr Univ. Bochum, Dortmund, Germany; [2]Inst. Neuroinformatik, Ruhr-Universität Bochum, Bochum, Germany; [3]Kinesiology & Applied Physiol., [4]Dept. of Kinesiology and Applied Physiol., Univ. of Delaware, Newark, DE

Abstract: Human locomotion is amazingly flexible. We walk effortlessly in varied environments, choose gaits and avoid obstacles of different sizes and shapes. Achieving that flexibility requires sophisticated mechanisms of stabilization as the human body is mechanically unstable during locomotion and the body's configuration changes throughout thegait-cycle. Combining flexibility and stability, therefore, is a challenge. Avoiding an obstacle, for instance, involves not only steering the foot over the obstacle, but also stabilizing the gait pattern against the perturbation caused by the avoidance maneuver. This requires estimation of the state of the body in space from sensory information and updating the movement plan by adjusting motor commands that integrate constraints from biomechanics, muscle dynamics and reflex pathways of the spinal cord. Here, we present a neural process model of human locomotion that is able to generate updatable movement plans for steady state locomotion. The model organizes movement plans at the task level. During swing, vestibular feedback is used to determine a target joint angle configuration for foot placement on each step that generates stable walking. The movement plan to reach that target configuration is generated as a minimal jerk trajectory and updated during movement based on sensory information. The supraspinal controller is based on an inverse internal model of the biomechanics, muscles, and spinal reflexes and generates descending commands that implements the task-level movement plan. At the spinal level, the descending commands are integrated with the stretch reflex during the swing phase. Stance leg control relies on dedicated spinal reflex pathways that are adopted from [1].The biomechanical model comprises 8 DoFs, realistic moment arms, and 22 Hill-type muscles. Muscles are innervated by α-motorneurons and are controlled by descending activations and reflex circuits. Our model is

able to combine stable locomotion at different speeds with varied movements of the swing leg, that enable stepping over obstacles of different heights and to resist external pushes. The swing leg by itself can execute arbitrary movements within the reachable workspace.

Title: Neural circuits for social behavior adaptations to environmental temperature.

Authors: *Z. ADAHMAN[1], R. OYAMA[1], T. ABE[2], J. S. RICEBERG[3], I. CARCEA[1]; [1]Pharmacology, Physiol. and Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ; [2]Neurosci. and the Mortimer B. Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY; [3]Neurosci., Mount Sinai Sch. of Med., New York, NY

Abstract: Thermoregulation is essential for survival. In mammals, changes in environmental temperature induce both autonomic and behavioral thermoregulatory responses. Particularly in the case of maternal behavior, environmental temperature influences the dams' behavior response in providing maternal care to poikilothermic neonates. We characterized these changes in dams at several levels: nest building, pup retrieval, and co-housing with another adult female and pups. Compared to room temperature, dams build larger nests in the cold and smaller nests in warm temperature (nest area at room temperature is 69.53±6.48 cm^2, cold temperature is 85.77±7.51 cm^2, and warm temperature is 38.38±2.75 cm^2, p=0.0004, N=16). Although dams retrieve acutely isolated pups similarly at all temperatures, during prolonged episodes (4 hours) at warm temperature they let pups disperse (average area covered by pups dispersed at room temperature is 84.78±2.95 cm^2, cold temperature is 35.51±1.70 cm^2, and warm temperature is 138.10±8.31 cm^2, p for time=0.14, p for temperature = 0.0003, p-value of time and temperature interaction=0.024, N=3). In the co-housing assay, dams and non-maternal females cooperate to spend more time together in nest at cold temperature (CT), compared to room (RT) and warm temperatures (WT) (p-value is 0.0001, 0.0001 and 0.02 for CT versus RT, CT versus WT, and RT versus WT respectively).
To understand the neural circuits controlling temperature-modulated social behavior, we investigated the activity of hypothalamic neurons that secrete the vasopressin neuropeptide.

Vasopressin plays important roles in maternal care, thermoregulatory processes, and other social behaviors. Using an activity reporter mouse line, we find elevations in ambient temperature activate vasopressin neurons in the paraventricular nucleus of the hypothalamus. Synaptic anterograde tracing from vasopressin neurons shows connections with structures implicated in thermoregulatory responses (lateral parabrachial nuclei), maternal behavior (periductal gray area), and other social behaviors (cingulate cortex, ventral tegmental area, dorsal raphe nuclei). Taken together, we hypothesize that warmer environmental temperatures control several components of social aggregation and nest-building by modulating the firing of vasopressin hypothalamic cells. Using a combination of activity-dependent gene expression and retrograde tracing, we will investigate the neural circuit mechanisms by which temperature information might reach vasopressin cells, and the extent to which these circuits control changes in social behaviors response to environmental temperature.

