Abstract: INTRODUCTION: Vagus nerve stimulation (VNS) paired with motor rehabilitation improves functional recovery from stroke and other neurologic injuries (Khodaparast et al., 2016; Dawson et al., 2021). Paired-VNS drives plasticity in both the injured and healthy nervous systems, but it is unknown if paired-VNS can improve motor performance in healthy animals. Moreover, the mechanisms by which paired-VNS drives changes in behavior remain unclear. Cholinergic signaling plays a critical role in learning, plasticity and reinforcement signaling, making it an appealing candidate to mediate the effects of VNS on motor learning and plasticity. In this study, we investigate the ability of paired-VNS to enhance motor learning in healthy animals and explore the role of cholinergic signaling in VNS-driven functional improvement. We hypothesize that paired VNS will improve motor learning in healthy animals through activation of cholinergic signaling. METHODS: To test the effects of VNS on motor learning, we implanted chronic stimulating electrodes on the left cervical vagus nerve of mice (Cortec; Microleads). Mice were trained to perform a dexterous forelimb reach for a food pellet using a novel automated behavioral system, CLARA. CLARA utilizes DeepLabCut to track real-time kinematics, which allows for high throughput, closed-loop stimulation based on behavioral metrics. Animals received VNS only after successful reach attempts (30hz, 0.6mA, 0.5s). To understand the role of cholinergic signaling during VNS, we performed *in vivo* extracellular recordings in the basal forebrain (BF) while delivering VNS in awake and anesthetized mice. In separate studies, mice learned to perform the skilled reach in the CLARA system, and VNS applied simultaneously with optogenetic inhibition of cholinergic neural activity within the basal forebrain (continuous, 0.5s, 0.5mW). RESULTS: In healthy animals, VNS paired with successful reaches enhanced acquisition of the task. Detailed kinematic analysis revealed that mice with paired-VNS made fewer targeting errors and displayed increased reach consistency compared to

controls. Additionally, VNS drove neural activity in the BF in awake and anesthetized mice. Moreover, optical inhibition of cholinergic BF neurons during VNS was sufficient to prevent VNS-driven enhancement of motor learning and eliminated the effects on reach kinematics. CONCLUSION: Our results demonstrate that VNS paired with reach success enhances dexterous motor learning in healthy animals, mediated in part, through the BF cholinergic neuromodulatory system.

Abstract: The limited lifetime of penetrating microelectrode arrays for effective recording and stimulation is a critical impediment for their clinical use. Both biotic and abiotic performance degradation mechanisms have been identified. This study focuses primarily on the abiotic mechanism of tip metal degradation and lead wire breakage for Utah Slanted Electrode Arrays (USEAs) that have been implanted in peripheral arm nerves of 3 human subjects for up to 17 months, compared with an unimplanted array as a control. The effects of in-dwelling time, stimulation dose, and spatial position of the electrodes are evaluated. This report compares 7 USEAs implanted in subjects S5, S6, and S7 for 3, 14, and 17 months, respectively, with one unimplanted control array. The tip metal condition was analyzed by SEM and scored based on observed damage ranging from 1 (no damage) to 4 (severe). Differences in metallization damage by array and subject were analyzed using ANOVA and post-hoc tests. The effects of stimulation

dose delivered by each electrode on tip metal degradation were also statistically evaluated. Additionally, correlations between saline and in-vivo impedances and tip damage were analyzed. Spatial statistics were used to evaluate patterns in the tip metal degradation . All implanted arrays had statistically more tip metal degradation compared with the control array. A gap between the tip metal and silicon shank was often observed in SEM. This gap likely resulted from Si etching in the physiological environment. Additionally, arrays implanted in S5 (3 months) had statistically less damage than those implanted in S6 and S7. Considerably improved electrode impedance stability was achieved for S7 compared with S6[1], despite no significant differences in their tip metal damage, highlighting the strong impact of leads and device architecture. Surprisingly, stimulation dose was not found to correlate with tip metal degradation. Spatial analysis of tip degradation revealed a statistically significant clustering of tip metal damage, suggesting spatial factors do impact tip metal stability. Significant IrOx tip metal degradation occurred in USEAs implanted in human subjects, and damage was worse in arrays implanted for longer periods (14 and 17 months). Damage was spatially clustered, not randomly distributed. The damage did not correlate with stimulation doses up to 19 mC, and did not have a simple relationship with impedance. Dissolution of Si that undercuts the tip metallization is a potentially important degradation mechanism for the tip metallization of USEAs. [1] George et al. Title: Magnetically aligned regenerative tissue-engineered electrical nerve interfaces: functional and histological evaluation and future directions

Authors: *A. S. LIM[1], E. W. ATKINSON[2], L. JIRACEK-SAPIEHA[3], M. KASPER[1], V. RIVERA-LLABRES[4], C. KULIASHA[3], C. M. RINALDI-RAMOS[4], C. E. SCHMIDT[1], J. W. JUDY[3], K. J. OTTO[1];

Abstract: Achieving a high-bandwidth recording and stimulation interface with the peripheral nervous system (PNS) is crucial for the success of potential therapeutics for the amputee population. Higher information resolution at the peripheral nerve level, i.e., recording and stimulating isolated nerve fibers and fascicles, may allow finer control of the bidirectional communication taking place. In regards to prosthetic limbs for amputees, high-bandwidth PNS implants may ideally support sophisticated, modern prosthetics with multiple degrees of freedom for both sensory information and motor control.
Our approach to a peripheral nerve interface takes advantage of the regenerative ability of the PNS while treating amputee phantom limb pain, i.e., excision of peripheral neuromas. Doctors often excise the neuroma from the nerve and redirect the distal end to nearby musculature to minimize recurrence of neuroma formation. With regards to the Magnetically Aligned Regenerative Tissue Engineered Electrical Nerve Interface (MARTEENI), the neuroma will be excised and the distal end inserted into our device with hopes to inhibit neuroma reformation. Regenerating nerve fibers will encounter a growth promoting environment via a tissue-engineered hydrogel composed of glycidyl methacrylate-hyaluronic acid and guided through magnetically-aligned microchannels. After natural hydrogel degradation, the regrown nerve fibers will be in close proximity to uniformly spaced microelectrodes. Our implant, referred to as the MARTEENI, may allow the field of neuroprostheses a reliable, chronic PNS interface with a sufficient input-output information bandwidth to support next-generation prosthetic devices.
The findings here are two-fold. 1) we demonstrate the functional and histological evaluation of MARTEENIs in regenerated Lewis rat sciatic nerves using a multimodal analysis approach including: electrochemical impedance spectroscopy (EIS), electrophysiological recordings, and immunohistological techniques. Our data suggests stable impedance magnitudes at 1 kHZ up to 2 months after nerve implantation. This is validated with 2D histology and 3D imaging. 2) we report our electrode characterization findings as we transition from platinum metal to devices incorporating sputtered-iridium oxide (SIROF). The data suggests that SIROF microelectrodes have lower impedance across the frequency domain and greater charge storage capacity relative to platinum microelectrodes of identical surface area which in turn will result in decreased noise floor, i.e., improving electrophysiology recording quality, for better microstimulation at the PNS.

Title: Decoding the network architecture and function of the central pattern generator for asynchronous flight

Authors: *S. HÜRKEY, S. RYGLEWSKI, C. DUCH;
Inst. of Developmental Biol. and Neurobio., Johannes Gutenberg Univ. Mainz, Mainz, Germany

Abstract: Decades of research on the neural control of locomotion provide insight into the architecture of central pattern generating (CPG) networks. In brief, patterned motor output is typically generated by premotor interneuron synaptic connections and membrane properties. However, the most prevalent form of animal locomotion, asynchronous insect flight, comes with specific constraints to CPG architecture. By combining electro- and optophysiology with Drosophila genetics we demonstrate that coordinated motoneuron (MN) firing does not rely on patterned activity of premotor interneurons, but instead is shaped by electrical synapses between MNs. This de-synchronizes MN firing to generate specific firing sequences, which in turn, are required for stable wing beat frequencies. Asynchronous flight as employed by >600,000 species requires neuronal firing de-synchronization by electrical synapses. Asynchronous flight muscles are specialized to generate high mechanical power at fast contraction frequencies (~100-1000Hz) to compensate for low Reynold numbers. They do not contract in synchrony with neurogenically controlled cycling of myoplasmic Ca^{2+}, but rather are stretch activated. However, muscle power is tightly controlled by the CNS, because MN firing at every ~20-40th wingbeat tunes muscular stretch activatability. Although the MN firing patterns are known in multiple species, the mechanisms for pattern generation and the resulting function remain unknown. Each of the 6 Drosophila wing depressor muscle (DLM) fibers is innervated by one MN. During flight all MNs fire at the same frequencies, though not simultaneously but in preferred sequences. Common MN firing frequencies result from shared but unpatterned, excitatory cholinergic input. The specific MN firing sequences are generated by ShakB mediated weak, non-rectifying, reciprocal electrical synapses between MNs, thus de-synchronization firing of electrically coupled MNs and bypassing pattern generation by premotor interneurons. Both *in vivo* and in models knock-down and overexpression of ShakB causes MN firing synchronization. Forced MN firing synchronization by targeted overexpression of ShakB results in fluctuating wingbeat frequencies, demonstrating that splay state firing serves even power production.

Title: Modulation of gap Junction voltage-dependence by the hyperpolarization-activated inward current

Authors: *M. DEMAEGD[1,2], C. STAEDELE[2,4], A. L. HARRIS[3], W. STEIN[2];
[1]New York Univ., New York, NY; [2]Biol. Sci., [3]Physics, Illinois State Univ., Normal, IL; [4]Dept. of Neuro- and Sensory Physiology, Univ. Med. Ctr. Göttingen, Univ. of Goettingen, Goettingen, Germany

Abstract: Voltage-dependent electrical synapses have an important role in shaping the direction and strength of electrical current that flows between neurons. The voltage-dependence often supports rectification between neurons of different types and modifies the synaptic drive as neuronal activity changes. In the crustacean stomatogastric ganglion, voltage-dependence has long been well-described for the electrical synapse between the descending projection neuron MCN1 (Modulatory Commissural Neuron 1) and the LG (Lateral Gastric) neuron in the gastric mill central pattern generator. Specifically, the electrical postsynaptic potentials (ePSPs) that LG receives from MCN1 increase in amplitude when LG's membrane voltage depolarizes, prolonging the duration of LG's bursts.Here, we show that this voltage-dependence is altered by the hyperpolarization-activated inward current (I_h). Specifically, when I_h was blocked with CsCl, ePSPS not only increased in amplitude, but also showed very little voltage-dependence between LG's resting membrane potential (-60mV) and spike threshold (-40mV). Instead, the LG membrane potential had to be hyperpolarized below resting potential to observe any voltage-dependence. Therefore, the dynamic range of the voltage-dependence shifted to more hyperpolarized values (Saline: EC50 = -64.98±5.06mV, N = 8; CsCl: EC50 = -82.87±10.37mV, N = 7). Modelling results indicate that such a shift may be enabled through presynaptic expression of I_h and the subsequent depolarization of the presynaptic membrane potential, which reduces the difference in membrane potential between the presynaptic and the postsynaptic neuron. Indeed, we found that I_h was present in the MCN1 axon presynaptic terminal and depolarized its membrane potential, while the postsynaptic LG membrane potential remained unaffected (N=4). Consequently, the dynamic range of the MCN1-LG electrical synapse voltage-dependence shifted toward the voltage range at which LG operates. Our data thus demonstrate that a presynaptic ionic current can modulate the dynamic voltage range over which an electrical synapse functions.

Title: Variability in encoding in identified leech neurons

Authors: *T. WRIGHT, J. AMMARI, V. PASMURTSEV;
Biol. Sci., California State University, Sacramento, Sacramento, CA

Abstract: It is now well established that there is considerable animal to animal variability in the production of rhythmic motor patterns. Recent work in the medicinal leech, *Hirudo medicinalis* has quantified the variability in the production of the motor pattern that drives the rhythmic constrictions of a bilateral pair of heart tubes. This variability begs the question: what parameters must be fixed in order to produce stereotyped behaviors despite the variability inherent within the nervous system? To address this question, we are exploring variability in the firing properties of the mechanosensory P (pressure,) and N (nociceptive) cells, which have been shown to have an influence on several behaviors in the leech (heartbeat, swimming,) and thus variability in their firing properties, while not directly involved in the cycle-to-cycle variability of the heartbeat pattern may never the less contribute to that variability. Because the output of many neural circuits is the firing of action potentials, the variability in the way that these neurons encode their inputs will contribute to the variability in the behaviors that we observe. There are several ways to assess encoding, including ramp current injections and FI Curves. Each of these protocols, while effective at measuring how neurons integrate their inputs, do not always capture the temporal dynamics likely to be observed in the nervous systems. To assess how leech neurons integrate inputs with different frequency characteristics, we recorded from several neuron types in adult leeches. For each neuron, we injected a white-noise signal (Gaussian White Noise (GWN) with a mean of 0 and an SD of 1 nA; cut-off frequency was 25 Hz) with a gain sufficient to produce at least 50 action potentials per injection. From this data we constructed a spike-triggered average of the input (STI; also known as a “Reverse Correlation”) and measured several parameters, including the delay to the peak of the STI, width, etc. We also assessed the normalized frequency response of the neurons to the stimulus. Finally, we computed return maps of the inter-spike intervals to assess how variable the ISIs were for each cell type. We show that the return maps for N cells are more variable than return maps for P Cells, and that the frequency response for both cell types are highly variable, with cells of each type acting as low-, band-, or high-pass filters.

Title: Dynamic mechanisms underlying continuous and episodic bursting patterns produced by a half-center oscillator

Authors: *G. CYMBALYUK[1], J. PARKER[1], R. J. ERAZO TOSCANO[1], S. A. SHARPLES[2], P. ELLINGSON[1], A. VARGAS[1], M. A. MASINO[3], P. J. WHELAN[4], R. L. CALABRESE[5]; [1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Univ. of St Andrews, St Andrews, United Kingdom; [3]Neurosci., Univ. of Minnesota, Minneapolis, MN; [4]Univ. Calgary, Calgary, AB, Canada; [5]Emory Univ., Atlanta, GA

Abstract: Specialized oscillatory neuronal circuits controlling rhythmic movements, central pattern generators (CPGs), are capable of producing a wide variety of rhythmic patterns [1-6]. For example, leech heart beat CPG is based on pairs of mutually inhibitory interneurons forming half-center oscillators (HCOs) and producing continuous bursting (period ~ 1 s) while isolated neonatal rodent spinal cord preparations exhibit continuous locomotor bursting rhythms (period ~ 1 s) and a complex pattern evoked by dopamine: a very slow episodic bursting rhythm (period ~ 50 s) in which episodes of the fast-bursting rhythm are interrupted by long pauses [1]. Recent studies provide evidence that the Na^+/K^+ pump current (I_{pump}) participates in the dynamics of neurons and is a target of neuromodulation [2,6,7]. Intracellular Na^+ concentration ([Na]i) controlling I_{pump} plays a pivotal role in the generation of both continuous and episodic bursting rhythms. We build a general model describing dynamics of [Na]i, which led us to unveiling general mechanicms implicated in episodic and continuous bursting patterns of the CPGs on different timescales across species: leech, zebrafish, and mouse. Drugs affecting ($[Na^+]i$ like monensin and pharmacological blockade of currents carrying Na^+ fluxes such as I_{pump} and h-current were compared with corresponding manipulations of parameters in a family of biophysical models. For example, we describe general mechanisms producing episodic bursting patterns by a mammalian CPG model composed of a basic HCO, and a zebrafish CPG, composed of mutually excitatory neurons. These mechanisms may be applicable to other

biological systems that engage in continuous and episodic activity.

Title: New tools and refinements to interpret the role of spinal interneurons in motor modularity

Authors: *T. S. SMITH[1], M. ABOLFATH-BEYGI[2], T. D. SANGER[2], S. F. GISZTER[1]; [1]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Biomed. Engin., USC, Los Angeles, CA

Abstract: Novel motor plans are translated through the spinal cord, to control the musculature quickly and efficiently. In the motor modularity model of movement, dynamic ‘building blocks’ are combined in sequence or parallel to compactly construct most motor commands. We define a motor ‘module’ as a neural element evoking stereotyped motor activity, extracted from kinetic or biological features (e.g. synergist muscle EMG). In the spinal frog, modularity can be studied without influence of higher centers using the hindlimb-to-hindlimb wiping reflex as an inducible behavior composed of adjusted phases and amplitudes of three motor modules.During wiping, the spinal cord must control 1) when modules are recruited and 2) how modules coordinate the motor pools to produce coordinated muscle synergies. Previously we have discovered interneurons whose spiking activity coincided with these observed muscle synergies, but how these interneurons precisely contribute to modularity is unclear. One method of elucidating this

relationship is to investigate patterns of motoneuron recruitment within motor pools and across synergist muscles. Our new braided intramuscular EMG electrodes can record the activity of multiple single motor units within a muscle, and thus the spiking of individual motoneurons. By concurrently recording single motor units within and across synergist muscles, with associated interneurons, we will test for subfractionated recruitment of motor units within motor pools and concerted recruitment across motor pools. Because the role of single neurons in the ongoing motor pattern may be minor and spinal-state dependent, we utilize the stochastic dynamic operator (SDO) framework to evaluate relationships between point-processes and continuous state (e.g. neural spikes to EMG) and point-processes to point-processes (e.g. neural spikes to single motor units). We have stably recorded interneurons and motor units in spinal frogs. Currently we are evaluating best practices for maximizing the predictive utility of the SDO to map the activity of neurons and recruited single motor units to ongoing motor state. We demonstrate here that incorporating background dynamics is necessary for best interpreting and predicting the state-dependent behavior and specificity of interneurons. We have also found that single motor units may be strongly tuned to activity of a synergist muscle, suggesting fixed patterns of muscle coactivations. As we continue to collect and interpret this data, we expect to further elucidate the neural underpinnings of spinal modularity. Furthermore, we anticipate our innovative tools to be broadly applicable to other realms of neuroscience.

Title: Involvement of the α3-subunit of Na^+/K^+-ATPase in the regulation of spinal motor network output

Authors: *F. SORRELL[1], F. W. HOOPER[1], E. AKKURATOV[2], A. APERIA[3], K. T. SILLAR[4], G. B. MILES[4];
[1]Univ. of St Andrews, St Andrews, United Kingdom; [3]Sci. for Life Lab., [2]Karolinska Institutet, Solna, Sweden; [4]Univ. St Andrews, St Andrews, United Kingdom

Abstract: The α3 subunit of Na^+/K^+-ATPase generates a large hyperpolarising current (the ultra-slow afterhyperpolarisation or ‘usAHP’) in lumbar motor neurons of neonatal mice following periods of prolonged, intense neuronal firing due to the rapid expulsion of intracellular sodium

(Picton et al., 2017). The neuron-specific α3 subunit is generally co-expressed with the ubiquitous α1 subunit, but its lower Na^+ affinity allows it to remain inactive or submaximally active until a considerable increase in Na^+ occurs (Azarias et al., 2013). The usAHP is thought to have a protective role as a fatigue-prevention mechanism in the locomotor network by facilitating a short-term 'motor memory' (STMM). Selectively blocking the α3 subunit using an acute application of the cardiac glycoside ouabain (1-3μM) reduces the amplitude of the usAHP and modulates the frequency of fictive locomotor-like rhythms in mouse spinal cords *in vitro* (Picton et al., 2017). To elucidate further the role of α3 Na^+/K^+-ATPase we here utilise an animal model harbouring the Rapid-Onset Dystonia-Parkinsonism gene mutation T613M in the α3-isoform encoding gene *ATP1A3*. This mutant α3 has a Na^+ affinity similar to wild-type α1 and is less efficient than wild-type α3 at rapidly restoring Na^+ load. We show, using whole-cell patch-clamp recordings, that lumbar motor neurons harbouring T613M fail to produce usAHPs (T613M n=38, WT n=35) and show a small but significant hyperpolarisation of the resting membrane potential (3-4 mV). At the network level, T613M does not affect spontaneous spinal motor activity (T613M n=17, WT n=14) or canonical drug-induced locomotor-like output (T613M n=14, WT n= 10). Similarly, when using a dorsal root stimulation to elicit locomotor-like output, T613M does not affect general properties of the locomotor rhythm but does produce a modest reduction in short-term 'motor memory' (T613M n=8, WT n=11). These data support a role for the Na^+/K^+-ATPase α3 subunit in the production of usAHPs in spinal neurons. At the network level, these data also support the involvement of α3 in STMM. However, the function of α3 in locomotor rhythm/pattern generation is less clear. We suggest that a compensatory mechanism, such as upregulation of α1-containing Na^+/K^+-ATPase may be able to rescue essential locomotor network behaviour in mutant models. Many movement disorders are linked to mutations in *ATP1A3*. These data advance our understanding of the fundamental role of Na^+/K^+-ATPase in motor networks and disease progression.

Abstract: Movement is essential for survival, enabling animals to explore their environment, obtain food, engage in social interactions, and escape predation. The neural circuits directly responsible for movement reside within the spinal cord, where networks of interneurons shape motor neuron activity to control the spatial and temporal patterns of peripheral muscle contraction. Despite recent insights into the developmental origin and function of spinal interneurons, their molecular identities and gene expression profiles remain enigmatic. A more thorough understanding of their identity will help provide insight into fundamental aspects of interneuron circuit organization and therapeutic potential in developmental motor disorders, neurodegenerative diseases, and traumatic spinal cord injury. The most abundant population of inhibitory interneurons in the spinal motor system is the evolutionarily conserved, ipsilaterally-projecting class of V1 interneurons, defined by expression of the homeobox transcription factor Engrailed1. Genetic ablation or silencing of V1 interneurons reduces the speed of locomotion and results in limb hyperflexion, indicating they influence diverse aspects of vertebrate motor output. In prior work, we found that V1 interneurons in neonatal mice constitute a molecularly heterogenous population that segregates into at least four mutually exclusive clades identified by the expression of the transcription factors Foxp2, MafA, Pou6f2, and Sp8. How this developmental molecular and cellular diversity relates to the complexity of mature neural circuits in the spinal cord remains unknown. Using single-nucleus RNAseq of V1 neurons isolated by flow cytometry at cervical, thoracic, and lumbar spinal segments across postnatal development (p0, p14, p28, and p56), we have identified approximately two dozen putative V1 cell types, revealing subtype-specific regulation of transcription factors, cell-adhesion molecules, and ion channels. Moreover, integration of transcriptomic data across development revealed that virtually all proposed cell types present at birth are preserved in adult neural circuits, suggesting their unique transcriptional profiles may confer distinct functional roles required for fine and adaptive control of complex movements. To our knowledge, this is the most detailed single-cell transcriptomic dataset focused on a single class of spinal interneuron to date, and will serve as a valuable resource for understanding the molecular architecture of neural circuits in the spinal motor system.

Title: V1 interneuron expressing the mafb transcription factor include renshaw cells and display bursting firing phenotypes and unique properties

Authors: E. K. BICHLER, A. F. RIVARD, *F. J. ALVAREZ;
Emory Univ., Atlanta, GA

Abstract: V1 cells are ventral inhibitory interneurons defined by the transcription factor (TF) En1 and are divided into four groups defined by MafA, Pou6f2, Foxp2 and Sp8 TFs. MafB is a TF expressed by MafA-Renshaw cells (RC) and some dorsal Pou6f2 V1s. MafB V1s uniquely show capacity for burst spiking. To analyze commonalties and differences in firing among different MafB V1s and along postnatal development we recorded whole-cell MafB V1s in spinal cord slices of P1 to P17 mice. MafB V1s were identified by GFP and tdT expression in *en1cre::mafbGFP::R26lsl-tdT* mice. RC identity was confirmed by post-hoc calbindin-IR. Recorded cells were subject to various stimulation paradigms to reveal different firing properties. These included short (400 ms) and long (2 s) depolarizing square pulses, hyperpolarizing pulses (1 s), slowly depolarizing triangular pulses to target slowly activating and inactivating mechanisms and very short pulses (3-5 ms) to evoke single action potentials. Bursting was found at all ages. It depends on TTA-P2 sensitive T-currents generating transient low threshold spikes (LTS during subthreshold depolarization) and afterdepolarizations (ADP after single Na+ spikes). They are best revealed with membrane hyperpolarization prior to depolarizing pulses. They are present in 100% RCs at any age with any depolarization protocol. In dorsal MafB-V1s, ADPs are evident after single spikes following short pulses (3-5 ms), but in longer pulses they are balanced by outward currents that block LTS and bursting in 50 to 70% of cells. In both cells, triangular pulses revealed firing hysteresis with higher excitability during ascending depolarizing ramps compared to descending hyperpolarizing ramps. We did not find evidence for persistent inward currents at any age. RCs showed higher excitability, more hyperpolarized action potential thresholds, higher gains in f-I curves, and higher steady-state firing. They also showed larger post-train afterhyperpolarizations (AHP) and at intermediate depolarizations large variability in interspike intervals (irregular firing) suggesting decorrelated inhibitory output with maintained excitatory drive. Dorsal MafB-V1s have lower excitability, more regular firing and spike-dependent accommodation. Properties that changed with age included amplitude and time course of post-spike AHPs and, in particular for RCs, the speed of action potentials rise and decay, significantly increasing firing rates. Thus, MafB V1s can burst spike but also display cell-specific plasticity that can alter their excitability and switch these cells between bursting and non-bursting and in the case of RCs between regular and irregular firing.

Title: Single cell transcriptomic analysis of spinal dI6 neurons in zebrafish and mouse reveals functional distinct subtypes and novel subpopulations

Authors: *A. B. IGLESIAS GONZALEZ, J. JAKOBSSON, J. VIEILLARD, M. LAGERSTROM, K. KULLANDER, H. BOIJE;
Uppsala Univ., Uppsala, Sweden

Abstract: The spinal locomotor network is frequently used for studies into how neuronal circuits are formed and how cellular activity shape behavioral patterns. A population of dI6 interneurons, marked by the Doublesex and mab-3 related transcription factor 3 (*Dmrt3*), has been shown to participate in the coordination of locomotion and gaits in horses, mice and zebrafish. Analyses of *Dmrt3* neurons based on morphology, functionality and the expression of transcription factors suggest the existence of different subtypes. Here, we have analyzed the transcriptomes of individual cells of the *Dmrt3* lineage from zebrafish and mice to unravel the molecular code that underlies their subfunctionalization by single cell RNA-sequencing. Indeed, clustering of *Dmrt3* neurons based on their gene expression verified known subtypes and revealed novel dI6 populations expressing unique markers. Differences in birth order, expression of axon guidance genes, neurotransmitters and their receptors, as well as factors affecting electrophysiological properties, provide the basis for their functional diversity and help explain functional and morphological differences. Our analysis provides the basis for experimentally determined parameters; early born *Dmrt3* neurons are ventrally located, active during fast swim, contact the soma of contralateral motor neurons, have low input resistance and high amplitude, to provide a strong mid-cycle inhibition to the opposite side. Meanwhile, late born *Dmrt3* neurons have more dorsal somas, are active during slow swims, contact contralateral dendrites of motor neurons, have higher input resistance and lower amplitude, to provide fine control of movements at slower speeds. In addition, the comparison between fish and mice provides insight into the evolutionary driven subspecialization concomitant with the emergence of limbed locomotion.

Title: Clonally related V2a/b neuron pairs in the spinal exhibit similar morphologies

Authors: *S. BELLO-ROJAS[1], M. W. BAGNALL[2];
[1]Washington Univ. In St. Louis, Saint Louis, MO; [2]Washington Univ., Saint Louis, MO

Abstract: The ventral spinal cord houses a variety of excitatory and inhibitory neurons. Precisely timed excitation and inhibition allow organisms to perform locomotor behaviors. However, it is unclear how spinal circuits achieve proper balance between excitation and inhibition. Spinal premotor neurons are divided into cardinal classes based on progenitor group of origin and differences in transcription factor expression. The p2 progenitor group gives rise to the broad class of V2 precursors, which are labeled by the early transcription factor *vsx1*. Interestingly, individual Vsx1+ precursors undergo terminal differentiation into an excitatory, Chx10+ V2a neuron and an inhibitory, Gata3+ V2b neuron. It is unknown whether these clonally related sister V2a/b neurons have shared fates, including location in the spinal and position within the spinal circuit. To label clonally related V2a/b neurons, we injected titrated amounts of a *vsx1*:GFP plasmid in zebrafish embryos at the one cell stage. *In vivo* time-lapse imaging of stochastically labeled *vsx1*+ V2a/b sister neuron pairs demonstrated that sister neurons stay relatively close to each other, with their somata remaining within 10-20 μm of each other within 3D space. Axon analysis revealed similar trajectories of ipsilateral, descending projections, showing areas of axonal overlap between sister neurons. Furthermore, total axon length of a V2a neuron was consistently longer than its sister V2b, suggesting differences in the structure of excitation and inhibition along the rostrocaudal axis of the spinal cord. Collectively, these data indicate that there are anatomical relationships unique to these clonally related pairs, suggesting an innate developmental relationship between sister neurons. Currently, we are performing electrophysiological experiments between sister and non-sister V2a/b neurons to evaluate the impact of a shared origin on circuit connectivity.

Title: Chemogenetic manipulation of astrocytes in the lateral parafacial region induces active expiration and sympathoexcitation in mice.

Authors: *D. MORAES[1], B. H. MACHADO[2], M. P. SILVA[3];
[1]Sch. of Med. of Ribeirao Preto, USP., Ribeirao Preto, Brazil; [2]Sch. Med. Ribeirao Preto, USP, Ribeirao Preto, Brazil; [3]Sch. of Med. of Ribeirao Preto, Ribeirao Preto, Brazil

Abstract: Previous studies demonstrated that the lateral aspect of the parafacial (pFL) region, which contains expiratory neurons, drives abdominal muscles (active expiration) and sympathetic outflow during high chemical drive (hypercapnia/acidosis). Astrocytes modulate neuronal activity/excitability and synaptic transmission as well as control the activity of motor circuits. Herein, we investigated the contribution of pFL local astrocytes to the central generation of the expiratory neuronal and neural activities and their impact on the sympathetic outflow and cardiovascular function of mice (7 weeks old - C57Bl/6). The pFL astrocytes were unilaterally activated by virally driven expression of designer receptors exclusively activated by designer drugs (hM3Dq) using the glial fibrillary acidic protein (GFAP) promoter. The *in situ* preparations of pFL-GFAP-hM3Dq mice received systemically clozapine N-oxide (90 µM) while the activities of pFL expiratory neurons, inspiratory (phrenic), expiratory (abdominal), and sympathetic (thoracic) nerves were extracellularly recorded. We observed that GFAP-hM3Dq-signaling activation induces an active expiratory pattern, with increased abdominal activity at the end of expiration, and evokes the pFL expiratory neurons firing. GFAP-hM3Dq-signaling activation also enhanced the sympathetic activity and perfusion pressure levels, without affecting the heart rate. On the other hand, GFAP-hM3Dq-signaling activation did not affect the hypercapnia-evoked active expiration and the concomitant response of sympathetic outflow. Besides, clozapine N-oxide did not affect the respiratory or sympathetic outflows in the absence of hM3Dq expression. These findings demonstrate that astrocytes modulate the activity of pFL neuronal circuit generating the expiratory and sympathetic activities in mice.

Title: Swallowing disorder following a clinical dose of buprenorphine in adult cats

Authors: *M. FRAZURE[1,2], K. YOUNG[2], N. MUSSELWHITE[2], C. GREENE[2], K. ICEMAN[2], T. PITTS[2];
[1]Dept. of Physiol., [2]Dept. of Neurosurg. and Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Opioid use has been associated with increased risk of infectious disease, including pneumonia. Individuals on opioids are more susceptible to chest infection due to opioid suppression of immune function, ventilation, cough, and secretion mobilization. While buprenorphine is a commonly used post-operative analgesic in veterinary medicine, its effects on the pharyngeal phase of swallow are unknown. Intramuscular buprenorphine (0.015 mg/kg) was administered to female cats (*n*=4; 12 months old) and videofluoroscopy was performed in the lateral plane 1 hour later. Animals were presented with 40% by volume barium sulfate in tuna water mixed to a thin consistency, and all ate voluntarily. Images were recorded at 30 frames/second and were compared to control feeding assessments using the Penetration Aspiration Scale (PAS). The PAS is an 8-point scale: 1-2 is considered normal, 3-6 is penetration of material into the larynx, and 6-8 is aspiration of material into the trachea/lungs. During control assessments, 75% (3 of 4 animals) had a PAS of 1, and the other animal had a PAS of 5 (material entered the airway, contacted the vocal folds, and was not ejected from the airway). After opioid administration, 50% (2 of 4 animals) exhibited significant aspiration (PAS=8); the most severe was the animal with penetration during the control period. One animal had a PAS of 4, and the final animal showed no significant deterioration of function. These results are consistent with the work of the Jackson Lab (doi: 10.1038/s41598-020-71804-2), reporting that specific genetic variance can lead to significant variability of opioid-induced effects on breathing. In 2 animals, swallow function failed with no appreciable response from the animal (i.e. no cough, throat clear, cessation of eating, etc.), one had worsened function which would not lead a clinician to withhold food/drink, and one animal showed no change. Our success in producing dysphagia (significant but varying by animal) with relatively small doses of opioid has potential implications for predicting aspiration pneumonia in post-surgical clinical cases.

Title: Development of an automated method for detection of onset and offset of multiunit inspiratory burst activity

Authors: *R. M. WADOLOWSKI, I. C. SOLOMON;
Physiol. and Biophysics, Stony Brook Univ., Stony Brook, NY

Abstract: In animal studies, inspiratory electromyogram (EMG) multiunit burst activity is commonly used for assessing various aspects of central respiratory control. In rats, however, breathing frequencies can range from 50-100 bursts/min, and it is often difficult to accurately capture the individual bursts using automated approaches due to the stochastic nature of motor unit recruitment and gradual onset and offset behaviors of motor unit activity. Accurate automated burst onset and offset timing detection would facilitate burst analysis, and approaches commonly used to estimate these timings include threshold and/or window-based smoothing or binning methods that attempt to minimize signal variance around the overall trend of the recorded signal. These approaches are limited by reliance on conservation of burst-to-burst characteristics so that a generalized parameter (e.g., threshold, rate of rise) can be applied to multiple bursts and prior knowledge about the record (e.g., burst duration, non-stationarity, signal/noise ratio (SNR)), and therefore can result in inadequate capture of the onset and/or offset. To overcome these limitations, we present a method for automated estimation of burst onset/offset that minimizes the need for prior knowledge of the record, and assess its capabilities using diaphragm EMG activity recorded from urethane-anesthetized rats with artificially varied SNRs. Our method operates in two phases: (1) detection of the occurrence of a burst in order to create an arbitrary window around the burst and (2) scanning within the window for the timepoint at which the precise burst onset and offset occur. Each phase is achieved by clustering of a time-delay embedded matrix of the original record so that each point, regardless of continuity, is discretized into burst or noise categories. Features of these discretized points are then used to inform probability density functions, which are used to find optimum timepoints for burst onset/offset. This approach allows the original record to inform the algorithm with individualized parameters per burst, which is necessary for accurate detection within a non-stationary signal. Comparison of the algorithm onset/offset timings against 3 user annotated versions of the same sequences of diaphragm EMG bursts with various SNRs revealed that in most cases, the algorithm produced timings that were within or close to user timing ranges at all SNRs, but at a more rapid processing speed (30 burst/second). We believe that this algorithm is a

viable alternative to manually annotated burst onset/offset timings, particularly for large data sets.

Title: Intrinsic and synaptic mechanisms controlling the expiratory activity of excitatory lateral parafacial neurones of rats

Authors: *K. S. MAGALHÃES[1], M. P. SILVA[1], A. S. MECAWI, SR[2], J. PATON[3], B. H. MACHADO[1], D. J. MORAES[1];
[1]Sch. of Med. of Ribeirão Preto, USP, Ribeirão Preto, Brazil; [2]Federal Univ. of São Paulo, São Paulo, Brazil; [3]Dept. of Physiol., Univ. of Auckland, Auckland, New Zealand

Abstract: Active expiration is essential for increasing pulmonary ventilation during high chemical drive (hypercapnia). Several studies demonstrated that the lateral aspect of the parafacial (pFL) region, which contains expiratory neurones, drives abdominal muscles during active expiration in response to hypercapnia. However, the electrophysiological properties and synaptic mechanisms determining the activity of pFL expiratory neurones, as well as the specific conditions for their emergence, are not fully understood. Using whole cell electrophysiology and single cell qRT-PCR techniques, we evaluated the intrinsic electrophysiological properties, the phenotype and the respiratory-related synaptic inputs to the pFL expiratory neurones, as well as the mechanisms for the expression of their expiratory activity under conditions of hypercapnia induced active expiration in *in situ* preparations of juvenile rats. We also evaluated whether these neurones possess intrinsic $CO_2/[H^+]$ sensitivity and burst generating properties. GABAergic and glycinergic inhibition during inspiration and expiration suppressed the activity of glutamatergic pFL expiratory neurones in normocapnia. In hypercapnia, these neurones escape glycinergic inhibition and generate burst discharges at the end of expiration. Evidence for the contribution of post-inhibitory rebound, Cav3.2 isoform of T-type Ca^{2+} channels and intracellular $[Ca^{2+}]$ are presented. Neither intrinsic bursting properties mediated by persistent Na^+ current, nor $CO_2/[H^+]$ sensitivity or expression $CO_2/[H^+]$ sensitive ion channels/receptors (TASK or GPR4) were observed. On the other hand, hyperpolarisation-activated cyclic nucleotide-gated and twik-related K^+ leak channels were recorded. Post-synaptic disinhibition and the intrinsic electrophysiological

properties of glutamatermic neurones both play important roles in the generation of the expiratory oscillations in the pFL region during hypercapnia in rats.

Title: Rhythmic movement by spinal motor networks is governed by rotational population dynamics

Authors: H. LINDÉN[1], P. C. PETERSEN[2], M. VESTERGAARD[3], ***R. W. BERG**[1];
[1]Dept. of Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [2]NYU Neurosci., New York Univ., New York, NY; [3]Max-delbrück-Centrum Für Molekulare Medizin, Berlin, Germany

Abstract: Most of the investigations on spinal rhythm generation are based on motor nerve recordings and single neuron recordings. Since flexor/extensor muscles alternate during movements, it is often assumed that the generation is accomplished by neuronal modules that alternate in opposition, which single neuron recordings seem to support. However, here we argue that when many neurons are monitored simultaneously a different picture emerges. We recorded hundreds of neurons from the lumbar spinal cord of turtles during rhythmic scratching and found that, rather than alternating, the neuronal population is performing a "rotation", i.e. cycling continuously through all phases (Figure). Rotational dynamics are observed across trials as well as behaviors. Since such rotation is difficult to explain with existing models of alternating neuronal groups, we propose a new theory that accounts for the rotational dynamics. Using a simplified network model, we show that in spinal networks with recurrent excitatory and inhibitory connectivity, there is no need for pacemaker activity or modular structures. Tonic input to the network controls the rhythm and pattern depending on the task. The model reproduces other experimental observations and provides a mechanism for multifunctionality. It also predicts that subsets of neurons, with both inhibitory and excitatory members, have the capacity to either speed up or slow down the movement. Figure caption: *Top left: Raster of neuronal population activity sorted according to phase. Middle left: Sorted population firing rates from top. Bottom left: Nerve activity of 3 motor nerves. Right top: neural space exhibit rotational activity (principal components). Bottom: muscle activity has less rotational activity.*

Title: Dynamic network states of the brainstem respiratory rhythmic network

Authors: *N. J. BURGRAFF[1], N. E. BUSH[1], J. RAMIREZ[1,2], N. A. BAERTSCH[1,3];
[1]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; [2]Neurolog. Surgery, [3]Pediatrics, Univ. of Washington, Seattle, WA

Abstract: Within the brainstem, rhythmic respiratory activity is produced and shaped through interactions between a distributed network located bilaterally along the ventrolateral medulla and certain areas within the pons. Of particular importance is the preBötzinger Complex, which produces periodic synchronized bursting activity that coincides with inspiratory activity fundamental to mammalian breathing. Perturbing this region *in-vivo* can result in respiratory failure and fatal apnea, and when isolated *in-vitro*, the preBötC remains sufficient for

rhythmogenesis. The interval between synchronized bursts is regulated by a gradual increase in excitation among preBötC neurons that eventually synchronize to produce a population burst. Implicated in this process are network-based mechanisms involving synaptic interactions between interconnected excitatory and inhibitory neurons, as well as intrinsic-based mechanisms within the preBötC involving burst-promoting inward cation currents such as the persistent sodium current (I_{NaP}). The contributions of these intertwined mechanisms are not static, but can be dynamically tuned by e.g. changes in excitability and neuromodulatory inputs. Here, we test the hypothesis that the dynamic nature of these rhythmogenic properties plays a key role in determining the stability of rhythmic bursting produced within the network. We find that manipulating network excitability by changing extracellular [K^+] altered rhythm stability. Increasing [K^+] increased rhythm stability to a maximum point (stability^{max}). Further increases in [K^+] above stability^{max} destabilized the rhythm, resulting in a bell-shaped stability curve. Understanding this fundamental property that the respiratory network can assume different rhythmogenic states may allow for better predicting responses to drugs that alter network excitability such as opioids. Accordingly, we exposed isolated preBötC networks within horizontal brainstem slices to opioids (DAMGO) at each point along the bell-curve of rhythm stability. Brainstem slices displaying rhythmic activity that was at, or below the point of stability^{max} became highly unstable and were silenced with low levels of DAMGO. In contrast, brainstem slices displaying rhythmic activity beyond the point of stability^{max} became stabilized by DAMGO and were resistant against silencing at high levels of DAMGO. The concept that the respiratory network can assume different rhythmogenic states with different opioid tolerances may provide a novel framework for improving the predictability of drug response and inspire new strategies for prevention and reversal.

Title: Swallow motor synchrony is restored with a 5HT1a agonist after cervical spinal cord injury

Authors: *M. N. MUSSELWHITE[1], M. FRAZURE[1], K. YOUNG[1], C. GREENE[1], N. MELLEN[2], K. E. ICEMAN[1], D. R. HOWLAND[3], T. PITTS[1];
[1]Kentucky Spinal Cord Injury Res. Ctr., [2]Dept. of Neurol., [3]Kentucky Spinal Cord Injury Res. Center; Robley Rex VA Med. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Oral ingestion requires synchronous motor activation to produce a rostral-caudal pressure cascade while ensuring protection of the airway. We have hypothesized that feedforward afferent information is necessary from bulbar and spinal pathways to promote precise motor recruitment and coordination with other airway behaviors (breathing). To test this hypothesis acute and sub-acute cervical C2-3 lateral hemisection was performed in adult cats while bilaterally recording from airway and chest wall musculature. Swallow was stimulated with water infusion into the oropharynx in sodium pentobarbital anesthetized adult cats. After hemisection, swallow motor pattern has distinct left-right asymmetries, with an increase in motor recruitment contralesionally and a delay in motor initiation ipsilesionally. The altered motor pattern produced pressure waveforms indicative of significant swallow dysfunction. This form was completely ameliorated with intravenous administration of a 5HT1a agonist, 8-OH-DPAT. To further confirm the specificity of action, the selective and competitive antagonist WAY-100635 returned the swallow pattern to the disordered state. While prior work has supported the importance of 5HT in swallow excitability, these new findings support involvement of serotonin in proper execution of motor actions.

Title: The postinspiratory complex (PiCo), a hub for postinspiratory laryngeal closure and swallow related behaviors.

Authors: *A. HUFF[1], M. KARLEN-AMARANTE[1,2], J. RAMIREZ[3,1];
[1]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; [2]Dept. of Physiol. and Pathology, Sch. of Denstistry of Araraquara, São Paulo State Univ., Araraquara, Brazil; [3]Neurolog. Surgery, Univ. Washington, Seattle, WA

Abstract: Breathing consists of three distinct phases: inspiration, postinspiration (postI) and active expiration. PostI is important for breathing, vocalization, cough, swallow and laryngeal control (closure). These behaviors involve laryngeal activity, which serves dual purposes for airway protection during swallow and mechanical slowing of expiration. Dysregulation of laryngeal activity during postI can result in foreign material to enter the larynx and trachea (aspiration) and cause pneumonia, a leading cause of death among many CNS disorders. PiCo, a medullary region composed of neurons that uniquely co-express both cholinergic and glutamatergic markers, has been shown to be active during postI, reset the respiratory rhythm when stimulated, and is proposed as the pattern generator for postI. The role of PiCo in other postI behaviors such as swallow is poorly understood. Our preliminary data revealed activation of PiCo can trigger not only postI, but also swallow, and both behaviors reset the respiratory rhythm. To evaluate the role PiCo plays in postI behaviors we targeted cholinergic and glutamatergic neurons by optogenetically stimulating PiCo in anesthetized spontaneously breathing adult ChATcre/Ai32(ChR2) and Vglut2cre/Ai32 mice. The ventral surface of the brainstem in the region of PiCo was exposed to optical pulses from a 447nM laser for durations ranging from 40-200ms. Swallow was evoked by peripheral stimulation of water injected into the oral cavity and by central stimulation, laser activation of PiCo. Swallow and postI laryngeal activity were measured via monopolar suction electrodes of the hypoglossal (XII) and vagus (X) nerves as well as bipolar electromyogram (EMG) of the submental, laryngeal complex and costal diaphragm muscles. We found a significant increase in swallow duration of water versus PiCo stimulated swallows (*p=0.02)*. Optogenetic stimulation of ChAT or Vglut2 neurons applied at random across different phases of breathing resulted in a significantly higher probability of triggering a swallow during inspiration than triggering laryngeal closure (*p=0.02, p=0.05 respectively).* Water swallows delayed the respiratory rhythm up to two times the normal respiratory rhythm, whereas PiCo stimulated swallows delayed up to half of the respiratory rhythm. Our data indicates PiCo is a hub for the generation of both postI activity and swallowing. Peripheral stimulation of swallow sends afferent information to the nTS shaping the swallow motor pattern. It is plausible that the absence of this afferent feedback in swallow triggered by PiCo stimulation bypasses the dorsal swallow group, directly activating the ventral swallow group.

Title: Biophysical mechanisms of bursts and burstlets in the respiratory preBötzinger complex

Authors: *R. S. PHILLIPS, J. E. RUBIN;
Mathematics, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Inspiratory breathing rhythms arise from synchronized neuronal activity in a bilaterally distributed brainstem structure known as the preBötzinger complex (preBötC). In *in vitro* slice preparations containing the preBötC, extracellular potassium must be elevated above physiological levels (to 7-9mM) to observe regular rhythmic respiratory motor output in the hypoglossal nerve to which the preBötC projects. Reexamination of how extracellular K^+ affects preBötC neuronal activity has revealed that low amplitude oscillations persist at physiological levels (1,2). These oscillatory events are sub-threshold from the standpoint of transmission to motor output and are dubbed burstlets. Burstlets arise from synchronized neural activity in a rhythmogenic neuronal subpopulation within the preBötC that fails to recruit the larger network events, or bursts, required to generate motor output. The fraction of preBötC oscillatory events that are subthreshold (burstlet fraction) decreases sigmoidally with increasing extracellular potassium (2). These observations underlie what is known as the burstlet theory of respiratory rhythm generation. In this computational study, we show how intracellular calcium dynamics in conjunction with a calcium-activated non-selective cationic current, modeled based on previous observations (3,4,5), can explain the key observations underlying the burstlet theory of respiratory rhythm generation. Thus, we provide a mechanistic basis to unify the experimental findings on rhythm generation and motor output recruitment in the preBötC.

Title: Peripheral sensory stimulation elicits global slow waves by recruiting somatosensory cortex bilaterally

Authors: *Z. P. ROSENTHAL[1], R. V. RAUT[2], R. BOWEN[3], A. Z. SNYDER[5], J. P. CULVER[4], M. E. RAICHLE[6], J.-M. LEE[7];

Sch. Med., Saint Louis, MO; [6]Dept Radiol & Neurol, Washington Univ. in St. Louis Sch. of Med., Saint Louis, MO; [7]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Slow waves (SWs) are globally propagating, low-frequency (0.5 - 4 Hz) oscillations that are prominent during sleep and anesthesia. Three decades of local electrophysiology and EEG recordings have demonstrated that SWs are essential to neural plasticity, memory, and grouping of other oscillatory events. However, much remains unknown about the mechanisms coordinating SW propagation at the macroscale - in particular why SW patterns change globally after focal injuries like stroke. Here, we investigate how specific cortical modules and their interhemispheric connectivity contribute to the initiation and global propagation of somatosensory-evoked SWs. To this end, we recorded cortical activity in awake and ketamine/xylazine anesthetized mice, using widefield optical imaging with fluorescent calcium indicator GCaMP6f (n=33, 10-12 week old males, JAX 024276*)*. We then characterize the spatiotemporal properties of cortical waves with space-frequency singular value decomposition and power spectral density analysis. We demonstrate that unilateral somatosensory stimulation evokes bilateral waves that travel across the cortex with state-dependent trajectories. Under anesthesia, we observe that rhythmic stimuli elicit globally resonant, front-to-back propagating SWs. By delivering focal photothrombotic lesions to right forepaw somatosensory cortex (S1), we show that somatosensory-evoked global SWs depend on bilateral recruitment of homotopic S1 cortices. Specifically, unilateral lesions of forepaw S1 disrupt the global coherence of forepaw-evoked SWs evoked from both contralesional (left paw $*P = 0.02$) and ipsilesional (right paw $*P = 0.03$) hemispheres. In contrast, ablation of forepaw S1 spares spontaneous global SWs outside the perilesional area ($^{NS}P = 0.85$), as well as SWs evoked by neighboring

somatosensory modalities (^{NS}P = 0.34). These results show that evoked slow waves may be triggered by bilateral activation of modality-specific, homotopically-connected cortical hubs. Our findings further highlight the existence of mechanisms by which focal injury may disrupt global brain network activity.

Title: Emerging slow waves in premotor cortex of behaving monkeys

Authors: *A. PAZIENTI[1], A. GALLUZZI[1], P. PANI[2], S. FERRAINA[2], M. MATTIA[1];
[1]Inst. superiore di sanità, Rome, Italy; [2]Sapienza Univ. of Rome, Roma, Italy

Abstract: The richness of brain dynamics has been often associated with criticality typically observed in quiescent-to-active state transitions, as an optimal condition for cognitive functions like sensory-motor control and information processing. However, boundaries between different dynamical states were also associated with a different critical transition, as in the sleep-wake cycle, when brain activity goes from asynchronous, highly irregular, to rhythmically regular with low complexity. In the latter condition neuronal assemblies oscillate synchronously, giving rise to the so-called slow waves activity (SWA), characteristic of the deepest sleep stages and under general anesthesia. Disentangling which of these two kinds of critical dynamics occur and what role plays criticality in brain activity still needs to be conclusively elucidated. In particular, criticism has been raised against the assessment of criticality based on coarse experimental measures resulting from the coalescence of local neuronal signals.
Here we address this issue using *in vivo* experiments, data analysis and theoretical tools that have the power to determine whether, and in which condition the brain activity reaches criticality. By measuring intracortical multi-unit activity (MUA) and local field potential (LFP) with multi-electrode arrays chronically implanted in the premotor cortex of two macaque monkeys, we found a rich repertoire of spatiotemporal patterns spontaneously emerging in resting epochs following overt movements in delayed-reaching tasks. Surprisingly, these patterns consisted of MUA Down-to-Up transitions coordinated in space as traveling waves, closely resembling SWA activity during NREM sleep-like anesthesia. We found that during the short resting-like

instances of the activity, but not during the execution of the task or the SWA, neural avalanches of the MUA displayed a scale invariant distribution of their size following power-laws with exponents predicted by the theory of synchronization phase transition.
We reproduced this dynamics in a network of spiking neuron models set to work close to the critical point separating the synchronous and asynchronous global states. Importantly, our neuronal data confirmed the model prediction that the size of the avalanches depends on the preceding level of activity, which determines the amount of "fatigue" accumulated by the network before its sudden activation.
Overall, these findings provide compelling evidence that the premotor cortex, while performing reaching tasks, only sporadically approaches the critical point separating synchronized (sleep) and desynchronized (wake) brain states.