Title: Interbrain correlation in prairie voles scales with degree of social interaction and pair bond status

Authors: *A. D. MCTIGUE[1], K. MURPHY[1], *L. E. BRUSMAN[1], Z. R. DONALDSON[2]; [1]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]MCBD/Psychology & Neurosci., Univ. of Colorado, Boulder, Boulder, CO

Abstract: Simultaneously recording neural activity from multiple individuals provides an opportunity to ask how the neural basis of complex behavior is shaped in real time during evolving social interactions. Previous work in humans has shown that, during interaction, oscillatory neural activity becomes synchronized. The degree of synchrony between two individual scales with relational variables - with romantic partners exhibiting stronger synchrony than individuals who do not know each other. This phenomenon, known as interbrain correlation, is not limited to humans, and has been documented in mice and bats. However, these species do not form the exclusive, monogamous pair bonds that are central to human experience. Here, we

asked whether interbrain correlation is observed in monogamous prairie voles and whether the correlation scales as a function of pair bonding. Using fiber photometry and GCaMP, a molecular sensor for calcium and proxy for neural activity, we found consistently increased interbrain correlations when two animals are interacting compared to when they are separated by a divider. The degree of correlation further scales with social engagement with the strongest correlations occurring during active dyadic interactions. Finally, we found that pair bonded animals exhibited stronger interbrain correlation with their partner than a novel animal. These data indicate that prairie voles provide an ideal model for examining the role of interbrain correlation in mediating attachment.

Title: Posterior hippocampus stress-regulating gene expression is associated with rodent behavioral inhibition and social boldness

Authors: E. K. MCMAHON[1], ***S. FARHAN**[3], *S. A. CAVIGELLI[2];
[1]Ecology and Biobehavioral Hlth., [2]Biobehavioral Hlth., Pennsylvania State Univ., University Park, PA; [3]Accelerated Premedical-Medical Program, Penn State Univ., University Park, PA

Abstract: Temperament suggests consistent individual responses to environmental conditions. For example, social boldness (SB) is defined as an individual's willingness to take risks and interact with social novelty. Another behavioral trait commonly studied is behavioral inhibition (BI), defined as avoidance and fear of the unfamiliar. The effects of BI in children include increased vulnerability for later-onset anxiety, cognitive disruption, and withdrawal (Biederman et al, 1993; Polivy, 2009), while long term effects of SB are not well understood. Characterizing the underlying mechanisms associated with these complex temperaments can improve our understanding of individual variation in social behavior and health trajectories. Behaviors related to SB and BI are associated with glucocorticoid (GC) production, however, changes in central nervous system function associated with these temperaments are less understood (Kabelik et al. 2021). We analyzed constitutive gene expression in the posterior hippocampus and stress-induced GC levels from blood collected immediately after acute restraint stress in 20 male Sprague-Dawley rats. Rat SB & BI temperament were assessed through repeated behavior

testing in the Novel Social, Novel Physical, and Partner Preference tests. Rats with regularly higher than median latency to approach social or physical novelty were categorized as high BI, and those with higher than median scores on a social boldness factor calculated from behavior in the novel social and partner preference test were categorized as high SB. We profiled genes involved in stress regulation (glucocorticoid receptor (*GR*), *FKBP5*, and *ADCYAP1*) and novelty reactivity (*neuroligin-2*) using qPCR, and compared gene expression to temperament (SB, BI) using regression analyses. We found that *GR* expression was a weak predictor of SB and BI. However, low *ADCYAP1* expression predicted greater SB, and a regression model with both *ADCYAP1* expression and stress-induced GC levels predicted BI better than each of these two variables independently. This combined model was not a better predictor of SB. GC production has been associated with both SB and BI in a variety of animal models and humans, but mechanisms driving this relationship are not clear. However, *ADCYAP1* in the hippocampus encodes the PACAP protein, which mediates the stress response and has been shown to regulate social behaviors. These results demonstrate a possible pathway by which glucocorticoid stress reactivity may affect temperaments that are associated with the tendency to approach and avoid novelty.