Title: Proposing a duty cycle model for alpha rhythms in human EEG

Authors: *M. MIYAKOSHI, S. MAKEIG;
Swartz Ctr. for Comp. Neursci, Inst. for Neural Comp., Univ. of California San Diego, La Jolla, CA

Abstract: We propose a duty cycle model for human alpha rhythm in scalp-recorded EEG. In the pulse width modulation (PWM) technology, a rectangular pulse wave with a fixed peak amplitude is used. The output is the time-averaged amplitude by duty cycle, which is the ratio between two discrete states, on and off. Today, quantifying EEG power in the frequency domain is a common practice. For example, the recently published Fitting Oscillations & One Over F (FOOOF) is an algorithm to model the power spectral density (PSD). However, as the single-trial EEG properties were 'discovered' after prevalence of trial-averaged event-related potentials (ERPs), recent studies on single-trial time-frequency domain EEG power studies discovered sporadic and discrete 'events' that disappears after averaging. In the same vein, we propose a new model of the classical human occipital alpha rhythm to free it from the implicit assumption of the stationary Gaussian process. We analyzed 34ch scalp EEG data recorded from 150 healthy

adults during eyes-open resting. Total of 270 brain independent components showed dominant alpha peak in the PSD plot that allowed model fitting. We developed the novel peak-power frequency (PPF) ribbon analysis, which sorts the time frames of the spectrogram so that PPF is sorted from low to high. We found the emerging PPF ribbon was fitted with a sigmoid with an extended lower and upper plateaus, which corresponds to off and on states of the alpha rhythm, respectively. The duty cycle ratio across the group was 10%-70% with flat distribution with the peak at 20%. The length of the upper plateau and the height of the PSD alpha peak were positively correlated ($r = 0.53$, $p < 10^{-16}$). Importantly, the peak power distribution across the upper plateau (average range 6.3-13 Hz) was flat with no Gaussian bump, indicating that Gaussian model is not supported. Thus, our duty cycle model is supported by the data, and the Gaussian model was rejected. The results shed light on the distribution of the temporal dynamics of thalamo-cortical network observed at the macroscale electrophysiology. The novel ribbon analysis provides more insights into the generative mechanism of EEG than PSD, which brings the richness of the unaveraged data back to the conventional mean-based statistics.

Title: Altered 12 hour rhythms in the dorsolateral prefrontal cortex of subjects with schizophrenia

Authors: *M. SCOTT[1], K. KETCHESIN[1], W. ZONG[2], M. L. SENEY[1], G. C. TSENG[2], B. ZHU[3], C. A. MCCLUNG[1];

Abstract: Schizophrenia (SZ) is a chronic neuropsychiatric illness associated with cognitive dysfunction and disrupted circadian behaviors. Our lab recently observed a distinct set of diurnally rhythmic transcripts in SZ subjects relative to a cohort with no history of psychiatric illness (non-psychiatric; NP) using rhythmic analysis of RNA-sequencing (RNA-seq) data from the dorsolateral prefrontal cortex (DLPFC), a region associated with executive dysfunction and heavily implicated in SZ. This study found that genes which gained 24 h rhythmicity in SZ were associated with mitochondria dysfunction and GABA-ergic signaling. In the current study, we

examine ultradian rhythms in the same DLPFC data using two types of analysis, a harmonic analysis that accounts for multiple rhythms at once (eigenvaluepencil analysis) and a sinusoidal nonlinear regression analysis that specifically tests for 12 h rhythms in transcript expression. In the eigenvaluepencil analysis, transcripts in the DLPFC of both NP and SZ subjects are enriched for rhythmic components with 12 and 24 h periods. Ingenuity pathway analysis indicates that transcripts with a 24 h rhythmic component are associated with circadian rhythm signaling and various intercellular communication pathways in NP subjects, but mitochondria and GABA receptor signaling in SZ subjects, consistent with our previous findings. In both cohorts, transcripts with 12 h rhythmic components are associated with mitochondria and EIF2 signaling pathways. In the NP cohort, these transcripts peak in expression at ZT 2-3 (~9 AM/PM), but in SZ we observe an anti-phasic shift, with these transcripts peaking in expression at ZT 8-9 (~3 PM/AM). Using the nonlinear regression analysis we observe significant 12 h rhythms in transcript expression and confirm that these are associated with mitochondria and EIF2 signaling pathways in both cohorts, peak at two distinct timepoints (ZT 2-3 and ZT 9), and have an anti-phasic shift in timing in SZ. However, this analysis also uncovered a significant loss of 12 h rhythms associated with the unfolded protein response pathway in SZ. These data suggest alterations at multiple levels in the rhythmic regulation of mitochondria, as well as an overall disruption in the 12 h rhythm system in SZ.

Title: Increase in sleep slow waves after cortical injections of sodium oxybate and the role of SOM+ interneurons.

Authors: *G. M. SPANO[1], W. MARSHALL[1,2], M. L. CAVELLI[1], G. TONONI[1], C. CIRELLI[1]; [1]Dept. of Psychiatry, Univ. of Wisconsin Madison, Madison, WI; [2]Dept. of Mathematics and Statistics, Brock Univ., St. Catharines, ON, Canada

Abstract: The systemic administration of sodium oxybate (SXB), the sodium salt of gamma-hydroxybutyric acid, promotes slow wave activity (SWA, 0.5-4 Hz EEG power) and increases non-rapid eye movement (NREM) sleep. These effects are mediated by GABAb receptors, which are expressed pre- and postsynaptically in cerebral cortex and many other brain regions. Because

slow waves are mainly a cortical phenomenon, we hypothesized that the effects of SXB are partly mediated at the cortical level. Because we found that SOM+ interneurons play a key role in SWA generation (Funk et al. JN 2017), we also hypothesized that the inhibition of SOM+ cells would prevent SXB from enhancing SWA. Adult mice (SOM-Cre [B6N.CgSsttm2.1(cre)Zjh/J; either sex) were implanted with a microdialysis cannula targeting left frontal cortex, and with EEG electrodes and laminar silicon probes (NeuroNexus, A1x16; 50um site spacing) in frontal and parietal cortex ipsi or contralateral to the injection site. In mice used for chemogenetic inhibition of SOM+ cells, the adeno-associated virus AAV8-hSyn-DIO-hM4D(Gi)-mCherry was injected in right frontal cortex. After the microdialysis probe was implanted at Day0, artificial extracellular fluid (aECF) was perfused (0.5ul/min) for 2hrs at Day1, followed by 90min of either aECF or SXB (500µg/ml). For chemogenetic experiments, clozapine-N-oxide (CNO; 0.1mg/kg) or saline was injected i.p. 20min before the infusion of SXB. EEG and local field potential signals were analyzed offline by visual inspection of 4-sec epochs to score sleep/wake states and perform power spectra analysis. During NREM sleep, SWA increased during the first 30min post-SXB injection relative to the 30min pre-injection (11 mice), while it did not change after the infusion of aECF or SXB preceded by CNO (7 mice). The SWA increase was present ipsi and contralateral to the SXB injection in frontal and parietal cortex (paired sample t-tests; SXB, all $p < 0.007$, Cohen's $d > 1.1$; CNO-SXB all $p > 0.43$, Cohen's $d < 0.32$). Using linear mixed effects models, we found no interaction between injection and electrode position and a significant effect of injection ($p = 2.1e\text{-}11$; $f^2 = 0.6625$). Post-hoc tests revealed SXB > CNO-SXB ($p = 1.2e\text{-}10$) and SXB > aECF ($p = 3.9e\text{-}10$). In 5 other mice whose microdialysis cannula was misplaced, the injection of SXB failed to increase SWA. These results show that SBX promotes SWA, at least in part, by acting directly on the cortex, and this effect involves GABAergic SOM+ interneurons. Our working hypothesis is that SXB potentiates the ability of these cells to inhibit all other cortical cell types via a GABAb mechanism, thus promoting the transition from ON to OFF periods during NREM sleep.

Title: Intensive Care Unit delirium is associated with impaired expression of key genes that regulate Rapid Eye Movement sleep and circadian rhythm

Authors: H. OSURU, E. DULKO, J. KLOS, N. ATLURI, M. ILLENDULA, T. LE, Z. ZUO, N. LUNARDI;
Anesthesiol., Univ. of Virginia Hlth. Systems, Charlottesville, VA

Abstract: Background: Delirious patients admitted to the Intensive Care Unit (ICU) after anesthesia and surgery commonly experience loss of Rapid Eye Movement (REM) sleep and circadian rhythm disruption. Experimental studies indicate that *BDNF* plays a crucial role in the gating of light inputs to the brain circadian pacemaker and that muscarinic acetylcholine receptors *Chrm1* and *Chrm3* are essential for REM sleep.**Objective**: To validate our recently established mouse model of ICU delirium by testing for loss of REM sleep and circadian integrity, and for impairment of *BDNF, Chrm1* and *Chrm3* expression, in aged mice subjected to anesthesia, surgery and Intensive Care environment (A/S/I). **Methods:** Aged C57BL/6J mice were randomized to insult (A/S/I) or control group and implanted with electroencephalographic (EEG) and electromyographic (EMG) electrodes for sleep recording. After 2 weeks, A/S/I animals were subjected to 3 h of sevoflurane anesthesia and laparotomy, followed by 2 h of propofol sedation and 12 h of ICU environment. Control mice did not receive A/S/I. 24 hour-long EEG/EMG recordings were obtained at the end of ICU conditions. Hippocampal tissue was collected at completion of EEG recordings for gene and protein expression analysis. **Results:** A/S/I mice exhibited a significant decrease in REM sleep during 12 hours of lights on (rest phase in mice) following ICU conditions. A/S/I mice also spent more time awake with lights on and showed a tendency to spend more time asleep with lights off (active phase), suggesting dysfunction of the internal circadian pacemaker. The expression level of several *BDNF* gene exons was decreased significantly in the hippocampus of A/S/I mice relative to controls (*exon I*:*, p=0.014; *exon IIa*:**, p=0.001; *exon IIb*:*, p=0.01; *exon IV*:**, p=0.006; *exon VI*:**, p=0.005; *exon VII*:**, p=0.004). *BDNF exons IIc, III, V, VIII* and *IXA* levels were unchanged. The expression of *Chrm1* and *Chrm3* genes was also reduced in A/S/I mice, while that of *chAT, Chrm2, Chrm4,* and *Chrm5* remained unchanged. Total *BDNF* protein levels were decreased by 22% and protein levels of *Chrm1 and Chrm3* by 16.4% and 15.5%, respectively, in A/S/I mice compared to controls.**Conclusions:** A/S/I caused disruption of circadian rhythm and loss of REM sleep in aged mice. These sleep-wake changes were associated with impaired expression of *BDNF, Chrm1* and *Chrm3*, key genes for the regulation of circadian rhythm and REM sleep. The changes in circadian rhythm and REM sleep induced by A/S/I are consistent with those experienced by patients with ICU delirium, and support the use of our animal model for future mechanistic studies on the role of sleep disturbances in the pathogenesis of delirium.

Abstract: Sleep spindles (SPI) are physiological events that occur during Non-Rapid Eye Movement (NREM) sleep in both human and rodents. They are thought to be critically involved in cognitive functions and can be measured using electroencephalography (EEG), in rodents and humans using similar modalities. From a drug development perspective, the evaluation of a drug effect on SPI can therefore provide valuable information on target engagement, efficacy and/or safety. Cav3.3 (T-type calcium channel) is known as an important risk gene for schizophrenia and Cav3.3 knock out mice show sleep spindle deficits similar to schizophrenia patients. The aim of the present study was to evaluate the effect of acute administration of a Cav3.3 blocker Compound-5j (Benzecon et al. 2017), in comparison to gamma-butyrolactone (GBL) and Zolpidem on SPI density in rats (i.e. number of SPI over NREM sleep duration).
Eight Sprague-Dawley male rats were instrumented with a telemetry device (TL11M2-F40-EET, Data Sciences International, St Paul MN, USA) under isoflurane anaesthesia. Global cortical EEG and electromyogram (EMG) signals were recorded from leads of the telemetry implant fixed on the skull and the dorsal muscles of the neck, respectively. After a post-surgery recovery period, animals were dosed on separate occasions during the light phase with vehicle (0.5% methylcellulose, *po*), Zolpidem (30 mg/kg, *ip*), GBL (250 mg/kg, *ip*) and Compound-5j (0.3, 3, 30 or 100 mg/kg, *po*) according to a cross-over study design with a 48h wash-out period between two recording sessions. EEG and EMG recording were performed during a 1-hour baseline period, and over two hours post-dosing. Visual EEG/EMG analysis of the whole recording for SPI number and density was performed by a trained-experimenter blinded to the treatment.
No difference in baseline values for sleep duration and SPI density was observed between groups. Although at the dose used, Zolpidem had no effect on NREM sleep duration and SPI density, an overall decrease in NREM sleep duration and SPI density was measured in animals dosed with GBL when compared to controls. Interestingly, Compound-5j was associated with a dose-dependent and significant decrease of SPI density, but without any modification of NREM sleep duration.
In conclusion, the present study is the first to identify a significant modification of SPI activity following pharmacological inhibition of Cav3.3 channels using acute oral dosing with the Cav3.3 blocker Compound-5j. This result is in line with previous work evidencing the critical role of Cav3.3 channels in SPI activity using genetic models.

Title: Unique EEG signature of a $GABA_A$-slow agonist; Propofol vs BB

Authors: *B. MACIVER[1], S. L. EAGLEMAN[2], M. F. DAVIES[3], H. S. MCCARREN[5], E. J. BERTACCINI[4], G. A. MASHOUR[6], D. PAL[6];
[2]Anesthesiol. Dept., [1]Stanford Univ., Stanford, CA; [3]Anesthesia, [4]Anesthesiology, Perioperative and Pain Med., Stanford Univ. and Palo Alto VA, Palo Alto, CA; [5]US Army Med. Res. Inst. of Chem. Def, Aberdeen Proving Ground, MD; [6]Anesthesia, Univ. of Michigan, Ann Arbor, MI

Abstract: IV anesthetic agents like propofol produce increased power in slow delta frequencies (0.1 to 3 Hz), with a general decrease in EEG frequencies above 30 Hz. Propofol is non-selective for $GABA_A$ response subtypes, it enhances all three $GABA_A$-subtypes (slow, fast and tonic). A new anesthetic, BB, selectively targets $GABA_A$-slow synapses to depress brain responsiveness. We hypothesized that a selective GABAA-slow agonist, BB, would produce a different EEG signature compared to the broad spectrum $GABA_A$ agonist (propofol), and tested this using rat EEG recordings. Male rats were used following IACUC approval from the US Army Medical Research Institute of Chemical Defense. Rats were anesthetized using isoflurane (3-5% induction, 1-3% maintenance; with oxygen @ 0.5-1.0 L/min. Stainless steel screw electrodes placed in drilled holes served as cortical EEG leads. Propofol produced an increased power in slow delta frequencies (0.1 to 4 Hz) with a general decrease in EEG frequencies above 30 Hz at loss of consciousness (LOC). BB increased theta activity markedly (3-5 Hz and 8-10 Hz), and slightly increased delta power, but did not depress high frequency responses above 30 Hz. Neither agent produced burst suppression activity at LOC. Both anesthetics produced a characteristic flattening of chaotic attractors, similar to volatile and dissociative anesthetics at LOC. Propofol's EEG effects were in agreement with those seen in previous studies across individuals and species. At LOC a generalized slowing in EEG was seen with increased power in frequencies below 4 Hz. BB produced a markedly different EEG pattern, with a selective increase observed in the theta frequency range. This is interesting because $GABA_A$ slow

synapses have previously been suggested to underlie theta frequency oscillations, while fast synapses control high, gamma frequency oscillations (30-60 Hz). Tonic $GABA_A$ responses produce a generalized depression of neuronal activity across all frequencies. BB and propofol shared the ability to flatten EEG chaotic attractors at LOC, similar to volatile and dissociative anesthetics. Flattened attractors are also seen in humans and thought to reflect a decrease in EEG information content at LOC. It appears that propofol's effects on fast and/or tonic responses contribute to it's respiratory and cardiovascular unwanted side effects, since these were not produced by BB.

Abstract: Fast-paced lifestyles can lead to decreased health and wellbeing, stress-related symptoms, and in many cases sleep disturbances including insomnia. The objective of the current study was to determine whether the natural, multicomponent drug Neurexan (Nx4) could mitigate acute insomnia resulting from exposure to an acute stressor. We administered Nx4 orally to rats and examined the sleep-wake EEG phenotypes with the male rat dirty cage exchange method (CEX) reported by Cano et al., (2008). We selected the CEX model as the molecular and electrophysiological correlates are characterized, and best represents human insomnia conditions. Adult male Sprague-Dawley rats (n=36; CEX;) were randomly assigned as part of a crossover design to one of 6 treatment groups: 1. change over to a clean cage (CCC), or 2. exchange to a dirty cage soiled for a week by another rat (CEX), or 3. vehicle gavage followed by transfer to a clean cage (Veh CCC), or 4. a dirty cage (Veh CEX), or 5. Nx4 gavage followed by transfer to a clean cage (Nx4 CCC) or 6. a dirty cage (Nx4 CEX). Rats were surgically instrumented with cortical EEG electrodes, habituated to a cable tether, and biopotentials recorded (Fig 1). Non-rapid eye movement sleep (NREMS), rapid eye movement sleep (REMS),

and waking states were determined manually off-line in 10 sec epochs. Investigators were blinded to treatments during sleep scoring. One-way ANOVAs compared treatment means for sleep latency and for 2 hrs after cage change for time in each state, state-specific episode duration and frequency. Mixed ANOVAs of time and treatment compared NREMS delta (0.5-4 Hz), NREMS gamma (30-60 Hz) and REMS theta (5-9 Hz) spectral windows. Nx4 CEX rats fell asleep 30.4 mins faster than Veh CEX rats and spent less time awake, with shorter and more waking episodes than Veh CEX rats. Moreover, Nx4 CEX rats were not different from Nx4 CCC rats on any outcomes. No changes between any treatment groups were detected in the EEG spectral windows examined. This research confirms that Nx4 treatment has somnogenic effects and ameliorate psychological stressor-induced acute insomnia.

Abstract: Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) are chemogenetic tools to activate or inhibit a targeted cell population. However, recent reports suggest that the prototypical DREADD agonist, Clozapine-N-Oxide (CNO), can affect brain activity and animal behaviour, putatively through conversion to clozapine. Despite the common use of DREADDs in neuroscience and sleep research, the potential effects of CNO upon sleep have never been systematically tested.We assessed sleep in 16 male C57BL/6 mice after intraperitoneal injections of commonly used doses of CNO and Compound 21 (Cmpd-21), a DREADD agonist which cannot convert to clozapine. Mice were housed under a 12/12 h light/dark cycle, chronically recorded with electroencephalography (EEG) and electromyography (EMG), and injected at light onset. All mice received saline and 5 mg/kg CNO in a counterbalanced design. Some animals also received 10 mg/kg CNO (n=14), 1 mg/kg CNO (n=12), and 3 mg/kg Cmpd-21 (n=7). Conditions were separated by a rest interval of at least 72 hours. Compared to saline, CNO suppressed rapid eye-movement (REM) sleep over the entire six hour observation period ($F_{1.788,22.05} = 7.382$, $p = 0.005$). Changes in sleep architecture consisted of reduced sleep onset latency and increased REM latency, particularly in the 1 mg/kg condition, as well as an increased duration and reduced number of non-REM (NREM) episodes for the 5 mg/kg and 10mg/kg CNO conditions in line with a report by Varin et al. 2018. We also found an increased duration and reduced number of REM episodes for 10 mg/kg CNO. EEG NREM power spectra showed a significant power increase between 0.5-1.25 Hz and decrease above 6 Hz in the 5 mg/kg CNO condition. In addition, CNO reduced the frequency of brief awakenings (4-16s wakefulness, $F_{1.968,23.62} = 10.38$, $p < 0.001$) during the first two hours after injection. Interestingly, Cmpd-21 also suppressed REM sleep, increased the duration and reduced the number of NREM episodes, and reduced the frequency of brief awakenings. Our preliminary results indicate that CNO and Cmpd-21 affect sleep. The pattern is similar to sleep after clozapine injections in rats (Sorge et al., 2004). However, the effects of Cmpd-21 suggest that even without clozapine back-metabolism, DREADD agonists can exert behavioural effects. This might be due to off-target binding at endogenous receptors (Jendryka et al., 2019). Our results require replication with alternative CNO and Cmpd-21 products and in an optimised experimental design. However, they indicate that chemogenetic experiments should include a DREADD-free control group and highlight the need for novel DREADD agonists and chemogenetic tools.

Title: Integrating information and reward into subjective value: lateral habenula activity predicts and causally influences online decision-making

Authors: *Y.-Y. FENG[1,2], E. S. BROMBERG-MARTIN[1], T. OGASAWARA[1], J. WHITE[1], K. ZHANG[1,2], I. E. MONOSOV[1,2,3,4];

Abstract: Every day, humans and other animals make decisions based on our preferences. Prevalent economic and computational theories posit that to make these decisions, individuals must integrate each option's attributes to compute its total subjective value. This is thought to be supported by neural systems for reinforcement learning, which use reward prediction errors (RPE) to update the values of states and actions to guide future decisions. A promising neural substrate for such value learning is the lateral habenula (LHb), known to broadcast RPEs and regulate the activity of midbrain dopamine neurons and other neuromodulators. However, the precise function of LHb RPE signals in decision-making is unclear. In particular, it is unknown whether LHb RPE signals truly reflect overall subjective value, accounting for all attributes defining an option, and it remains unclear whether the LHb RPEs thought to control learning also influence online decision-making. To answer these questions, we designed a multi-attribute decision-making task for monkeys and humans which requires integrating preferences for both primary reward and advance information about uncertain future outcomes. This task allowed us to precisely model the computation of subjective value, by observing subjects' choices between options with independently varied attributes including reward amount, uncertainty, delay, and timing of information to resolve uncertainty. To test LHb's role in this computation, we recorded neurons in LHb and in one of its key inputs, the anterior/ventral pallidum (Pal). We find that many LHb neurons integrate attributes in a manner consistent with subjective value, while many Pal neurons signal attributes such as information and primary reward in distinct manners (see companion poster). We next asked what role the value-related signals in LHb play in determining the ultimate decision. Consistent with previous work, LHb activity was negatively related to value. Therefore, we hypothesized that stronger LHb responses to an option would decrease the option's value and discourage its selection. Indeed, analysis of trial-to-trial response variance indicated that stronger LHb responses to an option predicted a lower probability of

choosing that option. To assess whether LHb value-related activity causally influences decision-making, we used weak electrical stimulation. We find that stimulating LHb during an option's presentation biases choice away from that option in a manner consistent with decreasing its value. These results suggest that RPEs signaled by LHb reflect subjective value integrated across multiple attributes and may influence online decision-making.

Title: Integrating information and reward into subjective value: common computations in humans, monkeys, and basal ganglia-lateral habenula circuitry

Authors: *E. S. BROMBERG-MARTIN[1], Y.-Y. FENG[1], T. OGASAWARA[1], J. WHITE[1], K. ZHANG[4], I. E. MONOSOV[1,2,3,4,5];
[1]Neurosci., [2]Neurosurg., [3]Pain Ctr., Washington Univ. Sch. of Med., Saint Louis, MO; [4]Biomed. Engin., [5]Electrical Engin., Washington Univ., Saint Louis, MO

Abstract: When faced with an uncertain future, humans and animals can be highly motivated to seek information to resolve their uncertainty. Some individuals pay a great deal for this information even when it apparently has no 'objective' value, suggesting that information has a subjective value of its own. However, we know little about the algorithms the brain uses to (i) compute an internal estimate of uncertainty, (ii) compute the subjective value of information to resolve that uncertainty, and (iii) integrate both information and primary reward to guide decision making. To begin to address these questions, we trained humans and monkeys to perform multi-attribute decision making tasks. Individuals chose between pairs of options that provided different probability distributions of primary rewards (money for humans, juice for monkeys). In addition, once chosen, different options provided either informative cues that indicated the upcoming reward outcome, or non-informative cues that did not. Importantly, this design allowed individuals to trade off primary reward to gain information about their future outcomes, while ensuring that the information had no 'objective' value (i.e. information could be used to predict reward outcomes but not to control them). We then fit models to each

individual's choice data to estimate the subjective value of information. We found that in both humans and monkeys (1) most individuals treated information as valuable, (2) the value of information was greatest when reward was uncertain and the information would resolve the uncertainty sooner rather than later, (3) the value of information was tied to a specific form of uncertainty that was remarkably similar across species. To uncover how this subjective value of information is computed by neurons in the brain, we recorded neuronal activity in monkeys. We targeted the lateral habenula (LHb), a nucleus implicated in reward prediction error coding and value learning, as well as its major input sources in the basal ganglia, including the anterior/ventral pallidum (Pal). Many Pal and LHb neurons responded to opportunities to gain information, juice reward, or both. However, there was a key difference: Pal neurons commonly responded to information and juice reward in distinct manners, while LHb neurons commonly integrated them together in a manner closely resembling their total subjective value. Thus, our data sheds new light on the computations humans and animals use to value information, and suggest that pallidum-habenula circuitry may perform a key step in this computation: integrating information and primary reward into subjective value.

Title: The role of the prelimbic cortex in renewal of extinguished behavior based on a return to a satiated interoceptive context

Authors: *C. M. P. THOMAS, E. A. THRAILKILL, M. E. BOUTON, J. T. GREEN; Psychological Sci., Univ. of Vermont, Burlington, VT

Abstract: We have previously shown that the rat prelimbic cortex (PL) is necessary for acquisition contexts to promote the performance of their associated instrumental behaviors, whether that context is physical (operant chamber) or behavioral (recent performance of a chained behavior). In the present experiment, we investigated the role of the PL in satiety level as an interoceptive acquisition context. Rats were trained to lever-press for sweet/fat pellets while sated (22 hrs continuous food access) followed by the extinction of the response while hungry (22 hrs food deprived). Pharmacological inactivation of the PL (with baclofen/muscimol infusion) appeared to attenuate renewal of the response upon a return to the sated context. In

contrast, animals that received a vehicle (saline) infusion showed renewal of the previously extinguished response. In a follow up test, we examined the sensitivity of the response to a change in physical context while animals were sated (interoceptive acquisition context). Interestingly, no effect of a physical context change was detected in either group (PL-inactivated or control), although overall responding in the PL-inactivated group was lower than controls. This pattern of results is consistent with the interpretation that during the initial training and subsequent extinction of the response both groups learned that the relevant contextual element was satiety state and not the physical context. Collectively, these preliminary results support the hypothesis that the PL monitors the relevant contextual elements (physical, behavioral, or satiety state) associated with reinforcement of a response and promotes the subsequent performance of that response in their presence.

Title: Midbrain dopamine neurons provide teaching signals for goal-directed navigation

Authors: *K. FARRELL[1], A. LAK[2], A. B. SALEEM[1];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Successful goal-directed navigation requires learning to accurately estimate location and select optimal actions in each location. Midbrain dopamine neurons are known to be involved in reward value learning, action selection, and have also been linked to reward location learning. Dopamine neurons are therefore ideally placed to provide teaching signals for goal-directed navigation. To test this, we imaged dopamine neural activity using a genetically-encoded calcium indicator and Miniscope as mice learned to navigate in a closed-loop virtual reality corridor and lick to report the reward location. Across learning, phasic dopamine responses developed that resembled reward prediction errors (RPEs) and indicated the animal's estimate of the reward location. We also observed the development of pre-reward ramping activity, the slope of which was modulated by both learning stage and task engagement. The

ramp slope was inversely correlated with locomotor speed, indicating that the ramp did not reflect motor vigour. The slope of the ramp was correlated with the accuracy of reward zone licks in the next trial, suggesting that the ramp sculpted accurate location-specific action during navigation. Both phasic and ramping activity were consistent with temporal difference error in a Q-learning model that incorporated belief about the current state of the agent. Preliminary analysis also shows that the ramping activity was also present in individual dopamine neurons, with variance in ramp slope across neurons. Our results indicate that midbrain dopamine neurons, through both their phasic and ramping activity, provide teaching signals for improving goal-directed navigation.

Title: Activity dynamics in the central nucleus of the amygdala during habit formation

Authors: *K. A. AMAYA, J. E. CARMICHAEL, J. A. PALMER, K. S. SMITH; Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Habits are behaviors that are notoriously automatic, consistent, and inflexible and emerge with repeated performance of an action. Neural recordings of key habit-promoting brain areas like the infralimbic cortex, dorsolateral striatum (DLS), and substantia nigra have characterized activity dynamics while a habit is formed and executed (Graybiel and Smith, 2013; Jin and Costa, 2010). Meanwhile, as the central nucleus of the amygdala (CeA) has been extensively studied with respect to threat learning, a smaller body of literature has implicated this amygdalar nucleus as being involved in reward seeking and habits as well. In particular, the CeA has been shown to be necessary for the general motivational influence of Pavlovian cues over instrumental behaviors and, separately, lesions to the CeA abolish habit formation (Corbit and Balleine, 2005; Lingawi and Balleine, 2012). Additionally, although there are no known direct projections between the two areas, contralaterally lesioning DLS and CeA similarly abolishes habit formation, further solidifying the idea that the CeA is involved in the habit formation process. To formally address this, we trained animals on an elevated plus-maze task that consistently required a specific response to earn rewards and subsequently quantified c-Fos

expression in the CeA. In the next experiment, we implanted animals with silicon probes targeting the CeA and recorded neural activity throughout training and during post-outcome devaluation extinction and reacquisition sessions. Our findings show that CeA neurons are recruited during habit formation (as evidenced by c-Fos expression) and that CeA neural activity may fluctuate as habits are formed to accentuate pre- and post-reward delivery.

Title: Dopamine neurons signal 'true' subjective value (willingness-to-pay) prior to bidding in a Becker-DeGroot-Marschak auction-like mechanism in rhesus macaques.

Authors: *D. F. HILL, R. W. HICKMAN, W. SCHULTZ;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Dopamine neurons play a prominent a role in choice behavior by signaling the utility of choice options when animals are presented with their associated cues. Dopamine neurons have also been shown to encode the relative value of chosen goods prior to choices being made, altering activity based on which good will be chosen. Whether these responses reflect the learned probability of reward, or an intrinsic, subjective value estimation remains unclear. To test whether dopamine neurons encode an estimate of one's 'true' subjective value, we trained rhesus monkeys to bid in a Becker-DeGroot-Marschak (BDM) auction to elicit their willingness-to-pay for juice rewards while recording from single midbrain dopamine neurons. The BDM is unique in that it is incentive compatible; that is, the best strategy is to bid one's 'true' value. Critically, the BDM offers a trial-by-trial measure of utility that more accurately resembles real-world moment-to-moment value fluctuations. Monkeys were trained to associate images of fractals with varying amounts of juice reward. They were then allowed to bid for the juice indicated by a specific fractal while paying the associated price from a fixed 'budget' of water. After their bid, they were shown the opponent's bid (i.e., random computer bid), revealing whether they had won or lost the auction. In two monkeys, dopamine responses to fractal cues reflected the bid that the animals would subsequently make, even when reward magnitude was held constant. That

is, when presented with fractals representing three separate reward levels, dopamine neuron responses varied with the monkeys' bids prior to the bids being made. Moreover, responses correlated with bids when analyzing reward levels individually. These data show that dopamine responses reflect an intrinsic value estimate of goods prior to actions taken to acquire them. These responses allow dopamine neurons to be involved in guiding actions to obtain the highest utility.

Title: The paraventricular nucleus of the thalamus contributes to early-life adversity-induced deficits in reward-related behaviors

Authors: *C. L. KOOIKER[1], M. T. BIRNIE[2], Y. CHEN[3], T. Z. BARAM[4];
[1]Anat. and Neurobio., [2]Pediatrics, Univ. of California, Irvine, Irvine, CA; [3]Pediatrics, [4]Univ. of California Irvine, Irvine, CA

Abstract: Rationale: Early-life adversity (ELA) is associated with poor cognitive and emotional health and increased risk for a variety of affective disorders, such as major depressive disorder and bipolar disorder. Many of these disorders are characterized by impairments in reward-related behaviors, and we find that these same deficits are provoked by rodent models of ELA. However, the brain regions and processes underlying these long-term consequences of ELA remain largely unknown. The paraventricular nucleus of the thalamus (PVT) is an important component of the reward circuit that encodes remote emotionally salient experiences to influence future motivated behaviors. We hypothesize that the PVT encodes adverse experiences as remote as the early postnatal period in mice, and that ELA-engaged PVT neurons subsequently contribute to deficits in reward-related behaviors in adults. **Methods:** We employ TRAP2 mice, which we exposed to a week of simulated ELA in a limited-resource cage between postnatal days 2-9. We induced the TRAP2 system using tamoxifen on P6, triggering Cre-dependent recombination in neurons activated during P6-P8. This leads to permanent marking of neurons activated during this epoch. We validated our findings using routine cFos immunohistochemistry

in WT mice. **Results:** ELA robustly and selectively activates PVT neurons to a degree much higher than typical rearing conditions. We are now characterizing the molecular phenotype of these ELA-engaged neurons, focusing on the stress-sensitive neuropeptide CRH and its receptors. Finally, we aim to silence these ELA-engaged PVT neurons during reward-related tasks in adult mice, with the possibility of ameliorating the observed ELA-induced deficits in reward-seeking behaviors. **Conclusion:** The PVT robustly and almost uniquely expresses cFos in response to emotionally salient events in neonatal mice. The PVT is thus poised as a potential contributor to deficits in reward-related behaviors following ELA.

Title: Acute stress impacts reward consumption via different VTA neural activity than reward anticipation

Authors: D. C. LOWES[1], A. A. AMILCAR[2], E. S. HOLT[3], L. YUSUFOVA[2], ***A. HARRIS**[4]; [1]Pharmacol., [2]Columbia Univ., New York, NY; [3]Res. Fndn. for Mental Hyg., New York, NY; [4]Psychiatry, Columbia University/Research Fndn. for Mental Hyg., New York, NY

Abstract: Acute stress impairs reward seeking, but the underlying neural circuitry deficits are incompletely understood. We recently demonstrated that acute stress impairs reward anticipation ventral tegmental area (VTA) GABA neurons projecting to the nucleus accumbens (NAc), but until now there has been little evidence of the effect of stress on reward consumption. We recorded single unit activity in the VTA as mice engaged in a cued-reward task after exploring a familiar environment and after exposure to restraint stress. We found that stress decreases reward consumption independent of its effects on reward anticipation (N=13 mice, $p<0.01$). Surprisingly, while we recently demonstrated that restraint-induced 4 Hz NAc LFP oscillation strength correlates with reward anticpation deficits, this oscillation did not correlate with the effect of restraint on reward consumption. In addition, while stimulating NAc-projecting VTA GABA neurons impairs reward anticipation, it spares reward consumption (N=5 mice, $p=0.47$). Finally, we found that restraint impairs the firing of putative VTA DA neurons during reward consumption ($n_{Familiar} = 80$ neurons, $n_{Restraint} = 80$ neurons, $p<0.05$) but had no effect on putative VTA GABA neurons during reward consumption ($n_{Familiar} = 29$ neurons, $n_{Restraint} = 22$

neurons, p>0.5). Together, these data suggest that stress impairs reward consumption via altered VTA DA activity, while stress impairs reward anticipation via altered VTA GABA activity.

Title: Role of Ventral Midbrain Dopamine Neurons in Familiarity

Authors: *R. KOLARIC[1], S. FLEURY[1], A. TOFT SØRENSEN[2], U. GETHER[3], S. MINGOTE[1];
[1]Advanced Sci. Res. Ctr., CUNY, New York, NY; [2]Ctr. for Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [3]Fac. of Hlth. and Med. Sciences, Univ. Copen, Copenhagen N, Denmark

Abstract: It is well established that dopamine (DA) neurons in the ventral midbrain signal novelty by increasing their bursting activity, while decreasing it after repeated inconsequential stimulus presentations. Thus, the lack of DA neuron burst activity is a physiological signature that a particular stimulus has become familiar. Here, we tested the hypothesis that decreasing DA neuron activity while animals explore objects for the first time enhances familiarization and improves subsequent novel object recognition (NOR).
NOR is dependent on the amount of pre-exposure to the familiar object, and we showed that one familiarization session results in poor novelty discrimination. The lack of increased exploration of a novel object is thought to reflect a stage of equal attention allocated to the familiar and novel stimulus. To investigate whether decreasing DA neuron activity prompts gain-of-function in NOR, we chemogenetically inhibited DA neurons in the ventral tegmental area (VTA) during the familiarization session of this NOR paradigm.
We injected an AAV *flp*-dependent hM4Di into the VTA of TH-*flp* transgenic mice to selectively inhibit DA neurons. The selectivity of the viral strategy was verified via immunohistochemistry staining. The virus was then activated via injection of Clozapine N-oxide dihydrochloride (CNO; i.p.) 30 minutes before trial. We found that inhibiting DA neurons during the familiarization phase resulted in enhanced novel object recognition in hM4Di+CNO male mice compared to controls, using the discrimination index (DI) for the time exploring the objects. Additionally, we observed similar effects in hM4Di+CNO female mice compared to controls, although sex-mediated differences in exploratory behavior emerged. Female mice tended to explore through shorter but more frequent burst-like visits to the object compared to

male mice whose visits to the objects tended to be longer but less frequent. Although hM4Di+CNO female mice showed no increase in DI for time exploring the objects, the DI for the average time per visit revealed a significant difference between groups, indicating that females also show increased discrimination. Finally, to confirm these results were due to an effect on familiarization processes, we conducted further trials in which DA neurons were only inhibited after the familiarization phase and during subsequent NOR session. Under this manipulation, we did not see an improvement in discrimination. These results suggest that suppressing DA activity ameliorates novelty discrimination by enhancing familiarity in both females and males despite differences in patterns of exploratory behavior.

Title: A data driven approach to analyze rat ultrasonic vocalizations

Authors: K. LAWSON[1], A. FLORES[1], R. HOEKENSON[1], C. M. RUIZ[1], S. V. MAHLER[2]; [1]Univ. of California, Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Rats emit ultrasonic vocalizations (USVs) to convey emotional arousal, and/or as a form of social communication about salient rewards and threats in the local environment. In adult rats, these USVs fit into two broad categories; “22kHz” calls that are produced when the rat is in a painful or dangerous situation, and “50kHz” calls, which are emitted during experience or anticipation of rewards like play, mating, or certain drugs of abuse. Relatively recent advances in USV detection hardware and analysis software have made it possible to examine more nuanced aspects of rat USVs, for example showing that “50kHz” calls occur at a range of frequencies and patterns—with up to 14 subtypes (Wright et al., 2010). It is not presently clear whether these complex signals contain information that could be of use to behavioral neuroscientists for interrogating the subjective states of rats.
Here, we examined USVs emitted by male and female Long Evans rats under a variety of circumstances, in hopes of narrowing down the information that is potentially contained within these mysterious vocalizations. We recorded USVs after administration of drugs like amphetamine, heroin, and ketamine, and examined how chemogenetic inhibition of nucleus accumbens or ventral tegmental area dopamine neurons impacted the rate of USV production. Further, we validated and employed Deepsqueak (Coffey et al., 2019) software to more precisely

identify the acoustical features of USVs, generating large datasets which allowed us to employ high dimensionality reducing analyses to determine how the characteristics of USVs are altered by these pharmacological and chemogenetic manipulations. We expect that these studies will facilitate further data-driven investigations into the insights USVs may afford into rats' subjective states during behavioral neuroscience experiments.

Title: Increased Startle Response and Anxiety-Like Behavior in a Mouse Model of Traumatic Stress

Authors: *B. L. W. SWEETEN[1], M. T. WATSON[2], J. G. TASKER[1];
[1]Cell and Mol. Biol., [2]Tulane Brain Inst., Tulane Univ., New Orleans, LA

Abstract: Post-traumatic stress disorder (PTSD) is a stress-and trauma-related disorder affecting approximately 8% of the population, with higher incidence rates among women and the military. PTSD is associated with hyperactivity of the amygdala, a key region for adaptive stress and fear processing. Amygdala hyperactivity is thought to be the cause of hyperarousal symptoms of PTSD, which include hypervigilance, increased startle response, heightened anxiety, and perturbed sleep. Specifically, traumatic stress disrupts the excitatory and inhibitory balance within the basolateral nucleus of the amygdala (BLA), resulting in long-term maladaptive stress processing. The purpose of this study is to determine the impact of intense, uncontrollable stress on hyperarousal symptoms and fear learning in a mouse model. Five-week-old male and female C57Bl6/J mice were tested on day 1 for their baseline acoustic startle response (ASR) to 15 110 dB white noise bursts delivered at a 30-s inter-tone interval. On days 2-4, the mice were exposed to 3 consecutive days of traumatic stress, which consisted of 40 2-mA, 2-s shocks while restrained over a 2-h period. The mice were retested on days 9-11 for ASR and were assessed for anxiety-like behavior using the elevated plus maze (EPM) and open field test. Cued fear conditioning was performed on day 15 and fear memory extinction was assessed on days 16-19. Finally, on day 22, mice were tested for ASR a final time. Mice exposed to the traumatic stress paradigm had significantly higher ASR on days 11 ($p<0.05$) and 22 ($p<0.001$) compared to

baseline, while control mice showed a similar ASR across the three time points. Mice exposed to traumatic stress showed an increase in anxiety-like behavior, spending less time in the open arms of the EPM ($p<0.05$) and more time in the perimeter of the open field compared to control mice ($p<0.05$). Finally, traumatic stress-exposed mice showed greater fear memory acquisition ($p<0.05$) but no difference in fear extinction compared to control mice. Our results indicate that this traumatic stress paradigm induces a hyperarousal phenotype and increases anxiety-like behavior in the mouse. We are using this model to further assess the cellular and molecular mechanisms underlying these behavioral endpoints induced by traumatic stress.

Title: Estrogen receptor beta in oxytocin neurons mediates social behavior and hypothalamic-pituitary-adrenal axis stress response in novel transgenic mouse line

Authors: *J. A. SHENG, R. M. DANIELS, A. M. MILLER, S. A. MYERS, N. J. BALES, R. J. HANDA;
Biomed. Sci., Colorado State Univ., Fort Collins, CO

Abstract: Estrogens (E) influence a myriad of neuroendocrine and behavioral functions. The dichotomous effects of E are regulated by two specific receptors in the brain, E receptor alpha (ERα) and E receptor beta (ERβ). These receptors have been shown to induce opposing actions on the hypothalamic-pituitary-adrenal (HPA) axis stress response and related behavior. While ERα is generally shown to produce an anxiogenic effects, ERβ produces anxiolytic effects. Reports further demonstrate ERs in modulating neuropeptide systems that drive sex differences in stress regulatory systems. Estrogen receptor β is predominantly co-expressed with oxytocin (OT) in the paraventricular nucleus of the hypothalamus (PVN), the core regulator of the HPA axis. Therefore, Es have been highly implicated in the OTergic system in mediating the stress response and associated behaviors. In this study, we used Cre/loxP recombination to delete exon 3 of the ERβ gene in OT neurons, generating a novel $OT^{cre}/ER\beta^{loxP/loxP}$ mouse model on C57BL/6 background. Controls used were $ER\beta^{loxP/loxP}$ or OT^{cre} mice. To validate this model, droplet digital PCR was used to quantify ERβ mRNA in the PVN, which showed ~50% reduction ($p<0.0001$) in adult M and F mutants (n=8/sex). Using a 3-chamber apparatus (n=12-15/sex), we next examined social behavior. In the social discrimination test, M and F mutants

showed decreased social interaction with the stimulus mouse (S1; p=0.0481). In the social recognition test, a second stimulus mouse (S2) was placed at the opposite end of S1 in the apparatus. While control F preferred interacting with S2 (p=0.0461), mutant F preferred the familiar S1 (p=0.0218). Interestingly, control M preferred S2, but mutant M interacted with S1 and S2 equally. In the social memory test, interaction with a 3rd stimulus mouse (S3) versus S1 was examined. Preference for familiar mouse in this test was observed in only mutant F (p=0.0313). Social behavior results implicate ERβ in the OTergic system in promoting social behavior in F but not M. Finally, stress-induced corticosterone secretion was decreased in mutant versus control F following acute restraint (p=0.0121), but not in mutant M (n=12-15/sex). This suggests Es actions on ERβ in OT neurons stimulate the HPA axis stress response in F, but not M. Taken together, these data indicate an important role of ERβ in the OTergic system in regulating sex differences in behavioral and neuroendocrine physiology. Understanding actions of E on these physiologic functions could be important for determining the underlying role of sex in stress-related diseases in humans, such as social disorders, anxiety, and depression. Title: Impact of Peripartum Stress on Postpartum Maternal Behavior and Associated Endocrine and Neurobiological Substrates

Authors: *J. PLUCHINO, J. GIFFORD, J. SCHWARZ;
Univ. of Delaware, Newark, DE

Abstract: The purpose of this study is to measure the impact of prenatal stress on postpartum maternal behavior in addition to the levels of estrogen receptor alpha (ERα), specifically in the medial preoptic area (mPOA), as well as measuring the effects of stress on anhedonia by sucrose preference test. A limited bedding and nesting (LBN) condition was applied to half of the cohort. They received 250 mL of bedding compared to the control group which received 4000 mL of bedding. The purpose of this condition is to simulate a stressful environment which simulates stressors a new mother might experience when lacking adequate resources to care for her infant. Maternal behaviors of LBN and control animals were recorded twice daily for 30 minute time

periods, once in the morning and once in the evening. The footage was then analyzed and hand-scored on a minute-by-minute basis, choosing from a list of 17 behaviors. A mixed model analysis was used to analyze the data. A sucrose preference test was performed to measure for anhedonia using a 1% sucrose solution for 48 hours at 4 timepoints throughout the study (prior to breeding, E20-22, P0-2, P7-9). Additionally, tissue samples were collected from a total of 60 animals (same animals that were observed with maternal behavior) and were sliced at 30 μm. Slices were then stained, mounted and analyzed via microscope to examine cell count of ERα in the mPOA. The analysis of maternal behavior, although ongoing, is anticipated to exhibit a decrease in positive maternal behaviors within the LBN group, characterized by postures such as arch back nursing, pup licking, and retrieving pups. In regards to the sucrose preference test, we found the most significant decrease in preference among both LBN and control groups during the P0-P2 and P7-P9 time points when compared to baseline measurements. Specifically, in the P7-P9 time point, there are distinct groups of dams with high and low preference, suggesting that stressors do not have a uniform effect on the entire cohort, regardless of group condition. In regards to the stained tissue, we anticipate a larger proportion of ERα found in the mPOA to be correlated with more positive maternal behavior. This analysis is ongoing. With a lack of research which specifically focuses on postpartum depression, the use of an animal model proposes a new approach in observation. The findings of this study should prove to be beneficial in elucidating biomarkers of PPD to aid in the proper and accurate diagnosing of cases.

Title: Characterizing the Role of Dopamine D3 Receptors on Dopaminergic Neurons on Anxiety like Behavior

Authors: *M. SHAW[1], M. BOCARSLY[2], V. A. ALVAREZ[1];
[1]Lab. on Neurobio. of Compulsive Behaviors, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [2]Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: Dopamine transmission in the striatum plays an important role in alcohol reward and reinforcement and is mediated by a family of G protein-coupled dopamine receptors, dopamine D1 - D5. The D1 and D2 receptors are often the focus of addiction research, and while the dopamine D3 receptor (D3R) has been indicated in alcohol seeking and relapse, very little is known about the specific role of this receptor. The purpose of this project is to behaviorally characterize the role of the dopamine D3R on midbrain dopaminergic neurons in alcohol intake.

We developed a novel transgenic mouse with a selective knockdown of D3Rs on the midbrain dopamine neurons (DATD3R KO). Because these studies employ a new transgenic model, potential behavioral phenotypes including, locomotion and anxiety-like behavior were explored. No differences were seen between DATD3R KO mice and littermate controls in basal locomotion or anxiety-like behavior using the elevated zeromaze, light/dark box, open-field and novelty suppressed feeding. We then assessed alcohol intake in the DATD3R KO mouse. No differences were seen in alcohol intake using two alcohol intake paradigms, an ethanol preference test and intermittent ethanol drinking task. These data indicate that D3Rs on dopaminergic neurons are not necessary in promoting increased preference for or consumption of ethanol.

Title: Aspartame exposure of male mice produces heritable behavioral phenotypes

Authors: *S. JONES[1], D. M. MC CARTHY[1], P. G. BHIDE[2];
[2]Biomed. Sci., [1]Florida State Univ. Col. of Med., Tallahassee, FL

Abstract: The use of low-calorie sweeteners as weight loss tools is highly prevalent. In the US, approximately 25% of children and 40% of adults report using low-calorie sweeteners. Aspartame is among the most widely used low-calorie sweeteners worldwide. We examined whether aspartame exposure produces behavioral changes in male mice, and if offspring derived from the aspartame-exposed males display behavioral alterations. We exposed adult (6-8 week) male C57BL/6 mice to drinking water containing aspartame (0.03% or 0.015%; to deliver aspartame at doses equivalent to 100% and 50%, respectively, of FDA's Acceptable Daily Intake for humans). Following 12 weeks of aspartame exposure, we analyzed anxiety-like behavior (open field test), spatial working memory (Y-maze), and spatial learning and recall memory (Barnes maze). The data were analyzed for statistical significance by ANOVA followed by *post hoc* pairwise comparisons among the different experimental groups, whenever a significant main effect or interaction effect was present. The mice exposed to either dose of aspartame displayed significant anxiety-like behavior, spatial working memory deficit, and a significant deficit in acquisition of spatial learning. A single administration of diazepam (3 mg/kg; i.p.) produced significant downregulation of the anxiety-like behavior, suggesting the involvement of GABA

neurotransmission in the aspartame-induced phenotype. The aspartame-exposed and control mice were bred with drug-naïve females. Male and female offspring derived from the aspartame-exposed males displayed anxiety-like behavior and spatial working memory deficit demonstrating heritability of these behaviors. Ongoing studies are examining whether the anxiety-like phenotype in the offspring responds to diazepam and if aspartame-induced changes in GABA neurotransmission are heritable as well. In summary, our data show that aspartame exposure even at levels equivalent to 50% of the FDA recommended human daily intake, carries the risk of adverse behavioral outcomes not only in individuals exposed to the aspartame but also their descendants.