Title: Multisite recordings of a highly recurrent hormone-sensitive macrocircuit across diverse social behaviors

Authors: *E. M. GUTHMAN, J. M. IRAVEDRA-GARCÍA, T. D. PEREIRA, A. L. FALKNER;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Social behavior is a fundamental aspect of animal life across species. Animals flexibly adjust their social behavior across a variety of external contexts and internal states to achieve access to resources, protect their territory, find mates, and raise offspring. These behaviors are controlled by the social behavior network (SBN), a highly-conserved and recurrent multiregional brain macrocircuit. SBN neural populations are united by their common expression of estrogen

receptor alpha (ERα), rendering them sensitive to the gonadal hormones estradiol and testosterone. Although dysregulated social behavior is a common symptom of many mental illnesses, the ways in which social context and internal state together influence SBN activity to change social behavior remain unknown. Here we discuss our development of novel tools and methods that we use to investigate how social context and gonadal hormone signaling influence SBN control of social behavior across sexes. Ongoing work combines novel method development for two-color, customizable full-brain fiber photometry recordings with automated tools for behavior discovery, classification, and quantification across context and hormone state. Specifically, using a combinatorial Cre-dependent and Cre-excluding viral strategy in the Esr1-Cre mouse line, we target ERα+ and ERα- SBN populations with different Ca2+ indicators. With these viral tools and our novel recording strategy, we are able to simultaneously track the activity of hormone-sensitive and insensitive populations during social behavior. We quantify behavior with an unsupervised approach, using the deep neural network, SLEAP, to track mouse posture dynamics. From these posture dynamics, we generate a set of behavior feature variable time-series representing social interaction between mice and cluster these feature variables for behavior classification. After two weeks of behavioral and neural recordings across 15 unique social contexts, mice are gonadectomized and experiments are repeated. Behavioral expression and SBN activity dynamics during behavior will be compared across sex, social context, and hormone state. Here, we present proof-of-principle data demonstrating the effectiveness of our methods, as well as findings demonstrating how mouse social behavior changes across social context and hormone state.

Title: Social defeat, but not subordinate status, reduces social reward and mesolimbic activation in Syrian hamsters (Mesocricetus auratus)

Authors: *E. WILLIAMS, K. L. HUHMAN, H. E. ALBERS;
Georgia State Univ., Atlanta, GA

Abstract: Social stress plays an important role in the etiology of many neuropsychiatric disorders that are characterized in part by behavioral deficits such as social withdrawal. Despite the potent effects of social stress in the development of neuropsychiatric disorders, little is known about the underlying mechanisms responsible for these effects. One way that social stress may contribute to psychiatric disorders is by reducing the rewarding properties of social interactions, thereby reducing social motivation. We investigated the impact of varying types of social encounters on social reward by comparing the reinforcing properties of social interactions in dominant, subordinate, and socially defeated Syrian hamsters. Social status was established during training over five consecutive days of five min parings with a same-sex conspecific. Dominant and subordinate hamsters were stable, age- and weight-matched dyads, while defeated hamsters were paired daily with a novel, larger resident aggressor (RA). All behavior, including duration of aggression, during training was quantified to determine if the "dose" of aggression received impacted social reward. Using an Operant Social Preference (OSP) task, we found that socially defeated hamsters made significantly fewer entries and had longer latencies to enter chambers containing novel, same-sex conspecifics compared to dominant and subordinate hamsters. Surprisingly, there was no difference in entries into the social chamber by hamsters with dominant versus subordinate status. Furthermore, subordinate hamsters experienced more aggression during training than did defeated hamsters. Therefore, the "dose" of prior aggression was not directly related to rewarding properties of subsequent social interactions. These data suggest that social instability may be more stressful than being submissive in a stable, albeit aggressive dyad. We also examined the resulting neural activation using cFos immunohistochemistry in brain regions associated with motivated behavior and reward, including medial prefrontal cortex (mPFC), nucleus accumbens (NAc), and ventral tegmental area (VTA). While mPFC activation was similar across all three groups, defeated hamsters had less activation in the VTA and NAc compared to dominant and subordinate hamsters. This difference in neural activation following social conditioning mirrors the behavioral differences seen in the OSP task. Thus, social defeat stress, but not stress associated with a stable subordinate status, reduces social reward and mesolimbic activation.