London, London, United Kingdom; [6]Transpharmation Poland Ltd., Univ. of Warmia & Mazury in Olsztyn, Olsztyn, Poland

Abstract: Duchenne muscular dystrophy (DMD) is a neuromuscular disorder in which dystrophin loss, caused by mutations in the *DMD* gene, affects muscle and cognitive-affective functions. In the past 30 years new DMD mouse models have emerged to investigate how

specific *DMD* mutations, impacting different dystrophin isoforms, contribute to neurobehavioural comorbidities. We examined anxiety-like behaviours, emotional reactivity and fear conditioning (FC) in two such models, bred on a C57BL/6 background: the *mdx52* mouse, in which exon 52 deletion eliminates production of both Dp427 and Dp140 brain dystrophins, and the *mdx*^{5cv} mouse, carrying a point mutation in exon 10 that exclusively impairs Dp427 expression. Hemizygous *mdx52* or *mdx*^{5cv} male mice and wild-type littermate controls (WT) aged 6-7 weeks and 3-4 months (n=8-17/genotype) were tested in the elevated zero maze (EZM) for 5 min to assess state anxiety; unconditioned fear responses (UFR) were then assayed by scruff-restraining mice for 15 s followed by 5 min of locomotor activity monitoring. In the EZM, *mdx52* and *mdx*^{5cv} mice displayed heightened anxiety, e.g., a significantly lower time spent in open maze sections compared to WT, at all ages. Enhanced anxiety was confirmed in 2-month-old *mdx52* mice compared to WT, as significant decreases in time spent in the central area of an open field (n=14 WT, 15 *mdx52*), or in the lit chamber in a light-dark choice test and in open arms of an elevated plus maze (n=9 WT, 12 *mdx52*). In the UFR assay, restraint-induced freezing time was found significantly higher compared to WT in young and adult *mdx*^{5cv} mice (>78% of test time in *mdx*^{5cv} vs <20% in WT) and *mdx52* mice (>80% of test time), indicating that cumulative Dp427 and Dp140 loss does not worsen fear responses in this test compared to selective Dp427 loss. Acquisition of cued FC was significantly impaired in *mdx52* and *mdx*^{5cv} mice, as reflected by a strongly reduced amount of freezing compared to WT in response to the conditioned stimulus (tone predicting negative reinforcement delivery). These findings resemble those obtained in analogous paradigms in the well-characterised *mdx* mutant mouse lacking Dp427 (*mdx23*), yet behaviour abnormalities were more clearly expressed in the present study. This indicates that loss of dystrophins at brain level is associated with enhanced emotional and stress reactivity and impaired amygdala-dependent associative learning for both proximal (*mdx*^{5cv}) and more distal (*mdx52*) *Dmd* mutations. Phenotypic commonalities observed across DMD mouse models in the assays described make emotional reactivity and fear learning optimal neurobehavioural readouts to investigate brain function-targeted therapies in DMD.

Title: Deletion of FKBP51 in POMC cells shapes the stress response and whole-body metbolism

Authors: *L. M. BRIX[1], A. S. HÄUSL[1], I. TOKSZOEZ[1], J. BORDES[1], L. VAN DOESELAAR[1], C. ENGELHARDT[1], H. YANG[1], M. SPRINGER[1], S. NARAYAN[1], M. L. PÖHLMANN[1], S. MITRA[1], J. DEUSSING[2], N. C. GASSEN[3], A. CHEN[4], M. V. SCHMIDT[1]; [1]Neurobio. of Stress Resilience, [2]Res. Group Mol. Neurogenetics, Max Planck Inst. of Psychiatry, Munich, Germany; [3]Dept. Psychiatry and Psychotherapy, Universitätsklinikum Bonn, Bonn, Germany; [4]Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: There is increasing evidence of a high co-morbidity of metabolic and mental health disorders, but the underlying mechanism linking these disorders is largely unresolved. The co-chaperone FKBP51 is a very promising candidate in this context, as it has previously been genetically and functionally linked to metabolic and psychiatric disorders and plays a central role in the regulation of the stress system, which is a common risk factor for both disorders. Furthermore, FKBP51 was shown to be expressed in POMC-positive cells, which play a key role in metabolic control in the arcuate nucleus (ARC) and are also central in mediating the body's stress response in the pituitary gland. We therefore here tested the hypothesis that FKBP51 expression in POMC-positive cells may be causally involved in the regulation of stress and metabolism.
Using a Pomc$^{Fkpb5\text{-}/\text{-}}$ knockout line or virally-mediated region-specific FKBP51 overexpression, we assessed the standard diet (SD) and high fat diet (HFD) induced metabolic phenotypes as well as basal and stress-induced hypothalamic-pituitary-adrenal (HPA) activity.
Our results confirmed that lack of FKBP51 in POMC cells of the pituitary leads to an enhanced Glucocorticoid receptor (GR)-mediated negative feedback and thereby a suppression of HPA axis function. At the same time, deletion of FKBP51 in POMC neurons of the ARC is driving resistance to diet-induced weight gain, which is independent of food intake.
Taken together, our data underline the cell type specific effects of FKBP51 in regulating the stress response and metabolism and position this protein as a promising molecular player and pharmacological target that acts at the interface of metabolism and stress related physiological changes.

Title: Molecular neurobiology of enrichment loss: role of microglia and the extracellular matrix

Authors: *M. A. SMAIL[1], R. SHUKLA[2], J. L. BOLLINGER[1], R. PARIKH[1], R. E. MCCULLUMSMITH[2], J. P. HERMAN[1];
[1]Pharmacol. and Systems Physiol., Univ. of Cincinnati, Cincinnati, OH; [2]Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Psychological loss can erode well-being and precipitate depression. Here, we emulate loss by exposing rats to protracted environmental enrichment and subsequently removal to an impoverished environment. Previously, multi-omics analyses revealed that enrichment removal (ER) dysregulates immune signaling and cell-matrix communication in the basolateral amygdala (BLA) of male rats. Here, we further investigate these microglia and extracellular matrix-related phenotypes to more clearly define their role in the mechanisms underlying loss. All studies feature 3 groups of adult male rats: environmentally enriched (EE), enrichment removed (ER), and control. EE and ER animals were housed in groups of 10 in large, multi-level cages with toys. After 4 weeks, ER animals were moved to single-housing, simulating the experience of loss. Two weeks after removal, brains were collected for analysis of microglia and matrix-related endpoints in the BLA. Immunohistochemistry revealed that microglia were smaller in EE and ER, and expressed significantly less CD68, a marker of phagocytosis, in ER alone. This supports the role of microglia previously identified in the multi-omics analysis and suggests that ER impairs the ability of microglia to interact with their surroundings. One such interaction suggested by the omics is digestion of the extracellular matrix. ER increased the total amount of WFA, a marker of extracellular matrix, in the BLA, as well as the number of perineuronal nets around inhibitory parvalbumin interneurons. This increase in perineuronal nets was accompanied by decreased synaptic input, both excitatory (vGLUT) and inhibitory (vGAT), onto the parvalbumin cells, providing a potential link between impaired microglia-matrix interactions and altered BLA output in ER. Altogether, these results suggest that ER impairs microglia activity, allowing for accumulation of extracellular matrix, blocking synaptic input onto parvalbumin interneurons, impairing their ability to inhibit the excitatory output of the BLA. In a region like the BLA that is critical for driving stress responses, this decreased plasticity could precipitate loss phenotypes and play a key role in driving subsequent behavioral impairments. This mechanism not only deepens our understanding of the molecular effects of psychological loss, but also reveals several intriguing targets, including microglia and perineuronal nets, that could be used to develop novel therapeutics aimed at ameliorating loss.

Title: Assessing mouse behavior and microglia morphology in a prolonged stress model of post-traumatic stress disorder

Authors: *J. HOLSTEN, T. COTHREN, K. PRESCOTT, D. MACQUEEN, T. PETERSON; Univ. of North Carolina Wilmington, Wilmington, NC

Abstract: Post-Traumatic Stress Disorder (PTSD) is characterized as exposure to a traumatic event, which manifests into dysfunctional behaviors such as hyperarousal and intrusive thoughts that can disrupt a person's well-being. Currently, PTSD is classified by the DSM-V criteria of outwardly expressed behaviors (i.e., anxiety, negative alterations in cognition and mood, and altered arousal and reactivity). However, there are various anxiety- and fear- related psychiatric disorders that share common symptomology with PTSD. Recent data suggests microglia alter their morphology and function in primary brain regions associated with the disorder (i.e., prefrontal (PFC), hippocampus, and amygdala) that accompany the dysfunctional behaviors. The current study used C57Bl/6j mice (male and female) to measure dysfunctional behavior and assess microglia morphology in a PTSD mouse model of prolonged stress. This stress model consisted of 2 hr restraint stress, 20 min forced swim, exposure to diethyl ether until unconscious, and single housing for the remainder of the study. This PTSD model has been shown to induce behavioral and physiological deficits that mimic the human condition. Behavior, corticosterone, and neuropathology measures were assessed across four groups (naïve; n = 11, single housed; n = 9, single prolonged stress (SPS); n = 9, and repeated prolonged stress (rSPS); n = 9). Stress groups displayed significant differences in anxiety-like ($p < 0.05$), social ($p < 0.05$), and nest building ($p < 0.05$) behavior tasks. Corticosterone levels had roughly a three-fold increase in stress groups compared to naïve animals ($p < 0.01$) suggesting the stress hormone was upregulated in stress groups compared to naïve animals. The data collected thus far have replicated behavioral and corticosterone levels from past animal and human studies. Immunofluorescence was conducted with ionized calcium binding adaptor molecule 1 (Iba1) to label microglia and DAPI, and imaged with a confocal microscope to create a 3-D image using z-stacks. Currently, we are imaging and analyzing branch (i.e., process length, number of processes, end points, etc.) and fractal data (i.e., fractal dimension, span ratio, complexity, etc.) of microglia in the PFC, hippocampus, and basolateral amygdala. Establishing the morphological and functional changes of microglia in these commonly used mouse models of PTSD is crucial for developing possible future treatments, as well as other disorders where microglia are maladaptive.

Title: Role of a Human Polymorphism (rs2304297) in the 3'-UTR of the CHRNA6 Gene in Nicotine-Modulated Behaviors in Adolescent Sprague-Dawley Rats

Authors: *A. CARDENAS[1], S. LOTFIPOUR[2];
[1]Univ. of California, Irvine, Irvine, CA; [2]Emergency Med. & Pharmacol., UCI, Irvine, CA

Abstract: The initiation of nicotine-containing product use typically occurs prior to the age of 18. Adolescence is a period in development where the maturation of brain neurocircuitry is vulnerable to nicotine exposure. With recent escalation of e-cigarette use among adolescents, it is critical to identify at-risk populations and potential therapeutic targets to prevent and treat nicotine dependence. In human adolescents, a single nucleotide polymorphism (SNP), rs2304297, at base pair 123 in the 3'-untranslated region (UTR) of the CHRNA6 gene (encodes the alpha(*α)*6 nicotinic receptor subunit), has been associated with increased smoking and substance use. Moreover, *α*6 nicotinic receptor subunits reach peak expression during adolescence in the mesolimbic dopaminergic neurons. To study the CHRNA6 3'-UTR SNP *in vivo*, our lab generated a human CHRNA6 3'-UTR mutant rodent line via CRISPR-Cas9 genome engineering where we replaced the 3'-UTR of the CHRNA6 gene in the rat with the human CHRNA6 3'-UTR containing either the non-risk allele, C ($\alpha6^{CC}$), or the risk SNP allele, G ($\alpha6^{GG}$). To evaluate the role of the CHRNA6 3'-UTR SNP in adolescent substance use, we assessed functionality of the SNP in nicotine-induced locomotor activity and anxiety-like behavioral measures that depend on the mesolimbic dopamine pathway. We hypothesize the *α*6 3'-UTR knock-in interacts with nicotine to influence locomotion and anxiety-like behavior with $\alpha6^{GG}$ rodents being more affected. Furthermore, in behavioral matched tissue, we hypothesize nicotine will enhance *α*6 mRNA expression in $\alpha6^{GG}$ versus $\alpha6^{CC}$ rats. To test our hypotheses, we used a low dose nicotine pretreatment paradigm in male and female rats where animals received either nicotine (2x, 30 μg/kg/0.1 mL, i.v., equivalent to a few cigarettes) or saline for one (acute) or four consecutive days (sub-chronic) during early adolescence (PN 31, 28-31). Immediately following nicotine exposure on P31, animals were placed into an open-field chamber. Our studies illustrate acute and sub-chronic nicotine exposure enhances locomotion and anxiolytic

behavior in a genotype-dependent manner. Additionally, sub-chronic nicotine exposure effects were sex-dependent. Preliminary results for α6 mRNA expression show no genotype, nicotine pretreatment, or sex effects, indicating that our observed behavior is not due to mRNA levels in the mesolimbic tissue. Taken together, our findings illustrate that our human CHRNA6 3'-UTR SNP knock-in is functional *in vivo.* Future studies are underway to evaluate mechanisms underlying our observed effects in our genetic variant rodents including neuronal activity and protein expression pattern in brain tissue.

Title: Effects of prenatal gabapentinoids exposure on human cortical neurons

Authors: M. ALHOMRANI[1], *A. ALAMRI[1], W. ALJUAID[1], O. BAHRI[1], E. ALOSIMI[1], H. HABEEBALLAH[1], E. ALMALKI[1], N. ALSOFUANI[1], Y. ALTHOBAITI[2], A. ALSHEHRI[1], N. ALTHIBITY[1], A. GABER[1], J. HAYNES[3], C. POUTON[3], ***W. ALSANIE**[1];

Abstract: Prenatal substance exposure is a major public health concern associated with many detrimental fetal consequences. Unfortunately, polysubstance use in pregnancy is common. Gabapentinoids are widely used as treatments in psychiatry and neurology; however, they have been increasingly reported as having potential for misuse. Moreover, gabapentinoids can cross the placental barrier. Due to difficulties in accessing fetal brains exposed to gabapentinoids, we used the human embryonic stem cell (hESC) line H9 to generate early, intermediate cortical progenitors and cortical neurons to modulate prenatal gabapentinoid exposure *in vitro*. Since the cortex is responsible for cognition and behavior, we focused on cortical development. We analyzed treated (10uM) and untreated (control) cultures for gene expressions, neurogenesis, and morphogenesis. At the early patterning stage, there was a significant increase in Tbr2+ intermediate progenitors in pregabalin- and gabapentin-treated cultures. In addition, there was a significant increase in the expression of cortical related genes *Pax6*, *Foxg1*, and *Tbr2* in pregabalin-treated cultures, whereas gabapentin significantly increased *Tbr2* expression solely. At the maturation stage, the number of mature cortical neurons was unchanged in pregabalin-treated cultures. At early maturation, gabapentin significantly increased Tbr1+ neurons, but not

Ctip2+ neurons. At the genetic level, we screened the effects of pregabalin on different cortical layer related genes. Pregabalin significantly increased expression of *Brn2* without significant effects on other screened genes. Meanwhile, gabapentin did not alter any cortical layer related genes. Regarding morphogenical analysis, both pregabalin and gabapentin significantly decreased neurite length, branches, and neurites of human cortical neurons. Our data also shows that the effects of pregabalin and gabapentin on the morphogenesis of cortical neurons differ based on the presence of maturation factors, such as GDNF and BDNF, suggesting a possible interaction mechanism. Our study demonstrates that exposure to gabapentinoids during early brain development may interfere with the neurogenesis and morphogenesis of various neuronal subpopulations. Currently, we are investigating gabapentinoids' effects on cortical neuron functionality.

Title: Impact of maternal cannabis vapor self-administration on offspring neurodevelopment and anxiety-like behavior

Authors: *H. V. WEIMAR, A. N. MALENA, D. E. GINDER, A. M. BROWN, R. J. MCLAUGHLIN;
Washington State Univ., Pullman, WA

Abstract: Cannabis is the most used illicit drug during pregnancy, yet little is known about the lasting impacts of prenatal cannabis exposure on neurodevelopmental endpoints. To address this issue, our laboratory recently used a novel cannabis vapor exposure model to show that vaporized cannabis exposure in pregnant rat dams alters the cognitive, emotional, and social phenotype of offspring across the lifespan. However, we also found significant differences between air-exposed and vehicle-exposed offspring on several of these endpoints, which suggests that forced vapor delivery in pregnant dams may produce an aversive state that likely confounds the effects of cannabis per se. To address this, we developed a novel model of prenatal cannabis exposure involving volitional intake of cannabis (or vehicle) vapor in pregnant

rat dams. We used this model in the current study to interrogate effects of maternal cannabis vapor self-administration on offspring development and anxiety-like behavior.
Female Sprague Dawley rats were trained to self-administer either Δ9 tetrahydrocannabinol (THC)-rich cannabis vapor (69.9% THC; 150 mg/mL) vapor or vehicle (VEH; 4:1 propylene glycol:vegetable glycerol) vapor on a fixed-ratio-1 schedule during one-hour sessions twice daily throughout mating and pregnancy. Another cohort of dams were included that did not self-administer either vapor (AIR) to assess potential effects of VEH vapor self-administration. Beginning after postnatal day (P) 80, offspring were tested in the elevated plus maze (EPM) test for 5 minutes to evaluate anxiety-like behavior in adulthood.
Results indicate that dams readily self-administered cannabis vapor throughout pregnancy. Cannabis self-administering dams showed greater discrimination for the vapor-associated operandum and received significantly more vapor deliveries than VEH self-administering dams. Cannabis-exposed offspring weighed significantly less than both VEH and AIR pups on P1, which aligns with findings in human studies. Surprisingly, female cannabis-exposed offspring spent less time in the open arms of the EPM compared to VEH and AIR offspring, whereas male cannabis-exposed offspring spent more time exploring the open arms than AIR offspring.
These results support vapor self-administration in pregnant rat dams as a feasible approach for modeling prenatal cannabis exposure. Moreover, our data indicate that maternal cannabis use may have sexually dimorphic effects on anxiety-like behavior in adulthood. Altogether, validation of this approach will provide a more translationally relevant way to assess effects of maternal cannabis use on offspring neurodevelopment.

Abstract: Though widely used as treatments in psychiatry and neurology, gabapentinoids have been increasingly reported as having potential for misuse. Due to a lack of safety studies, gabapentinoids at therapeutic doses are the last treatment option for various neurological diseases, such as neuropathic pain, during pregnancy. Taking this into consideration, gabapentinoid abuse in pregnant women, or even use at therapeutic levels, may impair fetal development. Here, we used primary mouse embryonic neurons to investigate whether prenatal exposure can impair fetal brain development. We focused on cortical and ventral midbrain development, as they are responsible for cognition and behavior. Early neurogenesis and morphogenesis were analyzed *in vitro* using cortical and ventral midbrain neurons isolated from E12.5 embryonic mouse brains (n=6) in 3D cultures (using ultra-short peptides). We investigated the expression of different cortical layers and ventral midbrain specific proteins in gabapentinoid-treated 3D cultures (using different doses), comparing these with untreated 3D cultures. In addition, we studied the morphogenesis *in vitro* in the 3D cultures. In embryonic mouse cortical neurons, pregabalin and gabapentin (in all tested doses) did not alter early development of preplate and deep layer cortical neurons in treated cultures, in comparison with untreated cultures. However, pregabalin and gabapentin significantly decreased neurite length of both preplate neurons and other deep cortical layer neurons. Meanwhile, in pregabalin-treated cultures, the number of branches significantly increased only in the other deep layer neurons not belonging to the preplate population. Nevertheless, in both cortical populations, the number of neurites and branches significantly decreased in gabapentin-treated cultures. In ventral midbrain neurons, pregabalin and gabapentin significantly increased neurite length of dopaminergic neurons, while the number of branches significantly increased in non-dopaminergic neurons. Pregabalin, but not gabapentin, significantly increased the number of neurites in non-dopaminergic ventral midbrain neurons. Our study demonstrates that exposure to gabapentinoids during early brain development may interfere with the neurogenesis and morphogenesis of various neuronal subpopulations. We are currently investigating gabapentinoids' effects on the functionality of the aforementioned neuronal populations.

Title: Amygdala-related behavioral phenotype of prenatal opioid exposure depends on history of early life stress

Authors: *B. L. SMITH, T. A. GUZMAN, T. M. REYES;
Pharmacol. & Systems Physiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: In the past decade, U.S. maternal opioid use has increased by 130%. Children with prenatal opioid exposure (POE) have an increased risk for impaired emotional control and increased functional connectivity in the amygdala. Consequently, we used mice to study amygdala-related behavioral consequences of POE. C57/Bl6 dams were given access to 0.3 mg/ml morphine in drinking water sweetened with 0.2% saccharin (MO, n = 24) from 10 days prior to conception until offspring were weaned on postnatal day (P)21, and control dams were given 0.2% saccharin (SCH, n = 16). A subset of MO dams were given limited bedding material from P2-9 to model early life stress (MO LB, n = 7). Adolescent MO LB offspring of both sexes had reduced time spent in the light compartment of the light dark test. In contrast, male MO offspring had increased social time in the social interaction test. In the elevated zero maze test, group differences were not observed but maternal MO consumption in the 3rd gestational week related to the amount of time male offspring spent in the open sections. In MO LB males, maternal MO consumption negatively correlated with time spent in the open sections but in the male MO offspring not exposed to LB, there was positive correlation between dose and open section time. Importantly, this replicates our prior studies demonstrating that prenatal MO exposure increases behavior related to exploration or novelty seeking, while prenatal MO combined with early life stress reduces exploration. This indicates that the behavioral effects of POE manifest differently if combined with early life stress.

Title: Effect of prenatal nicotine and THC on cognitive behaviours in adolescent male and female rats.

Authors: *V. LALLAI, L. MANCA, Y. SHERAFAT, C. D. FOWLER;
Univ. of California, Irvine, Irvine, CA

Abstract: Although there has been a decrease in the prevalence of tobacco smoking in many developed countries, exposure to nicotine/tobacco during pregnancy remains a substantial problem worldwide. Further, given the recent escalation in e-cigarette use among various age groups and legalization of cannabis, it has become essential to better understand the effects of nicotine and cannabinoid co-exposure on neural development and function, especially in consideration of vulnerable populations. These studies sought to systematically examine the effects of nicotine and THC prenatal exposure on cognitive behaviors in both male and female offspring rats. Dams were exposed to nicotine vape (5 mg/kg) or vape vehicle control, and oral THC (5 mg/kg) or vehicle control (sesame oil). Offspring were then tested in the pre-pulse inhibition test at PND21, novel object recognition task at PND35, and novelty suppressed feeding task at PND37. During adolescence, prenatal vape exposure in males and females resulted in a changed baseline startle reactivity, and significant effects were found in pre-pulse inhibition. Deficits in novel object recognition were also found in males prenatally exposed. Finally, modestly increased anxiety-associated behaviors were found with THC or nicotine exposure in the latency to approach novel food in an open field. Together, these studies demonstrate differential effects of prenatal exposure to e-cigarette nicotine vape and/or edible THC on cognitive processing tasks, with differing effects for males and females.

Title: Adolescent THC Persistently Alters Medial Prefrontal Cortex-Dependent Cognition in Rats

Authors: *M. X. MARTINEZ[1], V. ALIZO-VERA[1], C. M. RUIZ[1], S. B. FLORESCO[2], S. V. MAHLER[1];

Abstract: Epidemiological studies suggest a link between early adolescent cannabis use and risk of developing schizophrenia, but whether Δ^9-tetrahydrocannabinol (THC) actually precipitates schizophrenia symptoms remains unclear. Moreover, the neurobiological mechanisms underlying this relationship remains unknown. Evidence from rodents suggests that adolescent THC alters the function of medial prefrontal cortex (mPFC) circuits, and human studies also suggest a link between PFC abnormalities and schizophrenia. Here, we tested the hypothesis that adolescent THC causes mPFC changes that may have relevance to schizophrenia. We exposed male and female Long-Evans rats to THC (5mg/kg i.p.) or vehicle daily from postnatal day 30 to 43, and after they grew to adulthood (PD 67+), we examined performance on two mPFC-dependent cognitive tasks, operant set-shifting and probability discounting. After lever training, rats were trained on a set shifting task. They were required to press whichever lever was under a light cue, in order to receive a banana pellet reward. They then experienced a rule reversal, such that correct responses consisted of pressing either the right or left lever, irrespective of the light cue—a set shifting response indicative of cognitive flexibility. After completion of the set shifting task, rats then began the probabilistic discounting task. They were trained to choose between a small/safe lever which always delivered one pellet, or a large/risky lever that sometimes delivered four banana pellets, with a probability that decreased parametrically across the six blocks in a 50min session (100%, 50%, 25%, 12.5%,6.25%). Prior work showed that the dopamine-enhancing drug amphetamine facilitates prepotent "risky" responding on this task (St Onge and Floresco, 2009), and given the link between dopamine and schizophrenia, and our prior findings of mPFC dopamine changes after adolescent cannabinoid exposure, we examined how amphetamine (0, 0.25, and 0.5mg/kg) impacts behavior in adolescent THC- or vehicle-exposed groups. We found that adolescent THC had persistent effects on performance in both operant set-shifting and probabilistic discounting tasks, suggesting THC can persistently alter adolescent brain development of mPFC circuits. These findings may provide insight into the observed link between adolescent cannabis use and schizophrenia.

Title: Projection specific changes in dopamine 1 receptor function following adolescent intermittent ethanol

Authors: *J. D. OBRAY[1], L. CHANDLER[2];
[1]Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [2]Dept Neurosciences, Med. Univ. S Carolina, Charleston, SC

Abstract: We have previously demonstrated that adolescent intermittent ethanol (AIE) reduces medial prefrontal cortex (mPFC) dopamine 1 (D1) receptor function in adult male rats. These effects are believed to be related to deficits in executive function observed in adulthood following AIE. To further investigate these effects, male and female rats underwent an AIE paradigm starting at PD28 and ending at PD56. After completing the AIE paradigm the rats were injected with red retrobeads in the basolateral amygdala (BLA) and green retrobeads in the nucleus accumbens (NAc). Beginning 3 weeks after the injections the rats were euthanized and brain slices containing the mPFC were prepared for whole cell patch clamp electrophysiology. Electrophysiological measurements were made in visually identified neurons projecting to the BLA or NAc. Current clamp recordings (K-gluconate internal) were performed, and evoked firing was measured to assess intrinsic excitability. D1- and dopamine 2 (D2) receptor function was then assessed by measuring evoked firing in response to an injected current while bath applying SKF38393 or Quinpirole. We found that in AIE animals D1-receptor, but not D2-receptor function was reduced in neurons projecting to the BLA. This effect was consistent across both male and female rats. Female rats, however, displayed greater activation of BLA projecting pyramidal neurons during bath application of SKF38393 in both the AIR and AIE conditions. There were no clear changes in D2-receptor function based on treatment group or sex. Analysis is underway to determine the effects of AIE on D1- and D2-receptor function in mPFC pyramidal neurons projecting to the NAc.

Title: Effects of adolescent methamphetamine exposure on perineuronal net and parvalbumin+ cell density in the rodent mPFC

Authors: *A. S. BRINKS[1], L. K. CARRICA[2], D. J. TAGLER[3], J. M. GULLEY[2], J. M. JURASKA[2];
[1]Neurosci., Univ. of Ilinois At Urbana-Champaign, Champaign, IL; [2]Psychology Dept., Univ. of

Illinois At Urbana-Champaign, Champaign, IL; [3]Psychology Dept., Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: Adolescence is a time of enhanced vulnerability to several psychiatric disorders, including substance use disorder. While there are likely social factors that contribute to this vulnerability, ongoing maturation of brain regions critical for cognitive function may also contribute. Across adolescence, the medial prefrontal cortex (mPFC) undergoes significant reorganization, with parvalbumin+ (PV) inhibitory interneurons gaining their fast-spiking phenotype and perineuronal nets (PNN's) aggregating primarily around PV cells. Previous studies have shown PNN's are influenced by female, but not male, puberty with post pubertal females having fewer PNN's than prepubertal littermates. PNN's are also influenced by drug administration, though this is highly specific with heroin resulting in fewer PNN's and cocaine resulting in more PNN's. To assess the effects of methamphetamine (METH) on PV cells and PNNs rats were dosed with METH around female puberty (EA), male puberty (LA), and early adulthood. Male and female Sprague Dawley rats were exposed to 3mg/kg methamphetamine via intraperitoneal injection from either postnatal day (P) 30-38 (EA), P40-48 (LA), or P60-68 (Adult). Brains were collected one day after dosing and fluorescently labeled for PNN's and PV for density quantification. Preliminary results show that METH moderately increased PNN density after adult exposure in both sexes and during the pubertal times for each sex: EA for females and LA for males. PV density was decreased following exposure in both males and females in the LA timepoint but only males in early adolescence. While these results indicate an effect of METH exposure on both PV cell and PNN density, further results will include measures of mPFC volume to control for changing volume over adolescence and increased N. This will allow for further comparisons across age and sex.

Title: Cannabidiol modulates behavioral and gene expression alterations induced by spontaneous heroin withdrawal

Authors: *F. NAVARRETE[1], A. GASPARYAN[2], J. MANZANARES[3];
[1]Inst. de Neurociencias, Univ. Miguel Hernández - CIF: Q5350015C, San Juan de Alicante, Spain; [2]Inst. de Neurociencias, Univ. Miguel Hernández, San Juan de Alicante, Spain; [3]Inst. De Neurociencias,, Univ. Miguel Hernandez, San Juan de Alicante, Spain

Abstract: Background: Previous clinical data suggest that cannabidiol (CBD), a non-psychoactive constituent of the Cannabis sativa plant with anxiolytic, antidepressant, antipsychotic properties, and anti-addictive properties, may hold promise as a therapeutic tool for managing opioid use disorder (OUD). **Aims:** The objective of this study was to evaluate the effects of CBD on behavioral disturbances induced by spontaneous heroin withdrawal in CD1 male mice. Furthermore, quantitative real-time PCR (qPCR) experiments were carried out to evaluate the effects of CBD on gene expression changes induced by spontaneous heroin withdrawal in specific key targets. **Methods:** Spontaneous heroin withdrawal was evaluated 30 h after cessation of 8-days heroin treatment in CD1 male mice (5, 10, 20, and 40 $mg \cdot kg^{-1}$; every 12 h; 2 days each dose; s.c.). CBD effects (5, 10, and 20 $mg \cdot kg^{-1}$; i.p.) on withdrawal-related behavioral signs were evaluated by measuring anxiety-like behavior, motor activity, and somatic signs (rearing, jumping, rubbing, grooming, digging). Furthermore, qPCR experiments were carried out to evaluate gene expression changes of mu-opioid receptor (Oprm1), proopiomelanocortin (Pomc), cannabinoid CB1 receptor (Cnr1) and cannabinoid CB2 receptor (Cnr2) in the nucleus accumbens (NAcc), and tyrosine hydroxylase (TH) and Pomc in the ventral tegmental area (VTA). Statistical analyses were performed using one- and two-way analysis of variance (ANOVA) with repeated measures (RM). **Results:** Anxiety-like behavior, motor activity, and withdrawal-related somatic signs were significantly increased in heroin-treated mice. In addition, Oprm1 and Cnr2 in the NAcc and TH and Pomc in the VTA were upregulated, whereas Cnr1 and Pomc in the NAcc were significantly reduced in abstinent animals. Interestingly, the treatment with CBD significantly reduced anxiety-like behavior (10 and 20 mg/kg; $p<0.001$), hyperactivity (10 and 20 mg/kg, $p<0.001$), and somatic signs (5, 10 and 20 mg/kg; $p<0.001$) induced by spontaneous heroin withdrawal. Furthermore, CBD normalized the gene expression of Cnr1 and Pomc in the NAcc and of TH in the VTA, induced an additional up-regulation of Cnr2 gene expression in the NAcc, and did not change the increased gene expression of Oprm1 in the NAcc. **Conclusion:** The present study results provide evidence about the efficacy of CBD to modulate the behavioral and gene expression disturbances associated with spontaneous heroin withdrawal. Further studies are warranted to evaluate the potential therapeutic actions of CBD for the management of heroin withdrawal and to elucidate the precise underlying neurobiological mechanisms involved.

Title: Epigenetic priming drives aberrant gene expression in cocaine relapse

Authors: *P. MEWS[1], H. KRONMAN[1], Y. VAN DER ZEE[2], A. RAMAKRISHNAN[1], A. GURUNG[1], M. ESTILL[1], M. RYAN[1], A. REYES[1], B. GARCIA[3], S. SIDOLI[4], E. J. NESTLER[1]; [1]Dept of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Dept. of Psychiatry and Neuropsychology, Maastricht Univ., Maastricht, Netherlands; [3]Dept. of Biochem. and Biophysics, Univ. of Pennsylvania, Philadelphia, PA; [4]Dept. of Biochem., Albert Einstein Col. of Med., New York, NY

Abstract: Substance use disorders represent an enormous public health crisis and are among the most intractable illnesses in our society. An ongoing focus of research into the molecular pathology of addiction are mechanisms by which neuronal gene regulation is altered in a central brain region of reward, the nucleus accumbens (NAc). Stable changes in chromatin are proposed to underlie the maladaptive transcriptional states in this brain region, which persist despite long-term drug withdrawal. However, there is no direct link between drug-induced epigenetic marks and aberrant gene expression programs that drive relapse. A fundamental challenge is determining which neuronal subtypes are responsible: the NAc is composed primarily of two opposing types of medium spiny neurons (MSNs), the D1 and D2 dopamine receptor-expressing subtypes, which exhibit dramatic differences in activity and effects on drug reward. In these distinct subtypes, we examined how chronic cocaine modifies chromatin structure and characterized immediate versus persistent changes in gene regulation. We surveyed circuit-specific chromatin accessibility genome-wide in combination with unbiased histone modification profiling by mass spectrometry and ChIP-sequencing. We discovered that chronic cocaine persistently ‘scars’ chromatin structure in D1 MSNs, involving dramatic depletion of the histone variant H2A.Z at key neuronal genes related to synaptic plasticity. Genome accessibility is prominently increased at these genes even after prolonged withdrawal, linked to aberrant gene expression upon drug relapse. The histone chaperone ANP32E promotes the removal of H2A.Z, and we demonstrate that D1 circuit-selective ANP32E knockdown prevents cocaine-induced H2A.Z depletion and effectively blocks cocaine conditioned place preference. In contrast, the D2-specific knockdown of ANP32E enhances cocaine-related reward learning in this animal model. These findings provide new insight into circuit-specific epigenetic priming as a critical mechanism and promising clinical target employed by drugs of abuse to modify brain function and behavior in lasting ways.

Title: Electrophysiological correlates of affective processing in people with chronic consumption of psychoactive substances

Authors: *J. AVILA MORENO[1], J. D. RODRÍGUEZ[1], Y. V. MOLINA[1], D. LEÓN[2], S. ZARATE[1], F. CARDENAS[2], J. M. DURAN[1];

Abstract: Polydrug use of psychoactive substances is a worldwide problem, it has been shown that drug use is associated with deficits in attention, processing and identification of emotional stimuli that can be identified by changes on Event-related potentials (ERPs). Most studies of chronic drug use effects on ERPs have focused on a given class of addictive substances. However, this single-use drug profile represents only one part of consumptions spectrum since clinical population report the use of more than one drug. Although the high prevalence of polyconsumption, there are few studies evaluating emotional processing in that condition. The aim of the study was to evaluate patterns of cortical activity of affective processing in polyconsumers of psychoactive substances. Fifty Colombian men and women between 18 and 55 years old participated in this research, (25) consumers and (25) non-consumers of psychoactive substances. ERPs were obtained from EEG data recorded while individuals scored the valence of a set of stimuli taken from the International Affective Pictures System (IAPS). We found that, polyconsumers expressed lower average amplitude for the later P1- in posterior electrodes during 90-130 latency range for both valences, also non-consumers N1-Cz were more negative than for consumers during 170-210 latencies, particularly to pleasant images. In the posterior region polyconsumers had attenuated the P2 potential, while in the anterior zone they had higher negativity in N2 ERP. Non-consumer had more negative N3 potential than polyconsumers, but this negativity was bigger to unpleasant images. Finally, in the latency range of 700-1000 milliseconds non-consumer showed a more positive potential to aversive images than polyconsumers in parietal areas. Previous reports have been shown the critical role of P1, N1 and N2 on the attentional process underpinning allocation, orientation, and awareness of emotional stimuli as well as cognitive control and behavioral inhibition. These results could indicate that polyconsumption is associated with an insufficient ability for early visual processing of affective images, a reduction in the attentional orientation to the affective stimuli, a poor valence

processing specially of pleasant images and a worse ability to focus and process the task and select the appropriate response by inhibiting involuntary, impulsive, and inappropriate actions.

Title: Electrophysiological biomarkers in polyconsumers of psychoactive substances before and after a psychotherapeutic process

Authors: *J. RODRÍGUEZ ANIMERO[1], J. C. AVILA[1], V. MOLINA[1], D. LEÓN[2], S. ZARATE[1], F. CÁRDENAS[2], J. M. DURAN[1];

Abstract: Alterations in affective processing, especially depressive symptoms, increased negative affect, difficulties in emotion regulation, alterations in reward processing, and high rates of impulsivity are common among drug addicts. These changes in emotional appraisal and response can be identified by changes in event-related potentials (ERPs). Although advances in neuroscience research have helped to describe the neurobiological changes that occur during a substance use disorder or addiction, only a few studies have attempted to examine changes in functional brain activity that may accompany changes in behavior before and after treatment. Therefore, ERP measurement might fill a gap in treatment-response biomarkers to psychotherapeutic interventions, consider that the therapeutic goal in the treatment of addictions is not only abstinence as behavior, but an affective reprocessing, acquisition impulse control and decision-making skills, among others. This study aimed to evaluate the patterns of cortical activity before and after psychological treatment of polyconsumers of psychoactive substances during the assessment of affective images. Twenty-three Colombian polyconsumers between 18 and 55 years old who voluntarily initiated inpatient psychological treatment participated in this study. The ERPs were obtained from electroencephalographic data recorded before and after psychotherapeutic process while the participants scored the valence of a set of visual stimuli from the International Affective Pictures System (IAPS). We found that polyconsumers expressed a higher P1 posterior during 90-130 latency range, and the P2 were more positive during latencies 270-320, both for unpleasant images before treatment. Also, in the anterior

region polyconsumers had higher P3b positivity before treatment compared to post-treatment, particularly to pleasant images. In the latency range of 1000-1250 analysis showed that polyconsumers had a more positive LPP potential to pleasant images, however in the latency range of 1250-2490 subjects expressed LPP potential with higher negativity to aversive images in the parietal areas, both before treatment. These preliminary results can be associated with a process of self-regulation, cognitive control, and response inhibition besides emotion regulation and decrease in craving related to psychological treatment in polyconsumers. This interpretation helps to demonstrating the need for studies using ERPs that show the changes in neural activity associated with affective processing before and after psychotherapy and thus contribute to better practices and effective treatments.

Title: Capturing and profiling cocaine-recruited neuronal ensembles in the nucleus accumbens.

Authors: *M. SALERY, A. GODINO, Y. Q. XU, J. F. FULLARD, P. ROUSSOS, E. J. NESTLER;
Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The ability to first learn associations between the rewarding effects of a drug and the context in which it is experienced is decisive for precipitated drug-seeking and relapse in abstinent individuals. As learned associative memories have been proposed to be stored in sparse and highly discriminative populations of concomitantly activated neurons, emerging evidence supports the idea that drug-recruited neuronal ensembles could similarly encode addiction-related pathological memories. However, little is known regarding the dynamics and molecular mechanisms of both their recruitment upon initial drug exposure and their later contribution to relapse. Here, we postulate that subsequent reactivation of an initially-activated ensemble could support the encoding, the strengthening and ultimately the expression of drug-associated memories. A related goal is to explore the intrinsic (phenotypical) or acquired (plastic) cellular properties that would favor the allocation of specific cells to these functional ensembles and predict their further reactivation. Capitalizing on the activity-dependent labeling of neuronal ensembles in Arc-CreER^{T2} mice (Denny et al., 2014), we were able to capture cocaine-activated

cells in the nucleus accumbens and permanently tag them with fluorophores or channel-rhodopsin for further characterization, optogenetics, and single-nuclei sorting. We identified a subset of neurons activated at both early and late stages of drug exposure and show that the level of reactivation of the initial ensemble correlates with the amplitude of behavioral sensitization. Similarly, re-exposure to a cocaine-paired context in a conditioned place preference (CPP) paradigm was associated with an increased reactivation of cocaine-recruited ensembles. The behavioral consequences of such reactivation was further assessed using optogenetics-mediated artificial reactivation. We found that the reactivation of ensembles recruited at early- versus late-stages of drug exposure had opposite effects on CPP expression. We then isolated tagged nuclei with FACS and performed single nucleus RNA sequencing to analyze their transcriptional signature. Using activity-dependent transcriptional programs as a marker of recent activation, we successfully isolated a cluster of reactivated cells within the initially activated ensemble. Together, such multiscale and ensemble-specific approaches represent a pivotal step towards a better understanding of the cellular and molecular processes involved in the encoding of pathological memories associated with drug addiction. Title: Transcriptomic analysis of the nucleus accumbens after volitional heroin intake implicates Mbd3 as a key regulator in relapse susceptibility

Authors: *R. FUTAMURA[1], C. J. BROWNE[1], X. ZHOU[2], A. RAMAKRISHNAN[1], A. M. MINIER-TORIBIO[1], A. GODINO[1], M. SALERY[1], O. SIAL[4], B. ZHANG[2], Y. L. HURD[3], L. SHEN[1], E. J. NESTLER[1];

Abstract: Repeated opioid use causes molecular changes in the nucleus accumbens (NAc), a brain region critical for coordinating motivated behavior and reward processing. Dysfunction of the NAc can perpetuate compulsive drug-seeking and drug-taking behaviors to the extent of which voluntary control of these behaviors is lost. Further, molecular changes within the NAc

may support long-term susceptibility to relapse despite cessation of opioid use, induced by drug-related cues or re-exposure to the drug itself triggering intense drug craving. However, transcriptional regulation within the NAc induced by drug-seeking behavior has not been previously examined. Ongoing studies in our laboratory have identified broad patterns of transcriptional regulation throughout the brain reward system induced by volitional opioid exposure and drug-seeking behavior using heroin intravenous self-administration in mice. In these studies, mice self-administered saline or heroin for 15 days and underwent a 30-day homecage forced abstinence period, after which mice were challenged with either saline or heroin and underwent a drug-seeking test. Here, we focus on how transcriptional regulation within the NAc contributes to drug-seeking behavior. Using multiscale embedded gene co-expression network analysis (MEGENA), we identified a particular gene network in this brain region that is enriched with upregulated genes induced by heroin-primed drug-seeking. Within this network, methyl-CpG binding domain protein 3 (Mbd3), one of the most significantly upregulated genes within the NAc in this condition, was found to be a key hub gene. In addition, exploratory factor analysis linking behavioral outcomes from self-administration with gene expression uncovered a positive association between Mbd3 and addiction-like behavior. Taken together, these data suggest that Mbd3 is an important driver in controlling this gene network that associates with relapse-like behavior. Ongoing efforts include determining the cell-type-specificity of Mbd3 regulation in NAc D1 or D2 medium spiny neurons, manipulating Mbd3 using a knockdown approach, and examining changes to behavior that promote drug craving, and ultimately, relapse.

Title: Phosphodiesterase 1b is a key driver of a gene network in nucleus accumbens associated with addiction-like behaviors

Authors: *C. D. TEAGUE[1], X. ZHOU[1], Y. VAN DER ZEE[1], A. GODINO[1], D. M. WALKER[2], B. ZHANG[1], E. J. NESTLER[1];

Abstract: Cocaine use disorder (CUD) is a serious public health issue with no effective pharmacotherapies. Identifying treatments for CUD is hindered in part by an incomplete understanding of the coordinated changes in gene expression that drive long-lasting maladaptive plasticity in the brain and promote addiction-like behaviors. In this study, we conducted unbiased gene co-expression network analysis on a published RNA sequencing (RNA-seq) dataset from 6 different brain regions of animals that underwent cocaine self-administration followed by prolonged withdrawal plus context- or cocaine-induced reinstatement (Walker et al., *Biol Psychiatry*, 2018). We ranked gene networks by their fold enrichment in genes whose expression is significantly correlated with an "addiction index" (AI) - a composite score developed by machine learning to capture maladaptive, addiction-like behaviors during cocaine self-administration. We identify the gene encoding phosphodiesterase 1b (*Pde1b*), a Ca^{2+}/calmodulin-dependent enzyme that catalyzes the hydrolysis of cAMP and cGMP, as the strongest regulator of a gene network in the nucleus accumbens (NAc) that shows the highest magnitude association with the AI of all gene modules in this brain region. Our data suggest that *Pde1b* is primed in *Drd1*-expressing medium spiny neurons (D1 MSNs) following withdrawal from chronic cocaine. To investigate the role of *Pde1b* in regulating addiction-like behaviors, we are performing virus-mediated *Pde1b* overexpression or knockdown in the NAc followed by conditioned place preference (CPP), locomotor sensitization, and self-administration assays for cocaine in male and female rodents. Additionally, we will use RNA-seq to measure the effect of *Pde1b* manipulations on gene network activity and cocaine-induced transcriptomic changes in the NAc. Given successful drug discovery efforts focused on other PDE isoforms, this work may present a novel therapeutic approach for CUD.

Title: Molecular basis of ΔFosb action in drug addiction: mapping ΔFosb binding sites in nucleus accumbens medium spiny neurons

Authors: *S.-Y. YEH, M. S. ESTILL, L. SHEN, E. J. NESTLER;
Icahn Sch. Med. At Mount Sinai, New York, NY

Abstract: Drug addiction exacts a devastating impact on drug users, their family members, and the nation's public health. Although different in chemical structures and initial mechanisms affecting the brain, all classes of drugs of abuse induce the expression of the transcription factor ΔFosB in nucleus accumbens (NAc), a central node of the reward circuitry. Studies with ΔFosB genetic and viral manipulations in mice and rats suggest that ΔFosB in NAc neurons is involved in the development of addiction. However, the molecular mechanisms by which ΔFosB controls addiction remain incompletely understood. Here, we extend earlier work on revealing ΔFosB's transcriptional targets, which previously interrogated promoter regions only, by leveraging the CUT&RUN (cleavage under targets and release using nuclease) method to pinpoint ΔFosB binding genome-wide upon chronic cocaine exposure. Thousands of ΔFosB peaks were revealed, virtually all of which corresponded to consensus AP1 sites. Interestingly, one third of the loci are positioned at distal intergenic enhancers, while only ~15 percent of the peaks occur within known promoter areas, suggesting that a primary function of ΔFosB is coordinating distal regulatory elements with the transcription machinery. In addition, we identified ΔFosB peaks, as well as histone modifications linked to enhancer activity, specific to medium spiny neurons (MSNs) expressing either dopamine receptor D1 or D2 - the two major neuronal types in NAc, which adds to the early discovery that ΔFosB directs differential molecular and synaptic plasticity in D1- versus D2-type MSNs. Hundreds of only partly overlapping ΔFosB binding sites were identified in D1- and in D2-type MSNs that were also surrounded by active enhancer histone marks. Interestingly, ΔFosB enrichment was found at multiple genes associated with genetic risk for substance use disorders in human, supporting ΔFosB's key role in the genetic architecture of drug addiction. Further extension of this CUT&RUN approach to other chromatin regulatory mechanisms in D1- and D2-type MSNs within NAc will set the groundwork for understanding distinct roles of these MSN subtypes, and their adaptations to chronic drug exposure, in drug addiction.

Title: Elucidation of the astrocyte-specific transcriptome following exposure to cocaine

Authors: *L. M. HOLT[1], A. M. MINIER-TORIBIO[2], E. PARISE[1], C. BROWNE[1], R. FUTAMARA[1], S.-Y. YEH[1], M. ESTILL[1], Y. DONG[3], E. J. NESTLER[1];

[1]Mount Sinai, New York, NY; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Dept Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Drug addiction represents an enormous healthcare burden. To better understand its biological underpinnings, investigations of the transcriptional response to drugs of abuse have demonstrated lasting changes in gene expression throughout the brain's reward circuitry. Historically focused on neurons, emerging evidence increasingly indicates that astrocytes are also involved in disorders of the nervous system, including addiction. Indeed, candidate genes in astrocytes have been identified and, furthermore, manipulation of astrocyte function has been demonstrated to influence rodent behavioral responses to cocaine administration. However, the astrocyte-specific transcriptome following exposure to drugs of abuse has not yet been investigated. As an initial approach, we examined previously published work (Walker et al., *Biol. Psychiatry*, 2018) and identified numerous astrocyte-enriched genes within RNA-sequencing datasets from bulk homogenates of several brain reward regions that are associated with behavioral responses to cocaine self-administration. In parallel, to obtain more comprehensive and selective data, we utilized whole cell sorting of astrocytes and RNA-sequencing to investigate the astrocyte-specific transcriptome in several key brain regions involved in reward-processing, including the nucleus accumbens and prefrontal cortex, following chronic exposure to cocaine. Subsequent gene ontology analysis revealed a variety of pathways, including synaptic regulation, calcium signaling, and GPCR signaling in both brain regions as being prominently regulated by cocaine exposure. Additional analysis revealed several deduced upstream regulators of this abnormal transcription, such as CREB and several members of the STAT family. Furthermore, our analysis indicates a robust regional-specific response of astrocytes following exposure to cocaine. Current studies are directed at extending our findings utilizing cocaine self-administration in mice to establish the astrocyte transcriptome in response to drugs of abuse and to subsequently study the role of specific transcripts in contributing to the pathophysiology of addiction.

Abstract: Addiction is a devastating disorder that is exceptionally difficult to treat due to the high propensity for relapse even long after prolonged abstinence. The persistence of addiction is mediated at least partly by drug-induced changes in the physiology of reward-processing regions of the brain. Dysregulated signaling within the nucleus accumbens (NAc) is thought to play a critical role in promoting drug-seeking and relapse. Determining these changes may reveal more effective targets to treat substance use disorders. However, the molecular details underlying these adaptations remain incompletely understood. Here, we extend previous work focused mainly on candidate proteins of interest by contrasting whole-proteome changes induced by cocaine or heroin self-administration that persist through extended abstinence. Rats underwent 10 days of extended-access (6 hr/day) intravenous cocaine, heroin, or saline self-administration followed by 30 days of forced abstinence, after which they were euthanized from their homecages, and the NAc was extracted. Synaptosomes from these punch dissections were purified and analyzed by lipid chromatography-tandem (LC-MS/MS) mass spectrometry followed by label-free quantification. Using this approach, we identified unique patterns of induction or repression of numerous synapse-enriched proteins in NAc following prolonged withdrawal from cocaine or heroin self-administration. While most of these drug-regulated proteins are expressed by neurons, a significant subset is enriched in astrocytes or microglia, consistent with the intimate association of processes from these cell types with synapses. Interestingly, long-term withdrawal is associated with a greater degree of repression rather than induction of protein expression overall. We are now validating these findings and characterizing particular synaptic proteins that directly contribute to drug-seeking behavior. These studies will dramatically enhance our understanding of the molecular restructuring of synapses in the reward circuitry that underlie susceptibility to relapse.

Abstract: Opioid addiction exacts a devastating toll on individuals, their families, and the healthcare system. Treatment is made exceptionally difficult by prolonged susceptibility for relapse into compulsive drug-seeking and taking, often triggered by re-exposure to drug-associated cues or the drug itself. Lasting relapse susceptibility is thought to be mediated in part by persistent changes in gene expression within interconnected reward-processing regions of the brain. However, few studies have performed transcriptome-wide analyses throughout brain reward regions following volitional opioid intake. Here, we combine heroin self-administration in mice, RNA sequencing (RNA-seq), and advanced bioinformatics approaches to identify novel genes and gene networks throughout the brain's reward system that are regulated by opioid intake and drug-seeking. First, mice underwent 15 daily 4 hr self-administration sessions wherein lever pressing lead to intravenous delivery of saline or heroin (FR1, 0.05 mg/kg/inf). Mice were then euthanized either from their homecage 24 hr after the last session or after a 30-day homecage forced abstinence period. In the 30-day group, mice also received a challenge injection of saline or heroin (1 mg/kg) and were placed back into self-administration chambers for a 2 hr drug-seeking test, after which mice were immediately euthanized. This design enabled comparisons of multiple addiction-relevant outcomes, including first-ever heroin exposure, early withdrawal from chronic use, context-induced drug-seeking, and combined drug/context-induced drug-seeking. RNA-seq was conducted on six brain regions involved in reward-processing: medial prefrontal cortex, nucleus accumbens, dorsal striatum, basolateral amygdala, ventral hippocampus, and ventral tegmental area. Bioinformatic analysis of this rich dataset has uncovered numerous patterns of differential gene expression in a region- and condition-dependent manner. Further, exploratory factor analysis was used to link gene expression patterns across brain regions with behavioral profiles relevant to an addiction-like state. Employing multiscale embedded gene co-expression network analysis (MEGENA), we also identified gene networks in the ventral hippocampus that associate with susceptibility to relapse. Current work

focuses on modulating expression of genes within this network and studying the impact on heroin self-administration and drug-seeking behavior.

Title: Infralimbic-cerebellum anatomical map

Authors: *J. GUARQUE-CHABRERA[1,2], M. MIQUEL[1,2], K. KHODAKHAH[1];
[1]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY;
[2]Psychobiology, Jaume I Univ., Castellon, Spain

Abstract: Reciprocal pathways connecting the cerebellum and the medial prefrontal cortex (mPFC) provide a biological and functional substrate of their codependence to modulate cognitive and motivational functions. Dysfunction of both areas underlie the phenotypes of several neuropsychiatric disorders, and may operate as a risk factor for drug addiction. Extensive literature shows that the prelimbic (PL) and the infralimbic (IL) cortices, two areas included in the mPFC, play opposite roles not only over the initiation and inhibition of drug seeking but also regarding the control of goal directed and habitual behaviors respectively. Miquel's lab has reported that either a lesion in the vermal lobule 8 (L8) of the cerebellum or an IL deactivation facilitated the establishment of conditioned preference for cocaine-related cues. However, this effect was not replicated by PL deactivations. Cerebellum-IL functional relationships appear to be compensatory because simultaneous cerebellum-IL deactivations abolished the facilitative effect of separate deactivations. Moreover, unpublished results showed that IL but not PL deactivations during a repeated cocaine experience upregulates neuronal activity in the posterior vermis in rats. One of the relays for the cerebellum to modulate mPFC functions is the VTA. Indeed, we have shown that optogenetic manipulation of the cerebellar outputs targeting VTA

were able to modulate reward-related behaviors. However, anatomical projections from the IL to the cerebellum have been poorly described and it is far to be clear through which brain regions the IL might regulate cerebellar activity. Neither, if IL projections are monosynaptic or involve disynaptic pathways. Therefore, our goal is to create an anatomical map of the IL-cerebellum pathway in mice. We used a combination of monosynaptic and transneuronal viral (Herpes and Rabbies virus and AAVs) and classic (Fluorogold and BDA) tracing agents. Our results show that IL might send projections to both interposed DCN and inferior olive and these areas then will reach cerebellar cortex of L8 in the vermis.

Abstract: In abstinent drug users, cues previously associated with drug-taking maintain the ability to provoke drug craving and precipitate relapse long after the last instance of drug use. These persistent, maladaptive cue-drug associations are thought to be encoded in sparse patterns of strongly activated neurons termed '*neuronal ensembles'*. Our lab and others have previously used the activation of the immediate early gene *Fos* as a marker to identify and characterize ensemble neurons specifically activated during events of interest (e.g. the presentation of a drug-associated cue or the execution of a learned drug-seeking behavior). However, these approaches have poor temporal specificity, and the relationship between *Fos* and neuronal activity is not well understood. To address this issue, we will use a genetically encoded photo-activatable

calcium integrator, CaMPARI2, to permanently label active neurons in the infralimbic cortex (IL) of rats during cocaine relapse. UV light exposure permanently converts CaMPARI2 from green to red fluorescent state only in active neurons and allows permanent *in vivo* labeling of these neurons with sub-second temporal resolution. Following cocaine self-administration, we will label active neurons during cocaine-seeking (cocaine-memory ensemble) or novel context exposure (control ensemble) and use FACS to isolate CaMPARI2 labeled (red, active) neuronal nuclei. We will then use single-nuclei RNA sequencing to identify unique molecular alterations within cocaine-memory ensemble neurons and investigate if their enrichment is restricted to specific cell type clusters within the IL. Understanding how drug memories are maintained could enable us to prevent relapse by selectively weakening these persistent drug-related memories without influencing other memories.

Title: Contributions of zincergic neurons to drug-seeking behaviors

Authors: *O. SOLIS CASTREJON, E. VENTRIGLIA, B. LAING, J. BONAVENTURA, Y. APONTE, M. MICHAELIDES;
Natl. Inst. on Drug Abuse, BALTIMORE, MD

Abstract: Glutamatergic neurons to the striatum are thought to be implicated in drug seeking behavior. The striatum receives glutamatergic inputs from the prefrontal cortex, basolateral amygdala, hippocampus and paraventricular thalamus (PVT). Within a subset of glutamatergic neurons (zincergic), zinc (Zn^{2+}) is co-released with glutamate. These zincergic neurons that release Zn^{2+} exclusively express the Zn transporter 3 (ZnT3), a protein essential for Zn^{2+} transport into synaptic vesicles and necessary for synaptic Zn^{2+} release. A growing body of evidence shows that synaptic Zn^{2+} acts as a neuromodulator of both excitatory and inhibitory synaptic transmission to influence synaptic plasticity and regulate cognition, memory and affective processing. On a systems level, there is a lack of knowledge concerning the functional role of zincergic neurons on drug seeking behavior. The distribution of zincergic neurons in the

brain has been previously described using histochemical procedures based on Zn-selenide stains. However, to date there is no information regarding the molecular phenotype of zincergic neurons that project to the striatum. While it has been demonstrated that zincergic neurons are predominantly glutamatergic, recent studies have also reported a population of zincergic inhibitory neurons (interneurons) in the auditory cortex. By using fluorescent In situ hybridization, we found that in the neocortex, ZnT3 is mainly expressed in glutamatergic neurons. Interestingly, ZnT3 is expressed in parvalbumin and somatostatin interneurons but not in VIP interneurons. To further characterize zincergic neurons, we recently developed the Cre-ZnT3/DreO transgenic mouse. We injected into the prefrontal cortex a Cre-dependent virus driving synaptophysin-mRuby to label putative synaptic output sites. Preliminary results show that prefrontal cortical zincergic project to direct and indirect pathway striatal neurons. We are currently working on the functional role of zincergic neurons in the striatum.

Title: Brain-wide 3D profiling of neuronal ensembles reactive to relapse-promoting vs. relapse-suppressing cues in rats

Authors: *H. NEDELESCU[1], N. J. O'CONNOR[2], B. E. EASTWOOD[2], A. H. THAN[1], G. E. WAGNER[1], H. C. CHANG[1], G. L. DE NESS[1], A. CARROLL[1], Y. LIU[1], E. WHITNEY[1], N. E. EMERSON[1], Z. MIKULSKI[1], F. WEISS[3], J. R. GLASER[2], N. SUTO[4];

Abstract: Drug addiction is a chronically relapsing brain disease. While environmental stimuli signaling drug availability (S+) are well-known to promote relapse, we have found that environmental stimuli signaling drug omission (S-) can suppress relapse in rats. This bidirectional modulation of drug relapse is regulated by two functionally distinct coactive groups of infralimbic cortex (IL) neurons – neuronal ensembles or engram cells – with each group

selectively reactive to S+ or S- (as visualized by Fos protein). However, the neuroanatomical source of afferents that activate these neurons remains unknown. We have thus conducted brain-wide analysis to identify neuronal ensembles that send axonal projections (visualized by AAV2retro-GFP) to the IL and that are evoked by S+ or S- in different groups of rats trained to self-administer cocaine or alcohol. While automated brain-wide profiling is available for mice, similar procedures for rats are not yet established, even though rats are a preferred animal model for studying more complex behaviors to model drug addiction. Hence, we developed automated 3D brain-wide profiling for rats where image data and cell counts were registered using NeuroInfo to the Waxholm rat atlas (ref: https://www.nitrc.org/projects/whs-sd-atlas). Briefly, [1] whole slide images of serial brain sections were captured by a ZEISS Axioscan slide scanner microscope, [2] these 2D images were aligned and registered using NeuroInfo to the Waxholm rat atlas coordinate system, [3] Fos- and GFP-positive IL-projecting neurons were detected with single cell resolution in NeuroInfo using deep learning methods with anatomic specificity conferred by matching image data to the atlas coordinate space. This method provides superior cellular tagging (staining) and image resolution – especially for the larger rat brains – than similar methods using brain clearing and light-sheet microscopes. In my poster presentation, I will further describe our new NeuroInfo tool for rat brains by applying it to identify brain-wide neuronal networks reactive to relapse-promoting vs. relapse-suppressing stimuli. In short, this study provides a new tool for automated 3D brain-wide profiling of rats and expands our knowledge of brain circuitry mediating environmental modulation of drug relapse.

Title: Calreticulin as a target for cocaine in a ventral hippocampus to accumbens circuit

Authors: *A. L. EAGLE[1], M. A. DOYLE[1], H. M. KUHN[1], B. R. MURRAY[1], M. DYKSTRA[1], R. M. BASTLE[2], I. S. MAZE[2], A. ROBISON[1];

Abstract: Ventral hippocampus neurons that project to the nucleus accumbens (vHPC-NAc) are critical to cocaine seeking and the expression of cocaine reward. However, how drugs like cocaine modulate the physiology and gene expression within this circuit is unknown. We have identified that chronic cocaine, both experimenter- and self-administered, decreases the intrinsic excitability of vHPC-NAc neurons in *ex viv*o brain slices from male transgenic *Rosa26*$^{eGFP/L10a}$ mice. We next sought to identify gene targets of cocaine that may underlie this phenomena. Using innovative retrogradely expressing HSVs to drive the Cre-dependent expression of GFP-tagged ribosomes in vHPC-NAc neurons of *Rosa26*$^{eGFP/L10a}$ mice along with circuit-specific TRAPSeq (Translating Ribosomal Affinity Purification followed by 3rd-generation sequencing) we identified actively translating mRNAs differentially regulated by chronic cocaine. Following the trail of our TRAPSeq findings, we validated the ER resident chaperone protein, calreticulin, as a target for cocaine in vHPC-NAc neurons using traditional molecular assays: RT-PCR and Western blotting in whole vHPC punches from male C57Bl6/J mice and immunofluorescence in circuit-tagged transgenic male *Rosa26*$^{eGFP/L10a}$ mice. Ongoing studies using calreticulin overexpression AAVs and floxed calreticulin mice will identify whether calreticulin regulates cocaine-induced changes in excitability in vHPC-NAc neurons. These studies are poised to identify a novel ER protein that may regulate cocaine-induced changes in this circuit that would likely also underlie the relapse to cocaine seeking and reward.

Title: Localizing circuits and molecular mediators of cocaine contextual memories

Authors: *C. CABAN RIVERA[1], X. SHI[1], J. BARR[1], C. K. DO[1], C. LI[1], C. CHEN[1], L.-Y. LIU-CHEN[1], L. G. KIRBY[1], G. M. SMITH[2], E. M. UNTERWALD[1];

Abstract: Addiction is characterized by compulsive drug seeking and taking behaviors. Cravings triggered by the presence of environmental cues that were once associated to drug use are a main

contributor of relapse and once these drug-cue memories are formed they are difficult to erase. Addictive drugs like cocaine engage molecular pathways of associate learning, in which recall of an established memory is followed by its reconsolidation, strengthening that memory. The reactivation period is a critical time wherein memories are labile and vulnerable to behavioral and pharmacological interference. Given the widespread negative impact of drug use in our society, it is of great importance to understand the mechanisms underlying drug seeking behaviors to generate effective preventions and treatments. The goal of this study is to elucidate the anatomical and molecular substrates crucial for the maintenance of cocaine contextual memories, with a focus on the nucleus accumbens and GSK3b signaling. Designer receptors exclusively activated by designer drugs (DREADDs) were used to inhibit neurons at the nucleus accumbens. To accomplish this, adult male C57Bl6 mice underwent bilateral intracranial injections of an inhibitory DREADD (AAV2-hsyn-hm4D(Gi)-mcherry) followed by a cocaine conditioned place preference paradigm. Nucleus accumbens neurons were inhibited via systemic injection of clozapine N-oxide immediately following reactivation of cocaine contextual memory, and mice were re-tested for place preference 24 hours and 7 days later. A separate cohort of mice underwent cocaine conditioned place preference but instead received intracranial infusions of a selective GSK3 inhibitor, SB216763, into the nucleus accumbens following reactivation of cocaine contextual memory and then re-tested for place preference 24 hours later. Results show that chemogenetic inhibition of the nucleus accumbens immediately following reactivation of cocaine contextual memory significantly reduced a once established preference for the cocaine context. Furthermore, pharmacological inhibition of GSK3 in the nucleus accumbens following reactivation of said memory abolished preference for the cocaine paired context. These findings suggest the nucleus accumbens is important for the reconsolidation of cocaine contextual memories and that GSK3 is a key molecular mediator of this process.

Title: Presence of a peer, like subthalamic nucleus optogenetic manipulation, reduces escalated cocaine intake

Authors: C. VIELLE[1], L. VIGNAL[1], M. DEGOULET[1], Y. PELLOUX[2], ***C. BAUNEZ**[1]; [1]INT UMR7289 CNRS & Aix-Marseille Univ., Marseille, France; [2]Dept. of Physiol. and Neurosci., ITT, Genova, Italy

Abstract: Drug use disorders are a major worldwide public health problem for which no medication has been developed yet. The subthalamic nucleus (STN) high-frequency deep brain stimulation has been shown to prevent cocaine escalation and re-escalation, but its effects are still poorly understood. Besides, social context is known to be a key influential factor in drug use. Indeed, in both rats and humans, the immediate presence of a peer decreases recreational cocaine use. Yet, its effect on later stages of addiction's cycle has not been elucidated. Here, we thus assessed whether the presence of a peer can reduce the cocaine intake of rats having previously lost the control over their drug intake. Rats were first subjected to a cocaine escalation procedure, consisting in extended access (6h) to the drug over 20 days and were then tested for 2h self-administration sessions alone or in presence of a stranger observing peer. The effects of STN optogenetic inhibition and high-frequency stimulation were tested in these two various conditions. In the alone condition, both optogenetic STN inhibition and stimulation drastically reduced cocaine intake. The presence of a peer reduced the level of cocaine intake of the control rats, but did not reduce it further in the STN inhibited and stimulated groups. Those results show the importance of social factors in the study and cure of drug use disorders and highlight a possible role for the STN as a promising target for the treatment of addiction.

Title: Lateral entorhinal cortex neurons that project to nucleus accumbens mediate the expression of cocaine reward

Authors: *H. KUHN[1], B. R. MURRAY[1], D. BERMUDEZ[2], A. ROBISON[1], A. L. EAGLE[1]; [1]Physiol., Michigan State Univ., East Lansing, MI; [2]Neurosci. and Cognitive Sci., Univ. of Arizona, Tucson, AZ

Abstract: Neuronal circuits that synapse onto nucleus accumbens (NAc) medium spiny neurons are critical for regulating motivated behaviors, including those underlying drug reward and drug seeking. Lateral entorhinal cortex (LEC) is activated by craving in cocaine-dependent individuals and by cocaine-associated cues in rats. The LEC also sends axonal projections to the NAc (LEC-NAc), but how LEC-NAc neurons regulate drug reward and seeking behavior is currently unknown. We sought to determine how LEC-NAc neurons mediate drug seeking behavior and reward in mice. We used blinded behavioral experiments in 8-12 week old male and female C57Bl6J mice and replicated our findings across multiple cohorts to ensure scientific rigor. As has been previously shown for LEC neurons in general, we found that LEC-NAc neurons are activated by acute cocaine in mice as measured by cFos expression. We also used viral-mediated, circuit-specific DREADDs (Designer Receptors Activated by Designer Drugs) to show that LEC-NAc activity necessary for the expression of cocaine reward in conditioned place preference. Ongoing studies will determine whether this circuit also regulates relapse to cocaine seeking in a cue-dependent intravenous self-administration mouse model. These findings suggest that the previously unexplored LEC-NAc circuit is necessary for reward and implicate an entirely novel key pathway in the regulation of motivated behaviors relevant to cocaine addiction.

Title: A single acute fear experience redirects projections from the anterior cingulate: Evidence for a biological mechanism of anxiety and substance abuse disorders

Authors: E. L. BEARER[1,2], T. W. USELMAN[1], C. S. MEDINA[1], *R. E. JACOBS[3];
[1]Dept. of Pathology, UNM Sch. of Med., Albuquerque, NM; [2]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA; [3]Zilkha Neurogenetics Inst., USC Keck Sch. of Med., Los Angeles, CA

Abstract: Pyramidal neurons from anterior cingulate area (ACA) in the prefrontal cortex (PFC) project into striatum, thalamus, hypothalamus and reach as far as dorsal raphe (midbrain) and locus coeruleus (pons). Neural activity in ACA is reciprocally modulated by monoamine systems

arising in these same caudal brain regions: noradrenergic, dopaminergic and serotonergic. We previously reported that projections from PFC are redirected when these monoaminergic systems a genetically disrupted. Here we report that a single experience of acute threat also redirects ACA projections in wild type mice, and this change correlates with multiple subtle behavioral effects. Mice with or without acute threat (30m exposure to predator odor) (2,3,5-Trimethyl-3-thiazoline, TMT) were group-housed in an environmentally controlled facility for 3 weeks and then underwent manganese-enhanced MRI tract-tracing. Behavior was video recorded before odor, during odor and before tract-tracing. $MnCl_2$ (3-5nL of 0.6M in saline) with 0.5 mg/ml 3k rhodamine dextran was injected into right ACA and the location confirmed by post-injection MRI: $x = 0.59 \pm 0.13$ (R of midline), $y = +0.72 \pm 0.49$mm (bregma), $z = -1.04 \pm 0.36$ mm (deep) ($n = 24$). Longitudinal images were collected at 0.5, 6 and 24h after injection. Between imaging sessions animals were returned to their home cages. At conclusion of imaging, mice were sacrificed and perfusion-fixed brains processed for microscopy. Voxel-wise SPM comparisons between time points revealed progression of Mn(II) accumulation distally ($p<0.001$ FDR). Application of our new in vivo atlas to automated measurements of Mn(II) signal revealed dramatic anatomical differences in projections between animals experiencing acute threat and those without, including stronger connections to the PAG and hypothalamus after threat. Comparisons of projections between threat-exposed and mice with genetic disruptions of monoaminergic transporters suggested that fear-induced ACA projections were most similar to those in the norepinephrine transporter (NET) knock-out, where the interstitial amount of noradrenaline is increased. Acute threat further impacted ACA projections in mice lacking the serotonergic transporter (SERT). Future work will explore whether a single dose of cocaine, which inhibits all three monoamine reuptake transporters, has similar effects on ACA projection anatomy. Plasticity of ACA projections evidenced by this remodeling would produce enduring changes in reward circuitry, explaining how life-threatening experiences or cocaine exposure pose risks for anxiety and substance use disorders. Supported by NIH RO1 MH096093 (ELB) and DA018184 (REJ).

Title: Animal movements can be decoded to reveal choice, reward outcome, and the presence of optogenetic stimulation

Authors: *C. YIN[1], A. KOSTIUK[1], S. MUSALL[2], X. R. SUN[3], S. GLUF[4], A. K. CHURCHLAND[1];
[1]UCLA, Los Angeles, CA; [2]Inst. of Biol. Information Processing (IBI-3), Jülich, Germany; [3]Zucker Sch. of Med. at Hofstra/Northwell, Hempstead, NY; [4]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Developments in automated movement tracking open the door to understanding how movements on multiple timescales relate to diverse aspects of behavior and internal state. These tools are especially relevant to decision making: recent studies have revealed the considerable influence of uninstructed movements on neural activity (Musall, Kaufman et al., 2019). However, these findings have left unanswered how these movements relate to the other aspects of decision-making behavior at both the single-trial and session level. Further, the impact of optogenetic stimulation on such movements is not fully understood. To address this, we analyzed video datasets from 7 head-fixed mice trained on a two-alternative perceptual decision-making task. We deployed DeepLabCut to track the movements of 26 points on the mice (Mathis et al., 2018). We report three observations: 1. The movement pattern of mice tracked by DeepLabCut could predict upcoming choice, reward outcome, and trial history. This indicates that videos contain rich task-related information, much of which is hardly perceptible to human observers. 2. The variance remaining in the video tracking after task-related information was regressed out (termed “task-independent variance”) was associated with worse overall performance in 6/7 mice. This indicates that some spontaneous, uninstructed movements may reflect disengagement or may interfere with the animal’s ability to do the task effectively. 3. We found that movements could distinguish the presence vs. absence of transient optogenetic stimulation. This was true even when traditional movement metrics (e.g. reaction time) were unaffected. Interestingly, optogenetic stimulation of different pyramidal neuron cell types (FezF2, PlexinD1 and EMX) and brain areas (frontal vs. parietal cortex) triggered distinct movement changes, implying these changes are not merely the byproduct of stimulation, but contain rich information about the neurons being manipulated.These observations suggest that fluctuations of spontaneous movements on multiple timescales may uncover rich information about the internal state and neural activity of animals. Further, our analyses argue that fully understanding the impact of optogenetic perturbations can require a careful analysis of diverse movements.

Title: Cortex-wide decision circuits are shaped by distinct classes of excitatory pyramidal neurons

Authors: *S. MUSALL[1], X. R. SUN[2], H. MOHAN[3], S. GLUF[4], Z. J. HUANG[3], A. K. CHURCHLAND[4];
[1]Res. Ctr. Juelich, Juelich, Germany; [2]Dept. of Neurosurg., Hofstra University, Zucker Sch. of Med., Hempstead, NY; [3]Dept. of Neurobio., Duke Univ. Med. Ctr., Durham, NC; [4]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: To understand the neural circuits that maintain complex behavior, it is crucial to investigate the role of the distinct cellular subtypes that comprise them. Much effort has focused on inhibitory neuron subtypes but the functional roles of excitatory pyramidal neuron (PyNs) subtypes are less well understood. We used widefield calcium imaging to measure the cortex-wide activity of distinct PyN types and investigated their functional role in mice making auditory decisions. We studied neural activity in two knock-in driver mouse lines by expressing the calcium indicator GCaMP6 in two non-overlapping PyN populations: FezF2 (pyramidal tract, or PT) and PlexinD1 (intratelencephalic, or IT) neurons. Cortical activity was compared to a third line, EMX, which expressed GCaMP6 in all excitatory neurons. Using dimensionality-reduction methods, we isolated cortex-wide activity patterns from PT, IT and EMX mice. These analyses revealed major differences in the complexity and spatial layout of cortical activity patterns in each PyN subtype, both at a cortex-wide and a within-area scale. Next, we used linear encoding models to test for differences across PyN subtypes in relation to decision-making. In all PyN subtypes, the linear model predicted neural variance with high accuracy: up to 90% of variance in some areas. Interestingly, the relative importance of task variables differed across PyN subtypes. PT activity was better explained by the mouse's choice, especially in secondary motor cortex (M2), while IT activity was better explained by sensory and task history variables, especially in parietal cortex. Temporally restricted and cell-type specific optogenetic suppression confirmed a causal role for parietal cortex in sensory processing and M2 for formation of choice. Finally, we further probed the representation of choice by training decoders to predict the animal's decision based on the neural activity of each PyN cell type. Robust choice-predictive signals were found in EMX and PT populations in area M2. These signals ramped up throughout the stimulus and delay period. By contrast, M2 choice signals continuously decreased after the stimulus for IT neurons. For activity from an intersectional viral strategy that selectively labeled corticostriatal projection PyNs, the choice signal in M2 was again negatively weighted by the model. Our results argue that during decision-making, PyNs do not act as a monolithic group, but instead have distinct roles that are linked to their developmental lineage and projection target.

These distinct roles are evident across cortex and throughout a decision, and are especially clear in frontal structures late in the decision.

Title: Mixed representations of memory and visual information for flexible navigation decisions

Authors: *S. KIRA[1], H. SAFAAI[1,2], A. S. MORCOS[1], S. PANZERI[2,3], C. D. HARVEY[1]; [1]Harvard Med. Sch., Boston, MA; [2]'Istituto Italiano di Tecnologia, Rovereto, Italy; [3]Univ. Med. Ctr. Hamburg-Eppendorf (UKE), Hamburg, Germany

Abstract: The survival of many animals requires navigation by making decisions based on sensory cues and past experience. In particular, identical sensory cues can carry distinct meanings depending on the context, such as memories of recent experiences, and thus can require different behavioral actions to achieve a rewarding outcome. A key computation for flexible navigation decisions is therefore the integration of internal contextual signals with sensory signals to inform a goal location and guide an appropriate behavioral action. Here we aimed to reveal the cortical areas and neural mechanisms that are central to combining contextual information stored in memory and visual signals to mediate flexible decision-making during navigation.

We trained mice to perform a delayed match-to-sample task in a virtual reality T-maze. As the mouse ran through the maze, the mouse sequentially observed two cues separated by a short delay (~1 s). The mouse was required to combine the contextual memory established by the first cue and visual information of the second cue to choose an appropriate turn direction at the T-intersection. For a given visual stimulus in the second cue, the mouse responded flexibly with a different turn direction based on the contextual memory of the first cue.

We performed an optogenetic screen to identify cortical areas that are involved in flexible navigation decisions. We bilaterally inhibited different sites across the dorsal cortical surface by optogenetically activating inhibitory neurons in VGAT-ChR2 mice. Inhibition of V1, posterior parietal cortex (PPC), or retrosplenial cortex (RSC) induced a large decrease in the task performance, suggesting that these areas were critical for mice to perform the task.
Two-photon calcium imaging revealed that navigation goals were signaled by neurons that nonlinearly mixed specific combinations of contextual information from short-term memory and visual information. These mixed selectivity neurons formed efficient, easy-to-decode population codes that appeared to govern accurate decision-making because they were informative before correct choices but degenerated during errors. Such mixed selectivity neurons were present in most parts of posterior cortex, even in V1. Surprisingly, these cells were distributed across posterior cortex, including V1, and were densest in RSC and sparsest in PPC. We propose the flexibility of navigation decisions arises from distributed neurons that mix context and visual information within a visual-parietal-retrosplenial network, centered in RSC.

Title: Lesions of the anterior cingulate cortex impairs task engagement and ensemble encoding in dorsomedial striatum during reward-guided decision-making, with minimal impact on single-unit firing

Authors: *D. VAZQUEZ[1], N. PEÑA-FLORES[2], M. ROESCH[1];
[1]Univ. of Maryland, College Park, MD; [2]Univ. of Maryland, Col. Park, College Park, MD

Abstract: The anterior cingulate cortex (ACC) sends projections to the dorsomedial striatum (DMS), constituting part of the corticostriatal circuit—a circuit which has been extensively implicated in the development of goal-directed behaviors. However, there is little understanding of how the ACC might modulate downstream DMS signaling during reward-guided decision-making. In this study, we aimed to elucidate the role of the ACC in the modulation of downstream response-outcome encoding and action planning in DMS. To address this issue, rats were trained on a reward-guided decision-making task; reward value was manipulated by independently varying the size of or the delay to reward over several trial blocks. Subsequently, we unilaterally injected either ibotenic acid (experimental group) or saline (control group) into the rat ACC, and rats performed the previously learned reward-guided decision-making task

while we recorded from single neurons in DMS. We found that ACC lesions resulted in impairments across all trial-types and behavioral measures; lesioned rats performed significantly worse across all trial types, chose high-valued rewards less frequently than control rats, and had significantly slowed reaction and movement times. Ensemble analysis also seems to suggest that ACC lesions resulted in impaired population encoding in the DMS, but did not significantly disrupt encoding at the level of single units. These results suggest that the deleterious behavioral effects observed following ACC dysfunction do not arise as a result of single-unit disruptions of downstream action-outcome encoding when attention is necessary for learning (i.e., during block transitions), but rather are related to a breakdown in neural ensemble encoding during complex reward-guided decision-making.

Title: Mesoscale Activity Map (MAP) underlying a memory-guided decision acquired with standardized, multiplexed, brain-wide Neuropixels recordings

Authors: *S. CHEN[1], Y. LIU[2], Z. WANG[2], L. D. LIU[3,1], H. HOU[3,1], N.-W. TIEN[1,2], T. T. NGUYEN[4], N. LI[3,1], S. DRUCKMANN[2], K. SVOBODA[1];

Abstract: Our brains can maintain information over timescales of a few seconds to guide future actions. Such 'short-term memory' (STM) serves as the brain's post-it note and is essential for cognition, such as motor planning, decision-making, and foraging. The neural correlates of STM have been studied mostly one brain region at a time. For instance, neurons in the frontal cortex and related brain regions show persistent and slowly varying changes in spike rate that correlate with the maintenance of STM. Yet, how coordinated neuronal activity across inter-connected

brain regions collectively maintains STM remains poorly understood.We used up to five Neuropixels probes to simultaneously record the activity of hundreds of neurons across more than a dozen brain regions during a memory-guided delayed response task in the mouse. Anterior lateral motor cortex (ALM; part of M2) is an essential hub for the planning and execution of memory-guided directional licking[1]. Taking an anatomy-guided approach, we targeted regions that form multi-regional networks with ALM, including nuclei in thalamus, basal ganglia, midbrain, pons, medulla, cerebellum and others. Each recording was aligned into the Allen Mouse Common Coordinate Framework to assemble an activity map of STM-related activity[2]. These measurements were combined with detailed movement tracking and precise optogenetic perturbations. We developed pipelines for processing[3], analyzing, and sharing the large-scale neurophysiological and behavioral data (datajoint.io). 50,000 high-quality single units were obtained in 692 penetrations from 29 animals. Activity encoding sensory stimuli, choice, movement, and outcome, were distributed across the brain. Choice-selective neurons were more prevalent in the ALM network. At the level of population activity, choice encoding was correlated at the level of single trials across the brain regions of the ALM network. Movements were encoded more strongly in brainstem and midbrain compared to frontal cortex and thalamus. These data provide a foundation for understanding how STM and other neural computations are produced by multi-regional interactions across the brain (Yi Liu et al SFN 2021).

Title: Striatal control of action switching and decision bias

Authors: *J. K. BADYNA[1,2], E. A. YTTRI[1,3];
[1]Biol. Sci., [2]Ctr. for the Neural Basis of Cognition, [3]Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: When selecting actions in noisy and volatile scenarios, animals exhibit a high degree of flexibility with response to environmental contexts, quickly adapting to feedback to better

exploit future opportunities. These decisions are also made in the context of internal biases the animal possesses, which may be beneficial or maladaptive depending upon the environment. The neural underpinnings of these biases and how they can be modified is not well understood, but considerable work suggests that the representation of the decision environ relies critically on cortical-striatal pathways, whose circuit-level architecture is ideally suited for adapting decision policies via positive and negative reinforcement mechanisms. This reinforcement mechanism has been shown to be under the control of the direct and indirect pathways, respectively. To understand how these neural populations contribute to decision making across varying levels of reward conflict, we trained mice to push or pull a joystick within the context of a two-armed bandit task. Importantly, any changes in decision-making strategy across the different conflict levels was influenced purely by reward feedback information - the mice were not explicitly cued regarding optimal decisions nor environmental contexts. Decision strategies were altered by conflict level, but reach kinematics were not. Further, direct pathway (dSPN) stimulation exacerbated choice bias. Together, the data suggests that decision-making behavior is subject to the environment in which the decision is being made (even when that environment is only revealed through feedback information), and dSPN activity may serve to reinforce internal biases regarding decision-making.

Title: Neural signatures of vigor and proactive responses during perceptual decisions in dorsomedial striatum

Authors: *L. HERNÁNDEZ-NAVARRO[1], A. HERMOSO-MENDIZABAL[1], J. DE LA ROCHA[1], A. HYAFIL[2];
[1]IDIBAPS, Barcelona, Spain; [2]Ctr. de Recerca Matemàtica, Bellaterra, Spain

Abstract: Standard perceptual decision-making models postulate that responses are triggered in reaction to the stimulus, when the accumulated evidence reaches a decision threshold. This excludes, however, responses that are generated proactively at a time independent of stimulus. We have recently shown that, in a free reaction time (RT) auditory discrimination task in rats, reactive and proactive responses coexist and are triggered when either of two competing processes, respectively Action Initiation (AI) or Evidence Accumulation (EA), reaches a bound.

Importantly, the timing of proactive responses is strongly modulated by both physical fatigue and water satiety. However, the neural substrate of the AI process remains unclear although recent studies have shown ramping dopaminergic activity preceding proactive actions. The dorsomedial striatum (DMS) receives extensive dopaminergic innervation and it is involved in determining the response vigor. Hence, we performed population recordings in the DMS of 4 rats (n= 652 single units) to seek for neural substrates of the proactive AI process. A GLM analysis isolated the different contributions to trial-to-trial variations of individual spike rates and revealed that (1) a large fraction of DMS neurons encodes the current choice from response initiation to the response in the next trial, but we found no encoding of the stimulus information in any trial epoch; (2) a significant subpopulation already encodes RT during fixation, so that the timing of the response can be predicted from before stimulus onset; and (3) a large fraction of neurons show slow modulation of their baseline firing across trials, which parallels slow changes in RT along the session and strongly correlates with motor time and self-paced inter-trial interval, two common behavioral proxies of vigor. Overall, these results suggest that DMS activity, just as it seems to control vigor, may also play an important role in modulating the timing of proactive responses in perceptual decisions.

Title: Bayesian approach to pathological and physiological decision making: involvement of dorsal raphe nucleus serotoninergic neurons

Authors: *Y. PELLOUX[1], C. RAIS[2], M. VEGGI[2], L. NAVA[2], R. TONINI[3];
[1]Inst. Italiano di Tecnologia, GENOVA, Italy; [2]Inst. Italiano di Tecnologia, Genova, Italy; [3]Neuromodulation of Cortical and Subcortical Circuits Lab., Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Current theories do not satisfactorily explain the function of the neuromodulator serotonin (5-HT) on processing rewarding, aversive and ambivalent stimuli. Therefore, new theoretical perspectives are required to define 5-HT contribution to behavior. Our study aimed to assess through a Bayesian approach the contribution of serotonergic neurons of the dorsal raphe

nucleus ($DRN_{5\text{-}HT}$) in decision-making processes that require weighing recent observations and prior beliefs built upon previous experiences. Specifically, we applied Bayesian analysis on a probabilistic discrimination task in which mice are presented two wheels they can turn clockwise or anticlockwise for reward; wheel turning preference is then shaped by contrasting the probability of reward upon the different options. We validated the Bayesian analysis of probabilistic discrimination to be sensitive to the physiological conditions of uncertainty (evoked by tempering reward signaling) as well as pathological conditions (evoked by acute systemic injection of ethanol). By using fiber photometry, we found activation of $DRN_{5\text{-}HT}$ neurons after turning the wheels and at reward collection,, that that is when animals are provided feedback from their motor response. , This feedbackthat allows them to switch between consecutive actions or switch wheel turning preference their choice (behavioral switching). Antagonism of the 5-HT4 receptor subtype in the dorsolateral striatum reduced behavioral switching, as exemplified by an increase in perseverative responses and reduction in the unfavorable use of recent observations. Optogenetic silencing of the DRN prevented further reduction of the use of unfavorable recent observation upon following sessions, suggesting integrated function of the different DRN neuronal populations, and their target regions, in the acquisition and expression of probabilistic discrimination. Together, our results demonstrates the use of Bayesian approach of decision making in pathological and physiological conditions and suggest that $DRN_{5\text{-}HT}$ neurons respond to expected events to switch motor action, and possibly decisions.

Title: Dopamine dynamics during evaluation and reevaluation of neuroeconomic decisions

Authors: *A. KOCHARIAN[1], P. E. ROTHWELL[2], A. D. REDISH[2];
[1]Med. Scientist Training Program and Grad. Program in Neurosci., [2]Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Dopamine signaling in the nucleus accumbens core (NAc core) is an important neural substrate for value-based decision making. Positive changes in dopamine reflect reward

expectation and motivation-driven processes, but dopamine dynamics under economic conditions of varying flavor preference, value, and time budgets have not been extensively studied. Furthermore, decreases in dopamine have been seen in conditions of noxious stimuli or exogenous disappointment, but the dopamine dynamics in settings of internally-driven decision reevaluation are unknown.

Using fiber photometry and viral expression of dLight1.3b to monitor dopamine dynamics in mice during a neuroeconomic foraging task (Restaurant Row), we investigated how dopamine encodes evaluation and reevaluation of decisions. Mice were given 1 hr to forage for food rewards with varying time costs as they ran around a square maze with each corner ("restaurant") dispensing a differently flavored pellet. Upon entering a corner, mice first encountered an Offer Zone (OZ) in which a tone sounded, signaling the delay before reward would be delivered. After the tone presentation in the OZ, the animal could either accept or reject the offer. Mice could reject the offer by continuing to the next corner to receive an offer for a different flavored pellet. Mice could accept the offer by advancing into a Wait Zone (WZ), where the countdown to reward began. During the countdown, the animal had the opportunity to quit the trial at any point and only earned reward if it waited out the entire delay. Early in training, mice indiscriminately accepted most offers. As mice learned to budget their time, they increased their earnings by becoming more selective, rejecting offers for longer delays. The proportion of rewarded trials among accepted offers increased, as mice gradually reduced their quitting behaviors mid-countdown. The time invested before quitting also declined with training.

Dopamine dynamics in the OZ scaled with the value of the offer, consistent with descriptions of dopamine's role in valuation. Early in training, when mice initially accept low-value offers and quit the trial mid-countdown in the WZ, we observed a decrease in dopamine, reflecting re-evaluation processes. As training progressed, and mice transitioned from quitting to rejecting suboptimal offers, decreases in dopamine shifted from the time of quit to the time of offer rejection. This suggests that decreases in dopamine may transition to the earliest decision to reject, reminiscent of the established phenomenon that, with training, dopamine transients shift from the time of reward receipt to the earliest predictive cue.

Title: Cerebellar activity modulates spatial working memory decisions and neuronal interaction between the prefrontal cortex and hippocampus in mice

Authors: Y. LIU[1], S. S. MCAFEE[2], M. E. VAN DER HEIJDEN[3], M. DHAMALA[5], R. V. SILLITOE[4,3], *D. H. HECK[1];

Abstract: Spatial working memory (SWM) is a cognitive skill supporting survival relevant behaviors, such as foraging for food. In rodents, the medial prefrontal cortex (mPFC) and dorsal hippocampal CA1 region (dCA1) are jointly necessary for SWM. SWM-based decisions about maze-arm entry are associated with increased coherence of local field potential (LFP) oscillations between the mPFC and dCA1. Coherence facilitates neuronal communication, suggesting that SWM decision making involves increased mPFC-dCA1 communication. The mechanisms controlling task-specific modulation coherence are unknown. Several studies have implicated the cerebellum in SWM and we recently showed that Purkinje cells in cerebellar lobulus simplex (LS) and Crus I represent phase differences between oscillations in the mPFC and dCA1. Here, we asked whether the role of the cerebellum in SWM involves the modulation of mPFC-dCA1 coherence. We tested SWM performance in 9 adult mice (5 females, 4 males) by observing spontaneous exploration behavior in a plus maze. All mice expressed Channelrhodopsin2 in cerebellar Purkinje cells, had extracellular recording electrodes implanted into the mPFC and dCA1 and an optic fiber (465 nm) implanted over LS for optogenetic stimulation. Photoactivating LS Purkinje cells in the early stages of the SWM decision process impaired SWM performance and multiple aspects of neuronal activity in the mPFC and dCA1, suggesting a causal involvement of the cerebellum in SWM decision making and in the modulation of multiple aspects of decision related activity in the mPFC and dCA1. LFP peak activity in mPFC and dCA1 reflected decision outcome, with correct decisions associated with higher peak values than incorrect decisions. Stimulation of LS disrupted the LFP activity and decision related differences. The power of LFP oscillations in both the mPFC and dCA1 reached peak values during decision making in control trials, which were disrupted in trials with cerebellar stimulation. The coherence of beta and gamma range oscillations in mPFC and dCA1 increased during SWM decision making with higher coherence values observed during correct decisions in control trials. Cerebellar stimulation disrupted decision related coherence increases, which also no longer differentiated between decision outcomes. Granger causality showed no SWM related changes in control trials. LS activation caused increased dCA1->mPFC causality in the gamma range during correct vs. incorrect decisions. Our results suggest a causal involvement of the cerebellum in SWM, possibly through the modulation of multiple aspects of neuronal activity and functional connectivity between the mPFC and dCA1.

Title: Processing of attentional cues is selectively increased after action errors in the service of behavioral adaptation

Authors: *Y. GUAN[1], J. R. WESSEL[2];
[1]Psychological and Brain Sci., Univ. of Iowa, IOWA CITY, IA; [2]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Many theories of action error processing (e.g., Wessel, 2018; Purcell & Kiani, 2016) propose that errors trigger a processing cascade that involves attentional processes - such as orienting to the source of the error or the selective retuning of attentional representations of task relevant stimuli. Here, we aim to test whether attentional cues in the context of the Posner's attention network test (ANT; Posner & Rothbart, 2007) selectively benefit error processing. In the ANT, spatial cues provide valid information about where subsequent task-relevant stimuli will occur, thus directing attention to the cued location. The orienting effect is defined as the accelerated RT and increased accuracy with spatial (informative) vs. center cues (noninformative). However, little is known about the orienting effect and its underlying neural activities in post-error processing. We hypothesized that errors lead to an amplification of the beneficial effect of the attentional cues. Preliminary analyses of behavioral and EEG data (Fig.1) showed increased orienting effect on RT in post-error short RSI condition, and increased orienting effect on accuracy in post-error long RSI group. Time-frequency decompositions showed increased beta power (13-20 Hz) within 200ms following spatial vs. center cues in post error vs. post-correct condition. The increased beta power difference between spatial and center cues condition in post-error condition could reflect the enhanced attention triggered by spatial cues after error commission. This is consistent with Cómez et al. (2009), where increased beta power was found at the attended vs. unattended condition. Nonhuman studies with cats also showed sustained beta synchronization during attentional expectancy of stimuli (Roelfsema et al., 1997). In summary, we found that the orienting effect was modulated by error commission, in that errors were followed by greater orienting effect. Together with the beta effect, the results suggest processing of attentional cues is selectively enhanced after action errors in the service of behavioral adaptation.

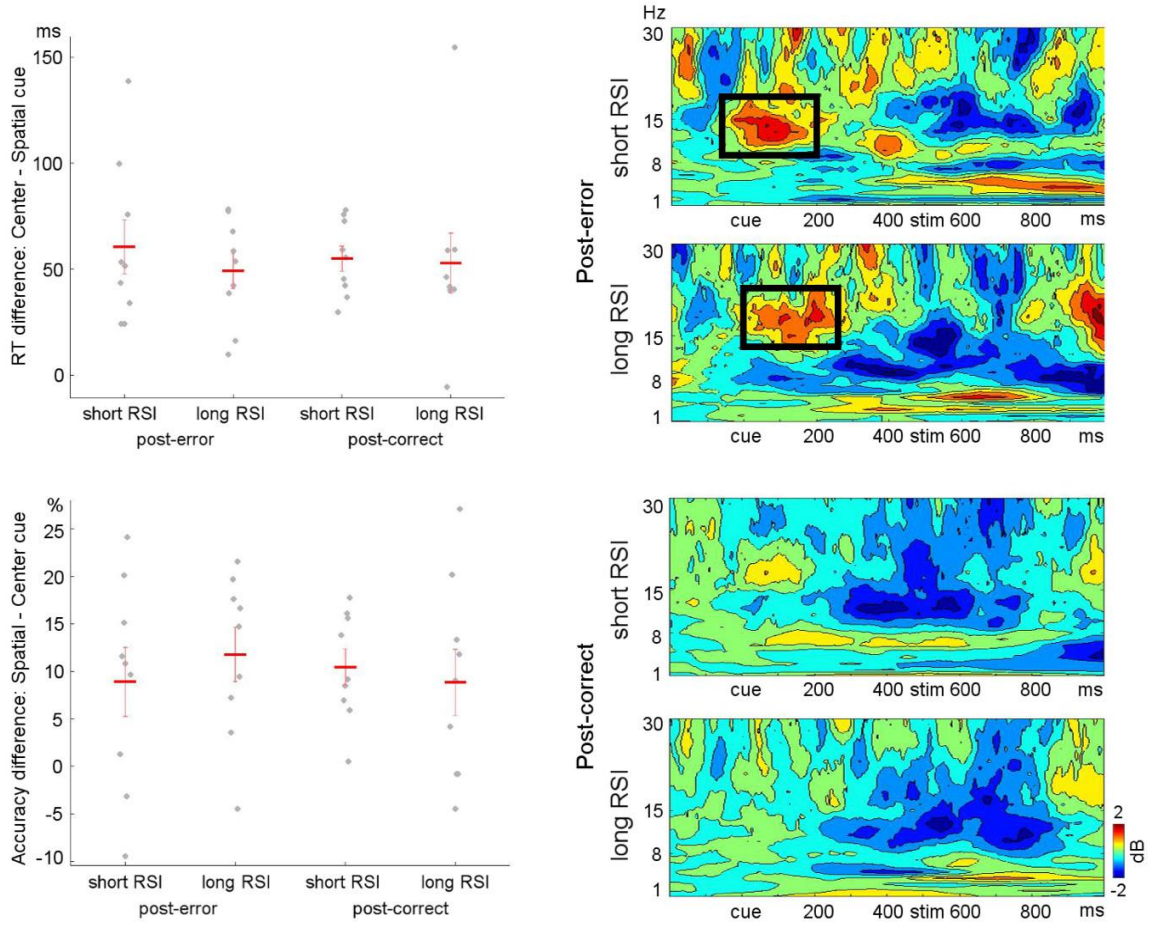

Figure 1. Behavioral results (left side) for reaction time (top left) and accuracy (bottom left) difference showing the orienting effect as a function of trial type (post-error vs. post-correct) and response-stimulus intervals (RSI; 1500 or 500ms) conditions. Grand mean time-frequency planes (right side) showing dynamic power changes at frontal midline electrodes (FCz Cz) relative to a 200ms pre-cue baseline as a function of trial type (post-error vs. post-correct) and RSI (long vs. short) conditions. Power values were obtained via subtracting power in center cue trials from spatial cue trials. Note the increased power at the beta band (13-20 Hz) after cue onset in the post-error conditions, which suggests orienting triggered by spatial cue facilitates the post-error processing.

Title: Assessing test-retest reliability of fronto-parietal fMRI activity patterns associated with cognitive control

Authors: *M. FREUND[1], R. TANG[3], T. BRAVER[2];
[1]Washington Univ. in St. Louis, Saint Louis, MO; [2]Washington Univ. in St. Louis, St Louis, MO; [3]Washinton Univ. in St. Louis, St Louis, MO

Abstract: A major goal of cognitive neuroscience is to understand the neural bases of individual differences in cognitive control abilities. Neural measures useful for individual differences analyses need to exhibit both high psychometric reliability and convergent validity. Task-activation fMRI has recently been questioned in terms of its suitability for studying individual differences, due to poor test-retest reliability (Elliot et al., 2020, *Psych. Sci.*). But, prior work has primarily assessed reliability using (a) classical test theory statistics (e.g., intra-class correlation), (b) traditional 'univariate' measures of neural activity, and (c) data from single cognitive control tasks (e.g., N-back). Here, we tested whether added sensitivity and reliability could be gained through a multivariate, multi-task approach. We adopted the "neural fingerprinting" approach (Finn et al., 2015, *Nat. Neurosci.*), leveraging the Dual Mechanisms of Cognitive Control dataset (Braver et al., 2021, *J. Cog. Neurosci.*), consisting of fMRI data acquired from human participants each performing four classic cognitive control tasks (AX-CPT, task switching, Sternberg, and Stroop). The sample of participants was split into two subsets: a subset (N = 15) that completed two testing sessions ("test" and "retest", >2 months apart), and a subset (N = 92) that completed only the first. A set of cortical regions commonly recruited across the four tasks by trials with high control demand was identified, primarily within fronto-parietal and cingulo-opercular areas. The neural activation pattern extracted from the high vs low-demand contrast, distributed across these regions, was treated as a multivariate analytic unit (one per task*participant). Pattern similarity was compared between and within-individuals, testing whether the pattern from an individual at one timepoint ("retest") was more similar to their pattern at another timepoint ("test"), relative to patterns from all other individuals at that timepoint — thus accurately identifying them via their neural fingerprint. In all comparisons, participants could be identified with high accuracy (80–100%), but critically, only when aggregating data across tasks into a single, task-general measure. Activation patterns extracted from matched-control brain regions did not demonstrate this sensitivity. Additional analyses explicitly compared multivariate and univariate measures in their reliability and sensitivity to individual differences Together, the results suggest that multivariate, multi-task fMRI may be a more sensitive and reliable tool for studying individual differences of cognitive control.

Title: Forcing the winning horse: how the amount of force on a push button affects the inhibition of finger release in a stop signal task.

Authors: *S. COLANGELI[1], S. RAMAWAT[2,1], I. B. MARC[2,1], P. PANI[1], S. FERRAINA[1], E. BRUNAMONTI[1];
[1]Dept. of Physiol. and Pharmacol., [2]PhD Program in Behavioral Neurosci., La Sapienza, Rome, Italy

Abstract: Suppressing a pending action is an essential ability when someone must cope with an unpredictable situation. This component of executive control has been extensively studied by the stop-signal task (SST). SST is a task requiring to respond with a movement to a go signal (go trials) but to refrain from the movement when occasionally a stop signal occurs after the go signal (stop trials). A theoretical model describes the outcome in stop trials as a race towards a threshold between a go and a stop process. Every time the go process runs faster than the stop process the movement cannot be interrupted (stop error trials). In addition, it has been hypothesized the go process as a two-stage process including: 1) a controlled stage (CS), that can be inhibited at any time; 2) a ballistic stage (BS), that cannot be inhibited. A point-of-no-return defines the crossing line between CS and BS. It has been reported that perceptual and cognitive variables can affect the duration of CS and influence the probability of the stop process to win the race. Besides these factors, for some effectors, the state of biomechanics variables could influence the start of the go process. For example, we can hypothesize that if we ask someone to push a button and then release it in response to a go signal, the strength applied to push the button at the beginning of a given trial could play a role in influencing the CS of button release and, consequently, the run of the go process against the stop process. Here we tested this hypothesis by studying 20 healthy volunteers performing a button release SST while monitoring the time evolution of CS by a force sensor resistor (FSR) fixed on a mouse button. The analysis of the perturbation of FSR revealed in a proportion of correctly stopped trials, defined as “partial errors”, an initial decline of the force applied on the button (as in go trials), followed by a rising back of it. This FSR pattern was never observed in stop error trials. Looking at the amount of force exerted on the button at the beginning of trials, it was significantly higher in partial error than in stop error trials, suggesting that trials started with an initial high force on the button have higher probability to turn in correct for higher differences between the force at the beginning of CS and that at the time of movement onset. Moreover, in partial errors the velocity of decay of the FSR signal was lower than in stop error trials, allowing subjects to stay within the CS for longer. These results point out that models of movement inhibition need to account for the biomechanical state of the effector before the go-signal.