Title: Release from social suppression initiates transcriptomic differentiation of the hypothalamic-pituitary-gonadal axis of the naked mole-rat

Authors: *M. FAYKOO-MARTINEZ[1,5], D. J. SOKOLOWSKI[2,5], K. YUKI[5], C. CHAN[2,5], H. HOU[5], M. PALMERT[5,6], T. PUGH[3], M. D. WILSON[2,5], M. M. HOLMES[1,7,4];

Abstract: Pubertal timing is highly heritable yet influenced by environmental conditions including psychosocial stressors. Pubertal timing, its susceptibility to social modulation, and associated health outcomes, all differ between males and females. Thus, understanding sex-specific mechanisms controlling pubertal timing has tremendous importance for human health. The naked mole-rat (NMR) is a unique rodent residing in large colonies of adults who remain in a pre-pubertal state due to the presence of a single, dominant breeding pair. How puberty is suppressed in adult NMRs is unknown, though sex differences in mechanism likely exist (e.g., males show reduced suppression). NMRs removed from the colony will enter puberty within a week. Here, we perform transcriptomic profiling of the hypothalamic-pituitary-gonadal axis in NMRs within the colony (breeders and subordinates) to animals that have been removed from their colony for 1 or 4 weeks (ex-subordinates), which triggers pubertal onset. The hypothalamus was separated into dorsal and ventral portions to separate populations relevant to stress input and reproductive output, respectively. By 1 week post-removal, we observe changes in the ventral hypothalamus of females, but not males. This includes the upregulation of *Trh*, the regulator of thyroid hormone activity and a key hormone related to the metabolic control of puberty. We found changes within the ovaries within a week which led us to focus on how the transcriptome changes and in which cell populations these changes occur in the hypothalamic-pituitary-gonadal axis of females during their first week of transition using single-cell RNA sequencing. Animals were removed from colony for 1 day, 4 days or 1 week (ex-subordinates) and compared to in-colony subordinates and breeders. To put these single cell gene expression changes in context we compared our data to single cell RNA-seq experiments performed in the mouse hypothalamus before and after puberty. Using canonical marker genes we are able to find broad cell populations shared between the NMR and mouse. Notably, within common cell populations of KNDy, AGRP/NPY+ and POMC+ neurons, we identified significantly higher levels of *Crhbp* relative to mice. CRHBP is a negative regulator of CRH expression and is an interesting candidate gene could related to psychosocial stress mediated pubertal suppression in NMRs. Here we will describe these results and ongoing work to elucidate the molecular mechanisms underpinning the striking pubertal suppression phenotype in NMR.

Title: Brain wide synaptic inputs to aromatase expressing neurons in the medial amygdala suggest complex circuitry for modulating social behavior

Authors: *J. DWYER[1], D. A. KELLY[2], J. F. BERGAN[3];
[1]Univ. of Massachusetts, Amherst Neurosci. and Behavior Program, Amherst, MA; [2]Dept. of Psychology, Univ. of Massachusetts Amherst Dept. of Psychology, Amherst, MA; [3]Psychology and Brain Sci., Univ. of Massachusetts At Amherst, Amherst, MA

Abstract: Social behaviors are critical for survival and depend on the integration of external and internal sensory cues. In mice, chemosensory information provides the primary sensory input to a conserved network of brain regions dedicated to executing social behaviors. The core brain regions that make up the social behavior network are established and conserved for all vertebrate species examined thus far. However, the cellular heterogeneity and overlap of functional circuits within many social brain regions has presented challenges for identifying the specific neural circuits require to execute social behaviors.
The medial amygdala (MeA) is a central node in the social behavior network and receives sensory input directly from the accessory olfactory bulb. The MeA integrates chemosensory signals with modulatory input from other brain regions and circulating hormones to guide behavioral responses through its projections to efferent behavioral centers. Aromatase, an enzyme that converts testosterone to estradiol, is expressed by a robust subset of neurons in nearly all brain regions of the SBN. Aromatase expressing neurons in the MeA are critical for aggression in both sexes and play an essential role in shaping the representation of social stimuli in the MeA.
Here, we used rabies-based circuit mapping from the specific aromatase expressing MeA cell population and CLARITY-based light-sheet microscopy to reveal an unbiased view of the brain regions that provide synaptic input to MeA aromatase expressing neurons. We observed both well-established connections (e.g., bed nucleus of the stria terminalis and accessory olfactory bulb), as well as novel and surprising inputs from areas involved in parenting and aggression, metabolism, fear and anxiety, and memory and cognition. These results confirm the central role

of the medial amygdala in social recognition behavior and point to an expanded role for its aromatase expressing neurons in the integration of multiple sensory and homeostatic factors, which can be used to modulate many other social behaviors.