Title: Anterior cingulate cortex proactively controls and monitors action during saccade countermanding

Authors: *S. P. ERRINGTON[1], A. SAJAD[1], J. D. SCHALL[2];
[1]Dept. of Psychology, Vanderbilt Univ., Nashville, TN; [2]Ctr. for Vision Research, Vision Sci. to Application, Dept. of Biol., York Univ., Toronto, ON, Canada

Abstract: Anterior cingulate cortex (ACC) is known as a hub for cognitive control. Convergent evidence across species and methodologies has supported its role in adapting behaviors and evaluating the outcome and value of actions. However, neurophysiological evidence for how ACC contributes to reactive and proactive control is sparse, and its role in conflict monitoring is debated. To address this we analysed a preliminary sample of 538 units recorded from 992 linear electrode contacts (50, 100, 150 µm spacing) across 18 independent sites. Sites spanned an 8 mm rostro-caudal zone, and contacts captured the dorsal (area 6/32) and ventral (area 24c) banks of the anterior cingulate sulcus of two macaque monkeys. Whilst recording neural signals, monkeys performed a saccade countermanding (stop signal) task, in which they were required to generate a saccade to a target on its appearance, but to inhibit this planned saccade when an infrequent stop-signal appeared. The time at which the stop-signal appeared varied, resulting in an equal probability of successful inhibition or committing an error. As such, this task offers a clear method in which neural signals can be attributed to the generation of actions and their monitoring. This analysis quantified the incidence of neurons (1) exerting reactive control, (2) detecting response conflict, or (3) nudging proactive control. We found no neurons meeting criteria to accomplish gaze-shifting or gaze-holding, nor modulating systematically enough within the relevant timeframe to exert reactive control of response inhibition. Likewise, we found no neurons meeting criteria to signal response conflict. Instead, we found numerous neurons that could enact proactive control by differentiating between successful and failed inhibition before presentation of the stop-signal. These neurons operated over different timescales: some recruited ~100 ms before the stop-signal and others predicting performance

during the preceding inter-trial interval. These results contradict a dominant theory of ACC function and offer new insights into the contributions of ACC to proactive control of behavior.

Title: Magnetoencephalography shows increase of right-inferior frontal gyrus beta power for response conflict - A generalized response inhibition function?

Authors: *P. L. DANIEL[1], J. BONAIUTO[2], G. BARNES[3], S. BESTMANN[3], A. R. ARON[1], S. LITTLE[4];
[1]Psychology, UCSD, La Jolla, CA; [2]Insitut des Sci. Cognitives Marc Jeannerod, CNRS, Bron, France; [3]Univ. Col. London, London, United Kingdom; [4]Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: It is well established that the right-inferior frontal gyrus (R-IFG) is recruited during outright action stopping, and that this relates to increases in beta (12-30 Hz) power. Some work has suggested that inhibition of incorrect response tendencies contributes to overcoming response conflict. However, very little research has implicated R-IFG in conflict, and to our knowledge, no one has shown this R-IFG beta signature of response inhibition during conflict. In the current study, we analyzed existing high-resolution magnetoencephalography (MEG) data recorded from a small cohort (N = 8) that completed many trials (n > 10,000 total) of a response conflict paradigm (Little et al., 2019). Subjects saw a random dot motion that varied in coherence (high, medium, low) and whether it accurately (70%; no conflict) or inaccurately (30%; conflict) predicted a subsequent movement cue. We tested the novel hypothesis that R-IFG MEG sensors would show increased beta on conflict trials, particularly so when the level of conflict was strongest (i.e., on higher coherence trials). We first computed average event-related spectral perturbations (ESRPs) at the group level for conflict and no conflict trials. We saw increased R-IFG low beta power during conflict. This was specific to R-IFG, as we did not see a similar increase in left-IFG (L-IFG) beta power. We then ran linear mixed effects models for subject-

specific low beta activity at the single trial level. Supporting the qualitative picture from the ERSP results, there was a significant main effect of response conflict on subject-specific low beta in R-IFG ($X^2(1) = 12.11$, $p < .001$), and not in L-IFG. Additionally, there was a significant interaction between conflict and coherence on subject-specific low beta in R-IFG ($X^2(2) = 6.76$, $p < .05$). To visualize this interaction, we computed average ERSPs for conflict and no conflict trials, for high, medium, and low coherence trials separately. We saw increased R-IFG low beta power during conflict for high and medium coherence trials, but not for low coherence trials. Pairwise comparisons revealed the difference in R-IFG subject-specific low beta was significant for high coherence trials only ($Z = -4.02$, $p = .0001$). Our results show that R-IFG beta is recruited on response conflict trials, especially those that would appear to require punctate response inhibition. This suggests a more generalized role for response inhibition, beyond stopping tasks to conflict scenarios.

Title: Beta-band in the premotor cortex of non-human primates predicts the strategy adopted in a selective stopping task

Authors: *M. ANDUJAR[1,2], F. GIARROCCO[1], G. BARDELLA[1], P. PANI[1], S. FERRAINA[1]; [1]Dept. of Physiol. and Pharmacol., [2]Behavioral Neurosci. PhD Program, Sapienza Univ., Rome, Italy

Abstract: Among motor cortical oscillations, those in the Beta (β) frequency range [~12–30 Hz] have received particular attention. Different theories arose about the role of sensorimotor β activity in cognitive control, including those suggesting that β-activity subserves the maintenance of a sensorimotor set, like, for example, a strategy adopted by an agent moving in a changing environment. Here, we focused on the role of β- activity in encoding the strategy adopted by two rhesus monkeys (Macaca mulatta) trained in the Stop Selective Task (SST). In this task, participants are required to cancel the planned movement after a particular stimulus (Stop signal) but not after a different one (Ignore signal) occurring randomly after a Go signal during the reaction time (RT). Behavioural studies suggest that participants can adopt different strategies to adapt to the task demands, inhibiting the response only upon discriminating the Stop signal, or whenever detecting an imperative signal. We hypothesize that these different strategies rely on the relative prevalence of one of two inhibitory controls (i.e. proactive and reactive inhibition)

and that the level of β- activity can be used to predict which strategy will be adopted at the single trial level. To test this hypothesis, we recorded Local Field Potentials, by means of Utah arrays (96 Channels) implanted on the dorsal premotor cortex of the monkeys performing the SST, and used β-power as predictor of the strategy adopted. First, we confirmed that β-power decay is positively correlated with RTs, independently of the strategy emerging behaviorally, suggesting that β-activity is regulating the level of motor responsiveness. Secondly, we found that β-power exhibited different patterns of response to the presentation of the Ignore signal, increasing only when a certain strategy was behaviorally emerging. Then we analysed the after-Ignore single trial β-activity via a multiclass-classification algorithm and found that strategies can be described based on β-activity similarity between different trial types. Finally, we used a binary linear classifier to test if the level of β-activity before the Go signal could account for the strategy adopted. We found that, independently of the level of movement preparation (modelled by RT duration), β-band is a reliable predictor of the strategy. We therefore suggest that the β-activity level before the Go signal indicates the amount of proactive control and drives the subsequent response pattern to an imperative stimulus. Our results are thus in agreement with the hypothesis that β-band subserves the maintenance of a sensorimotor set.

Title: Cortical β-bursts following unexpected events in auditory, visual, and tactile modalities

Authors: *J. R. TATZ, A. MATHER, J. R. WESSEL;
Univ. of Iowa, Iowa City, IA

Abstract: The human brain constantly monitors the environment for unexpected events in the service of potentially adapting behavior. For example, in a cross-modal oddball (CMO) task, in which motor responses are made after (sometimes unexpected) sensory stimuli, the brain tracks their occurrence and adapts behavior by slowing reaction times. Using the CMO, Wessel and Huber (2019, PLoS Comput Biol) found that while the brain tracks Bayesian surprise terms separately for auditory and visual stimuli, a crossmodal fronto-central P3 event-related is

triggered by both events. Independent component analysis revealed that the neural generator underlying this P3 was also active after stop-signals in a separate task that required active motor inhibition, suggesting that surprising events trigger a common inhibitory network through which they slow reaction times. The present study fulfilled two purposes: First, we replicated and extended Wessel and Huber's findings to include a tactile modality. Second, we tested whether recently discovered indices of inhibition - namely, burst-like beta activity at fronto-central scalp sites (Wessel, 2020, J Neurosci) - also occurred after unexpected events. We recorded extracranial EEG from participants who completed a CMO task with unexpected auditory, visual, and tactile events. Like unexpected auditory and visual events, tactile events also induced motor slowing, particularly early in the experiment, when Bayesian surprise was high. Replicating Wessel & Huber, our analysis suggested that the fronto-central P3 reflects separate Bayesian surprise terms across the three sensory domains. In terms of beta bursts, both the original Wessel and Huber dataset (n = 55) and our current three-domain dataset (n=21) showed increased β-burst rates at the FCz electrode following unexpected events. These differences were significant within the first 200ms following unexpected auditory events in both experiments, and as early as 75ms following tactile unexpected events in the new data. These findings suggest β-bursts as a potential early marker of inhibition after unexpected events across sensory domains—i.e., even in contexts that do not explicitly require inhibition.

Title: Greater Adiposity Influences Working Memory and Cognitive Inhibition

Authors: *B. A. LARSEN[1,2], B. S. KLINEDINST[3,2], J. GRUNDY[4], A. A. WILLETTE[3]; [1]Biomed. Sci., [2]Neurosci. Grad. Program, [3]Food Sci. and Human Nutr., [4]Psychology, Iowa State Univ., Ames, IA

Abstract: INTRODUCTION: Obesity rates of adults in the U.S. have increased from 30.5% in 1999-2000 to 42.4% in 2017-2018, with a further projected prevalence to nearly 50% by 2030. Greater adiposity has been consistently associated with exacerbated brain atrophy and central glucose hypometabolism in prefrontal cortices that govern executive functions, including inhibitory control, working memory, emotion regulation, and cognitive flexibility. However, there is a paucity of research elucidating how neural physiology that governs these executive

functions is impacted by obesity. Thus, our primary aim of this study was to investigate whether such electrophysiological changes due to obesity could be detected in healthy young adults. **METHODS**: In this cross-sectional study, we recruited 60 participants (18-40 years, 55% female) and examined real-time neural electrophysiology using electroencephalography (EEG) on 34 lean participants (mean body mass index (BMI)=22.1±2) and 26 overweight/obese participants (mean BMI=34.9±6.1) while they completed four cognitive tasks which separately focused on inhibitory control, working memory, emotion regulation, and cognitive flexibility. Serum proteomics were collected, and glycemic control was quantified from glycated hemoglobin (HbA1c) serum measures. We directly assessed body composition via dual energy X-ray absorptiometry (DXA). Structural equation modeling was utilized in to probe direct/indirect associations between body composition, cardiometabolic biomarkers, and EEG waveforms. **RESULTS**: After controlling for age, sex, HbA1c, and DXA android/gynoid ratio, we found that higher body fat percentage was associated with a significantly slower response in order to reach trough amplitudes on the FC1 electrode (196.3±134.4 milliseconds (ms) versus 204.4±311.1ms; β=0.94, p<0.001), as well as a significantly slower response in order to reach peak amplitudes on the FT7 electrode (215.9±129.9ms versus 334.1±327.2ms; β=-0.537, p=0.019) during a Stroop task. Furthermore, we found that higher body fat associated with significantly slower responses in order to reach trough and peak amplitudes on the FT7 electrode (202.9±95.4ms versus 567.2±434.5ms, β=-0.87, p=0.032; and 543.4±205.2ms versus 613±333.9ms, β=-0.79, p=0.049, respectively) during an Operation Span task. No differences were observed between obese and lean subjects for emotion regulation or cognitive flexibility tasks. **CONCLUSION**: Young adults with greater adiposity may have impaired cognitive inhibition and decreased working memory capacity compared to lean counterparts.

Title: Task-instruction modulates intra-individual variability and motor response inhibition to negative stimuli in older and younger adults

Authors: *S. MIRAJKAR, S. E. WILLIAMS, J. D. WARING;
Psychology, St. Louis Univ., Saint Louis, MO

Abstract: Intra-individual variability (IIV) refers to inconsistencies in an individual's behavioral task responses. Increased IIV may indicate inefficient cognitive processing and decreased central nervous system integrity. Previous literature has identified a relationship among higher IIV, age-related neurodegeneration and decline across several cognitive domains. In the domain of executive functioning for example, higher IIV is linked with poorer response inhibition. However, the impact of aging on the relationship between IIV and emotional response inhibition is an open question given reported age-related changes in emotion regulation. The present study examined if age and/or task instruction modulated the relationship between IIV and motor response inhibition to emotional stimuli. We used an emotional stop signal task that displayed human faces with happy, fear, or neutral expressions in 'Stop' trials. Older (age = 60-86 yrs) and younger (age = 17-27 yrs) men and women (N = 237) completed one of three versions of the task, which differed in instructions about the stop-signal: emotion was task-irrelevant for the stop-signal for two versions, and task-relevant in the third version. Stop signal reaction times (SSRT) were calculated for each facial expression separately, and fear and happy SSRTs were also compared to neutral. IIV was measured using the standard deviation of the response time for accurate 'Go' trials. We observed a significant relationship between response consistency and inhibition only when emotional attributes of the stop-signal were relevant to task goals; when task instructions required overt focus on emotion, the people with the more consistent responses (i.e., lower IIV) had more efficient response inhibition (i.e., lower SSRT) for fear expressions compared to neutral. Negative stimuli can promptly elicit attention and are more effective measures of involuntary interference to tasks than positive stimuli. Task-goals may amplify these characteristics of negative stimuli. Although IIV differed between age groups, age did not moderate the relationship between IIV and response inhibition, suggesting neural resources similarly support response consistency and inhibition in both older and younger adults.

Title: Functional connectivity dynamics of the frontoparietal and default mode networks during cognitive control in children with attention-deficit hyperactivity disorder

Authors: *A. D. CASCONE[1], C. MICHAEL[3], O. SPORNS[4], J. R. COHEN[2];
[1]Neurosci. Curriculum, [2]Dept. of Psychology and Neurosci., Univ. of North Carolina at Chapel

Hill, Chapel Hill, NC; [3]Univ. of Michigan, Ann Arbor, MI; [4]Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Cognitive control deficits in children with attention-deficit hyperactivity disorder (ADHD) have been associated with altered functional connectivity relative to typically developing (TD) children. Much functional connectivity work in ADHD has focused on stable connectivity assessed across several minutes. However, children with ADHD experience fluctuations in behavior on a much shorter timescale. Therefore, dynamic functional connectivity approaches that assess patterns of functional connectivity on the order of seconds are well-suited to understand how disrupted brain function underlies cognitive control deficits in ADHD. These approaches have found that more variable functional connectivity is associated with better cognitive control performance in TD children and reduced inattention in children with ADHD, however it is presently unclear whether variability in functional connectivity is associated with cognitive control performance in children with ADHD. To examine this, children with ADHD and TD children completed a Go/NoGo task in an MRI scanner. We used an edge-time series approach, which temporally unwraps traditional measures of functional connectivity and yields pairwise cofluctuation time series for each pair of brain regions in a network, to quantify task-based functional connectivity dynamics within the frontoparietal and default mode networks. We predicted that less variable functional connectivity in these two networks would be associated with fewer commission errors on the Go/NoGo task (i.e., better cognitive control performance) in both groups. In the TD group, Pearson correlations did not reveal significant relationships between functional connectivity dynamics and cognitive control performance. In the ADHD group, contrary to our hypothesis we found that more variable frontoparietal network, but not default mode network, connectivity was related to fewer commission errors. This analysis represents one of the first examinations of dynamic functional connectivity during active engagement of cognitive control in children with ADHD, and suggests that reduced variability (i.e., greater stability) of functional connectivity in the frontoparietal network may represent a mechanism underlying cognitive control impairments in children with ADHD. Future analyses will examine functional connectivity dynamics between the frontoparietal and default mode networks and during successful versus failed attempts at cognitive control in children with and without ADHD to further uncover patterns of functional connectivity dynamics that underlie cognitive control deficits in ADHD.

Title: Transient beta modulates decision thresholds during human action-stopping

Authors: *V. MURALIDHARAN[1], A. R. ARON[1], R. SCHMIDT[2];
[1]Univ. of California San Diego, La Jolla, CA; [2]Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Prefrontal beta oscillations are a mystery when it comes to their role in executive control. Action-stopping, an extensively studied executive function in humans, involves bursts of beta oscillations in prefrontal-basal ganglia regions. To determine the functional role of these beta bursts we utilized the well-developed computational framework, i.e. the Race Model describing action-stopping.
We incorporated beta bursts in three race model variants, hypothesizing that a transient increase in beta could 1) modulate decision thresholds, 2) change stop accumulation rates, or 3) promote the interaction between the Stop and the Go process. We then tested the model predictions using EEG recordings in humans (two datasets; N=12 and N = 23) performing a Stop-signal task, and found that the model variant in which beta increased decision thresholds for a brief period of time best explained the empirical data. This was confirmed by several observations. First, the threshold variant of the model predicted that the probability of responding during the stop trials would decrease if a beta burst occurred close and prior to latency of stopping, i.e. the stop-signal reaction time, SSRT. The experimental data revealed a similar trend. Next, this model variant also predicted an effect on go trials, unlike the other two variants, such that the time when a beta burst ended or the threshold reset is when the response was more likely to occur. In the experimental data, we observed this as an increase in the probability of burst end times close and prior to the go reaction times in comparison to a null distribution where the burst end times were distributed uniformly (Kolmogorov-Smirnov test, $p<0.001$). Finally, the model predicted during successful stop trials, the threshold modulation would likely occur just prior to the stopping time. The experimental data corroborated that finding with an increased probability of bursts occurring 50ms before the stopping time. The fitted model parameters indicated that beta bursts modulate Go process thresholds stronger than that of the Stop process (0.7 ± 0.1 vs 0.3 ± 0.1, $p=0.008$). These results suggest that prefrontal beta influences stopping by temporarily holding the response from execution. Our study further suggests that beta could act as a pause, where the Stop process can intervene and modulate behavior during the time beta increases the response thresholds, thus implying that human action-stopping could be a multi-staged process.
Overall, by introducing transient oscillations into the race model and testing against human electrophysiological data, we provide a novel functional account of the role of prefrontal beta in executive control.

Abstract: Neuropsychiatric disorders are often accompanied by cognitive impairments/intellectual disability (ID). It is not clear whether there are converging mechanisms underlying these debilitating impairments. We found that many autism and schizophrenia risk genes are expressed in the anterodorsal (AD) subdivision of anterior thalamic nuclei, which has reciprocal connectivity with learning and memory structures. CRISPR-Cas9 knockdown of multiple risk genes selectively in AD thalamus led to memory deficits. While AD is necessary for contextual memory encoding, the neighboring anteroventral (AV) subdivision regulates memory specificity. These distinct functions of AD and AV are mediated through their projections to retrosplenial cortex, using differential mechanisms. Furthermore, knockdown of autism and schizophrenia risk genes *PTCHD1*, *YWHAG*, or *HERC1* from AD led to neuronal hyperexcitability, and normalization of hyperexcitability rescued memory deficits in these models. This study identifies converging cellular to circuit mechanisms underlying cognitive deficits in a subset of neuropsychiatric disease models.

Title: Responses to local and global deviance in subcortical structures

Authors: *A. MAZANCIEUX[1], F. MAUCONDUIT[2], A. AMADON[2], F. MEYNIEL[1];
[1]UNICOG, Neurospin, CEA, Gif-sur-Yvette, France; [2]Neurospin center, CEA, Gif-sur-Yvette, France

Abstract: The brain faces a stochastic environment, the ability to detect regularities and their violations is thus crucial to adapt our behaviour. Previous proposals [1] posit that the noradrenergic (NA) system plays a key role in the detection of surprising events and the adjustment of behavior. Supportive evidence comes from non-human animals and pharmacological manipulation or recording of the Locus Coeruleus (LC), the major NA nucleus; in humans it comes from indirect measures like the P300 component and pupil dilation, which are NA-dependent [2]. Few studies more directly measured the LC activity with fMRI [3], some of them did not use procedures to locate this nucleus accurately. Here, we tested in 15 human subjects whether NA increases for unexpected stimuli using pupilometry and dedicated fMRI methods (including neuromelanin-sensitive images to locate the LC in each subject). We extended previous findings by investigating the anatomical specificity in the pons but also neuromodulator specificity by comparing with the substantia nigra (SN) related to dopamine (DA). We also extended the classical auditory oddball task [2, 3] and used the "local-global" paradigm [4] that distinguishes two temporal scales for deviance. Stimuli consisted of patterns of four identical sounds plus a fifth one that could be either identical or different, corresponding to a local (within-pattern) standard and a local-deviant respectively. Each pattern type was either frequent (80%) or rare (20%) in a sequence, corresponding to a global (across patterns) standard and a global deviant, respectively. . Pupil size transiently increased for local standards and local deviants when they were global deviants. Using event-related analyses, we found the same result in the LC activity and SN. We demonstrate anatomical specificity by showing that the effect of deviants decreased in voxels further from the LC. Overall, our results confirm the role of catecholamines in the detection of unexpected stimuli and validate a method to investigate neuromodulator-specific subcortical structures to test other hypotheses in future studies.

Title: Neural ensemble dynamics of auditory thalamus upon sensory learning

Authors: *M. HASEGAWA[1,2], Z. HUANG[2], J. GRÜNDEMANN[1,2];
[1]Dept. of Biomedicine, Univ. of Basel, Basel, Switzerland; [2]Deutsches Zentrum für Neurodegenerative Erkrankungen, Bonn, Germany

Abstract: Sensory cortices receive and process uni- and multisensory information to guide behaviours. However, so far, the encoding of uni- and multisensory inputs during complex behaviours in sensory thalamic nuclei preceding cortex is poorly understood. Here, we established a gradient refractive index lens-based two-photon calcium imaging approach to monitor the activity of large populations of individual auditory thalamus (medial geniculate body, MGB) neurons in mice during a multisensory go/nogo task. We tracked the same populations of MGB neurons across learning and found distinct ensembles of MGB neurons that encode auditory, visual and multisensory stimuli as well as task features. The activity of individual MGB neurons was plastic and their sensory responses changed dynamically across reward-association and task learning. Furthermore, using dimensionality reduction, go/no-go stimuli could be well distinguished on the population level across the learning phases independent of the stimulus modality. Our data suggests that MGB neurons flexibly encode multisensory information across learning supporting the view that sensory thalamic nuclei are actively involved in cognitive processes beyond a classic relay function.

Title: Sex-specific effects of paraventricular thalamic nucleus functional connectivity on depression and anxiety symptoms in humans

Authors: *S. M. KARK[1], S. J. GRANGER[1], J. G. ADAMS[1], L. MCMILLAN[1], I. CHEN[2], R. M. BENCA[2], M. A. YASSA[1];
[1]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [2]Psychiatry and Human Behavior, Univ. of California, Irvine, Orange, CA

Abstract: The paraventricular thalamic nucleus (PVT) is a subnucleus of the dorsal midline thalamus. The PVT is a sensor and integrator of salient experiences and memories—both rewarding and aversive—functions made possible partly by its reciprocal connections with the nucleus accumbens (NAc) and amygdala (AMY). We recently established that resting-state functional connectivity (RSFC) of the human PVT is highly consistent with this region's known anatomical and functional connections observed in rodents. Disruption of this circuitry is associated with depressive- and anxiety-like behavior in rodents, often as a function of sex, suggesting aberrant RSFC of the PVT might contribute to the severity of psychopathological symptoms in humans. Here, we collected self-reported depression and anxiety scores (Beck Depression Inventory-II and Beck Anxiety Inventory), and resting-state functional magnetic resonance imaging (fMRI) scans in a human sample (n=75, 55 females) that endorsed a range of depression and anxiety symptom severity. Factor analysis applied to the depression and anxiety symptom scores empirically differentiated symptom classes in this sample. RSFC was calculated as the time-series correlations between the activity of the PVT with the AMY and NAc. In females, but not in males, greater PVT-AMY RSFC was associated with higher anxiety symptoms. In males, but not in females, greater PVT-NAc RSFC was associated with more severe symptoms overall, but with anhedonia-like symptoms in particular. These findings suggest that changes in the PVT circuitry impact depression and anxiety symptoms in sex-specific ways.

Title: Temporal dynamics and function of locus coeruleus norepinephrine during learned behaviors

Authors: *V. BRETON-PROVENCHER, G. T. DRUMMOND, M. SUR;
Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The release of norepinephrine (NE) from locus coeruleus (LC) neurons has been linked to multiple functions including arousal, action and sensory gain, and learning. How and whether specific components of behavior are encoded by LC-NE activation remains poorly understood. Here we show that distinct temporal dynamics of LC-NE activity enable two functions during learned behavior - facilitating task execution and encoding reinforcement to improve performance accuracy. To examine these functions, we trained mice on a go/no-go auditory task with graded stimulus detection and task performance. Optogenetic inactivation demonstrated that LC-NE affects this behavior in two ways. First, silencing LC-NE activity affects the animal's ability to respond to low stimulus intensities. Second, silencing LC-NE activity changes response bias, or the animal's ability to adjust its behavior on subsequent trials based on the outcome of their decision. Targeted recordings of LC-NE neurons using photo-tagging showed that transient LC-NE activation preceded behavioral execution and followed reinforcement. Signal levels of LC-NE execution or reinforcement activation depended on stimulus evidence. The LC-NE execution signal scaled up with the go stimulus intensity, hence encoding reward expectation. The LC-NE reinforcement signal was highest after a punishment and scaled up with surprise, including reward following low stimulus evidence. Together, our results suggest that differential timing of LC-NE activity is critical in supporting complementary roles in learned behavior. In a separate study (*see companion poster Drummond et al.*), we show that these distinct temporal signals are also spatially segregated among LC-NE cortical outputs, and that these spatiotemporal dynamics further refine LC-NE roles in learned behavior.

Title: Targeted functions of locus coeruleus norepinephrine in a learned behavior

Authors: *G. DRUMMOND, V. BRETON-PROVENCHER, M. SUR;
Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The locus coeruleus (LC) serves as the primary source of the neuromodulator, norepinephrine (NE), in the brain. Through a widely divergent set of projections, LC neurons have been suggested to release NE throughout the brain to regulate arousal and attention. However, LC-NE is also implicated in more precise roles such as mediating learning, promoting task execution, and signaling unexpected uncertainty. How LC-NE activity facilitates distinct aspects of behavior is unknown. We have found that in mice performing an instrumentally conditioned go/no-go task with graded auditory stimulus detection, LC-NE activity dually reflects both behavioral execution and reinforcement encoding (*see companion poster by Breton-Provencher et al.)*. Silencing this LC-NE activity decreases performance by reducing responses on low stimulus evidence trials, and by diminishing the effect of trial history on task performance. Here, we explored whether these temporally distinct task execution and performance optimization signals are also spatially segregated, such that spatiotemporal targeting of LC-NE release could enable modulation of multiple aspects of a learned behavior. Using retrograde tracing, we found that LC-NE neurons exhibit a modular organization with a subset of LC-NE neurons projecting to either motor cortex or prefrontal cortex, but not the other cortical region. Using two-photon calcium imaging of LC-NE axons, we found that the two phasic components of LC-NE activity were heterogeneously distributed among cortical regions such that the task execution signal was higher in motor cortex while the negative reinforcement signal was widely distributed among cortical targets. Optogenetic silencing of LC-NE axons specifically in the motor cortex recapitulated the effects of whole LC inactivation on task execution, but did not alter the effect of trial history, whereas optogenetic silencing of LC-NE axons specifically in the prefrontal cortex alone did not affect task performance. Together, these results suggest that modular targeting of LC outputs enables diverse functions whereby some NE signals are segregated amongst targets to facilitate task execution, while others are broadly distributed to promote reinforcement encoding and performance optimization.

Title: Rodent Lateral Posterior (LP) thalamus input to Anterior Cingulate Cortex (ACC) tracks ongoing and post-factum perceptual uncertainty

Authors: *Y. LEOW[1], T. LUO[1], M. SUR[2];
[1]Dept. of Brain & Cognitive Sci., [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Perceptual uncertainty guides sensory-driven actions, and can be conveyed through multiple sensory and associative brain areas. The LP thalamic nucleus, is a higher order visual thalamus and the rodent homolog of the primate pulvinar. LP is extensively connected to multiple visual and associative cortical areas. The medial subdivision of the pulvinar/LP also has reciprocal connections with the prefrontal ACC, an area important for action selection and top-down modulation of visual processing. Interaction between the pulvinar and ACC has been associated with impaired sensory filtering and over-responsiveness to stimuli. We hypothesized that by integrating input from multiple visual areas and the parietal cortices, higher order visual information conveyed by LP to ACC contribute to decision-making computations performed within the ACC. Here, we imaged calcium activity of LP→ACC axons with two-photon microscopy in mice (n = 6 mice, 10 sessions, ~400-500 boutons) trained on a global motion direction discrimination task under a two-alternative forced choice paradigm. To serve as a proxy for sensory-driven perceptual uncertainty, we varied the proportion of coherent dots moving in target directions. Task-responsive LP→ACC activity varied with multiple task variables on different timescales. To account for time-varying task events and motor activity, we employed a linear encoding model (Generalized Linear Model, GLM) to predict LP→ACC axonal activity with behavioral variables, as well as to examine their relative contributions to LP→ACC encoding. We found that a significant proportion (~30%) of LP→ACC axons show coherence-dependent responses throughout different epochs of the task. Furthermore, perceptual uncertainty-associated activity often persisted beyond the visual stimulus presentation period, into time of choice and post-reinforcement. Some LP→ACC axons also exhibited reward-associated responses that scaled with the coherence of the preceding stimulus. Our results suggest LP involvement in decision-making beyond ongoing visual processing and perceptual evidence accumulation to include a potential involvement in conveying information on post-factum perceptual uncertainty.

Title: Altered purinergic receptor transcript expression in the frontal cortex in Schizophrenia

Authors: *A. LUNDH[1], J. A. HOEFLINGER[3], S. ASAH[1], K. ALGANEM[1], R. ALNAFISAH[1], R. E. MCCULLUMSMITH[1], S. M. O'DONOVAN[2];
[2]Neurosci., [1]Univ. of Toledo, Toledo, OH; [3]Ohio State Univ., Columbus, OH

Abstract: Schizophrenia (SCZ) is a neuropsychiatric disorder that is estimated to affect around 1% of the United States population and is characterized by psychotic symptoms such as hallucinations and delusions, as well as reduced emotional expression, motivation, cognitive and motor impairment. SCZ is difficult to diagnose and the mechanisms behind it are poorly understood. Dysregulation of the purinergic system is implicated in SCZ, including the receptors which modulate the activity of purine neurotransmitters like adenosine triphosphate (ATP) and ADP. ATP acts on the purinergic P2X receptors, which consists of 7 different receptors (P2X1-7). ATP and other purines also act on the P2Y receptors (P2Y1, 2, 4, 6, 11, 12, 13, & 14). However, expression of P2Rs in neuropsychiatric disorders has not been explored. To address this gap in our knowledge, we assayed P2X (P2X4, 5, 7) and P2Y (P2Y12, 13) receptor transcript expression in the frontal cortex of SCZ and non-psychiatrically ill controls (n=20/group) using qPCR. We also mined postmortem brain transcriptomic datasets using the R shiny application Kaleidoscope (kalganem.shinyapps.io/Kaleidoscope/), to assess P2 receptor expression in different brain regions (anterior cingulate cortex (ACC) and dorsolateral prefrontal cortex (DLPFC)) in different diseases (SCZ, Major depressive disorder (MDD) and bipolar disorder) and a model (chronic unpredictable stress (CUS)) of neuropsychiatric disorders. We found that P2X7 and P2X4 receptor transcript expression was significantly altered (Student's t-test, $p<0.05$) in the frontal cortex in SCZ. There was no significant change in expression of P2Y receptors. In silico analysis also confirmed alterations in the expression (Log2FC) of different P2X receptor transcripts in SCZ. The use of antipsychotic medications and purinergic receptor expression was also analyzed in silico and alterations in the expression (Log2FC) of different P2X receptor transcripts were found with antipsychotic treatment. Protein expression and localization of P2Rs will also be qualitatively assessed in the frontal cortex of SCZ subjects (n= 3-5 slides/subject, n=3 subjects/grp) using immunohistochemistry. In summary, these data suggest that purinergic receptor expression is altered in a region-specific manner in SCZ and may contribute to the pathophysiology of disease. Future studies will expand upon these findings, including an analysis of cell-specific alterations of the purinergic receptor expression in SCZ.

Abstract: Abstract
Perturbation of Cell-subtype specific Active Kinome Networks in Schizophrenia
Imami AS, Shedroff ES, Joyce AW, Sahay S, Alganem K, Ryan W, Henkel ND, McCullumsmith RE
Schizophrenia is an illness with significant consequences for patients and their families. Since the disease affects executive function, the Dorsolateral Pre-frontal Cortex (DLPFC) has been an area of interest. We previously reported perturbed protein kinase activity of kinases, including AKT, in postmortem brain samples of patients with schizophrenia. We are now extending this hypothesis to the cell level, with a focus on frontal cortical pyramidal neurons. We used laser capture micro dissection to isolate DLPFC pyramidal neurons from matched pairs of schizophrenia and control PM brain samples (n = 20). We then utilized the PamChip STK kinome array assay for high throughput characterization of kinase activity in the samples. We then deployed well-characterized bioinformatics approaches to identify upstream kinases implicated in schizophrenia. We identified several kinases of interest, including c-Jun N-terminal kinases (JNK), extracellular signal-regulated kinases (ERK) and p38 mitogen-activated protein kinases (P38). These kinases belong to the mitogen-activated protein (MAP) kinase family and are associated with inflammatory responses. We then applied a novel technique of identifying the kinase interaction networks in high throughput kinase activity data. This modelling allowed us to identify the network-level changes in pyramidal neurons in schizophrenia. This is the first study to examine the subkinome at the cellular level in schizophrenia and to identify active kinome network changes in this often devastating illness. Our data provides an important new starting point for understanding how signaling networks are perturbed in severe mental illness.

Title: Limited common gene enrichment in astrocyte subpopulations and psychiatric disorder associated biological pathways

Authors: X. ZHANG, A. WOLFINGER, R. SHUKLA, A. LUNDH, R. MCCULLUMSMITH, **S. M. O'DONOVAN**;
Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Astrocytes play an essential role in normal and pathological brain function. Clinical and experimental evidence implicate critical roles for astrocytes in the pathogenesis of serious mental illnesses but our understanding of the role of astrocytes in neuropsychiatric disorders is still limited. There is also growing evidence that astrocytes are targets of psychotropic medications. Using a bioinformatic approach, we conducted enrichment analysis of publically available gene signatures from murine astrocyte cell subtypes (https://holt-sc.glialab.org/sc/), human psychiatric (Schizophrenia, major depression) and neurological disease signatures (Alzheimer's disease, epilepsy) obtained from DisGeNet (www.disgenet.org) and drug signatures from DSigDB (http://dsigdb.tanlab.org/DSigDBv1.0/). In enrichment analysis of disease and astrocyte subpopulations, the density index score, indicating similarity of gene enrichment across datasets, was highest for major depression related signatures and astrocyte subpopulations. However, enrichment of astrocyte-subpopulation gene signatures and different psychotropic drug (e.g antipsychotics) signatures was low. Interestingly, gene ontology analysis identified enrichment of immune, metabolic and signaling processes in different astrocyte subpopulations and across psychiatric disorders and Alzheimer's disease, in line with previous reports of dysregulated biological processes in these disorders. In particular, common enrichment of an astrocyte subpopulation which may be associated with neurogenesis, and depression signatures were observed at the biological pathway level. Overall, similarities in gene enrichment were found in astrocyte subpopulations and neurological disorders, but there was limited common enrichment with psychotropic drug signatures.

Title: The role of the ATPome in cognitive disorders

Authors: *X. WU, X. ZHANG, R. SHUKLA, A. JOYCE, H. E. EBY, R. E. MCCULLUMSMITH, S. M. O'DONOVAN;
Neurosciences, The Univ. of Toledo, Toledo, OH

Abstract: Major depressive disorder (MDD) and schizophrenia (SCZ) are devastating cognitive disorders that greatly reduce patients' life quality and are costly to our society. Despite decades of investigation, available treatments for these disorders are only partially efficacious. To develop more effective pharmacotherapies, a more sophisticated understanding of disease pathophysiology is required. Adenosine triphosphate (ATP) is the brain's main energy carrier. A large family of enzymes called ATPases utilize ATP to carry out many essential cellular functions. ATPase dysfunction is widely reported in a variety of cognitive disorders, including SCZ and MDD. To assess how ATPase dysfunction may contribute to the pathophysiology of SCZ and MDD, we conducted bioinformatic analysis. We analyzed 24 publically available MDD and SCZ transcriptomic datasets (14 SCZ and 10 MDD, male and female postmortem brain tissue) using two ATPase targeting gene lists, one bioinformatically predicted and one experimentally demonstrated. We extracted significant gene expression data for the ATPase targeting genes from the transcriptomic datasets. Next, we performed pathway enrichment and pathway clustering (parent-child analysis) to determine which biological processes these significant ATPase genes are involved in. We identified approximately 300 significantly altered genes from each dataset based on the median number of significant ATPase related genes, confirming dysregulation of ATPases in MDD and SCZ at the transcript level. We found similar significant pathway clusters across all disease and sex groups. However, pathway analysis identified significant enrichment of metabolic and stress response pathway clusters in male MDD datasets, suggesting that ATP utilization by ATPases is dysregulated across cognitive disorders but with unique disease- and sex-specific differences. These findings provide insight into dysregulation of ATPase and ATP utilization in the pathophysiology of cognitive disorders.

Title: Assessing the validity of methods to report a schizophrenia diagnosis.

Authors: *G. WOOLWAY, S. LEGGE, I. JONES, J. WALTERS;
Cardiff Univ., Cardiff, United Kingdom

Abstract: Background: Participant diagnoses in psychiatric research are derived from a variety of sources, ranging from self-report to those determined following lengthy diagnostic research interviews. Schizophrenia case definitions usually rely on detailed research interviews, which impacts sample sizes and generalisability of clinical cohorts. In this study we aimed to (i) assess the reliability and validity of self-report, clinician report and diagnostic interview methods of diagnosing schizophrenia within a research context and, (ii) investigate whether schizophrenia cases ascertained via these different methods display differences in genetic liability to schizophrenia. **Method:** Participants were taken from the National Centre for Mental Health (NCMH; n=292) and CardiffCOGS (n=600) cross-sectional studies. These cohorts collected multiple sources of diagnoses including self-reported, clinician diagnosis and research diagnosis obtained from a clinical assessment based on the SCAN interview. We investigated the positive predictive values (PPV) of self-reported and clinician diagnosis compared to the gold standard research diagnosis. Polygenic risk scores (PRS) were calculated using the latest schizophrenia GWAS to compare the genetic liability of participants that only provided a self-reported diagnosis with participants that continued participation to obtain the research diagnosis. **Results:** The PPV of self-reported schizophrenia to a formal research diagnosis of schizophrenia (n=78) was 76%, and increased to 85% when including both schizophrenia and schizoaffective depressed research diagnoses. The PPV of a clinician diagnosis to a research diagnosis of schizophrenia (n=22) was 82%. In comparison, the PPV of self-reported (n=59) broader psychosis to a research diagnosis of schizophrenia was only 41%. We found no evidence for a significant difference in the schizophrenia PRS between participants who had a self-reported diagnosis only and participants who had a research diagnosis in NCMH (OR=0.93; 95% CI=0.72,1.19; P=0.55) or CardiffCOGS (OR=1.02; 95% CI=0.86,1.22; P=0.78). **Discussion:** These findings show that a self-reported diagnosis of schizophrenia has a high PPV of receiving a schizophrenia diagnosis from research interview and that there are not significant differences in genetic liability to schizophrenia. Less stringent methods of assessing a schizophrenia diagnosis may be useful to gain larger sample sizes.

Title: Substance use in individuals at high genetic and clinical high risk of psychosis

Authors: *C. AMIR[1], C. BEARDEN[1], S. WOODS[2], D. PERKINS[3], E. WALKER[4], T. CANNON[2], B. CORNBLATT[5], K. CADENHEAD[6], J. ADDINGTON[7], D. MATHALON[8], B. STONE[9], M. KESHEVAN[9];

Abstract: Substance abuse occurs at elevated rates in patients with chronic schizophrenia and a role for cannabis has been suggested in the onset of psychosis, but substance use in populations at high risk for developing psychosis is limited. Here, we aim to elucidate the relationship between substance use and psychosis in two distinct high risk populations. Specifically, we examined substance use in both youth at clinical high risk (CHR) of developing psychosis (n = 735; mean age = 18.50; 42.45% female) and age-and sex-matched typically developing (TD) controls (n= 278; mean age = 19.60, 49.64% female), and participants with chromosome 22q11.2 deletion syndrome (22q11DS, n= 82; mean age= 16.67, 55% female), one of the strongest genetic risk factors for psychosis, compared to age-and sex-matched TD controls (n= 72; mean age = 15.93, 58% female). We found significantly greater alcohol and THC use severity in CHR participants compared with controls at baseline. While TD males had higher tobacco, alcohol, and THC use severity than females, there were no sex differences in CHR drug use severity. Results of mixed modeling of substance use over time indicated that CHR youth had higher alcohol and tobacco use severity compared with controls, and higher THC use severity, with significant increases in use over time. Clinical status was assessed at the two-year follow-up period:109 CHR participants were in remission, 92 were symptomatic, 71 met criteria for prodromal progression, and 90 had developed psychosis. All CHR subgroups, except those whose symptoms remitted, had greater baseline tobacco use than controls. CHR participants who were symptomatic, those who were in remission, and those who developed psychosis had greater baseline THC use than controls. These results together support higher rates of substance use in CHR youth relative to controls. However, in youth with 22q11DS, we did not find elevated rates of substance use relative to controls. This points to a potential difference in substance use

patterns between these two high risk populations. These results suggest that there may be secondary risk factors at play in CHR substance use, and to the need to examine symptom progression as it relates to substance use.

and Neurosci., Univ. of Georgia, Athens, GA; [9]Departments of Pharm. and Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Cavum septum pellucidum (CSP) is an atypical brain structure which, by some accounts, has higher prevalence in psychiatric disorders. CSP is hypothesized to be a sign of early abnormal neurodevelopment which may also be associated with psychotic disorders. Some reports suggest that an abnormally large CSP (≥6 mm) is associated with cognitive deficits in psychosis samples. However, this has not been systematically investigated in a large sample. The present study utilized standard as well as novel measurements of CSP, and assessed the relationship between CSP metrics, psychiatric status, and cognition. **Methods:** Participants were 1,266 psychosis spectrum patients (26.9% bipolar with psychotic features, 32.8% schizoaffective disorder, and 40.4% schizophrenia) and 734 healthy controls from the Bipolar Schizophrenia Network on Intermediate Phenotypes 1 and 2 studies who completed a T1 weighted magnetic resonance imaging scan. Mean age was 37 years (50.3% male) for the patient group and 35.5 years (41.8% male) for the healthy group. Five raters, blind to group membership, rated the CSP as present or absent, determined the length of the CSP (number of slices anterior to posterior), and hand-traced the CSP boundaries for volume, all following a reliability process. Chi-Square analysis examined the prevalence of CSP in healthy controls compared to psychosis spectrum patients. Mann-Whitney U tests were used to assess for group differences in CSP length and volume. Cognition was assessed using the Brief Assessment of Cognition in Schizophrenia (BACS). The association of CSP with cognition was examined using analysis of variance with age, sex, and race as covariates and Spearman correlations with false discovery rate correction for multiple comparisons. **Results:** Psychosis spectrum patients did not have a higher prevalence of CSP compared to healthy controls (74.4% of patients; 75.1% of controls) and there was no difference in the proportion of patients with small, intermediate, and large CSP. There were no group differences in CSP length or volume. BACS scores did not differ between participants with and without a CSP or among the length categories, regardless of group. **Conclusion:** In this large sample, no approach to CSP quantification, including binary, categorical size, or absolute size, revealed any difference between psychosis patients compared to healthy controls. In contrast to some prior reports, an abnormally large CSP was not associated with greater cognitive deficits. This suggests that within the idiopathic psychosis population, the presence of a CSP may be a normal variant with limited impact on psychiatric or cognitive outcomes.

Title: Investigating genetic alleles shared between schizophrenia and blood metabolite concentrations

Authors: *S. E. SMART, A. F. PARDIÑAS, L. HUBBARD, J. T. R. WALTERS;
Div. of Psychological Med. & Clin. Neurosciences, Cardiff Univ., Cardiff, United Kingdom

Abstract: Introduction
Metabolites are small molecules present in biological samples (e.g. tissue, blood, urine, cerebrospinal fluid). In recent years large metabolite datasets have become available and valuable insights into the genetic architecture of metabolites have emerged. Metabolites have also been investigated as potential biomarkers for schizophrenia and other neuropsychiatric disorders, though to our knowledge no replicated findings have emerged. Our aim in this study was to identify genetic variants that influence both schizophrenia and measurable metabolites.
Methods
Genome-wide association study (GWAS) summary statistics for metabolites were acquired from three studies: TwinsUK/Kora F4 (Shin, et al. 2014; N=7,824), SP2 (Chai, et al. 2019; N=1,954), and VUMC (Dennis, et al. 2021; N=up to 88,107). The schizophrenia summary statistics were acquired from the Psychiatric Genomics Consortium Schizophrenia Wave 3 (SWG of PGC, 2020; N=67,390 cases and N=94,015 controls).
All GWAS summary statistics were aligned to hg19, the MHC region (chr6:28477797-33448354) was removed, as were SNPs with MAF < 1% or INFO < 0.9. We performed exploratory pairwise GWAS comparisons between each metabolite and schizophrenia using GWAS-pw (Pickrell, et al. 2016). Genomic loci were defined using independent blocks of linkage disequilibrium as defined by Berisa and Pickrell (2016). Following the example of Pickrell, et al. 2016 and Giambartolomei, et al (2014), we identified loci where the posterior probability was >90% that the locus containing a genetic variant that influences both the metabolite and schizophrenia.
Results
Of the 801 GWAS summary statistics tested, there were 16 metabolites where the posterior probability of a locus containing a genetic variant that influences both the metabolite and schizophrenia was greater than 90%. Thirteen of these metabolites were identifiable (two monohexosylceramides, vitamin B1, blood platelet volume, monoclonal antibodies, immature granulocytes, glucose, eosinophils, complement C4, urea nitrogen, albumin, fibrinogen cleavage peptide, and indolelactate), while three had not been characterised. For 14 of the metabolites, only one locus reached this probability threshold, but for the other 2 metabolites, two loci passed this threshold (blood platelet volume and complement C4).
Discussion
We have shown co-localisation of genetic association signals for schizophrenia and a number of

metabolites. We intend to conduct further downstream analyses to examine whether these metabolites may be candidate biomarkers or are causally implicated in schizophrenia.

Title: Astrocyte-neuronal metabolic interaction: implications for psychiatric disorders

Authors: *Y. JOUROUKHIN[1], M. V. PLETNIKOV[2];
[1]Dept. of Physiol. and Biophysics, Jacobs Sch. of Med. and Biomed. Sci. SUNY, Univ. at Buffalo, Baltimore, NY; [2]Dept. of Physiol. and Biophysics, Jacobs Sch. of Med. and Biomed. Sci. SUNY, Univ. at Buffalo, Buffalo, NY

Abstract: Metabolic alterations have been described in patients with major psychiatric disorders. Astrocytes maintain brain homeostasis and support neuronal metabolism providing nutritional and energy substrates like glucose and lactate and play a role in neurotransmission by uptake excess of glutamate from extracellular space. We studied the role of *NPAS3* (Neuronal PAS domain protein 3), a transcriptional factor highly expressed in astrocytes, in regulation of metabolic interactions between astrocytes and neurons. RNA-seq analyses of hippocampal samples of mice with astrocyte-specific deletion of Npas3 (Npas3 KO) revealed 40-fold decrease in expression of the *Solute Carrier Family 25, Member 18* (*Slc25a18*) and decreased levels of its protein product, the mitochondrial glutamate carrier 2 (GC2). Reduced expression of GC2 resulted in decreased mitochondrial respiration, deficit of glutamate uptake and decreased production of lactate. Mice with astrocyte-specific deletion of *Npas3* have decreased density of parvalbumin-positive (PV+) inhibitory neurons in prefrontal cortex and reduced glutamate decarboxylase (GAD) immunoreactivity in PV+ presynaptic boutons on pyramidal excitatory neurons. Moreover, we found decreased dendritic spine density in layers 2/3 and 5 of cortical pyramidal neurons. Primary astrocytes transfected with a construct expressing GC2 has restored decreased lactate release back to the control levels. Moreover, deficit of cognitive outcomes measured by trace fear conditioning test was ameliorated by intraperitoneal administration of lactate 30 minutes before the training session. Our findings suggest a previously unknown role for *Npas3* in regulation of astrocyte-neuronal metabolic interaction: lactate release and uptake of extracellular glutamate. Excess of extracellular glutamate combined with decreased release of

lactate affect functioning of cortical inhibitory neurons, leading to cognitive deficiency which maybe relevant to major psychiatric disorders.

Title: Modulating cerebellar-motor cortex connectivity using transcranial focused ultrasound

Authors: *J.-F. NANKOO[1], A. FOMENKO[1], J. BAARBÉ[1], S. TRAN[1], X. XIA[1], Y. WANG[1], N. RAIES[1], A. M. LOZANO[2], R. CHEN[1];
[2]Dept Neurosurg., [1]Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Although established non-invasive brain stimulation techniques, such as transcranial magnetic stimulation (TMS), can target the cerebellum, they lack the spatial focality to allow detailed investigations of the cerebello-cortical networks. Transcranial low intensity focused ultrasound (TUS) is a novel stimulation technique that uses acoustic waves to alter neuronal excitability. TUS can reach deeper brain structures with greater focality compared to other non-invasive brain stimulation techniques. This makes TUS particularly well-suited to target functional subregions of the cerebellum. Here, we investigated the effects of cerebellar TUS (cbTUS) on motor cortical (M1) excitability.
Hypotheses: 1) Longer TUS duration will induce greater inhibition of M1 excitability; 2) TUS will transiently lower M1 excitability post sonication; 3) cbTUS specifically targeting cerebellar lobule VIII using neuronavigation will lead to greater inhibition and longer lasting effects compared to TMS-based scalp coordinates.
Methods: In Experiment 1, 500 ms of cbTUS was applied at 3cm lateral and 1cm below the inion. Motor evoked potentials (MEPs) were measured using TMS applied to contralateral M1. MEPs were measured at pre-TUS, after 150ms, 300ms, and 450ms of TUS, and 150ms post-TUS. In Experiment 2, the effects of cbTUS when stimulating the same location as Experiment 1, was compared to lobule VIII stimulation. MEP were measured at pre-TUS, after 150ms, and 450ms of TUS, and at 5ms, 50ms, 150ms, 1000ms and 2000ms post-TUS.
Results: In Experiment 1 cortical excitability was significantly reduced 150 ms after 500 ms of TUS (26% decrease in excitability). In Experiment 2, the time point of peak inhibition was dependent on the cerebellar lobule being stimulated. When targeting lobule VIII, the peak

inhibition was at 450 ms after the start of TUS (38% decrease in excitability).
Conclusion: cbTUS can effectively modulate motor cortical excitability. This is the first investigation of cerebellar TUS in humans, and provides the first step towards modulating specific lobules of the cerebellum non-invasively.

Title: Morphosonic - a morphologically structured intramembrane cavitation model reveals fiber-specific neuromodulation by ultrasound

Authors: *T. LEMAIRE[1], E. VICARI[1], E. NEUFELD[2], S. MICERA[1];
[1]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]Computat. Life Sci., IT'IS Fndn., Zuerich, Switzerland

Abstract: *Objective.* Low-Intensity Focused Ultrasound Stimulation (LIFUS) is emerging as a promising technology for the remote modulation of neuronal activity, but an incomplete mechanistic characterization hinders its clinical maturation. Intramembrane cavitation has been proposed as a candidate mechanism, but it has only been studied in single or two-compartment computational models of brain neurons. Here, we developed a computational framework to investigate this mechanism in multi-compartmental, morphologically structured neuron models, and used it to study ultrasound neuromodulation of peripheral nerve fibers.
Approach. We recast NEURON's internal cable representation to enable the simulation of multi-compartment models with temporally and spatially varying membrane capacitance. This allowed to seamlessly incorporate the multi-Scale Optimized Neuronal Intramembrane Cavitation (SONIC) paradigm across an arbitrary number of connected compartments, while simultaneously ensuring numerical stability and accuracy. Within this framework, we then implemented single-cable models of myelinated and unmyelinated peripheral axons in order to compute their response to spatially-varying pressure fields.
Results. We predict that by engaging mechanoelectrical bilayer coupling, LIFUS can exploit fiber-specific differences in membrane conductance and capacitance to selectively recruit myelinated and/or unmyelinated axons in distinct parametric subspaces. This fiber-specific

neuromodulation is conserved across a wide range of acoustic field distributions and allows to design specific LIFUS protocols to modulate the spiking activity of different fiber types concurrently and independently over physiologically relevant regimes.
Significance. These theoretical results consistently explain recent empirical findings and suggest that LIFUS can simultaneously yet selectively engage multiple neural pathways, opening up opportunities for peripheral neuromodulation currently not addressable by electrical stimulation, such as the specific targeting of nociceptive and sensory fibers. More generally, our framework can be readily applied to other neural targets in order to investigate electrophysiologically relevant LIFUS neuromodulatory effects and guide the development of application-specific LIFUS protocols.

Title: Noninvasive, spatially-precise and cell-type specific deep brain neuromodulation using transcranial focused ultrasound

Authors: *Y. YANG[1], C. PACIA[1], D. YE[1], L. ZHU[1], H. BAEK[1], Y. YUE[1], J. YUAN[1], M. MILLER[2], J. CUI[1], J. CULVER[2], M. R. BRUCHAS[3], H. CHEN[1];

Abstract: Objective*:* Critical advances in the investigation of brain functions and treatment of brain disorders are hindered by our inability to selectively target neurons in a noninvasive manner in the deep brain. This study aimed to develop sonothermogenetics for noninvasive, deep-penetrating, spatially-precise and cell-type-specific neuromodulation by combining a ultrasound sensitive ion channel TRPV1 with focused ultrasound. **Methods:** The sensitivity of TRPV1 to FUS sonication was evaluated *in vitro*. It was followed by *in vivo* assessment of the success rate of sonothermogenetics in the activation of genetically defined neurons in the mouse brain by two-photon microscopic calcium imaging. Behavioral response evoked by sonothermogenetic stimulation at a deep brain target was recorded in freely moving mice that were sonicated by the customized miniature wearable focused ultrasound. **Results/Discussion:**

TRPV1 was found to be a sonothermogenetic actuator. FUS sonication at the mouse brain *in vivo* selectively activated neurons that were genetically modified to express TRPV1 (Fig. 1A). Temporally precise activation of TRPV1-expressing neurons was achieved with its success rate linearly correlated with FUS-controlled mild temperature rise as measured by *in vivo* magnetic resonance thermometry. FUS stimulation of TRPV1-expressing neurons of the Parkinsonian circuit at the striatum repeatedly evoked rotating locomotor behavior in freely moving mice (Fig. 1B). FUS sonication was confirmed to be safe based on inspection of neuronal integrity, inflammation, and apoptosis markers. Sonothermogenetics is a noninvasive and cell-type-specific neuromodulation approach with the capability to target the deep brain. **Scientific Rigor:** The scientific rigor of this research was controlled by the highest-standard experiment design, data analysis, result reporting and reproducibility including but not limited to: 1) Including positive and negative controls; 2) Quantifying the success rate and reporting raw data of the key results; 3) Repeating the key results by the third party.

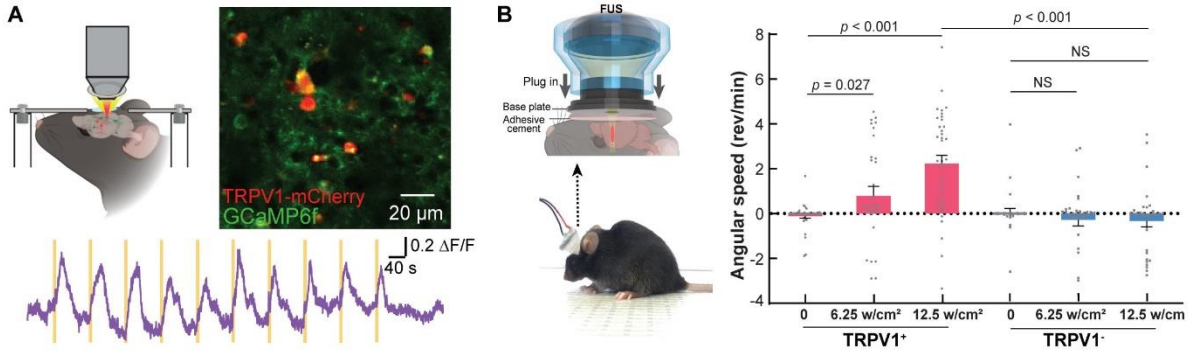

Figure 1. (A) Sonothermogenetics in the mouse brain in vivo. The mouse head was fixed in the stage for simultaneous FUS stimulation and two-photon Ca^{2+} imaging. The coexpression of TRPV1 and GCaMP was observed in vivo. FUS can repeatedly activate neurons expressing TRPV1. The orange bar indicates the FUS on time. (B) Experimental setup for *in vivo* sonothermogenetic stimulation of the striatum in freely moving mice (left panel). The miniaturized wearable FUS transducer was plugged into a base plate adhered on the mouse head. The comparison of the mean angular rotation speed of $TRPV1^+$ mice versus $TRPV1^-$ mice with FUS stimulation at I_{spta} = 0, 6.25, and 12.5 w/cm^2. The positive and negative values indicate rotation in the contralateral and ipsilateral directions, respectively. Error bars represent the standard error of the mean.

Title: Noninvasive, Multifocal Deep Brain Interventions

Authors: *T. WEBB, M. G. WILSON, H. ODÉEN, J. KUBANEK;
Univ. of Utah, Salt Lake City, UT

Abstract: Transcranial focused ultrasound has opened new avenues for noninvasive and spatially specific intervention in deep brain circuits. Low energy interventions include neuromodulation, targeted drug release, and transient disruption of the blood brain barrier. We developed and validated a non-human primate model to test the efficacy and safety of these new applications. The model uses a 256-element transducer to deliver ultrasound into specific deep brain circuit/s on demand, using fast electronic focusing. The electronic focusing allows the device to be fixed with respect to the head and so deliver ultrasound into the desired regions reproducibly across sessions. The device can target multiple deep brain regions simultaneously or in concert. The animal is awake and head-fixed during the ultrasound delivery, thus empowering researchers to quantify the effects of the ultrasonic interventions on behavior in real time. We validated the method by stimulating a deep brain region, the lateral geniculate nucleus (LGN), during a visual discrimination task. Data across multiple sessions show an immediate and reversible ipsilateral bias, thus validating successful and accurate delivery of ultrasound into the deep brain. The task also provides a sensitive measure of the safety of daily ultrasonic neuromodulation since any damage to the LGN would result in a deterioration of the subject's discrimination accuracy. Our data show the opposite effect, with the subject's performance improving across sessions. Thus, our data show that ultrasound delivered into specific deep brain regions can flexibly modulate behavior. We are currently testing the effects of the ultrasound pressure amplitude, frequency, and duty cycle. This investigation will provide the field with parameters that effectively excite or inhibit neurons. This model will provide data on the efficacy and safety of new transcranial applications of ultrasound and thus accelerate their translation into clinics. The developed hardware and software can be applied also for noninvasive and multifocal stimulation of the human brain.

Title: Effective Ultrasound Stimulation in Human Peripheral Nervous System

Authors: *T. RIIS, T. WEBB, J. KUBANEK;
Biomed. Engin., Univ. of Utah, Salt Lake City, UT

Abstract: Low-intensity ultrasound can stimulate excitable cells in a noninvasive and targeted manner, but which ultrasound parameters are effective has remained elusive. Ultrasound frequency is a key parameter: it governs the choice of the transducer, the size of the focal region, and depth of penetration. Yet, whether lower or higher frequencies stimulate the nervous system effectively is unknown. This question could not be addressed in previous studies because changes in frequency lead to large changes in the stimulated volumes, and therefore to large changes in the probability of registering a response. The objective of this study is to control for differences in stimulated tissue volume and evaluate which ultrasound parameters are effective in stimulating excitable cells. We used a single ultrasonic transducer and matched stimulation volumes for different frequencies using a metallic aperture. We applied the ultrasonic stimulation to the peripheral nervous system, receptors and nerve endings of the index finger in particular, in 26 human subjects. We tested the response to ultrasound stimuli while varying the parameters of frequency, pressure level, duration, stimulus kind (continuous stimulation and pulsed stimulation), and duty cycle. Subjects were instructed to report a percept verbally, describing it as either pain, warm, cold, vibration, or tap. We found that low frequencies (300 kHz) are substantially more effective in generating tactile and nociceptive responses in humans compared to high frequencies (900 kHz). The strong effect of ultrasound frequency was observed for all pressures tested, for continuous and pulsed stimuli, and for tactile and nociceptive responses. The prominent effect of frequency may be explained by a mechanical force associated with ultrasound. The effect is not due to heating, which would be weaker at the low frequency. Notably**,** we observed a quadratic dependence of response frequency on the pressure level. This suggests an involvement of a mechanical effect based on ultrasound intensity, most likely candidate of which is the acoustic radiation force. This controlled study reveals that ultrasonic stimulation of excitable cells is stronger at lower frequencies, which guides the choice of transducer hardware for effective ultrasonic stimulation of the peripheral nervous system in humans. The results also inform on the mechanism involved in the ultrasound bioeffects.

Title: Induction of human motor cortex plasticity by theta burst transcranial ultrasound stimulation

Authors: *K. ZENG[1], G. DARMANI[1], A. FOMENKO[1], X. XIA[1,2], S. TRAN[1,3], J.-F. NANKOO[1], Y. SHAMLI OGHLI[1,3], Y. WANG[1,2], A. LOZANO[1,4], R. CHEN[1,5];
[1]Krembil Res. Institute, Univ. Hlth. Network, Toronto, ON, Canada; [2]Sch. of Psychology, Shanghai Univ. of Sport, Shanghai, China; [3]Inst. of Med. Science, Univ. of Toronto, Toronto, ON, Canada; [4]Div. of Neurosurgery, Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada; [5]Div. of Neurology, Dept. of Medicine, Univ. of Toronto, Toronto, ON, Canada

Abstract: Background and Hypothesis: Transcranial focused ultrasound stimulation (TUS) is a novel, non-invasive neuromodulation method that is beginning to be applied in human subjects. We hypothesize that long-term potentiation (LTP)-like plasticity can be induced in the human motor cortex by repetitive low-intensity transcranial focused ultrasound stimulation (TUS). **Materials and Methods**: Three repetitive TUS, theta burst patterned TUS (tbTUS), regularly patterned TUS (rTUS) and sham TUS, were delivered to motor cortex in 15 healthy subjects in separate sessions in random order. The tbTUS and rTUS protocols had same total sonication duration and total time of stimulation. Motor evoked potential (MEP) evoked by single-pulse and paired-pulse TMS was recorded before and at 5 min, 30 min and 60 min after TUS. Short interval intracortical inhibition (SICI) and intracortical facilitation (ICF) were measured for paired-pulse TMS. The effects of motor cortex tbTUS on movement performance in a visuo-motor task and the effects of ipsilateral occipital cortex tbTUS on motor cortex excitability were also assessed. **Results**: MEP amplitudes significantly increased at 5 min (43.4%) and 30 min (27.5%) and returned to baseline level at 60 min after tbTUS. SICI was significantly attenuated at 5 min and 30 min, and ICF was significantly enhanced at 5 min after tbTUS. The movement time on a visuo-motor task was significantly shortened after tbTUS. In contrast, the rTUS, sham TUS and occipital tbTUS had no effect on the MEP amplitudes elicited by both single-pulse and paired-pulse TMS. In addition, the MEP amplitudes elicited by lateral-medial directed TMS were unchanged after tbTUS. **Conclusions**: The tbTUS protocol is capable of inducing LTP-like plasticity in human for at least 30 min. The plasticity occurred at the cortical level and involved both inhibitory and excitatory cortical circuits. This LTP-like plasticity was specific to theta burst patterned TUS and could not be explained by sensory confounds associated with TUS. **Significance:** tbTUS is a novel paradigm to induce cortical plasticity in human and has the potential to be developed for neuromodulation treatment for neurological and psychiatric disorders, and to advance neuroscience research.

Title: Hearing damage associated with transcranial ultrasound for neuromodulation and blood-brain-barrier opening

Authors: *J. BASILE, G. RODRIGUEZ ORELLANA, H. H. LIM;
Univ. of Minnesota, Minneapolis, MN

Abstract: Ultrasound (US) research has grown rapidly in the past decade for noninvasively modulating brain regions with high spatial resolution and performing targeted drug delivery by transiently opening the blood-brain-barrier (BBB). Studies have also quickly moved into humans citing diagnostic US imaging tissue safety ranges in an FDA guidance document (Docket: FDA-2017-D-5372) with some parameters having additional histological safety data in animal models. Our lab discovered that US applied to the head readily activates the auditory system through vibrations of cerebrospinal fluid that then directly vibrate fluids within the cochlea (Guo et al., Neuron, 2018). We have also demonstrated that neural responses to US stimuli closely resembled those to air-conducted stimuli and that frequency specific activation of auditory regions can be achieved using amplitude-modulated US. Due to the potential applications of US induced auditory activation, our group was interested in characterizing safe levels of US pressure for the hearing system.

In anesthetized guinea pigs, we collected auditory brainstem responses (ABRs) and electrocochleography (ECochG) induced by air-conducted acoustic pure tones (2, 4, 8, 12, 20, and 30 kHz) and broadband noise at varying levels (10-70 dB SPL) before and after US stimulation with specific parameters that have been used in previous studies for either neuromodulation or BBB opening experiments. Control data was also collected for characterizing the stability of the recording protocol and for standard noise-induced hearing loss (NIHL). We assessed ABR and ECochG thresholds, amplitudes, and latencies over time to identify changes that are associated with hearing damage. Many tested US parameters showed neurophysiological changes associated with hearing loss. Threshold shifts were most prevalent in the high frequencies with some more severe cases of US stimuli causing threshold shifts in the middle frequencies as well with a similar pattern to NIHL. Other US parameters that appear to contribute to hearing damage in addition to pressure level are duration, duty cycle, and center frequency. Caution is urged when performing transcranial US stimulation studies in humans,

especially when targeting brain locations closer to the regions of the cochlea or if perception of sound is noted by individuals during stimulation. Future studies will include an in-depth characterization of the US parameters of interest also in large animal models that better mimic the head size in humans.

Title: UNITE Study (UMN-GE) for COVID-19: a pilot study of the efficacy of ultrasound application to the spleen in the treatment of hospitalized patients

Authors: *M. NEWHOFF[1], *M. N. COLLINS[2], R. S. GRAHAM[2], S. DOORNINK[2], W. SWANSON[2], A. TUMA[2], D. P. ZACHS[3], C. PULEO[6], J. ASHE[6], K. WALLACE[6], R. MADHAVAN[6], A. P. J. OLSON[4], E. J. PETERSON[5], H. H. LIM[3];
[2]Otolaryngology, [3]Biomed. Engin., [4]Pediatrics, [5]Div. of Rheumatic and Autoimmune Dis., [1]Univ. of Minnesota, Minneapolis, MN; [6]Gen. Electric Res., Gen. Electric, Niskayuna, NY

Abstract: Ultrasound stimulation of the spleen is an emerging noninvasive modality for reducing systemic inflammation. It has been shown to attenuate disease symptoms and inflammatory markers of rheumatoid arthritis in humans and mice, as well as in animal models of sepsis. Treatment applications as short as 3 minutes can reduce the production of pro-inflammatory cytokines in LPS-stimulated human blood, while stimulation of only 2 minutes per day across 7 days drives significant recovery from inflammatory arthritis in mice. Splenic ultrasound is believed to exert its anti-inflammatory effects via activation of noradrenergic fibers innervating the spleen that receive input from vagus efferents, thereby activating the cholinergic anti-inflammatory pathway in a manner comparable to vagus nerve stimulation.
Severe complications of SARS-CoV-2, the virus that causes COVID-19, are believed to be caused by elevated levels of cytokines and other inflammatory factors, the so-called “cytokine storm,” that leads to multiorgan dysfunction. We therefore sought to determine whether splenic ultrasound, applied for 9 minutes daily for 7 days, could attenuate levels of inflammatory markers or improve the clinical outcomes of patients hospitalized with COVID-19.
In a pilot study of 30 patients, we found that daily splenic ultrasound yielded improvement in patient outcomes, including a reduction in the number of days hospitalized, a reduction in the duration and volume of oxygen supplementation, and a reduction in mortality rate (zero deaths in

the ultrasound treated group) in patients receiving splenic ultrasound in addition to standard-of-care treatment in comparison to a control cohort of patients receiving standard-of-care treatment alone. A clinically meaningful improvement in symptoms was achieved in about half the time (4 vs 8 days) for ultrasound treated patients compared to the control cohort.
We propose that splenic ultrasound has the potential to reduce inflammation in health conditions associated with acute or chronic inflammatory states, such as in COVID-19, and potentially in a manner comparable to that achieved via implantable vagus nerve stimulators, but without the risks associated with surgery or off-target vagus nerve activation effects.

Title: Magnetic nanoparticle neuronal stimulation: Avoiding misclassification of optical and vibration induced artifacts

Authors: *E. H. ZHANG[1], P. LIANG[3], M. ABDEL-MOTTALEB[2], B. NAVARRETE[1], Y. AKIN-YILDIRIM[1], M. ALBERTERIS-CAMPOS[1], I. T. SMITH[2], S. CHEN[3], S. KHIZROEV[1]; [1]Electrical and Computer Engin., [2]Biomed. Engin., Univ. of Miami, Coral Gables, FL; [3]Cell. Nanomed, Irvine, CA

Abstract: In recent years, multiple nanoparticle approaches to neuroscience have opened new avenues in brain imaging, interfaces, and treatment. Of particular interest are nanoparticle mediated methods for wireless deep brain stimulation (DBS), which can produce strong localized responses. One of these approaches involves the direct electrical stimulation of neurons with magnetoelectric nanoparticles (MENPs). Magnetoelectric (ME) stimulation of neurons works by using nanoparticles to convert magnetic pulses into localized electric fields, which then generate action potentials in nearby neurons. As the magnetic pulses produce significant artifacts in electrode-based measurements of action potentials, data for neuronal signals typically comes from calcium imaging or related methods. However, imaging approaches are susceptible to a particular artifact related to the mechanical vibrations induced in the magnetic component of the nanoparticles and their optical characteristics. This artifact can produce an apparent neuronal activation through local intensity changes that imitates real neuronal firing. Here we report

differentiating factors between the false activations and true action potentials that we used to successfully isolate the two types. A few critical waveform characteristics are apparent in the false action potentials, which are useful for identifying artificial activity. Differentiating between the two signal types is critical to avoid unintentional misclassification of vibrational effects as neuronal firing.

Abstract: Wireless brain stimulation could facilitate the study of brain circuits more quickly and easily and can treat neurological disorders. Magnetoelectric nanoparticles (MENPs) provide a minutely invasive brain stimulation approach that does not require surgery, by transforming the energy transmitted through remotely applied magnetic fields into local electric fields. Coercivity

(Hc) is a significant property of the MENPs which pertains to its resistance to change in magnetization in the presence of a magnetic field. The coercivity field is an extrinsic parameter which is a fraction of the anisotropy field, an intrinsic parameter of the material of which the magnetostrictive core of the core-shell MENPs is made. In this study we demonstrate the effect of a magnetoelectric nanoparticle's coercivity on its ability to excite nearby neurons. We have varied the coercivity field from below 100 to over 900 Oe during the MENPs synthesis process. We studied the relationship between applied magnetic fields and the coercivity of the MENPs by applying A.C. magnetic fields ranging from below 300 Oe to above 1000 Oe. We found that the magnetically applied field had to exceed the coercivity of the MENPs to maximize the efficiency of neuronal firing. To assess the effect of MENPs with varying coercivities on neurons, we imaged calcium signals in rat hippocampal cell cultures. The results indicate that MENPs that exhibit high coercivity (Hc > 800 Oe) dramatically increase the effect of the MENPs on neuronal modulation, with consistent neuronal firing upon activation of the MENPs with an external A.C. magnetic field. This enhancement to MENPs shows promising potential that could accelerate them to be a new approach for treating neurological diseases.

Title: Astrocytes contribute to retinal ganglion cell neurodegeneration in a glaucoma patient-specific pluripotent stem cell model

Authors: *C. GOMES[1], K. B. VANDERWALL[2], Y. PAN[1], X. LU[1], S. S. LAVEKAR[2], K.-C. HUANG[2], C. M. FLIGOR[2], C. ZHANG[1], T. R. CUMMINS[2], J. S. MEYER[1];

Abstract: Retinal ganglion cell (RGC) degeneration is a primary characteristic of glaucoma, although non-cell autonomous mechanisms have also been implicated in RGC dysfunction. Astrocytes associate with RGCs in the nerve fiber layer of the retina and optic nerve, where they can contribute to RGC neurodegeneration. However, the mechanisms by which astrocytes promote neurotoxicity and contribute to glaucoma remain unknown. Human pluripotent stem cells (hPSCs) can serve as powerful tools for the *in vitro* study of neurodegenerative diseases, including neuron-glia interactions. Using hPSC-derived cells from a glaucoma patient with an Optineurin (OPTN) E50K mutation as well as isogenic control cells obtained by CRISPR/Cas9 gene editing, we explored how the OPTN(E50K) mutation affects RGC-astrocyte interactions leading to neurodegeneration. hPSC-derived OPTN(E50K) astrocytes show increased propensity to develop reactive phenotypes and exhibited significant changes in protein expression as well as autophagy dysfunction. Transcriptional analysis by RNA-seq showed upregulation of the inflammatory pathway and downregulated expression of cell cycle genes in OPTN(E50K) astrocytes, suggesting a senescent phenotype exhibited by glaucomatous astrocytes. Subsequently, the contribution of astrocytes to RGC neurodegeneration was analyzed in co-culture experiments. Importantly, OPTN(E50K) astrocytes induced neurodegenerative phenotypes in RGCs, including decreased neurite length and complexity, together with increased excitability. Conversely, healthy isogenic control astrocytes were capable of rescuing degenerative phenotypes observed in OPTN(E50K) RGCs. Additionally, as glaucoma astrocytes secreted reduced levels of growth factors, suggesting a deficit in their neurosupportive role, the supplementation of OPTN(E50K) RGCs with these factors at least partially rescued many of these phenotypes, highlighting the role of astrocyte-derived factors in RGC support. Taken together, these results are the first of its kind to identify a neurotoxic phenotype in hPSC-derived astrocytes from a glaucoma source, as well as to identify a role for astrocytes in the neurodegenerative process associated with glaucoma through non-cell autonomous mechanisms, highlighting these glial cells as novel potential therapeutic targets.

Title: Autophagy disruption induces mTORC1 hypoactivation and leads to neurodegeneration in glaucoma OPTN(E50K) retinal ganglion cells

Authors: *K.-C. HUANG[1,2], C. GOMES[3,2], K. B. VANDERWALL[1,2], S. S. LAVEKAR[1,2], C. M. FLIGOR[1,2], J. HARKIN[4,2], J. S. MEYER[3,2,4,5];

Abstract: Optineurin (OPTN) mutations contribute to multiple neurodegenerative diseases including glaucoma, with the more severe forms resulting in normal tension glaucoma due to an E50K mutation in the OPTN gene. Previously, we have derived retinal ganglion cells (RGCs) from human pluripotent stem cells (hPSCs) with an OPTN(E50K) mutation, which exhibited decreased neurite length and complexity when compared with controls as well as a hyperexcitable state. However, the mechanisms connecting the OPTN(E50K) mutation to resulting neurodegenerative phenotypes have not been fully characterized and furthermore, pharmacological intervention to preserve damaged RGCs has been limited. In this study, we derived RGCs with the OPTN(E50K) mutation as well as corresponding isogenic controls from hPSCs to explore mechanisms that induced RGC neurodegeneration. OPTN(E50K) RGCs exhibited a higher number of OPTN puncta along with an overall reduced expression of OPTN protein. Since the OPTN protein plays a primary role as an autophagy receptor, OPTN(E50K) RGCs revealed an accumulation of the autophagosome protein LC3 in a punctal manner that was less likely to be co-localized with OPTN, suggesting that OPTN(E50K) results in a partial loss of function and is unable to recruit LC3. More so, the increased expression of lysosomal proteins was observed in OPTN(E50K) RGCs, indicating that autophagosome accumulation is due to a disruption of autophagosome and lysosome fusion. As this accumulation can activate the stress energy sensor AMP-activated protein kinase (AMPK) and inhibit mTORC1, OPTN(E50K) RGCs demonstrated increased phosphorylated AMPK expression and decreased the mTORC1 effector phosphor-S6 expression, suggesting that reduced mTOR activity may be partially responsible for some neurodegenerative phenotypes. In addition, pharmacological inhibition of mTOR in wild-type RGCs resulted in similar disease-related phenotypes, while activation of the mTOR pathway in OPTN(E50K) RGCs partially rescued neurodegenerative phenotypes. Moreover, these disease-related phenotypes were observed specifically within RGCs but not cortical neurons with an OPTN(E50K) mutation, suggesting that autophagy dysfunction due to

the OPTN(E50K) mutation may act specifically within RGCs to lead to neurodegeneration. Thus, the results of this study demonstrate that autophagy dysfunction can result in profound neurodegenerative phenotypes, and further studies of these pathways may lead to the identification of new targets for therapeutic approaches to glaucomatous neurodegeneration.

Title: Understanding and overcoming obstacles to functional integration faced by transplanted human stem cell derived retinal ganglion cells

Authors: *E. A. AGUZZI, K. Y. ZHANG, A. NAGALINGAM, X. CHANG, D. J. ZACK, T. V. JOHNSON, III;

Abstract: Optic neuropathies, including glaucoma, are characterized by progressive loss of retinalganglion cells (RGCs) and ultimately cause permanent vision loss. Novel neuroprotective approaches to preserving endogenous RGCs following disease onset are emerging. However, because the mammalian retina lacks regenerative capacity, only interventions aimed at RGC replacement and optic nerve regeneration hold potential for reversing blindness. Here, we aim to characterize the mechanisms and barriers to donor human RGC integration following intravitreal transplantation *in vivo*. We demonstrate that under homeostatic physiologicalconditions, the internal limiting membrane (ILM) impedes the migration of transplanted RGCsinto the host retina. To circumvent the ILM, we intravitreally injected the nonspecific protease Pronase-E in immunodepleted mice of both sexes. This enzyme digests the ILM, therebydisrupting the barrier faced by donor RGCs, without affecting the health and survival ofendogenous retinal neurons or glia. Alternatively, intravitreal human RGC transplantation wasperformed in Lama1^{nmf223} mice of both sexes, which harbor a point mutation in the *Lama-α1*gene, and which exhibit developmental ILM defects. Samples sizes included ≥8 mice pergroup and experiments were replicated at least twice, always with observers masked totreatment group. Both proteolytic and

transgenic ILM disruption was associated with an increase in donor RGC survival by ~1.5-fold, though overall survival remained <1%. Somal co-planarity into the host RGC layer also increased by ≥10-fold ($p<0.001$) after both experiments, while dendrite extension into the host inner plexiform layer significantly increased by ≥25-fold after proteolytic treatment ($p<0.0008$) and by ≥100-fold (<0.0001) in the transgenic experiments. Ongoing work aims to characterize the functional connectivity ofdonor RGCs within the host retinal neurocircuitry. Our observations provide advancement inthe understating of human RGC engraftment and synaptogenesis in the adult mammalianretina, and may point towards methods for clinically translating regenerative medicineapproaches to optic neuropathy.

Abstract: Age-related Macular Degeneration (AMD) and Retinitis Pigmentosa (RP) are two major retinal degenerative (RD) conditions that result in irreversible vision loss. Permanent eye damages can also occur in battlefields or due to accidents. To develop a cellular therapy for the above retinal diseases, we tested: 1. Transplant sheets of human embryonic stem cell (hESC) derived retina organoids (RO) into immunodeficient rho S334ter-3 (RD) rats; 2. Transplant sheets of hESC derived RO into immunodeficient Royal College of Surgeon (RCS) rats; 3.

transplant co-grafts of hESC derived RPE and sheets of RO into immunodeficient RCS rats. Vision function and transplant development was tested with different techniques. The H9 hESCs and CSC-14 hESCs (NIH 0284) were differentiated into retina organoids and characterized by immunohistochemistry (IHC), flow cytometry and qPCR. H9 hESC were also cultured and spontaneously differentiated to RPE cells. The hESC-RPE were seeded and cultured around 30 days on ultrathin parylene substrates to produce polarized monolayer RPE implants. For the preparation of hESC-RPE+RO co-grafts, RO sheets were dissected out and combined with RPE implants with the help of suitable bio-adhesive agents, alginate. Growth and development of transplants was evaluated by Optical Coherence Tomography (OCT). Visual function was tested by optokinetic testing (OKT), and electrophysiological recording in the superior colliculus (SC recording). Histological assessments were performed using H&E staining and immunohistochemistry. OCT imaging demonstrated successful surgical transplantation and longtime survival of the ROs and co-grafts. Histological evaluation confirmed the survival and development of the ROs and co-grafts. OKT and SC recording showed significant vision improvement by transplantation of ROs and co-grafts, compared to age-match control and sham. The success rate of rats with response to light in SC recording is higher in co-graft than in RO alone. The study supports the possibility of combining RPE+RO into a co-graft, which can mature and improve vision function after transplanted into the subretinal space. This novel technique can become a new cellular therapy for complete replacement of a degenerated retina and RPE.

Title: Modeling blood-brain barrier phenotypes in glaucoma with human pluripotent stem cells

Authors: *S. LAVEKAR[1], J. HUGHES[2], C. GOMES[3], K.-C. HUANG[1], S. G. CANFIELD[2], J. S. MEYER[4];
[1]Biol., Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [2]Indiana Univ. Sch. of Med.,

Terre Haute, IN; [3]Stark Neurosciences Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Stark Neurosciences Res. Inst., Indiana Univ., Indianapolis, IN

Abstract: Glaucoma is a neurodegenerative disease that affects the retina and optic nerve, resulting in the degeneration of retinal ganglion cells (RGCs) and subsequent loss of vision. While RGCs are the primary cell type affected in the disease state, neighboring cell types are known to influence the disease state as well. In particular, cell types that contribute to the blood brain barrier (BBB), including astrocytes and microvascular endothelial cells, can selectively modulate RGCs to maintain their overall homeostasis and form a tight barrier between the blood and the brain. However, previous studies have demonstrated that these barrier properties may be compromised in the progression of glaucoma, yet the mechanisms by which the barrier is compromised have remained elusive. Thus, the overall goals of this study were to adapt human pluripotent stem cell (hPSC)-based models of the blood-brain barrier to the study of barrier integrity in glaucoma. To achieve this, hPSCs were directed to differentiate into cells of the BBB, including RGCs, astrocytes, and endothelial cells, and then assembled into a model of the BBB using an established transwell assay. The ability of these cell types to contribute to an in vitro barrier model was tested for their ability to recapitulate characteristic properties including transendothelial electrical resistance (TEER), permeability and rhodamine transport. Results revealed the enhancement of barrier properties upon the establishment of the barrier model with RGCs, astrocytes, and endothelial cells compared to endothelial cells grown alone. Conversely, the versatility of this system to model aspects of barrier dysfunction in glaucoma was tested using an hPSC line with a glaucoma-specific Optineurin (E50K) mutation. Upon developing the barrier model with glaucoma-specific cell types, results demonstrated highly compromised barrier integrity, including reduced TEER and increased barrier permeability, indicating BBB dysfunction. To begin to identify factors that could result in barrier dysfunction, results also revealed an increased expression of TGFB2 in OPTN(E50K) astrocytes, indicating a potential role for TGFB2 in disease manifestation. To test this, exogenous TGFB2 was applied to cultures of healthy cells assembled into the barrier model, which resulted in barrier dysfunction similar to those obtained with glaucoma OPTN(E50K) cells. Thus, the repurposing of this barrier model for glaucoma has immense potential for mimicking aspects of diseases affecting RGCs and the BBB, particularly high throughput analyses and drug screening to rescue neurodegenerative phenotypes.

Title: Pairing transcriptional profiling and stereology to survey the role of Chd8 in the postnatal mouse brain

Authors: *S. A. LOZANO[1], K. CICHEWICZ[1], S. FRANK[2], A. WADE[1], R. ORTIZ[1], J. ZHU[1], J. BENNETT[2], W. AMARAL[2], P. BEAUREGARD[1], P. LAVENEX[3], D. G. AMARAL[2], A. S. NORD[1], C. P. CANALES[1];
[1]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [2]Psychiatry and Behavioral Sciences, The M.I.N.D. Inst., Univ. of California Davis, Sacramento, CA; [3]Univ. of Lausanne, Lausanne, Switzerland

Abstract: *Chd8,* which encodes a chromatin remodeling factor, has emerged as a leading risk gene for neurodevelopmental disorders (NDDs), including Autism Spectrum Disorder (ASD). Mice with heterozygous germline loss-of-function mutations to *Chd8* exhibit genomic, neuroanatomical, and behavioral pathology that aligns with clinical features of ASD. Thus, mapping the transcriptomic landscape of *Chd8* mutants offers a route towards resolving the molecular consequences of *Chd8* haploinsufficiency and better understanding ASD etiology. We used RNA-sequencing in cerebral cortex, hippocampus, and cerebellum from *Chd8* adult heterozygous mutants and wild-type littermates to examine putative differences in gene expression. From these data, we identified differentially-expressed genes (DEGs) that were altered across all three brain regions, as well as region-specific signatures. Through weighted correlation network analysis, we characterized modules that are dysregulated in adult brain and ultimately detected perturbation to neuroinflammatory and metabolic pathways. Parallel unbiased stereological assessment of adult mutant cortices indicated sex-specific differences in cortical volume without significant differences in cell numbers. Interestingly, a module of sex-specific DEGs was identified in bulk RNA-seq data that could corroborate a genotype-by-sex interaction linked to pathology in adult mouse brain. Taken together, our findings suggest that *Chd8* dosage augments gene expression in a brain region-specific and sex-specific manner, but additional resolution is needed to conclude the specific cell types and functional consequences of these effects. Ongoing efforts focus on employing single-cell approaches to investigate the effects of *Chd8* haploinsufficiency with cell-type specificity. This work represents the crucial first steps towards pinpointing molecular pathways that are disrupted in *Chd8* mutants and may reveal new insights to the molecular and cellular origins of severe NDDs.

Title: In vivo functional imaging of the Cntnap2 KO model of autism

Authors: *T. SIERRA-ARREGUI, O. PENAGARIKANO;
Pharmacol., Univ. of Basque Country (UPV/EHU), Leioa, Spain

Abstract: One of the most accepted theories about the pathogenesis of Autism Spectrum Disorder (ASD) is the alteration in the proportion of excitatory projection neurons (PNs) and inhibitory cortical neurons (cINs). Thus, postmortem studies identify migration abnormalities of PNs, reduced number of cINs and an alteration in glutamatergic and GABAergic receptors, which supposedly lead to associated changes in both excitatory and inhibitory networks. In this work, we characterized the bio-distribution of glutamatergic and GABAergic receptors in the Cntnap2 mouse model of autism, a model characterized by disruption of both PNs and cINs. For this purpose, we performed PET-CT of the mGlu5 and GABA(A) receptors, with ^{18}F-FPEB and ^{11}C-Flumazenil, respectively, in a group of Cntnap2 knockout and wild type mice. We analyzed the following ROIs: olfactory bulb, cortex, hippocampus, dorsal and ventral striatum, thalamus, hypothalamus, amygdala, septum, cerebellum and brain stem. Radioligand quantification was performed using the binding potential (BP_{ND}) for ^{18}F-FPEB, using cerebellum as the reference region, and the total volume distribution (V_t) for ^{11}C-Flumazenil, using in this case heart as reference region. Statistical analyses were performed with Student's t test comparing WT and KO for each region. Our results indicate a normal distribution of mGluR5 in Cntnap2 mice and a tendency towards lower concentration GABA(A) in all areas analyzed, although it did not reach statistical significance. Our results are in agreement with physiological alterations in GABAergic transmission and more precisely, reduced GABA(A)R mediated inhibition, described in the literature for this mouse model. Future research is necessary to determine the contribution of these observations to the pathophysiology of the disorder.

Title: Involvement of nACh-NKCC1-GABAA cascade in the embryonic development of visual predisposition to biological motion in domestic chicks

Authors: *T. MATSUSHIMA[1], M. MIURA[1], N. PATZKE[1], N. TOJI[1], K. WADA[1], Y. OGURA[2], K. J. HOMMA[3], P. SGADÒ[4], G. VALLORTIGARA[4];
[1]Dept. of Biology, Fac. of Sci., Hokkaido Univ., Sapporo, Japan; [2]Information Sci. and Technol., Univ. of Tokyo, Tokyo, Japan; [3]Dept. of Mol. Biology, Fac. of Pharmaceut. Sci., Teikyo Univ., Tokyo, Japan; [4]Ctr. for Mind/Brain Sci., Univ. of Trento, Rovereto, Italy

Abstract: Predisposed preference for biological motion (BM) appears early in newly hatched domestic chicks (Vallortigara et al. 2005). It also appears in newborn human babies as an early behavioral characteristic associated with familial risk of ASD (Simion et al. 2008, Di Giorgio et al. 2015). In chicks, the BM preference is induced through non-specific post-hatch experiences such as walking in darkness or visual exposure to non-biological motion pictures (Miura & Matsushima 2016, Miura et al. 2020). The induced BM predisposition would canalize visual attention of chicks, making them selectively attend to living organisms such as the mother hen and siblings. Imprinting also causes influx of thyroid hormone to telencephalon, which makes the sensitive period keep opening until 4-8 days post-hatch (Yamaguchi et al. 2012). Imprinting thus comprises a series of dynamic events leading to robust development of social behaviors. Is the BM preference dissociable from the accompanying memory formation of imprinting? Inspired by the finding that sodium valproate (VPA) impairs social predisposition (Sgadò et al. 2018), we surveyed molecular machineries involved in the canalizing process. Embryonic 14 days eggs received single injection of chemical agents, and a week later, post-hatch chicks were trained and tested. Acute effects of the agents on spontaneous movement of embryo were also recorded. VPA and ketamine suppressed the embryonic motion, but the hatchlings showed distinct behaviors even though both block NMDA receptors; VPA selectively impaired the imprinting memory, whereas ketamine impaired the BM predisposition. Blockade of NMDAR by MK-801 similarly arrested the embryos, but the chicks showed no behavioral impairments. Nipecotic acid (GABA uptake inhibitor) and bicuculline methiodide (GABA-AR blocker) impaired BM but not memory. Finally, tubocurarine (blocker of nicotinic ACh receptor) arrested embryos and selectively impaired BM, and bumetanide (inhibitor of cation-chloride transporter, NKCC1) caused a comparable BM impairment without arresting embryos. VPA reduced neuron/glia ratio of telencephalon and acutely enhanced histone H3K27 acetylation in dissociate neuron culture, while ketamine had no effects. Cascade of nACh, NKCC1 and GABA-A in CNS could thus underlie the BM predisposition, which develop independently from the mechanism for memory formation. Vallortigara et al. Abstract: Atypical sensory processing is currently included within the diagnostic criteria of autism. Thecerebellum is known to integrate sensory inputs of different modalities through its connectivity tothe cerebral cortex. Interestingly, cerebellar malformations are among the most replicated featuresfound in postmortem brain of individuals with autism. We studied cerebellar integration of sensoryinformation in a mouse model of autism, knockout for the Cntnap2 gene. Cntnap2 is widelyexpressed in Purkinje cells and has been recently reported to regulate their morphology. Further,individuals with CNTNAP2 mutations display cerebellar malformations and CNTNAP2 antibodiesare associated with a mild form of cerebellar ataxia. Previous studies in the Cntnap2 mouse modelshow an altered cerebellar sensory learning. However, a physiological analysis of cerebellarfunction has not been performed yet. We studied sensory evoked potentials in cerebellar Crus I/IIregion upon electrical stimulation of the whisker pad in alert mice and found striking differencesbetween WT and Cntnap2 KO mice. In addition, single-cell recordings identified alterations inboth sensory-evoked and spontaneous firing patterns of Purkinje cells. These changes wereaccompanied by altered intrinsic properties and morphological features of these neurons. Together,these results indicate that the Cntnap2 mouse model could provide novel insight into thepathophysiological mechanisms of ASD core sensory deficits.

Title: Predicted metabolites from multiple microbiome sequencing datasets modulate Autism Spectrum phenotype in mice

Authors: S. IWAI[1], X. YIN[1], A. PHILLIPS[2], G. E. DEITZLER[3], K. WEST[1], E. RUTHERFORD[1], P. LAL[1], K. DABBAGH[1], T. PALMER[4], D. WALL[4], M. DAVID[2], ***T. DESANTIS**[1];
[1]Second Genome, Inc., Brisbane, CA; [2]Oregon State Univ., Corvallis, CA; [3]Oregon State Univ., Corvallis, OR; [4]Stanford Univ., Stanford, CA

Abstract: Introduction: Gut microbiome dysbiosis is associated with central nervous system disorders such as autism spectrum disorder (ASD). The impact of intestinal microbial metabolism in ASD can be estimated from multiple cohorts then tested in vivo. Methods: Ten 16S rRNA amplicon, three shotgun metagenomics and one metatranscriptomics sequencing data from stools of 588 ASD and 518 age- and/or sex-matched neurotypical pediatric subjects were analyzed. Differentially abundant microbial metabolites associated with ASD were predicted, followed by meta-analysis to identify concordance across datasets. Selected metabolites were tested in CNTNAP2 mice for modulation of brain RNA-seq pathways and behavior associated with ASD. Results: We identified two bile acids, Glycodeoxycholate (GDC) and Ulsodeoxycholate (UDC), with others as concordantly decreased in ASD across datasets. Brain RNA-seq of the mice fed the metabolites exhibited enrichment of neuronal system and neurotransmitter receptors and postsynaptic signal transmission pathway gene expressions. Increased habituation exploration and decreased anxiogenic behavior were observed with GDC and UDC fed CNTNAP2 mice, respectively. Conclusion: By applying prediction algorithms and meta-analysis to a large set of microbiome sequencing data, we were able to identify metabolites that modulate behaviors in mice. This approach accelerates the drug discovery process in ASD and can be translated to other disease areas of interest.

Title: Exposure to Autism-specific maternal autoantibodies leads to longitudinal changes in brain structure, neurometabolite profile, and ASD-relevant behaviors in rats

Authors: *M. BRUCE[1], A. COUCH[2], S. GRANT[1], E. KIM[2], D. ROWLAND[1], R. J. MADDOCK[3], M. D. BAUMAN[4], A. VERNON[2], J. VAN DE WATER[1];
[1]Univ. of California - Davis, Sacramento, CA; [2]Kings Col. London, London, United Kingdom; [3]Univ. California Davis, Sacramento, CA; [4]Univ. California, Davis, Sacramento, CA

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by altered social, communicative, and repetitive behaviors, though of unknown etiology. The Van de Water lab has previously identified a set of potentially pathogenic autoantibodies (aAb), specific to ASD, in the plasma of ~20% of mothers of ASD children. We have termed this phenomenon maternal autoantibody-related (MAR)-ASD. However, mechanisms linking these aAb to altered neurodevelopment is still unclear. Therefore, we have created an active immunization model in rats, whereby we induce endogenous aAb production in rat dams to specific epitopes related to ASD diagnosis in the clinical population. To evaluate the impact of gestational MAR-ASD aAb exposure, offspring outcomes were evaluated using behavioral testing, *in vivo* longitudinal neuroimaging, and postmortem brain immunohistochemistry (IHC) along with transcriptional profiling. Using these methods we confirmed that IgG is present, and persists postnatally in the brains of MAR-ASD rat pups; evaluated at postnatal day 2 (P2) using IHC. To examine longitudinal effects of MAR-ASD aAb exposure, we utilized behavioral testing and magnetic resonance imaging and spectroscopy (MRI/S). MAR-ASD rat offspring displayed alterations in communicative, social play, and stereotyped behaviors compared to control animals. Additionally, MRI/S analysis of rat offspring revealed sex-specific volumetric changes in total and regional brain volume in cortical, cerebellar, and midbrain structures. Simultaneous spectroscopic analysis of neurometabolites in the prefrontal cortex (PFC) of rat brains revealed a persistent increase in taurine and decrease in choline in MAR-ASD rat offspring compared to controls which was confirmed using *ex vivo* nuclear magnetic resonance (NMR). Overall these data reveal alterations in brain development and behavior in our MAR-ASD rat model which exhibits substantial translational capacity.

Title: Mechanisms of atypical sensory information processing within the somatosensory cortex of autism mouse models

Authors: *V. SAKKA[1,2,4], A. A-BHASKARAN[5], T. GAUVRIT[3], A. FRICK[1];
[1]INSERM U1215, Bordeaux Cedex, France; [2]Univ. of Bordeaux, Bordeaux, France; [3]Univ. of Bordeaux, 33000 - BORDEAUX, France; [4]Friedrich Schiller Univ., Jena, Germany; [5]McGill, Montréal, QC, Canada

Abstract: Atypical sensory experience - in particular in the tactile domain - is a key feature of autism spectrum disorder (ASD). Sensory information is processed within the neocortical circuits which are highly amenable to studies via physiological measurements both in humans and mice. Understanding the neurobiological underpinnings of atypical sensory information processing necessitates rigorous analysis in animal models. In mouse somatosensory cortex, we measured in vivo the activity of layer 2/3 neurons - either singly or in populations - evoked by tactile paw stimulation in monogenic mouse modes of ASD. These measurements were combined with those of spontaneous activity and neuronal intrinsic excitability, enabling the identification of mechanisms. Notably, we found complex and nuanced phenotypes across the different mouse models composed of both cellular and circuit alterations. Analysis revealed that most parameters were more variable in the ASD models in comparison with their controls, but also between the different models. Our results mirror the plethora of different phenotypes met on human patients with ASD. Finally, they can be the first step towards a therapeutic approach, suggesting targetable mechanisms at the level of neocortical circuits.

Title: An RNA Targeting Approach for Correction of Pathogenic Nucleotides Implicated in Genetically-Linked Intellectual Disabilities

Authors: *J. L. CARTER[1], J. A. HALMAI[1], J. A. NOLTA[2], K. FINK[1];
[1]Neurol. Department, Stem Cell Program and Gene Therapy Center, MIND Institute, Inst. for Regen, [2]Stem Cell Program and Gene Therapy Center, Inst. for Regenerative Cures,, UC Davis Med. Ctr., Sacramento, CA

Abstract: Genetically-linked intellectual disabilities (ID) are complex neurodevelopmental disorders. Strategies for targeting ID genes at the DNA level are difficult and potentially dangerous due to DNA repair pathways. ADAR2 is a brain-enriched protein which post-transcriptionally modifies double-stranded RNA (dsRNA) by deaminating adenosine nucleotides to inosine, thereby enabling translational machinery to create a functional adenosine to guanosine edit within the transcript. The CRISPR associated protein 13 (dCas13b) is a catalytically inactive RNA binding protein which achieves site directed RNA editing when fused to the ADAR2 deaminase domain (ADAR2DD). A single guide RNA (sgRNA) sequence forms a dsRNA substrate for dCas13b-ADARDD2 binding at the complementary target while enabling RNA editing at a single base. However, the CRISPR Cas13 system has yet to be employed for RNA editing of G-to-A mutations in patient-derived neuronal cells. We created induced pluripotent stem cell (iPSC) from the most common variant of Jordan's Syndrome, a G-to-A mutation in Exon 5 (E198K) of *PPP2R5D*. Here, we have differentiated isogenic and variant iPSCs to neural stem cells (NSCs) to evaluate RNA editing efficiency and efficacy. Towards this goal, we have designed and screened E198K sgRNA to identify lead gRNA which have high on-target editing and low-moderate off-target editing in the *PPP2R5D* transcript. We demonstrate sgRNA structure is readily amenable to fit sequence constraints within the target transcript, thus improving on-target editing efficiency. We are also using our *in vitro* neurodevelopmental model to begin understanding the consequence of G-to-A mutations on *PPP2R5D* targets at the phosphoproteomic and transcriptomic levels. To our knowledge we are the first to employ the CRISPR RNA editor system to correct G-to-A mutations in a patient-specific neuronal model. These studies support the potential for CRISPR/dCas13 systems to selectively edit mutant transcripts harboring G-to-A mutations while providing an alternative editing technology for neurodevelopmental disorders.

Title: Single-cell interrogation of genetically defined neurodevelopmental disorders in human brain

Authors: *C. DIAS[1,2], S. AKULA[2,1], M. TALUKDAR[2,1], K. WALSH[3,1], C. A. WALSH[1,4,2]; [1]Genet. and Genomics, Boston Children's Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]Tufts Univ., Boston, MA; [4]Howard Hughes Med. Inst., Boston, MA

Abstract: Neurodevelopmental disorders (NDDs) such as autism spectrum disorder (ASD) are characterized by significant heterogeneity. The unique features of these conditions (impairments in joint attention or shared enjoyment in ASD for example) necessitate better understanding of these disorders in the human brain specifically. Recent attempts at assaying functional changes on the single cell level in human brain have focused on broad, non-biologically defined categories. We hypothesize that different genetic drivers associated with NDDs have both divergent and shared functional mechanisms in different cellular subpopulations. To test this hypothesis, we are conducting single nuclei RNA sequencing (snRNA-seq) on post-mortem brain from individuals with known genetic disorders associated with NDDs including structural variation (n=6) and Fragile X (n=6) as well as age and sex matched neurotypical controls (n=8). Our preliminary data demonstrates that recurrent structural variation exhibits marked cell-type specific effects in human brain, a finding that has important consequences for identifying critical cell types of interest. We additionally demonstrate for the first time on the single cell level the parallel consequences of both *FMR1* gene deletion and 5' UTR *FMR1* trinucleotide expansion in a variety of neuronal and non-neuronal subtypes. Overall, our data demonstrate the importance of studying genetically defined neurodevelopmental disorders in human brain tissue, and yields novel insight into functional mechanisms which will be critical to understanding the heterogeneity underlying these disorders so apparent on the clinical level. Additionally, findings from this work can be used to inform future rational and personalized therapeutic development for functionally impairing symptoms and co-morbidities.

Title: Physiological indicators of negative attentional bias in children with prenatal substance exposure are related to caregiver emotional literacy

Authors: *J. E. NORRIS[1], A. MELON[2], J. HEIDARY[1], E. BARD[2], L. E. ETHRIDGE[1]; [1]Psychology, Univ. of Oklahoma, Norman, OK; [2]Pediatrics, Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Prenatal alcohol and drug exposure has a profound effect on development and subsequently social, cognitive, and emotional wellbeing. Previous work has shown that children exposed to adverse childhood experiences (ACEs), including prenatal alcohol and drug exposure, monitor facial expressions of emotion differently from children from settings with low exposure risk. Emotion processing in the child's caregivers can impact the effectiveness of parent-child therapeutic interventions for developmental consequences of ACE exposure but limited work has evaluated physiological relationships between child emotion processing and caregiver emotional literacy. Nine caregiver-child dyads participated in emotion identification tasks using eye-tracking technology to record gaze-point and search strategy data. All children had confirmed or suspected prenatal alcohol or drug exposure. Adult participants [N = 9; Mean age = 41.842 years, SD = 8.34; 9 females] were instructed to search for a specific target emotion from six faces expressing emotions ranging from positive to negative (happy, neutral, sad, anger, fear, and disgust). The child task differed with child participants [N = 10; Mean age = 4.11 years, SD = .99; 5 Females] only required to identify the face expressing a negative emotion, where 5 faces expressed a neutral emotion and 1 expressed either sad, fear, or anger. Areas of interest (AOIs) were predefined to include the eyes, the mouth and nose, and the whole image for each image on a trial. Children were significantly faster to fixate on eyes over mouths for sad faces $t(9) = -2.47$, $p = .036$ but not for other negative emotions. Faster speeds to find sad faces in children were correlated with slower identification speeds for sad and fearful images in their adult caregiver, (p's $< .05$). Children exhibited an initial pattern of attention to eyes over mouth for sad trials, but not other negative emotions. Children's ability to quickly find and fixate on sad images was negatively correlated with their caregiver's speed to find and identify negative emotions, suggesting a potential sensitization or attentional bias to negative emotions, particularly sadness, in children related to reduced negative emotional literacy in their caregiver. These findings suggest that physiologically characterized emotional literacy in the caregiver may be relevant to negative emotion processing in children who have experienced ACEs, and may be informative for optimizing individual outcomes for parent-child-oriented therapeutic interventions.

Title: Social Regulation of Developing Mesolimbic Dopamine Circuitry

Authors: K. PACKARD[1], S. HU[1], J. WANG[2], *M. OPENDAK[2,3,1];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]New York Univ., New York, NY; [3]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Infants rely on the mother to provide them with the sensory stimulation needed for normal brain development. However, harsh or neglectful care can perturb the mother's ability to regulate the infant brain - an early marker of lasting socioemotional impairments. Recent work has highlighted the mesolimbic dopamine system as a critical interface between early quality care and the ability of the mother to regulate the infant's threat response, but specific mechanisms remain unclear. Furthermore, the lateral habenula(Lhb) has been consistently implicated as a locus of dysfunction in psychopathology in adults. Here, we assessed how rearing experience impacted maternal regulation of core nodes of the mesolimbic dopamine circuit, including the lateral/medial habenula and ventral tegmental area (VTA). To modulate maternal care quality, we employed the Scarcity-Adversity model of low bedding (SAM-LB), in which a dam provided limited bedding resources handles pups more roughly. Following control or SAM-LB rearing from PN8-12, rat pups were exposed to odor-shock conditioning with or without maternal presence at postnatal days 18-20 (PN18, before weaning) and postnatal days 26-28 (PN28, after weaning). 2-Deoxyglucose (2-DG) uptake was used as a proxy measure of regional engagement. In control-reared pups, we observed that maternal presence suppressed 2-DG uptake in the VTA, and lateral habenula. Using chronic VTA recordings in awake-behaving control-reared pups, we observed that maternal cues were associated with increased unit responses, while threat cues were associated with decreased unit responses. The effect of maternal presence was abolished in adversity-reared pups, with early rearing significantly altering patterns of functional connectivity within this circuit. We next assessed the role of this circuit in social behavior using optogenetics. Following virus transduction (ChR2-EYFP, NHpr-EYFP, EYFP control) into Lhb or VTA at PN1, pups underwent control or SAM-LB and then tested on social behavior with the mother (PN18) or peers (PN28). Engagement of this circuit modulated social behavior at both ages. Taken together, these data suggest that lasting social impairments following early adversity may be due to impaired maternal regulation of the mesolimbic dopamine circuit.

Title: Impact of trauma exposure and endocannabinoid signaling on frontolimbic white matter pathways in children

Authors: *H. MARUSAK, A. MORALES, B. BORG, J. EVANSKI;
Wayne State Univ., Detroit, MI

Abstract: The endocannabinoid system (eCB) is present and functional in early pregnancy and plays a key role in modulating pre- and post-natal brain development, including myelination processes. Recent studies in adolescents and adults link a common variant (C385A) in the gene encoding fatty acid amide hydrolase (FAAH) with higher eCB levels, lower anxiety, and altered frontolimbic development. Frontolimbic white matter pathways demonstrate a protracted maturational course across childhood and adolescence, are associated with anxiety symptoms, and shown to be sensitive to the effects of environmental stress. Here, we examined the impact of the FAAH C385A polymorphism and trauma exposure on anxiety and integrity of frontolimbic white matter pathways in children. We leveraged data collected from the ongoing large-scale NIH Adolescent Brain Cognitive Development (ABCD) study (n = 10,774; $M \pm SD$ age = 9.92 ± 0.62 years; 47.9% female; 54.3% White, 13.8% Black, 19.3% Hispanic, 2.1% Asian, 10.4% Other). Saliva samples were used for genotyping and parents reported on their child's anxiety symptoms and trauma exposure using the Child Behavior Checklist and the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS) traumatic events screener, respectively. Fractional anisotropy (FA) was estimated from DTI data for frontolimbic white matter pathways. Overall, 43.4% of youth were FAAH A-allele carriers or homozygotes (52.1% were CC homozygotes), and 35.7% of youth were exposed to trauma (64.3% unexposed). Trauma-exposed youth demonstrated higher anxiety symptoms and higher FA of the right and left uncinate fasciculus and corpus callosum (forceps minor), as compared to trauma-naïve youth. There was no main effect of the FAAH C385A variant or trauma x FAAH interaction on anxiety symptoms. However, there was a main effect of FAAH genotype on FA in the left and right fornix and left parahippocampal cingulum, such that FA was higher in CC homozygotes as compared to A-alleles. There was also a significant trauma x FAAH interaction for FA in the left and right fornix, right uncinate fasciculus, corpus callosum, and right parahippocampal cingulum. Follow-up analyses in gene groups separately demonstrated that the effects of trauma on white matter integrity were significant in the CC (but the not A-allele)

group. In particular, trauma-exposed CC homozygotes demonstrated greater FA than trauma-naïve CC homozygotes. These results highlight the role of trauma exposure and endocannabinoid signaling in modulating frontolimbic development and anxiety risk.

Title: Developmental predator odor exposure and the expression of innate fear

Authors: *N. COLLINS[1], L. W. AYERS[2], S. FERN[1], S. ROSS[1], T. L. ROTH[1], J. B. ROSEN[1]; [1]Univ. of Delaware, Newark, DE; [2]Widener Univ., Chester, PA

Abstract: Early life stress in both humans and rodents shapes neurodevelopment and later behavior, including higher incidences of psychopathology. Previous work in our laboratory demonstrated the capacity of predator odor exposure (TMT, a synthetic component of fox feces) to induce robust freezing in naïve rodents without prior learning. Further, if this odorant is administered during early development with the presence of a dam the quality of maternal care and later defensive responses of the progeny are altered. More specifically, dams exposed to TMT during the first three weeks of life (PN1-21) engage in significantly longer nursing bouts compared to dams exposed to a noxious control odor (butyric acid, BTA). When tested for freezing to TMT during adolescence (PN30), offspring exposed to TMT during development froze less than rats exposed to BTA (Ayers et al., 2015). The present study sought to extend these findings to another predator odorant, and examine the extent of maternal care quality in modifying defensive freezing in the progeny. First, a log-dose response for PN30 freezing was established by exposing PN30 animals (without developmental odor exposure) to concentrations of BTA, TMT, bobcat urine, and water. Results replicated previous findings in our laboratory, such that animals exposed to TMT at doses of 100 µmole or 300 µmole had significantly higher freezing compared to similarly matched doses of BTA or water. However, a 5 mL dose of bobcat urine was ineffective at inducing freezing behavior compared to control odors. Together, these data suggest that TMT, but not BTA or bobcat urine, elicits a defensive freezing response. Current work is examining the role of maternal care in modifying defensive responses in offspring exposed to predator odor during early development, and exploring concomitant molecular changes in the brain.

Title: Impact of Prenatal Cannabis Exposure on Childhood Anxiety and Frontolimbic Neurodevelopment

Authors: *M. M. FARAJ, A. MORALES, J. EVANSKI, B. BORG, H. A. MARUSAK; Wayne State Univ., Detroit, MI

Abstract: Cannabis use is common among pregnant women and during the pre-conception period (up to 22%); however, prenatal cannabis use may have detrimental effects on childhood outcomes, including neurodevelopment. Indeed, research shows that constituents of cannabis, including Δ^9-tetrahydrocannabinol (THC), can cross the placenta and alter fetal neurodevelopment, and prenatal cannabis exposure is associated with cognitive, motor, and social deficits that last into the adulthood of offspring. Leveraging the ongoing large-scale NIH Adolescent Brain Cognitive Development (ABCD) study, recent studies also link prenatal cannabis exposure after (but not before) knowledge of pregnancy to lower intracranial volume and white matter volumes. Here. we examine the impact of prenatal cannabis exposure on childhood anxiety symptoms and frontolimbic brain regions involved in emotion regulation and anxiety risk. This is important because anxiety disorders are the most common childhood mental disorders, and the endocannabinoid system — which may be disrupted by cannabis exposure — plays a key role in modulating frontolimbic development and is implicated in anxiety. Neuroimaging data were collected from 11,206 children ($M \pm SD = 9.91 \pm 0.62$ years; 47.7% female; 54.4% White, 13.5% Black, 19.8% Hispanic, 2% Asian, 10.3% other), and prenatal cannabis exposure was assessed based on parents' retrospective report. In this sample, 4.1% of parents reported cannabis use before knowledge of pregnancy (n = 454), and 1.2% reported use after knowledge of pregnancy (n = 135). Regional gray matter volumes and functional activation during an emotional n-back task were estimated for the amygdala, hippocampus, dorsal anterior cingulate cortex (dACC), and insula. Prenatal cannabis exposure during and after knowledge of pregnancy was associated with higher childhood anxiety symptoms. Controlling for whole brain volume, cannabis exposure before, but not after, knowledge of pregnancy was associated with larger volumes of the right insula. During the emotional n-back task, cannabis exposure *after*, but not before, pregnancy was associated with heightened dACC response to emotional faces relative to neutral faces. Cannabis exposure was not associated with volume or activation in other areas. These data indicate that prenatal cannabis exposure may increase child anxiety and alter frontolimbic development. Results of this study may inform educational interventions to discourage pregnant women or those who are contemplating pregnancy from using cannabis.

Health care professionals can use this information and encourage the public to urge women to refrain from cannabis use during pregnancy.

Abstract: Smaller hippocampal volume predicts improvements in posttraumatic stress symptoms in pediatric cancer patients following a novel martial arts-based intervention
Authors: Zazai Owens, Allesandra Iadipaolo, Craig Peters, Cindy Cohen, Elimelech Goldberg, Martin Bluth, Jeffrey Taub, Felicity Harper, Christine Rabinak, Hilary Marusak
Young people with cancer endure an enormous amount of stress and trauma prior, during and after their cancer treatments. The treatment phase can take a physiological, and emotional toll on youth and many pediatric cancer patients report posttraumatic stress symptoms (PTSS). Our prior research in pediatric cancer populations has demonstrated associations between PTSS and variation in stress-sensitive brain regions, such as the hippocampus. In tandem, prior studies in adults with breast cancer consistently link smaller hippocampal volumes to cancer-related PTSS, particularly re-experiencing PTSS (e.g., flashbacks, nightmares). The present study examines the impact of a novel martial-arts based intervention on hippocampal volume and PTSS in pediatric cancer patients, and whether baseline (i.e., pre-intervention) hippocampal volumes predict changes in PTSS over time. Eighteen pediatric cancer patients or survivors (ages 5-17 years, 8 female) participated in this 4-week prospective study. Participants underwent structural magnetic resonance imaging (MRI) scans at baseline and then completed 4 weekly Kids Kicking Cancer classes. Kids Kicking Cancer is a martial arts-based therapy that integrates meditation, breathing, and physical movements, and has been shown to lower pain and distress in pediatric cancer and other populations (e.g., sickle cell, schoolchildren, adults with opioid use disorder). Before and

after the 4-week program, participants self-reported on cancer-related PTSS. Analyses examined whether PTSS and hippocampal volumes changed over time, and whether hippocampal volume at baseline predicted change in PTSS. Overall, PTSS symptoms and hippocampal volumes did not change significantly over the 4-week period. However, youth with smaller left (but not right) hippocampus at baseline demonstrated greater reductions in PTSS over time. Exploratory analyses suggests that the association between hippocampal volumes and change in PTSS was driven by re-experiencing PTSS. Results from this pilot study suggest that smaller hippocampal volumes may predict reductions in cancer-related PTSS following a martial arts-based intervention. They also extend prior studies suggesting that a martial arts-based approach may be effective for reducing pain and distress in pediatric cancer populations.

Title: Association between spatial acuity and empathy in typically developing young children

Authors: *R. LLOYD, J.-B. QUILLIEN, A. BYGD, R. MILLER;
Psychology, Univ. of Minnesota, Duluth, Duluth, MN

Abstract: Raine et al (2002) report that persistently antisocial individuals demonstrated spatial but not verbal cognitive deficits at three years of age. Verbal deficits did not emerge until eleven years of age. The authors posit an “early starter” model in which early spatial deficits are a marker for right hemisphere impairments in affect which then results in antisocial behavior, possibly including mother-infant bonding. The subsequent verbal deficits are interpreted as resulting from these social deficits. We examined the relationship between spatial acuity and the positive social quality, empathy, in 29 typically developing 3-5 year olds (17 males; 12 females) from The Children’s Place at the University of Minnesota Duluth campus, a facility for children whose parents are faculty and staff at the University. Spatial acuity was assessed by measuring the speed and accuracy of maneuvering in two, successively difficult, physical mazes. Since the validity of instruments measuring empathy in children this young have been called into question, we developed our own instrument in which 16 very short vignettes were read to the child. After each vignette the child was asked if they were more like the empathic character or more like the

non-empathic character. Empathic responses were then totaled. When empathy scores were regressed against the total number of wrong turns in the two mazes, a significant quadratic relationship ($p<0.048$) was found with an R-square of 0.223. When the data were submitted to a quadratic hierarchical regression analysis (empathy as the dependent variable), with age entered into the equation first, followed by total number of wrong turns, the R-square value increased significantly from 0.181 to 0.324. Thus, 14.3% of the variability in empathy scores can be associated with accuracy in the two mazes independent of the age of the child. Male and female children did not differ in total number of wrong turns ($p=0.889$), speed in the first (smaller) maze ($p=0.662$), speed in the larger maze ($p=0.557$), or Empathy score ($p=0.274$, $r^2=0.048$). Care must be taken in the interpretation of these data. For any given age, children will develop at different rates. The relationship between empathy and spatial acuity, after controlling for age, may merely reflect general neurological development. Data in additional cognitive/neurological domains are now being collected to determine if this relationship between empathy and spatial acuity in very young typically developing children is specific in nature, independent of other levels of cognitive development, per Raine et al. We are also attempting to widen our reach of participants to a larger, more generalizable population.

Title: Offspring of Calorically Restricted Mothers Exhibited Neuroanatomical and Behavioral Alterations

Authors: *K. BERTA, S. LUTCHMAN, J. BRUMBERG;
Queens College, City Univ. of New York, Flushing, NY

Abstract: Calorie consumption during prenatal development has been shown to impact postnatal health, and inadequate prenatal caloric intake in particular has been linked with later physical and mental health issues. To better study this, adult female CD-1 mice were placed on a calorically restricted diet before and throughout pregnancy. Pups birthed to calorically restricted mothers were assayed for their behavior, microglial and neuronal morphology along with perineuronal net density in the barrel cortex was assessed to gauge the impact of a restricted prenatal diet. An open field paradigm was conducted to examine anxiety levels in the resulting pups through analysis of locomotor activity. While no dramatic differences to behavior were

found, the oldest group of control mice spent the least amount of time in the outer arena during the open field paradigm. Female prenatally restricted pups also expressed less willingness to explore in the open field compared to control pups. Mice that were calorically restricted in utero had significantly fewer perineuronal nets compared to non-restricted mice. There was also a sex difference with female offspring being more affected by maternal caloric restriction than male offspring. The microglia of prenatally restricted mice were more rammified compared to non-restricted mice. Mice that had been calorically restricted in utero had significantly smaller neuron somata, a difference which was specific to certain layers of the barrel field. From studying the impact of food restriction in mice, this data can be used to better understand the effects of inadequate caloric intake on children born to mothers during times of food shortage.

Title: Developmental trajectory of the trigeminal nerve: a diffusion tensor imaging study

Authors: *E. E. OSOKIN, B. KAYA, I. CIOFFI, M. MOAYEDI;
Fac. of Dent., Univ. of Toronto, Toronto, ON, Canada

Abstract: The trigeminal nerve is the largest cranial nerve and is a mixed nerve. It innervates the craniofacial region, including skin on the face, teeth, oral mucosa, cranial vessels, the temporomandibular joint, and the muscles of mastication. Most of these structures undergo significant growth and change during development through adolescence. Although there is evidence that brain regions and the white matter connecting them undergo structural changes with age, it is not known whether the trigeminal nerve undergoes developmental changes. Diffusion-weighted imaging (DWI), and structural T1-weighted imaging allow the study of neural microstructure and microstructure, respectively. Microstructural characteristics of the trigeminal nerve can be investigated by fractional anisotropy (FA), and the cross-sectional area of the nerve can be measured based on structural T1 images. Here, we aimed to determine whether the microstructural and macrostructural features of the trigeminal nerve change with age in a large cohort of children and young adults. In a second aim, we tested whether there were sex differences in the developmental trajectory of the trigeminal nerve. We obtained approval for the study from the University of Toronto Research Ethics Board. We acquired data from 202 MRI

participants (99 F, 103 M; aged between 6-15 years), from the Child Mind Institute database. We first delineated both trigeminal nerves, and extracted FA values at the root-entry zone (REZ), and measured cross-sectional areas at two locations: REZ and cisternal segment. We performed two multivariate analysis of covariances—one for each outcome measure—and tested whether our metrics of trigeminal nerve structure (FA and nerve cross-sectional area) are affected by age, sex, and the interaction age-by-sex, while controlling for the data collection site. We found that FA and cross-sectional area significantly increased with age for the right nerve (both $p<0.005$), and that the cross-sectional area of the left nerve was significantly positively related to age ($p<0.05$). Neither sex nor age-by-sex interaction had significant effects on either outcome measures (all $p>0.05$). Our study provides novel normative data on the structural development of the trigeminal nerve and lays the groundwork for future studies aimed at investigating whether abnormal nerve development contributes to chronic craniofacial pain conditions.

Title: Electroencephalographic measures of rapid auditory processing at pre-experience baseline predict infant behavior during an interactive acoustic experience

Authors: *K. WOLFERT, T. REALPE-BONILLA, C. ROESLER, A. A. BENASICH;
Ctr. for Mol. & Behavioral Neurosci., Rutgers Univ., Newark, NJ

Abstract: Interactive acoustic experience during infancy has been shown to impact neural measures of rapid auditory processing on a group level, enhancing markers of acoustic discrimination and generalizing to novel auditory stimuli. However, individual differences observed in training performance may capture variance in cortical maturation and neural plasticity. To explore how the baseline state of the auditory cortex impacts learning, we examined neural measures of auditory processing in 4 month-old infants (N = 18) and behavioral measures of their performance during auditory training sessions. Before training, we recorded dense-array electroencephalographic (EEG) data as infants passively listened to tone pairs containing rapid spectrotemporal changes presented in an oddball paradigm. Event-related potential peaks were characterized at frontal electrode clusters in both left and right hemispheres. We also examined demographic and behavioral predictors: measures of maternal age and

education, ratings of infant-caregiver interactions during play (Parent/Caregiver Involvement Scale), and standardized assessments of cognitive, language, and motor development. After the pre-training sessions, infants received six eyetracker-based training sessions in which they learned to discriminate sound pairs at increasingly fast inter-stimulus intervals (ISIs). We hypothesized that a combination of factors, particularly those related to acoustic discrimination, would predict three metrics of training performance: time engaged in the task, discrimination index (d-prime), and fastest ISI reliably detected. Elastic net regularized regression models were used to evaluate the relationship between baseline measures and training behavior, identifying the best predictors in the presence of multicollinearity. Nested cross-validation was used to select regularization parameters and assess prediction error. Predictive models were identified for all three metrics (engagement $R^2 = 0.99$, d-prime $R^2 = 0.49$, fastest ISI $R^2 = 0.78$). For metrics most directly related to acoustic discrimination (fastest ISI and d-prime), EEG measures associated with more mature auditory processing (i.e. faster latencies of N2 and P2 peaks) predicted better training performance. Maternal age and cognitive/motor skills also predicted fastest ISI and d-prime, whereas maternal education was predictive of engagement. These results help us understand the factors influencing experience-dependent plasticity during development and suggest that future protocols might be optimized by adjusting the timing of training to coincide with peak receptiveness to acoustic experience.

Title: Topographic maps in the human neonate

Authors: *M. A. BARNETT, M. J. ARCARO;
Psychology Dept., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Topographic maps of the sensory periphery are a fundamental feature of information processing in the adult primate brain. The adult visual system comprises several topographic maps of visual space spanning occipital, temporal, and parietal cortices. The adult somatomotor system comprises several maps of the body spanning parietal and frontal cortices. Here, we asked whether topographic representations of visual space and the body are present at birth in humans. We performed seed-based correlation analyses on resting-state fMRI data in 34

neonates at gestation weeks 38-42 from the developing human connectome project (developingconnectome.org). Primary visual and somatomotor cortices were identified anatomically based on the location of the calcarine and central sulci, respectively. Each of these anatomical regions were segmented into 5 bands along their respective long axes and correspond to representations of either different parts of retinal eccentricity or different parts of the body in adults. Pearson correlations were computed between the activity in each seed band and all voxels in the brain. Occipital, temporal and posterior parietal cortices were most strongly correlated with visual seeds. Anterior parietal and frontal regions were most strongly correlated with somatomotor seeds. There was a clear topography of correlations along the cortical surface for both visual and somatomotor seeds with neighboring cortical regions most strongly correlated with neighboring seeds. These topographic gradients were symmetric between hemispheres and matched the large-scale organization of visual and somatomotor maps found in adults. A secondary seed-based analysis using a probabilistic atlas of face- and scene- areas in temporal cortex revealed a lateral-medial distinction consistent with the eccentricity organization in adults with little evidence for domain-specific correlations. The somatomotor topography is consistent with recent studies that showed anatomically distinct representations of the body within primary somatomotor cortex in neonates (Dall'Orso et al. 2018; Meltzoff et al. 2019). In addition, topographic correlations were found both anterior and posterior to primary somatomotor cortex as well as in the lateral sulcus likely corresponding to the SII and PV maps. We also found evidence for a topography of thalamo-cortical correlations though these results varied across subjects, possibly indicating immaturity of these pathways. Overall, our results provide evidence that a proto-organization of topographic maps is established prenatally which can provide a scaffold for later modifications through experience.

Title: Eeg spectral activity and its association with sensory-motor coordination in blind and sighted children

Authors: *H. VITALI[1], C. CAMPUS[1], S. SIGNORINI[2], V. DE GIORGIS[2], F. MORELLI[2], G. PAPALIA[2], M. FASCE[2], M. GORI[1];

Abstract: Vision acquires an increasingly important role in the first years of age, both for the maturation of neural processing and the interaction with the environment. Literature data show a different spectral composition of brain activity in blind than sighted adults, particularly an absence or a reduction of the alpha activity. Moreover, the lack of vision compromises the ability to reconstruct spatial information leading, on one side, to a reduced exploration of the external environment, and on the other side, worst motor skills. This result suggests a greater difficulty in sensory-motor coordination. Despite this, few studies are investigating the development of alpha activity in the first years of life. Here we explore, from EEG retrospective data, the spectral power of resting-state EEG to reconstruct the developmental trajectory of alpha activity and its association with motor coordination impairment indices in blind and sighted children between 0 and 11 years of age.The results show that background activity has two peaks in both sighted and blind subjects, progressively merging during development. The first one shifts with age, while the second corresponds to the classical alpha band observed in typical adults. However, blind subjects show weaker and slower maturing posterior alpha activity, with a first significant differentiation between 3 and 6 years of age. Starting from this period, reduced alpha activity also increases the probability of motor coordination impairment in blind subjects, suggesting that in blind children, some processes could fail. To investigate if the alpha activity could have a role in the sensory-motor coordination in the first three years of life, we indagated the modulation of the non-nutritive sucking (NNS) motor behaviour and its relationship with cortical rhythms. NNS is one of the first coordinated muscular activities and represents an excellent marker of neural system functioning. The results showed that NNS frequency correlates with the baseline alpha activity in somatosensory and SMA areas in blind and sighted children and acquires a different role during the sucking behaviour. Specifically, only in sighted children, also a beta band correlation was found along the visuomotor pathway. These results suggest that visual experience mediates the neural mechanisms generating neural oscillations during the first years of life. Moreover, they indicate that alpha and beta oscillations have a role in the optimal development of the neural network involved during sensory-motor coordination.

Title: Oxytocin-paired orofacial stimulation in neonatal mice

Authors: *K. R. DAY, C. SMITH, E. A. HAMMOCK;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) is an essential neuropeptide involved in social behaviors such as mother-infant attachment. Milk and saliva contain OXT produced by the mother that may be shared with the infant during early life care, such as grooming or breastfeeding. We have previously identified oxytocin receptor (OXTR) in the orofacial region of neonatal mice, which may be sensitive to maternal (exogenous) OXT cues during the neonatal period. We propose that exogenous OXT may cue the infants' oxytocin receptors (OXTR) to label maternal touch as "social" since OXT is not available from non-social tactile stimuli. To begin to investigate this potential role, we hypothesize that OXT co-applied with tactile stimulation will modulate acute infant behavior responses to orofacial touch. Neonatal male and female C57BL/6j wildtype mice were habituated to a socially isolated environment for two hours on the day of birth (P0). After habituation, tactile stimulation was applied to the whisker pads and external mouth of neonates for 30 seconds with a paintbrush coated in either saline, a low dose (1.56pg/uL) of OXT in saline, or a high dose (1.25ng/uL) of OXT in saline. Neonates were observed for an additional 60 seconds after stimulation. This experiment establishes an ethogram for investigating motor behavior of neonatal mice on the day of birth. Our results demonstrate changes in neonatal behavior in response to the presentation of tactile orofacial stimulation paired with exogenous OXT exposure in a socially isolated setting. We also observed behavioral differences between neonates with and without prior nursing experience. Exogenous OXT paired with somatosensory stimulation may facilitate optimal nursing and infant attachment in early social development.

Title: Saturation of structural plasticity at individual CA1 dendritic spines

Authors: *J. FLORES, K. ZITO;
Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Learning is crucial for survival. One intriguing aspect of learning in humans is that efficiency of learning can be improved when there are breaks between episodes of learning. Long-term potentiation (LTP) of synaptic strength has been proposed as a cellular basis of learning and memory. Notably, it has been shown that LTP can saturate in the hippocampus of rodents and that this saturation can lead to deficits in behavioral learning tasks. LTP saturation has also been shown to occur in hippocampal slices following a single theta burst stimulus (TBS). Intriguingly, this saturation is released over time. Thus, it is possible that release from saturation of LTP in the hippocampus contributes to the increased efficacy of spaced learning over massed learning paradigms. We propose that LTP saturates at individual dendritic spine synapses. In the hippocampus, most excitatory synapses occur at small protrusions on dendrites called dendritic spines. Spines are dynamic and have been shown to grow and stabilize during learning in vivo and in response to high-frequency stimulation in vitro. The size of a spine is strongly correlated with the strength and size of its associated synapse. Here, we use 2-photon glutamate uncaging and time-lapse imaging to show that structural LTP can saturate at individual dendritic spines after a single LTP induction. Additionally, this structural saturation is accompanied by a saturation of AMPAR insertion, thus spine size and synaptic strength both saturate in response to a single glutamatergic stimulus. We also show that saturation of LTP does not spread to spines on other dendrites on the same cell. Notably, if the intensity of the second stimulus is increased, spines can once again exhibit structural LTP, although the magnitude is reduced compared to size-matched control spines. Furthermore, individual spines are fully recovered from saturation and can undergo further structural LTP if the second stimulus is administered 60 minutes after the initial stimulus. Using 2-photon fluorescence lifetime imaging (2p-FLIM) of a genetically-encoded CaMKII FRET probe, we show that 30 minutes following structural LTP induction at single spines, CaMKII activation in response to high-frequency stimulation is significantly reduced. We are currently investigating the mechanisms that lead to this alteration in CaMKII signaling and postsynaptic saturation of LTP at single spine synapses. This work will further our understanding of the signaling mechanisms that underlie learning.

Title: Learning binds previously unrepresented inputs into functional synaptic clusters via spinogenesis

Authors: *N. HEDRICK[1,2,3], Z. LU[7], E. A. BUSHONG[4], S. SINGHI[5], P. NGUYEN[5], B. LIM[6], M. H. ELLISMAN[5], T. KOMIYAMA[5,2,3];

Abstract: Plasticity in the motor cortex is thought to underlie the generation of novel skilled motor patterns. Such motor learning is accompanied by the formation of new dendritic spines in the motor cortex, but how new spines modify the existing circuit is unknown. Using longitudinal in vivo 2-photon imaging the glutamate reporter, iGluSNFR, we monitored the spatial and functional context of spinogenesis on apical dendrites of layer 2/3 excitatory neurons in the motor cortex during motor learning. We found that new spines primarily form in dendritic subdomains showing clustered, task-related spines during previous learning sessions. A subset of these spines show hallmarks of synaptic potentiation leading up to the spinogenesis event, suggesting that the strengthening of select inputs facilitates nearby new spine formation. By characterizing the glutamatergic signals at new spines, we found that they exhibit strong co-activity with nearby task-related spines, and thus functionally engage with their parent clusters. This co-activity is a behaviorally relevant signal, as it is selective to movement periods, and signals movements that are similar to the learned movement pattern. To understand the microstructural details of new spines and their environment, we performed correlated light- and electron microscopy (CLEM) on dendrites imaged in vivo. We found evidence supporting a filopodial search-and-capture model of spinogenesis, whereby hotspots of nascent filopodia sample the surrounding neuropil, forming synapses with pre-existing axonal boutons not associated with the imaged dendrite. Functional data suggests that the new successful connections are then filtered based on their co-activity with nearby spines; those exhibiting functional clustering survive, while those that do not are eliminated. These data support a model in which select dendritic sub-domains randomly sample potential new inputs while simultaneously ensuring that only those that are functionally related are incorporated into the dendritic repertoire. Finally, we used CLEM to reconstruct the axonal inputs to imaged dendrites, allowing us to ask whether the strong co-activity of new spines with nearby task-related spines could be explained by sharing of the same inputs. Surprisingly, most new spines do not share an axon with any other spine on the imaged region of dendrite, an observation supported by functional measurements showing that new spines do not show sufficiently high co-activity levels to be consistent with axon sharing. Thus, learning-related new spine formation utilizes local dendritic mechanisms to bind previously unrepresented inputs into the dendritic representation.

Title: CaMKII plays a non-enzymatic role in activity dependent new spine stabilization

Authors: *N. CLAIBORNE, ***N. CLAIBORNE**, *N. CLAIBORNE, K. ZITO;
Univ. of California Davis, Davis, CA

Abstract: The spontaneous outgrowth of new dendritic spines and their ability to stabilize and persist for hours and even years, are linked to learning and lasting memory. Most new spines are transient, and only a subset need to stabilize to support lasting memory. Our lab has shown that glutamatergic stimulation mimicking synaptic input onto a new spine enhances its survivorship. This enhanced stabilization requires the interaction between the GluN2B subunit of the NMDAR and CaMKII, implicating a role for CaMKII in this phenomenon. CaMKII performs both enzymatic and structural/scaffolding roles at dendritic spines, however, it is unknown which of these roles is needed to enhance survivorship. My goal is to determine which role CaMKII is playing in new spine stabilization.
I first used a genetic approach to determine if CaMKII kinase activity is required for activity-dependent new spine stabilization. I expressed GFP-tagged kinase-dead mutant, K42R, with DsRed Express in organotypic hippocampal slice cultures. New spines were identified using 2-photon time-lapse imaging and a single new spine per cell was stimulated with high-frequency glutamate uncaging. The survivorship of stimulated and unstimulated control new spines was monitored for 70 min. Glutamate uncaging onto a new spine on cells expressing kinase-dead CaMKII-K42R enhanced spine stability at 70 min compared to unstimulated new spines, suggesting CaMKII kinase activity is not required to enhance new spine stability.
To independently determine if new spine stabilization requires CaMKII kinase activity and avoid overexpression effects, I used a pharmacological approach. Hippocampal slices were incubated for 30 min staurosporine (Sta), a CaMKII kinase inhibitor that retains GluN2B-CaMKII binding, or vehicle control. Stimulated new spines incubated in either vehicle or Sta were more stable than unstimulated new spines. This supports that CaMKII kinase activity within the GluN2B-CaMKII complex is not required to enhance new spine stability following glutamatergic

stimulation.
CaMKII kinase activity plays a known role in synaptic plasticity, however my results suggest that it may be dispensable for new spine stability. To determine if CaMKII is required in a structural capacity for new spine stabilization, I knocked down CaMKII in hippocampal slice cultures. CaMKII knock-down blocked activity-dependent new spine survivorship. Rescuing CaMKII with GFP-tagged shRNA-resistant CaMKII restored activity-dependent new spine stabilization. Together, these results indicate that CaMKII is required to enhance new spine stability downstream of glutamatergic stimulation in a kinase-independent manner.

Abstract: Dendritic spines are small, highly polarized protrusions on excitatory neurons serving as sites of postsynaptic input. Plasticity of dendritic spines is necessary for learning, while stable dendritic spines are thought to encode long-term memories. The polarized nature of dendritic spines suggests their plasticity and stability may be mediated by polarity proteins. The polarity protein Partitioning defective 3 (Par3) regulates mature dendritic spine formation in vitro, and several single nucleotide polymorphisms (SNPs) and copy number variation (CNV) of *Pard3*, which encodes Par3, are associated with intelligence, schizophrenia, and autism spectrum disorder (ASD). Together, these data implicate Par3 in mature dendritic spine stabilization, which may play a role in cognition and social interaction. However, the mechanisms of Par3 in dendritic spine plasticity and cognition *in vivo* remains completely unknown. We established a novel Par3 mouse model to conditionally knockout Par3 in postnatal forebrain pyramidal neurons. We found that loss of Par3 *in vivo* increases immature dendritic spines and increases overall dendritic spine density in the CA1 region of the hippocampus. In addition, loss of Par3 *in vivo* alters spatial learning in the Morris water maze, phosphorylation of cytoskeletal regulating

proteins, and levels of synaptic proteins. Together, our data suggest that Par3 plays a role in regulation of mature dendritic spine stability and cognitive functions.

Title: Plastic changes to dendritic spines in the cerebellar and prefrontal cortices underlie the decline in motor coordination and working memory during successful aging

Authors: *M. VÁZQUEZ HERNÁNDEZ[1], N. I. MARTÍNEZ-TORRES[2,3], I. GONZALEZ-BURGOS[4];

Mexicano del Seguro Social, Guadalajara, Mexico

Abstract: Old age is the last stage of life and by taking a multidimensional view of aging, Neuroscientists have been able to characterize pathological or successful aging. Psychomotor and cognitive performance are recognized as two major domains of successful aging, with a loss of motor coordination and working memory deficits two of the most characteristic features of elderly people. Dendritic spines in both the cerebellar and prefrontal cortices diminish in aging, yet the plastic changes in dendritic spines have not been related to behavioral performance neither the changes in the cerebellar or prefrontal cortices. As such, motor coordination and visuospatial working memory (vsWM) was evaluated here in aged, 22-month-old rats, calculating the density of spines and the proportion of the different types of spines. These animals performed erratically and slowly in a motor coordination related paradigm, and the vsWM was resolved deficiently. Spine density was reduced in aged animals, and the proportional density of each of the spine types studied diminished in both the brain regions studied. The loss of dendritic spines and particularly, the changes in the proportional density of the different spine types could underlie, at least in part, the behavioral deficits observed during aging. This study shows the plastic changes in different dendritic spine types that might underlie the behavioral alterations in motor and cognitive abilities associated with aging. Further neurochemical and molecular studies will help better understand the functional significance of the plastic changes to dendritic spines in both successful and pathological aging.

Title: Plasticity of GluN2B at Ventral Hippocampal Synapses in the Infralimbic Cortex

Authors: *Y. CASTILLO-OCAMPO, A. HERNANDEZ, M. COLON, P. LOPEZ, J. T. PORTER;
Ponce Hlth. Sci. Univ., Ponce, Puerto Rico

Abstract: Our laboratory recently found an increase of GluN1 subunit expression at ventral hippocampus(vHPC)-to-infralimbic cortex (IL) synapses after auditory fear conditioning (AFC) suggestingthat AFC increases the number of NMDA receptors at this synapse. In addition to changes in thenumber of NMDA receptors, synaptic transmission can also be altered by changes in theexpression of GluN2 subunits. GluN2B has larger single-channel conductance and slower decaykinetics which alters the basal state of synapses and affects the induction of synaptic plasticity.Since increases in GluN2B expression contributes to various forms of synaptic plasticity andmemory formation, we hypothesized that the expression of GluN2B would increase after AFC.Ventral hippocampal synapses were labeled with channelrhodopsin-EYFP in male and femalerats. On the first day, animals were exposed to AFC with paired tones and foot shocks orpseudoconditioning with unpaired tones and shocks (PSEUDO). The next day animals wereexposed to two tones to measure fear recall. Then animals were sacrificed and synaptosomeswere isolated from IL and GluN2B was labeled with fluorescent antibody. Then, we used FACSto identify double-labeled (EYFP+/GluN2B+) synaptosomes which represent presynaptic vHPCinputs and postsynaptic, membrane-bound GluN2B. We found increased GluN2B expression onvHPC-to-IL synapses in the males exposed to AFC compared to the PSEUDO group. In contrast,the female AFC and PSEUDO groups expressed similar levels of GluN2B on the vHPC-to-ILsynapses. In conclusion, the data suggest that AFC induces sex-dependent changes in theexpression of GluN2B subunit on vHPC-to-IL with increased GluN2B expression in the males.These changes in NMDA synaptic communication may contribute to altered fear expression afteran aversive event.

Title: Structural changes in dendritic spines of Fos-expressing neuronal ensembles in the nucleus accumbens during novel context and cue-induced cocaine craving

Authors: *D. E. OLIVARES[1], F. RUBIO[1], E. M. HILAIRE[1], A. HENRY[1], L. KANE[1], C. MEJIAS-APONTE[2], B. T. HOPE[1];
[1]Behavioral Neurosci., [2]Integrative Neurosci., Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD

Abstract: Learned associations between discrete cues (or contexts) and drug effects are thought to be encoded by sparsely distributed patterns of neurons called “neuronal ensembles”. Here, rats undergoing cocaine self-administration were exposed to two different stimuli after a period of abstinence: novel context or cocaine-related cue. We determined whether neuronal activation induced specific changes in dendritic spines of activated neurons within the nucleus accumbens core (NAcc), an area where Fos-expressing ensembles have been associated with cue-induced cocaine seeking. We trained rats to self-administer cocaine (0.75 mg/kg/infusion, days 1-6; 0.375 mg/kg/infusion, days 7-12). We trained rats to lever press for cocaine infusions paired with 3.5-s light cue. After training, rats were injected in NAcc with a cocktail of AAVs encoding Cre recombinase and Cre-dependent GFP for sparse neuronal labeling. After 3 weeks of abstinence in their home cages, rats were exposed for 30 min to either a novel context (non-drug related) or cocaine-cue light associated with drug intake (relapse test). A third group of rats were not exposed to any stimulus. Rats were sacrificed at 60 min and brains were processed for Fos immunohistochemistry, endogenous GFP, and clearing tissue prior to confocal imaging. Morphological analysis of GFP-labeled spines on NAcc Fos-positive neurons and Fos-negative neurons were performed using 3D reconstruction of images. Dendritic tree complexity, spine density and spine head and neck measurements from the proximal (<50 um from soma) and distal (>70 um from soma) were performed using Neurolucida software. In proximal dendritic segments, Fos-positive neurons had significantly larger spine head diameter than Fos-negative neurons for both relapse and novel context groups. This can be explained by an increased proportion of mushroom-like spines. The distal dendritic segments responded differently. After novel context exposure, Fos-positive neurons had larger spine head diameters compared to Fos-negative neurons. In contrast, after cue-induced cocaine, Fos-negative neurons had larger spine

heads relative to Fos-positive neurons. This increase in the relapse group can be explained by larger spine head diameters in mushroom spines in the Fos-negative neurons as well as alterations in levels of the mushroom and filopodia/long thin spines. We hypothesize that distal dendritic segments of NAcc medium spiny neurons respond differently to novelty or cocaine-associated cues, and different mushroom spine adaptations in Fos-positive (compared to Fos-negative) neurons are induced during reactivation of a cocaine-cue learned-association.

Title: Ibotenic acid induced lesions impairs the modulation of dendritic spines plasticity in the prefrontal cortex and amygdala, phenomenon that underlies working memory and social behavior.

Authors: *N. MARTINEZ TORRES[1,2], M. N. VÁZQUEZ HERNÁNDEZ[3], F. MARTÍN AMAYA BARAJAS[4], M. FLORES-SOTO[5], I. GONZALEZ-BURGOS[6];

Mexicano del Seguro Social, Guadalajara, Mexico

Abstract: The lesion induced by Ibotenic acid (IA) emulate some of the symptoms associated with schizophrenia, such as impaired working memory that is predominantly organized by the medial prefrontal cortex (mPFC), or difficulties in social interactions that are mainly organized by the amygdala (AMG). The plastic capacity of dendritic spines in neurons of the mPFC and AMG is modulated by molecules that participate in the known deterioration of working memory, although the influence of these on the socialization of schizophrenic patients is unknown. Therefore, the effect of a neonatal IA induced lesion on social behavior and working memory was evaluated in adult rats, along with the changes in cytoarchitecture of dendritic spines and their protein content, specifically the postsynaptic density protein 95 (PSD-95), Synaptophysin (Syn), AMPA receptors, and brain-derived neurotrophic factor (BDNF). Both working memory and social behavior were impaired, and the density of the spines, as well as their PSD-95, Syn,

AMPA receptor and BDNF content was lower in IA lesioned animals. The proportional density of thin, mushroom, stubby and wide spines resulted in plastic changes that suggest the activation of compensatory processes in the face of the adverse effects of the lesion. In addition, the reduction in the levels of the modulating factors also suggests that the signaling pathways in which such factors are implicated would be altered in the brains of patients with schizophrenia. Accordingly, the experimental study of such signaling pathways is likely to aid the development of more effective pharmacological strategies for the treatment of schizophrenia.

Title: Microglia eliminate immature synapses in autism associated Nav1.2-deficient mice during development

Authors: *J. WU[1], J. ZHANG[2], M. EATON[1], X. CHEN[2], Z. QUE[3], M. OLIVERO-ACOSTA[1], Y. YANG[1];

Abstract: Microglia play a key role in regulating synaptic remodeling. Multiple studies have showed that synaptic abnormalities in neurological diseases such as autism and schizophrenia are mediated by microglia. Our recent studies suggested that severe deficiency in *Scn2a*, which encodes voltage-gated sodium channel Nav1.2, result in major behavioral deficits and increased neuronal excitability in adult mice. Microglia can sense the neuronal hyperactivity and be recruited to the synapses. Microglia is also known to prune immature spines. However, the roles of microglia in Nav1.2-deficinet mice are unclear. Here we report that the dendritic spine density in adulthood is decreased, accompanied by the changed microglia morphology in hippocampal CA1 region of Nav1.2 deficient mice. We also observe a strong accumulation of engulfed post-synapse (PSD95) within microglia lysosome, suggesting elevated pruning of microglia. As microglia synaptic pruning during development is critical for spine density in adulthood, we further studying the spine density in the early stage of development. We observe extensive immature spines of Nav1.2-deficient neurons. Interestingly, the post-synapse loss and increased

microglial synaptic engulfment occurred at P30, but not P4 or P10. Synapse elimination mediated by the activation of classical complement pathway has emerged as an important process during the development of brain. C1q and C3 localize on “weak” synapses as the “eat me” signal for microglia during the synaptic pruning. Thus, we studied the involvement of complement signals in our mouse model. We find that the density of C1q and C3 in Nav1.2-deficient neurons are significantly increased at P30 compared to these of the WT mice. Our results indicate that complement-mediated microglial synapse elimination might play a key role in the impaired neuronal plasticity, revealing a potential cellular mechanism underlying *Scn2a* deficiency-related neurodevelopmental disorders.

Title: Molecular mechanisms of heterosynaptic spine shrinkage

Authors: *J. JANG, L. K. PARAJULI, K. ZITO;
Ctr. for Neurosci., Univ. of California Davis, Davis, CA

Abstract: Competitive interaction between activated synapses and adjacent inactive synapses is thought to play an important role in balancing excitability of dendritic segments, cells, and the neuronal network. In a previous study, we showed that activity-dependent synaptic potentiation in multiple spines drives spine shrinkage in inactive neighboring spines (Oh et al., 2015). This heterosynaptic spine shrinkage requires activation of calcineurin, IP_3Rs, and mGluRs. However, much remains unknown about the molecular mechanisms of heterosynaptic spine shrinkage. Here, we examined the cellular and molecular mechanisms that regulate heterosynaptic plasticity of spines on local dendritic segments using two-photon glutamate uncaging and time-lapse imaging in CA1 hippocampal pyramidal neurons. We found that blocking ion flux through NMDA receptors with L-689,560, a competitive inhibitor of the NMDAR glycine binding site, converted long-term spine growth of clustered stimulated spines to long-term spine shrinkage, as expected. Notably, shrinkage of neighboring unstimulated spines was converted from long-term to short-term, suggesting that the signaling for heterosynaptic shrinkage is only partially intact. In contrast, when glutamate binding to NMDARs was blocked by CPP, the result was complete inhibition of homosynaptic and heterosynaptic structural plasticity. Interestingly, protein

synthesis inhibition did not suppress enlargement of stimulated spines, but completely blocked short-term and long-term heterosynaptic spine shrinkage. Furthermore, when the stimulated spine cluster is small, the unstimulated spine showed transient or two-phase shrinkage; only with robust activation of multiple stimulated spines did consistent long-term spine shrinkage ensue. Our results support a model in which: 1) induction of long-term heterosynaptic spine shrinkage depends on Ca^{2+} influx, 2) for both short-term and long-term shrinkage, newly synthesized plasticity proteins are required, and 3) at least two different groups of signaling molecules (for short-term and long-term shrinkage) participate in heterosynaptic spine shrinkage.

Title: Cartography of synaptic memory engrams using activity-dependent, genetically encoded reporters of synapse potentiation.

Authors: *A. JACOB[1], F. LATINI[1], A. FARAONE[1], M. DI CAPRIO[1], M. MAINARDI[2,1], A. CATTANEO[1];

Abstract: The encoding and retrieval of memories occur via the recruitment of specific neuronal ensembles, termed “cellular engrams” (Josselyn et al., 2020, Science). Engram formation correlates with synaptic plasticity processes, such as long-term potentiation (LTP), which has been proposed as a cellular mechanism supporting learning and memory (Takeuchi et. al, 2014, Phil. Trans.; Ryan et al., 2015, Science). However, neuronal activation during the encoding phase of memory recruits specific subsets of the synapse repertoire on the activated neurons. This paradigm shift of spatial scale, from whole-cell to synaptic memory engrams, prompted us to develop SynActive (Gobbo et al., 2017, Nat Comm), a genetic toolbox based on regulatory sequences from Arc mRNA and synaptic-targeting proteins sequences, that allows the expression of any protein of interest specifically at potentiated synapses. Here, we have exploited SynActive to control the expression of mVenus to label potentiated dendritic spines recruited by learning and memory processes. Temporal control over the expression of SynActive-mVenus was obtained via the TetON, doxycycline-dependent system, and AAV vectors were used to introduce the constructs into the mouse brain. Then, mice were exposed to contextual fear

conditioning (CFC) to obtain the synaptic map supporting the encoding of this specific form of associative learning. In addition to mapping the whole array of CFC-linked potentiated synapses, we combined SynActive with GFP Reconstitution Across Synaptic Partners (GRASP), to characterize the potentiated synapse pattern between structurally connected brain regions (Choi et al., 2018, Science). In SynActive-GRASP, one split-GFP fragment was expressed constitutively by presynaptic neurons, while the postsynaptic half was synthesized in a SynActive-dependent fashion at potentiated spines. After extensive validation of SynActive-GRASP in cultured neurons, we stereotaxically injected AAVs for the pre-and post-synaptic components in the CA3 and CA1 regions of the mouse hippocampus, respectively. Comprehensive analysis of reconstituted GFP at the CA3-CA1 potentiated synapses following CFC, revealed a spatially nonuniform and clustered pattern, providing an imaging basis to the observations that the same neuron could encode different memories in different synaptic subsets (Abdou et al., 2018, Science; Kastellakis et al., 2019, Cell Rep). The SynActive toolbox represents a new approach to map and characterize synaptic memory engrams in a variety of memory tasks, both in physiological and pathological (neurodevelopmental syndromes and neurodegeneration) - contexts.

Title: Investigating the brain state and pupil dynamic modulation by frequency-dependent optogenetic regulation of the lateral hypothalamus

Authors: *K. TAKAHASHI[1,2], F. SOBCZAK[1,2], X. YU[3];
[1]Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany; [2]GTC Neurosci., Univ. of Tübingen, Tübingen, Germany; [3]MGH/HST Martinos Ctr. for Biomed. Imaging and Harvard Med. Sch., Charlestown, MA

Abstract: ***Introduction***. Lateral hypothalamus (LH) plays a crucial role in regulating the brain state, which is reflected in pupil dynamics that serve as a specific arousal indicator. The activation of awake promoting neurons in the LH leads to brain state changes that depend on

stimulation frequencies. Animal behavior also varies depending on optogenetic stimulation frequencies of neurons in the LH. Although LH activation modulates both brain states and pupil dynamics, the influence of frequency-specific LH activation on brain state and pupil size regulations is under-examined. Since the LH also regulates the autonomic system, it is important to examine the relationship between LH-mediated brain state and pupil dynamic changes, which will help elucidate the dual regulatory roles played by the LH. Here, we activated CaMKII+ neurons in the LH of anesthetized rats and recorded pupil size changes and local field potentials (LFP) in the anterior cingulate cortex (ACC). Optogenetic activation of the LH induced stimulation frequency-dependent pupil dilation and cortical LFP power changes. These results suggest that the LH can modulate both brain state and pupil dynamics with similar frequency-dependent regulatory mechanisms. ***Methods***. We performed optogenetic stimulation on CaMKII+ neurons of the LH in five adult Sprague-Dawley rats under anesthesia and concurrently recorded LFP signals in the ACC and pupil size (**Fig. 1a**). All acquired data were processed with Matlab and DeepLabCut. ***Results***. LH activation evoked robust LFP changes in the ACC (**Fig. 1b**) and pupil dilation (**Fig. 1c**). In particular, we observed LFP delta (1-4Hz) power reduction in the ACC with an exponential decay feature (**Fig. 1d**) and logarithmic growth of the maximum pupil diameter (**Fig. 1e**) as a function of optogenetic stimulation frequencies from 1 to 20Hz at the LH. ***Conclusion***. This work shows that frequency-dependent optogenetic activation of the LH can induce pupil dilation and brain state modulation simultaneously in a similar manner, suggesting a distinctive up-regulatory role of the LH on both brain state and pupil dynamics.

Title: A closed-loop controller for inducing clusters in neuronal populations in real-time

Authors: *S. FARAMARZI GANJ ABAD[1], T. NETOFF[2];
[1]Univ. of Minnesota, Minneapolis, MN; [2]UNIVERSITY OF MINNESOTA, MINNEAPOLIS, MN

Abstract: Symptoms of Parkinson's disease and essential tremor are associated with pathological synchronization of neurons. Therapeutic effect of the conventional treatment, high frequency Deep Brain Stimulation (DBS), is therefore attributed to chaotic desynchronization of neurons with electrical pulses. A promising new technique, called Coordinated Reset (CR), has more persistent therapeutic effects than conventional DBS. In CR, multiple electrodes deliver periodic and phase-locked stimuli to different regions of the brain. Theoretical studies suggest that CR may increase synaptic plasticity by inducing clusters in neuronal populations. As an alternative approach, we tested a closed-loop controller called the Input of Maximal Instantaneous Efficiency (IMIE) that induces clusters with a uniform input signal. Here we present an experimental test of IMIE in hippocampal slices with fluorescence imaging to measure neuronal oscillations and electrical stimulation to control them. We modeled pathological synchronization in brain slices by bath perfusion of a cholinomimetic drug, carbachol. Then we divided the CA1 region of the hippocampus to 4 arbitrary regions of interest (ROIs). The phase of each ROI was estimated from the average fluorescence data analyzed with a new discrete Fourier transform algorithm called the Sliding Windowed Infinite Fourier Transform (SWIFT). We estimated the phase response curve (PRC) by stimulating the slice and measuring the change in the oscillation phase. Using the estimated phase in real-time and the PRC, IMIE determined the stimuli to disperse the oscillation phases. Stimulation was delivered when the population was most vulnerable to cluster dispersal. We observed a significant difference in the average phase difference between ROIs before and after modulation. Interestingly, the desynchronization persisted beyond the modulation for seconds. Our work is the first experimental demonstration of a real-time closed-loop control of clustering in neuronal populations in brain slices with a single electrode stimulus. We are extending our work to in vivo modulation of neuronal activities in real-time.

Title: Impaired GABAergic signaling on glia alters hippocampal and cortical network activity and long term contextual memory.

Authors: *R. A. WIRT[1], A. M. LEISGANG[2], E. FLORES[1], A. PLATT[3], L. A. CREW[1], J. M. HYMAN[3], J. W. KINNEY[2];
[1]Neurosci., [2]Brain Hlth., [3]Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Contextual processing and recall are reliant on coordinated activity between the hippocampus (HC) and frontal areas of the brain and involve coordination of excitation and inhibition. While glia support neurons interacting in these areas, their role in systems communication is still unclear. To better understand how glial cells support normal brain function, we developed a mouse with significantly decreased GABAB receptors on glia (GABABflox X CX3CR1cre-er; GABAB). Subjects were implanted with a 64 channel device to record local field potentials (LFPs) and neuronal spiking activity in the HC and anterior cingulate cortex (ACC). A conditioned place preference (CPP) recall task was used to measure long-term memory (21 days after conditioning) and we found that GABAB mice remote recall was impaired, but their recent contextual memories appeared intact. Local field potentials revealed multiple possible sources of these long-term memory deficiencies. We found that GABA mice had significantly decreased gamma power (30 - 120 Hz) in the HC and impaired theta-gamma coupling in the ACC. We also found hypersynchrony between the ACC and HC in the theta (5 - 12 Hz) and delta (1-4 Hz) bands. Most notably, we found GABAB mice had significantly fewer hippocampal sharp-wave ripples (SWR), which are thought to underlie memory consolidation. The impairments found in these electrophysiological signals suggest glia, in particular GABAergic signaling on glia, may have a more active role in neural systems than previously thought. Any of these effects could potentially impair long-term memory formation, consolidation, or recall, but the combined effect could be catastrophic for memory function.

Title: Anterior cingulate cortical hippocampal desynchronization linked to cilia dysfunction in PCM1 knockout mice

Authors: *L. A. CREW[1], R. A. WIRT[1], C. CHANG[2], A. CHENG[2], E. FLORES[2], K. N. CALVIN[1], E. C. OH[2], J. M. HYMAN[3];
[1]Neurosci., [3]Psychology, [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Network interactions between the hippocampus (HC) and anterior cingulate cortex (ACC) are critical for efficient memory performance and impaired ACC-HC interactions are thought to contribute to the cognitive deficits seen in schizophrenia (SZ). Although many genes have been identified to contribute to the development of SZ, underlying genetic processes, such as primary cilia functioning, have been less studied and may provide better insight into factors influencing cognitive symptoms. Cilia are rod-like organelles that extend from cell surfaces, providing motility and sensory functions and act as signaling devices during development. A known gene associated with primary cilia dysfunction, pericentriolar material 1 (PCM1), has shown to affect neurogenesis and leads to behavioral phenotypes, such as memory deficits, related to SZ. Recent research has revealed that localized cilia in the HC and ACC are altered in genetic knockouts of PCM1. We hypothesized that dysregulated cilia functioning leads to disruption in network oscillatory activity in the ACC and HC, thus, compromising cognitive performance. To test this hypothesis, we recorded from PCM1 knockout mice during spatial exploration and found substantial alterations in ACC and HC electrophysiology. Notably, spectral changes showed decreased theta power, irregular theta peak frequencies, and increased delta power in PCM1 -/- mice in both brain regions. This increase in delta power resulted in an overall decrease in the theta/delta ratio, a metric designed to show proportional instances of theta and delta that has been linked to human SZ cognitive symptomatology. We found significantly lower ACC-HC theta coherence in PCM1 -/- animals, which is surprisingly consistent with the desynchronization hypothesis of SZ. All together, we found remarkable changes in HC and ACC network activity in a knockout mouse associated with SZ that are coherent with a leading SZ mechanistic explanation, thus, these findings help to link genetic, behavioral, theoretical, and electrophysiological mechanisms that lead to cognitive deficits observed in SZ.

Title: Anesthetic-induced spontaneous state transition synchrony and oscillatory activity correspondence are region-dependent

Authors: *E. B. BLACKWOOD[1], B. P. SHORTAL[1], A. PROEKT[2];
[1]Neurosci., [2]Anesthesiol. and Critical Care, Univ. of Pennsylvania, Philadelphia, PA

Abstract: At fixed concentrations of general anesthesia, the brain spontaneously transitions through discrete states of arousal that are readily identifiable from electrophysiological recordings. These transitions are induced by subcortical signals, and under the prevailing model, they are synchronous throughout the cortex. However, asynchronous local transitions between sleep states have been observed in species such as cetaceans, reptiles, and possibly sleep-deprived rats. Given that sleep states can be local, it is worth investigating whether anesthetic state transitions can also happen asynchronously. If signals to transition first arrive at spatially restricted cortical regions and then spread to connected regions, we should observe transient asynchrony of states and their transitions. Furthermore, if transition synchrony between pairs of regions reflects functional connectivity, the distinct activity patterns of each electrode in pairs with more synchronized transitions should be related by a more consistent correspondence. We recorded local field potential (LFP) from rats held under 1−1.2% isoflurane in oxygen, either from the right primary visual (V1) and motor (M1) cortices (n=4) or from left and right V1 (n=4). We computed time-frequency spectrograms of LFP at each electrode and used non-negative matrix factorization (NMF) to project them onto compact bases of spectral components. We then identified discrete activity states and transition times for each electrode from the relative power over time of each of its NMF components. In both sets of recordings, the correspondence (normalized mutual information) of discrete states and the synchrony of state transitions were higher for within-region than cross-region electrode pairs, indicating that oscillatory activity and transition timing differed on a region-to-region basis. To measure activity correspondence without imposing discrete states, we also used canonical correlation analysis to compare series of NMF component scores; correspondence was again higher for within-region than across-region pairs. Mean transition synchrony was also higher for left/right V1 pairs than for M1/V1 pairs (bootstrap, $p < 0.001$), but this contrast was not reflected in activity correspondence differences. These results support a model of decentralized transition induction but suggest that regions with more synchronized transitions may not be more synchronized in general. Future research should record from a greater number of regions and test more specific models of how weak, nonspecific inter-region coupling can consistently give rise to transitions that appear global macroscopically.

Title: Using multiple evoked and functional network metrics to measure and interpret cortical connectivity patterns in humans

Authors: *L. H. LEVINSON[1], S. SUN[2], C. J. PASCHALL[3], A. KO[4], J. A. HERRON[4], K. E. WEAVER[5], S. I. PERLMUTTER[6], J. G. OJEMANN[4];
[1]Neurosci., [2]Bioengineering, [4]Neurolog. Surgery, [5]Radiology, [6]Dept Physiol. & Biophysics, Washington Natl. Primate Res. Ctr., [3]Univ. of Washington, Seattle, WA

Abstract: Electrical stimulation of the cortex can be used to change patterns of neural activity, a technique that, in the future, may be used in neuro-rehabilitative therapies. For instance, electrical stimulation could induce and enhance neuroplasticity after a stroke event, altering cortical connectivity to bypass injured areas and promote functional recovery. To accurately understand how activity can be modulated, we need robust, interpretable metrics of functional and effective cortical connectivity. Many groups use cortico-cortical evoked potentials (CCEPs) to measure cortical responses to stimulation and use changes in CCEP magnitude as a proxy for changes in effective connectivity between sites; however, the neural bases of CCEPs are incompletely understood. This makes it difficult to interpret CCEPs, limiting the information we can use while developing protocols to induce or enhance connectivity changes. We may improve our ability to interpret CCEP results by combining CCEPs with metrics of activity with well-established ties to behaviors and neural outputs, such as resting state functional connectivity (rsFC) measures. This will allow us to functionally refine plasticity-inducing stimulation protocols. While previous studies have compared CCEP networks to various rsFC measures, results have been variable and, to our knowledge, no study has systematically compared CCEP results to rsFC networks built using a wide variety of computational techniques, including amplitude-amplitude (e.g. correlation, coherence), phase-phase (e.g. phase locking), phase-amplitude (e.g. phase-amplitude coupling), directed (e.g. Granger causality), and graph theoretical measures. Here, we perform such comparisons in stimulation and resting datasets from individual human subjects. By examining the relationships between CCEP and rsFC networks within and across subjects, we will build a robust, multifaceted metric of cortical connectivity that can be used to measure and interpret changes in brain activity after plasticity-inducing brain stimulation.

Title: Low-dose radiation impairs neurogenesis in human forebrain organoids

Authors: *L. PARKITNY[1], S. OSENBERG[1], L. BRONK[2], A. LAGRONE[1], F. GUAN[3], M. W. GABER[5], D. GROSSHANS[4], M. MALETIC-SAVATIC[1];

Abstract: Exposure to galactic cosmic ray (GCR) and solar particle event (SPE) radiation during interplanetary spaceflight may exert adverse effects on the adult human brain. Particularly susceptible to these effects are hippocampal neuroprogenitor cells which generate newborn neurons throughout life. Neurogenesis plays a critical role in brain plasticity and has been linked to cognition and mood control. Here, our main aim was to generate a relevant in vitro model to test the effects of GCR/SPE-like radiation on the human brain and, in particular, NPCs, neurons, and astroglia. We predicted that exposure to spaceflight-like conditions would result in anti-neurogenic effects such as increased cell apoptosis and reduced NPC proliferation. First, we developed a method for delivering GCR/SPE-mimicked doses of proton radiation to tissues contained in a culture plate, using the Geant4 Monte Carlo software package. Dose validation was performed via ETB3 film and Advanced Markus Chamber measurements. Then, to test the radiation effect on neurogenesis and relevant cell types, we generated human forebrain organoids which, in their early stages, are principally composed of NPCs but become increasingly heterogeneous as they mature. Organoids were exposed to a single or multi-dose course of low (4 keV/µm) or high (15 keV/µm) linear energy transfer (LET) proton radiation at a cumulative dose of 0.5 Gy to simulate long-term GCR/SPE-like exposure. We tested the radiation effects at multiple time points during the subsequent organoid maturation. We examined cell proliferation and apoptosis using a combination of imaging, immunohistology, flow cytometry, and transcriptomic methods. Radiation was associated with abnormal cell function; expression of activated caspases was elevated acutely and subacutely by as much as 40% of that in control organoids. On day 3 following radiation, the proliferation marker Ki-67 was reduced by 25%, and subsequent growth of irradiated organoids was impaired; this was associated with a reduced expression of Pax6, an NPC marker. Our data show that low-dose proton radiation induces cell apoptosis and impairs cell growth. These data are relevant to space flight as well as for clinical contexts where proton therapy is employed. Having developed this model, we will now test several newly developed pharmacological and non-pharmacological agents that might attenuate these anti-neurogenic effects of radiation.

Abstract: Epilepsy is a devastating neurological condition affecting 3 million adults in the U.S. alone. Most epileptic seizures initiate focally in the temporal lobe (TLE) and ~30% of these cases are unaffected by medical treatment. Refractory TLE usually starts with an initial seizure, followed by a seizure-free latent period, before chronic seizures appear. The unpredictable nature of the disease imposes a major challenge for clinicians: only some patients develop chronic seizures, which can emerge anytime in the days to years after the initial episode. Thus, the disease course is unknown during latency and immediate treatment cannot be prescribed. This work aims to identify activity changes in hippocampal neurons during latency that could predict the development and severity of chronic seizures in the pilocarpine model of TLE. Transgenic mice expressing the red genetically-encoded calcium indicator jRGECO1a in excitatory projection neurons were implanted with 1) an optical window providing access to the hippocampus and 2) EEG electrodes to monitor hippocampal and cortical seizures. We used two-photon microscopy to record from CA1 and DG neurons before and after the administration of pilocarpine hydrochloride, documented the severity of the resulting seizures according to the Racine scale, and detected the appearance of chronic stages using the EEG recordings. Analyses of calcium transients recorded from jRGECO1a-labeled neurons in DG and CA1 reveal a rapid transformation of the activity of CA1 neurons from a normal to pro-epileptic state upon pilocarpine treatment. Starting on the first day after the pilocarpine treatment, we identified a significant increase in CA1 firing rate, as well as a substantial increase in synchronous firing across CA1 pyramidal cells. These changes persisted throughout the latency period. Increased synchronicity of DG neuronal firing was identified several weeks after pilocarpine administration, suggesting a gradual failure of its gating properties. Preliminary analyses suggest these changes correspond to the severity of chronic seizures. These data begin to unveil the pro-

epileptic hippocampal transformation during the latent phase of pilocarpine-induced epilepsy. The development of significant synchronous firing events may serve as a biomarker for predicting the long-term outcome of chronic seizure development in pilocarpine-treated mice.

Title: Investigating the effects of reduced GABA levels in gad1b null zebrafish on neural activity in the optic tectum

Authors: C. R. DUFFY[1], Y. LIU[2], Y. CHEN[3], P. MA[3], P. KNER[2], *J. D. LAUDERDALE[1]; [1]Cell. Biol., [2]Sch. of Electrical and Computer Engin., [3]Statistics, Univ. of Georgia, Athens, GA

Abstract: Reduced levels of gamma aminobutyric acid (GABA), the main inhibitory neurotransmitter, is connected to health issues such as epilepsy, stiff person syndrome and anxiety. GABA is formed by the decarboxylation of glutamate by glutamic acid decarboxylase (GAD). While most vertebrates have two *GAD* genes, known as *GAD1* and *GAD2*, zebrafish have three *gad* genes: *gad1a*, *gad1b*, and *gad2*. Using whole mount RNA *in situ* hybridization, we show that in the in the 1 dpf zebrafish spinal cord, the paralogs *gad1a* and *gad1b* are both expressed, though they are expressed in different neurons. In the 5 dpf zebrafish optic tectum, both are expressed, but exact localization needs to be investigated further. While the mice model of null *Gad1* causes neonatal fatality, we've created a *gad1b* null zebrafish which has reduced GABA levels, investigated using HPLC, and displays hyperactivity in the brain as measured by electrophysiology. This provides a unique model to study the effects reduced GABAergic signaling has on neural development. Using an *elavl3:Gcamp5G* expressing fish, and light sheet microscopy, we imaged activity in the 5 dpf zebrafish optic tectum of ten fish for each of the following three conditions: *gad1b*-null, wild type treated with pentylenetetrazol (PTZ-a drug that blocks the $GABA_A$ receptor), and wildtype with no treatment. For each larva, five recordings were made of two minutes in length. Patterns of activity were compared both within each fish and between fish. We found wild type activity is localized to the specific layers of the tectal neuropil, and PTZ treated fish activity is seen broadly throughout the whole tectum, as expected. *gad1b*-null larvae show an increase in the area of activity in the neuropil as well as in the cell

body layer. The increased activity in *gad1b*-null larvae is consistent with activity-dependent failure of surround inhibition of the tectal micro-circuits mediating visual input, and is providing insight into the impact of reduced GABA on neural development and function.

Title: Diurnal and Multidien Rhythm of Interictal Epileptic Discharges and Epileptic Seizures in an Animal Model of Temporal Lobe Epilepsy Using Tetanus Toxin

Authors: *M. NAKATANI[1,2], A. GHESTEM[1], A. IVANOV[1], C. BERNARD[1];
[1]Inst. de Neurosciences des Systems, INSERM UMR_S 1106, Aix-Marseille Univ., Marseille, France; [2]Dept. of Neurol., Juntendo Univ., Tokyo, Japan

Abstract: Attempts to predict the likelihood of epileptic seizures based on the circadian and multidien rhythms have received increasing attention not only to improve the quality of life, but also to avoid the secondary injuries including sudden unexpected death in epilepsy. However, whether such rhythms exist in the beginning process of the acquisition of epileptogenicity in an epileptic animal model is still unexplored well. In this study, we aimed to investigate the occurrence patterns of interictal epileptic discharges (IEDs) and epileptic seizures using an animal model of temporal lobe epilepsy. We enrolled 10 male Sprague-Dawley rats and 4 rats were treated with tetanus toxin (TeNT) to develop spontaneous focal epileptic seizures (Jefferys et al., 1995, Nilsen et al., 2006). A 30 ng TeNT dissolved in phosphate buffered saline (Sigma-Aldrich, USA) with 0.2% bovine serum albumin (Sigma-Aldrich, USA) were stereotactically injected to the CA3 region of the hippocampus. An insulated tungsten electrode was inserted to the same coordinate to record the electroencephalogram with sampling rate 1000 Hz and DC setting for two months. We evaluated the occurrence pattern of the IEDs more than 1000 μV and epileptic seizures during continuous recording periods. The seizure onset pattern in each seizure was additionally identified based on the classifications previously proposed (Jirsa et al., 2014). Three out of 4 rats developed IEDs and spontaneous seizures. Regarding the IEDs, they were often observed during the daytime, which is a sleep period for rats. Although the total number of IEDs dramatically fluctuates over time, there seemed a diurnal variation in which the number of

IEDs go up and down every several days. Ictal seizures also tended to be more frequent during the daytime. Two to four onset patterns were observed in each rat, and the onset pattern changed from SN onset pattern, which is characterized by the sudden baseline shifts, to SNIC or SupH pattern over time. No clear regularity was detected in the onset pattern. Interestingly, epileptic seizures appeared more frequently one week before the period of frequent IEDs. As previously reported, both IEDs and seizures almost disappeared approximately 50 days after the drug administration. We conclude that some circadian rhythm of IEDs and epileptic seizures appear even at the beginning of epileptogenesis.

Title: Roles of pannexin1 in epilepsy

Authors: P. WHYTE-FAGUNDES[1], D. TASKINA[1], L. DONALDSON[1], C. ZOIDL[1], ***G. ZOIDL**[2];
[1]Biol., [2]York Univ., Toronto, ON, Canada

Abstract: The molecular determinants of excitation-inhibition imbalances promoting seizure generation in epilepsy patients are not fully understood. Experimental evidence suggests that Pannexin1 (*Panx1*), an ATP release channel, modulates excitability of the brain. Here, we use zebrafish larvae with Panx1a and Panx1b channels genetically knocked out or pharmacologically inhibited to evaluate the consequences of targeting Panx1 for antiepileptic drug therapies. Pentylenetetrazole was used to chemically induce seizures during *in vivo* recordings of local field potentials and for behavioral and molecular phenotyping. We find that loss-of-function *panx1a* gene mutations, or pharmacological blockade of both channels significantly reduces ictal-like events and seizure-related locomotion. Loss of *panx1a* also improves survival rates and transcriptome data demonstrate altered metabolic and cell signaling states. The pro- and anticonvulsant activities of both Panx1 channels affect ATP release and the purinergic receptor *P2rx7*. In summary, the present study highlights the importance of *panx1a*$^{-/-}$ as the primary source for pro-convulsant activities in the zebrafish. We present models suitable for targeting different neuronal circuitries of the zebrafish, which will allow dissecting *in vivo* the mechanisms of how the brain is guarded from excessive excitability, and which functions require *Panx1*.

Title: Layer- and pathway-specific disruption of perisomatic inhibition in the somatosensory cortex of the stargazer model of absence epilepsy

Authors: *S.-Y. SONG, A. MAHESHWARI, J. L. NOEBELS, X. JIANG;
Baylor Col. of Med., Houston, TX

Abstract: Absence seizure is a special type of epilepsy in children featured by generalized spike-wave (SW) electroencephalography (EEG) change. While earlier studies attribute the origin of SW discharges of absence seizure to the thalamus, there is now growing evidence that the cortex exerts a more prominent role in the generation and expression of SW activity, and their focal onset zone may reside in the somatosensory cortex (S1). To provide more insight into the minimal circuit elements necessary for the induction of SW discharge, we take advantage of a monogenic mouse model of absence epilepsy, stargazer, to examine what circuit defect may be specifically developed in the S1 as a result of mutations in *Cacng2*, a gene encoding an AMPA receptor trafficking protein stargazin (*stg*). We examined spontaneous excitatory postsynaptic currents (sEPSCs) of both excitatory and parvalbumin-expressing (PV^+) inhibitory neurons in S1 across the layers from homozygous stg (*stg*/*stg*) mutant mice and then compared to their wildtype littermates. In addition, simultaneous eight-cell patch recordings were performed on S1 neurons across the layers to examine cell-type specific connectivity change in *stg*/*stg* to further dissect the specific cell types and pathways impacted by the genetic lesions. The amplitude and frequency of sEPSCs recorded from PV^+ interneurons located in the S1 deep layers (Layer V and VI) were significantly decreased in *stg*/*stg* compared with wildtype littermates, while the PV^+ interneurons in Layer II/III and Layer IV showed no significant difference between genotypes. These effects appear to be cell type-specific as sEPSCs recorded from excitatory neurons across all layers in S1 did not change significantly in *stg*/*stg*. Consistent with this, our connectivity mapping indicates that connectivity from excitatory neurons to PV^+ interneurons in S1 deep layers was severely disrupted in *stg*/*stg*, while their connectivity in superficial layers and Layer IV remained intact. In addition, the connectivity from PV^+ interneurons to excitatory neurons and the connectivity between excitatory neurons across all layers showed no significant change in *stg*/*stg*, indicating the circuit changes in *stg*/*stg* is both layer-specific and pathway-specific.

This layer-specific and pathway-specific disruption of perisomatic inhibition as a result of single-gene mutations in absence seizure not only provide new insight on the circuit mechanisms underlying absence seizure, but also help to direct the field toward the development of innovative circuit-based interventions for absence epilepsy and its related comorbidities.

Title: Sustained network activation prevents post-traumatic epilepsy

Authors: *O. C. GONZALEZ[1], S. SOLTANI[3], S. CHAUVETTE[4], B. MARSH[2], I. V. TIMOFEEV[5], M. V. BAZHENOV[1];
[1]Dept. of Med., [2]Neurosciences Grad. Program, UCSD, La Jolla, CA; [3]Psychiatry and neurosciences, CERVO Brain Res. Center, Univ. Laval, Québec, QC, Canada; [4]CRIUSMQ, Quebec, QC, Canada; [5]CRIUSMQ, Univ. Laval, Quebec, QC, Canada

Abstract: Traumatic brain injury remains one of the most common factors leading to acquired epilepsy. Post-traumatic epilepsy (PTE) is characterized by a prolonged epileptogenic period which has been reported to extend up to 15 years after the occurrence of the brain trauma. Additionally, an age-dependent effect on the development of PTE has been reported. Recent *in vivo* studies demonstrated that older animals were more susceptible to the development of epilepsy following cortical undercut as compared to younger animals. The mechanism that gives rise to PTE remains to be fully understood but may involve misregulation of synaptic weights through homeostatic synaptic scaling. In response to brain trauma, there is a reduction of network activity within and near the traumatized as thus deafferented brain area. This triggers homeostatic up-regulation of synaptic strength in an attempt to recover normal levels of network activity. If trauma is severe, homeostatic scaling may overcompensate and increase synaptic weights such that the network is primed for transitions to seizure states. In this new study, we tested the hypothesis sustained network activity following cortical deafferentation could prevent homeostatic up-scaling and PTE. Using a detailed biophysical model of the neocortex, we found that a sustained depolarization was capable of preventing up-scaling of synaptic weights to a pathological state and thereby preventing occurrence of spontaneous recurrent seizures. In contrast, a sustained hyperpolarization of the traumatized network resulted in increased

homeostatic up-scaling, triggering a severe pathological state characterized by the occurrence of frequent spontaneous recurrent seizures. Furthermore, our analysis demonstrates that pathological increases in synaptic weights drives seizure generation by perturbing extracellular potassium concentration dynamics and initiating a positive feedback loop between extracellular potassium concentration and neuron firing rates. This feedback loop drives increased excitability and hypersynchrony eventually leading to spontaneous seizure onset. These findings from the computational model were validated with our *in vivo* experiments in mice where cortical undercut was followed by activation of DREADDs (hM3DGq or hM4DGi) to alter baseline network activity around the undercut area. hM3DGq prevented and hM4DGi exaggerated seizure activities. Together, these results provide evidence for the role of homeostatic synaptic scaling in the development of post-traumatic epilepsy and may provide new insights into novel treatments or preventative measures for trauma-induced epilepsy.

Title: Epileptiform activity triggered by KCC2 blockade in subicular circuits

Authors: M. ANSTOETZ, M. P. FISKE, *G. MACCAFERRI;
Northwestern University-Feinberg Sch. of Med., Chicago, IL

Abstract: Depolarizing excitatory GABAergic signaling following the reduced expression of the KCC2 membrane transporter has been observed in subicular tissue of patients suffering from temporal lobe epilepsy. However, as many other alterations are inherently present in epileptic tissue, it is difficult to assess unequivocally whether impaired KCC2 function alone is epileptogenic or other epilepsy-related changes are also necessary. Here, we have addressed this question in a reduced model in vitro, and have studied the mechanistic involvement of a specific class of interneuron, i.e. the parvalbumin-expressing cell. Pharmacological blockade of KCC2 by the selective antagonist VU0463271 applied to isolated subicular slices from non-epileptic mice was sufficient to generate hypersynchronous population discharges in simultaneously patch-clamp recorded pyramidal neurons. Spontaneous events displayed the same pharmacological dependency on $GABA_A$ and AMPA postsynaptic receptors, as described for interictal events in human epileptic tissue in vitro. Calcium imaging of slices exposed to VU0463271 revealed

clusters of spontaneously co-active subicular neurons, whose estimated area was comparable to the axonal spread of single parvalbumin-expressing interneurons. Light-evoked activation of channelrhodopsin conditionally expressed in this class of cells was able to trigger interictal-like discharges, similar to VU0463271-induced spontaneous events. In contrast, light stimulation of archaerhodopsin expressed in the same neurons reduced the frequency of spontaneous interictal-like activity. Lastly, preliminary data suggest that this type of epileptiform synchronization may not be reversible upon washout of VU0463271.In summary, our results indicate that the loss of KCC2 function in subicular networks is sufficient to induce interictal-like events via altered GABAergic signaling originated by parvalbumin cells and that no other changes, commonly present in epileptic tissue, are necessary. In addition, this type of activity may trigger maladaptive changes preventing the return of the network to the original state. These results corroborate the idea that impaired KCC2 function may act as a key epileptogenic step in the progression of temporal lobe epilepsy.

Title: Optimization of the SMART dynamic bike to improve motor function in Parkinson's disease

Authors: *A. RIDGEL[1], P. GATES[2], R. MELCZAK[3];
[1]Exercise Science/Exercise Physiol., [2]Biomed. Sciences/Exercise Physiol., [3]Exercise Physiol., Kent State Univ., Kent, OH

Abstract: High-cadence dynamic cycling improves functional motor scores in individuals with Parkinson's disease (PD). However, variability in responses among individuals suggests that an adaptive controller could help to decrease that variability. **PURPOSE:** To develop a Speed Manipulated Adaptive Rehabilitation Therapy (SMART) model for control of a custom designed motorized dynamic cycle and to evaluate the model accuracy for predicting motor function changes and physical effort. **METHODS:** Individuals with PD (N=16) completed three sessions of dynamic cycling under three different acceleration and velocity settings. Outcome measures included the pre and post UPDRS scores, cadence, and effort. Effort was defined as percent

positive power over the length of the session, indicating the ability to keep up with the motor. Demographic data included body mass index (BMI), age, gender, disease duration, medication dosage, most-affected side, and exercise history. Multiple linear regression models were built to examined how baseline UPDRS III scores, medication dosage, cycling cadence, entropy of cycling cadence (variability) and rider effort (power) affected the change in UPDRS III scores after a single bout of high-cadence cycling. **RESULTS:** This model showed that effort (p=0.04) and baseline UPDRS (p=0.01) significantly contributed to the variance in the change of UPDRS III after high-cadence dynamic cycling. Age (p=0.06) and daily medication intake (p=0.09) were not significant contributors. It is important to note because the testing and exercise were done with individuals 'on' medication. The second model showed that effort during high-cadence cycling explained 64% of the variance (p = 0.04) and that BMI (p=0.006) and age (p=0.04) were significant contributors. **CONCLUSION:** These findings suggest that symptom presentation, rider effort, age and BMI are important predictors of UPDRS III improvement after high-cadence dynamic cycling. These models will be further tested in a broad range of individuals with PD (different ages, BMI, baseline UPDRS, medication dosage) to optimize the SMART controller.

Abstract: Ratio of excitatory and inhibitory synaptic processes in anti-nociceptive *raphe magnus* nucleus, activated by *periaqueductal gray matter*, on a model of Parkinson's disease when protection with hydrocortison

Neda. Behnam Dehkordi, V.H. Sarkisian, M. Hovsepyan, M.V. Poghosyan, J.S. SarkissianL.Orbeli Institute of Physiology, National Academy of Sciences of Armenia, 22 Orbeli Bros str., 0028 Yerevan, Armenia
Objective: In neurodegenerative diseases, most often Parkinson's disease (PD), antinociceptive centers are involved in neurodegeneration, which is accompanied by constant pain that cannot be relieved by drugs. We tried to find out the mechanisms of this phenomenon.**Methods:** In 3 series of experiments on 13 Albino rats, the impulse activity of 390 single neurons of Raphe Magnus (RMg) nucleus was analyzed during high-frequency stimulation (HFS) of Periaqueductal gray matter (PAG) in normal conditions, on a rotenone model of PD and when protection with Hydrocortisone. **Results: T**he number of neurons responding with depressor reactions decreased many times, with an increase in those responding with excitatory ones. This is the result of excitotoxicity, which is indicative of neurodegenerative damage to RMG neurons. Under conditions of exposure to Hydrocortisone, depressive reactions sharply increased with a significant increase in the number of neurons involved in them. In the PD model, in RMG neurons on the PAG HFS, a pronounced increase in the prestimulus frequency of activity preceded by post-stimulus depressor effects was shown. With hydrocortisone, a significant decrease in the prestimulus frequency preceded by excitatory post-stimulus manifestations of activity was obtained, which clearly indicates in favor of protection. The post-stimulus frequency of activity of RMG neurons, in the PD model, accompanied by excitatory effects much more exceeded the norm, also indicating tremendous excitotoxicity. Under conditions of protection, there was a powerful decrease in the post-stimulus frequency in the PD model accompanied by excitatory effects. **Conclusion:** The successful protective effect of Hydrocortisone is documented. The PD model provides evidence of the involvement of the important antinociceptive structure RMG in the neurodegenerative process. Reciprocal interaction with PAG, and the possibility of therapeutic provision with hydrocortisone is revealed. The PD model provides evidence of the involvement of the important antinociceptive structure RMG in the neurodegenerative process.

Abstract: Huntington's Disease (HD) is a neurodegenerative disorder caused by a CAG trinucleotide repeat expansion in the Htt gene for which no therapies are available. This mutation causes HTT protein misfolding and aggregation, preferentially affecting medium spiny neurons (MSNs) of the basal ganglia. Transcriptional perturbations in synaptic genes and neuroinflammation are key processes that precede MSN dysfunction and motor symptom onset. Understanding the interplay between these processes is crucial to develop effective therapeutic strategies to treat HD. We investigated whether protein kinase CK2α', a kinase upregulated in MSNs in HD and previously associated with Parkinson's disease (PD), participates in the regulation of neuroinflammation and synaptic function during HD progression. We used the heterozygous knock-in zQ175 HD mouse model that lacks one allele of CK2α' and performed cytokine proteome profiling, RNA-seq, electrophysiological recordings, and behavioral analyses. We showed that CK2α' haploinsufficiency in zQ175 mice ameliorated neuroinflammation, HTT aggregation, excitatory synaptic transmission deficits, and motor dysfunction. Our RNA-seq analyses also revealed a connection between α-syn, a protein associated with PD, and the transcriptional perturbations mediated by CK2α' in HD. We found that CK2α' increased α-syn serine 129 phosphorylation (pS129-α-syn), a post-translational modification linked to α-synucleinopathy, and its accumulation in the nucleus of MSNs in zQ175 mice and in patients with HD. Our data demonstrated that CK2α' negatively contributes to HD by promoting striatal synucleinopathy and neuroinflammation.

Title: Neuroprotective roles of Estrogen and Cytisine in a 6-OHDA Mouse Model of Parkinson's Disease

Authors: *S. ZARATE, G. PANDEY, A. GONZALEZ, E. ONYEWUENYI, J. ABSHIRE, K. WILLIAMS, S. CHILUKURI, M. HOOK, R. SRINIVASAN;
Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Univ. Col. of Med., Bryan, TX

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder caused by the loss of midbrain dopaminergic (DA) neurons with an incidence rate of 2:1 in men versus women. PD will affect over 12 million people by 2040 underscoring a need for neuroprotective treatments. Unfortunately, current treatments for PD are symptomatic, cause severe side effects, and lose efficacy over time. Previously, we showed that the smoking cessation drug, cytisine exerts neuroprotective effects only in female mice by attenuating the endoplasmic reticulum (ER) stress response pathway in combination with17-β-estradiol. Here, we further characterize the role of 17-β-estradiol in female parkinsonian mice. We induced parkinsonism in four groups of mice by unilateral injection of 6-OHDA in the dorsolateral striatum. The four groups included: 1) ovariectomized (OVX) female mice treated with alternate day i.p. injections of 0.2 mg/kg cytisine, 2) sham-operated female mice treated with alternate day injections of cytisine, 3) sham-operated female mice treated with alternate day injections of saline, and 4) OVX female mice treated with alternate day i.p. injections of saline. PD related behaviors in all four groups were assessed using apomorphine rotations, pole test, and gait analysis with the Digigait system. We found that cytisine attenuation of apomorphine rotations was lost in OVX cytisine treated females. During pole test, we found no change in time to descend between all four groups after 6-OHDA lesion. Interestingly, all mice displayed spontaneous rotational behavior during pole descent with saline treated mice showing 2-fold more rotations than either OVX or intact cytisine treated mice. Gait analysis during a forced walking test showed that the left hindpaw was turned outward in sham operated saline treated female mice but not in either OVX or intact cytisine treated mice. These data suggest either a potential role for local brain derived 17-β-estradiol in the neuroprotective effect of cytisine or mechanisms related to sex specific differences in cytisine pharmacology.

Title: Vesicular glutamate transporter expression mediates mitochondrial oxidative stress related to dopamine neurodegeneration

Authors: *S. A. BUCK[1], T. KUNKHYEN[2], S. A. RUBIN[1], C. E. J. CHEETHAM[2], Z. FREYBERG[3];
[1]Psychiatry, [2]Neurobio., [3]Psychiatry, Cell Biol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Parkinson's disease (PD) is characterized by dopamine (DA) neurodegeneration, but some DA neurons are relatively protected compared to others. Recent evidence suggests DA neuron expression of vesicular glutamate transporter 2 (VGLUT2) plays a role in mediating this selective vulnerability. To date, however, the mechanism behind this protection conferred by VGLUT2 is still unknown. Considering the role of mitochondrial dysfunction in PD etiology, we hypothesized VGLUT2 expression may improve mitochondrial resilience to oxidative stress observed in DA neurons in animal models of PD and human PD. To test this hypothesis, we employed the genetically tractable *Drosophila melanogaster* model. We employed a tyrosine hydroxylase (TH)-Gal4 driver to induce DA neuron-specific RNA interference (RNAi)-mediated knockdown of *Drosophila* VGLUT (dVGLUT), which caused a 44.0%-63.6% decrease in TH^+/$dVGLUT^+$ neuron density, a 51.3%-69.0% decrease in percent of TH^+ neurons that are $dVGLUT^+$, and a 36.1%-51.4% decrease in average number of dVGLUT mRNA grains in TH^+ neurons compared to control genotypes. To test if dVGLUT's neuroprotective properties are linked to its ability to lower potentially neurotoxic reactive oxygen species (ROS), we analyzed the impact of DA neuron dVGLUT RNAi on mitochondrial oxidative stress using flies that express MitoTimer, a mitochondrially-localized DsRed mutant that shifts fluorescence from green to red when oxidized, in DA neurons. Using paraquat (10 mM, 5 days), a pesticide model of PD that induces oxidative stress in DA neurons, we performed multiphoton imaging of brains from exposed MitoTimer flies and measured mitochondrial oxidative stress in distinct DAergic projection areas. We found an intriguing sex difference, as control females had lower mitochondrial ROS in all DAergic regions analyzed compared to control males ($P<0.05$). Conversely, DA neuron dVGLUT RNAi increased ROS in females ($P<0.01$) but not males, suggesting dVGLUT plays a role in mediating sex differences in mitochondrial oxidative stress and may provide a new mechanism for greater protection from DA neurodegeneration in females versus males. Finally, paraquat increased mitochondrial ROS levels in the DAergic fan-shaped body of all genotypes ($P<0.05$) with the greatest increase observed in the male dVGLUT RNAi group ($P<0.05$). Together, these findings uncover a novel mechanism of dVGLUT-mediated

protection, highlighting its role in mediating mitochondrial oxidative stress in DA neurons in the paraquat model of PD.

Title: Exercise-related motor recovery in the rat 6-OHDA hemi-parkinson's model without increased striatal dopamine biosynthesis: a glimpse into exercise impact in human Parkinson's disease?

Authors: E. A. KASANGA[1], M. SHIFFLET[2], ***M. SALVATORE**[2];
[1]Inst. of Healthy Aging, Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [2]Univ. of North Texas Hlth. Sci. Ctr., Ft Worth, TX

Abstract: Exercise can mitigate the progression of motor impairment in Parkinson's disease (PD), which strongly infers that there is a critical neurobiological response to exercise that diminishes the rate of nigrostriatal dopamine (DA) neuron loss or function. Identifying the mechanisms of this exercise response in rodent PD models arguably points to the most germane pharmacological or gene-based approach to treat motor impairment in PD. However, for optimal translation of these mechanisms to human PD, the exercise modalities used in rodents must be practicable for the human PD patient. Moreover, the identification of these exercise mechanisms, once the practical considerations of exercise are engaged in a rodent PD model, may necessitate investigation in areas outside of striatum, given more than 80% loss of DA is already present at onset of motor impairment. To begin to address these gaps, we trained four to five month old Sprague-Dawley rats to exercise on a treadmill prior to induction of nigrostriatal lesion. Seven days after lesion, motor impairment was established by a minimum of 25% reduction in the use of the forepaw associated with lesion. Rats were then segregated into the non-exercise (NE) and exercise (EX) groups with similar impairment. Treadmill exercise was initiated for three times per week, 40 minutes each session, for three weeks, with motor assessments done the day following the last exercise session each week. The treadmill exercise regimen produced highly significant recovery (~50%) in forepaw use with nine exercise sessions over the three-week period of exercise. Notably, this motor recovery was not associated with any recovery of striatal tyrosine hydroxylase (TH) protein or DA tissue content loss. Moreover, there was a significant

decrease of TH protein and DA tissue content in the striatum, contralateral to lesion, in the EX group. Taken together, our results show that an exercise regimen in an established rat PD model that matches the intensity, frequency, and duration used in exercise programs in PD patients does induce recovery of motor function, demonstrably lost prior to exercise initiation. Moreover, the results also indicate that exercise-mediated motor recovery may not require any increase in striatal dopamine biosynthesis.

Title: Non-invasive neurosurgery: Dance participation modulates brain signal in subgenual cingulate gyrus (Cg25) while decreasing depressive symptoms for people with Parkinson's Disease over 8-months

Authors: R. E. BARNSTAPLE[1], K. BEARSS[1], A. M. PAGLIUSO[1], G. R. LEVKOV[1], R. J. BAR[1], P. M. DI NOTA[1], *J. DESOUZA[2];

Abstract: As global incidence of neurodegeneration is on the rise, recent studies have investigated the potential for dance to foster adaptive plasticity in these conditions. Results have shown that dance participation leads to brain-based changes in expert dancers (Bar & DeSouza 2016) and older adults, and can modify disease progression for people with Parkinson's Disease (PwPD; Bearss & DeSouza, 2021). While there are indications of improvements in motor and psychological symptoms as a result of participation in dance, the neural mechanisms underlying these are currently unclear. Our current study follows participants in a Dance for PD classes over 8 months and correlates outcomes on the Geriatric Depression Scale (GDS) with a subset of 8 participants' functional imaging changes. Using an anatomical seed in subgenual cingulate gyrus (Cg25, a node of the depression network) and surrounding area, we probed BOLD signals while subjects visualized learned choreography accompanied by the music they danced to in the studio. GDS scores of PwPD were collected in the dance studio before and after class and showed a significant decrease ($p<0.05$, paired t-test), indicating a reduction in depression. BOLD signals were averaged during visualization during 4 scanning sessions (September, December, January

and April) for all 10 PwPD (28-scans in total; fig C). We ran a correlation on GDS and BOLD signal data pre/post for all subjects with two or more scanning sessions and found a significant correlation between reduced BOLD signal from Cg25 and reduced GDS scores across our dataset (Pearson Correlation of 0.83 of $t(5)=-3.3099$, $p<0.025$, Fig E). Cg25 is a traditional target for deep brain stimulation in treatment-resistant depression; changes in signal strength from this area correlated with improvements in depression scores suggest dance-based learning accompanied by music may be facilitating network reconfiguration. This is the first study to identify a neural substrate for changes associated with dance and contributes to our understanding of mechanisms involved in adaptive plasticity.

Title: Development of a novel neuroprotective agent to treat Huntington’s disease

Authors: *S. KORTAGERE, S. DAS;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Huntington's disease (HD) is a fatal neurodegenerative genetic disorder caused by increased CAG repeats in exon 1 of the Huntingtin gene. Huntington's Disease is characterized by uncoordinated movement (Chorea), psychomotor impairment, cognitive impairment and neuropsychiatric abnormalities in addition to other somatic symptoms. The CAG repeat generates a mutant form of huntingtin protein (HTT) which is toxic to brain cells. The HTT protein can interfere with a variety of cellular functions including packaging and release of neurotransmitters and mitochondrial functions and protein degradation. This HTT protein activity also causes aberrant changes to glutamatergic neurotransmission causing an excess glutamate release in various regions of the brain leading to excitotoxicity and cell death. In addition, the major glutamate transporter also called excitatory amino acid transporter 2 (EAAT2) present predominantly on astrocytes is downregulated in several neurodegenerative diseases including HD causing a significant accumulation of synaptic glutamate. We have recently developed a novel small molecule activator of EAAT2 and characterized its ability to increase the uptake of glutamate in MDCK-hEAAT2 TRANSFLEX plate assay. Results from the assay showed that GTS467 increased glutamate uptake with an EC50 value of 35.3nM. Further, GTS467 was tested for in vivo bioavailability with three modes of administration (i.p, i.v and p.o). The oral bioavailability was determined to be 80.34% and the compound has a half life of 1.81h in the brain. Based on these good physicochemical properties, GTS467 was tested in a transgenic mouse model of HD developed in R6/2 mice expressing the human HTT 128Q repeats for locomotor and cognitive effects. Results from the study showed that the HTT mice had significant deficits in locomotor and cognitive phenotypes measured using open field task and novel object recognition tasks and treatment with GTS467 dose dependently improved the performance of mice in these tasks. Current studies are aimed at understanding the mechanism by which GTS467 confers protection in HD.

Abstract: Lowering the expression of the pathogenic mutant huntingtin (mHTT) mRNA and protein is a leading therapeutic approach for the treatment of Huntington's Disease (HD). Clinical trials involving the use of HTT -lowering antisense oligonucleotides (ASO) have shown promising pharmacodynamic potential data although they have halted poor pharmacokinetic and safety margins. Notably, ASOs are normally delivered intrathecally or directly into the brain via invasive methods. Recently, small molecules directly targeting HTT mRNA, such as Branaplam (LMI070), have been discovered. These small molecules provide the advantage of greater distribution and non-invasive delivery methods. Branaplam targets splicing of the exon junction 49-50 of HTT pre-mRNA, promoting retention of a pseudo-exon within intron 49 which contains a premature stop codon, subsequently resulting in nonsense mediated decay (NMD)-dependent mRNA and consequential protein lowering. However, Branaplam and other HTT mRNA targeting compounds do not modulate endogenous rodent Htt splicing due to differences in the target sequence, precluding pre-clinical efficacy and tolerability studies in standard rodent models. To overcome this, CHDI has generated and CRL is characterizing a new mouse model i49 Exon Q175, containing the humanized exon 49-50 junction on an existing Q175 knock-in model. The Q175 knock-in mouse contains human exon 1 mHTT with an expanded CAG repeat (~179 repeats) within the native mouse huntingtin gene. Thus, this animal model is representative of HD genetics and consistently displays associated motor symptoms and behavioural deficits, accompanied by brain atrophy and metabolite changes. This makes it a suitable model for preclinical safety and efficacy testing. In the novel i49 Exon Q175 mouse model the mouse intron 49 genomic region has been replaced with the human one, including the Branaplam target sequence, via Crispr-Cas9. In addition, the wt mouse allele (Q7) has been targeted to contain the human sequence in intron 49, which enables us to also affect expression of the non-expanded allele in mice. Here, we validate these models and demonstrate significant human intron 49 retention and disruption of the endogenous 49-50 junction upon acute treatment with LMI070, in both periphery and CNS. Moreover, we investigate mutant and wt Htt protein reduction following 21 days sub-chronic treatment with LMI070. Further work will be aimed at studying compound mediated effects on mutant and wt Htt protein isoforms levels, and on behavioral and brain phenotypes.

Abstract: Several drug modalities aimed at lowering levels of mutant HTT (mHTT) are currently in development for the treatment of Huntington's Disease (HD). Importantly, mHTT mRNA is increasingly being considered an important therapeutic target, and HTT lowering pharmacodynamic data have been recently shown in clinical trials with the use of antisense oligonucleotide (ASO) targeting HTT mRNA. However, those trials have recently been stopped for insufficient safety over therapeutic margin.
Notably, ASOs are delivered intrathecally into the spinal cord or directly into the striatum due to their poor distribution. Small molecules aimed at the same target will provide the potential advantages of greater distribution, non-invasive delivery methods and higher patient accessibility. In this context, a growing number of small molecules targeting RNA are being identified and this class of molecules are progressing into the clinic. One such molecule is Branaplam (LMI070) targeting directly HTT mRNA and is now moving forward to clinical trials for HD. Branaplam was originally designed to target splicing of SMN2 exon 7, but also targets splicing of the exon junction 49-50 of HTT pre-mRNA, promoting retention of a pseudo-exon within intron 49b which contains a premature stop codon, subsequently resulting in nonsense-mediated decay (NMD)-dependent mRNA and consequential protein lowering.
CHDI, with Charles River Early Discovery, has discovered a novel compound (Compound Y) targeting the same mechanism. Herein, we describe the *in vitro* and *in vivo* profile of Compound Y. Potency was assessed in an HD-relevant human stem cell model and demonstrated concentration-dependent splicing modulation and HTT protein-lowering. Moreover, Compound Y exhibited favourable ADME and PK properties, as well as significant HTT mRNA splicing and protein-lowering *in vivo* in brain and peripheral tissues of an HD rodent model.

Abstract: In Huntington's Disease (HD), the mutant Huntingtin (mHtt) CAG repeat length is inversely correlated with the age of onset of motor symptoms. However, this CAG repeat length does not account for all of the variance in HD onset, suggesting other genetic and environmental factors may be involved. Recent Genome Wide Association Studies (GWAS) for genetic modifiers of HD motor symptom onset revealed several genome-wide genetic variants that are significantly associated with modifying HD age of motor onset. One of the most significant loci identified was on chromosome 15 adjacent to a gene, FAN1, which has a known function in DNA repair. Specifically, FAN1 has been shown to be involved in the repair of certain DNA lesions (i.e. interstrand cross-links) and may also be involved in the mismatch repair (MMR) pathway. In order to pursue unbiased molecular analyses of the impact of the Fan1 mutation on the mutant huntingtin-induced molecular pathogenesis in vivo, we crossed homozygous Fan1 hypomorphic knockdown (Fan1-KD) alleles onto mHtt knock-in mice with 140 CAG repeats (mHtt-KI-Q140 vs. Q140). We found a significant increase in the somatic CAG repeat instability in Fan1-KD/Q140 mice compare to Q140 at 6m. Moreover, we found neuropathological evidence of increased disease severity in Q140 mice with a reduction of Fan1 expression. We also performed transcriptomic analysis of these mice at 12m, and identified selective changes in Q140 brains with reduced Fan1 expression compared to Q140 controls. Together, our study provides novel insights into how a Fan1 deficiency could modify molecular and cellular pathogenesis in a full-length mHtt knock-in mouse model.

Title: Exploration of the effects of Huntingtin lowering on stress resistance in aged Huntington disease neurons

Authors: *E. MACHIELA, N. POLTURI, R. JELOKA, J. AQUINO, Y. XIE, A. L. SOUTHWELL;
Col. of Med., Univ. of Central Florida, Orlando, FL

Abstract: Huntington’s disease (HD) is an autosomal dominant disease caused by a CAG repeat expansion in exon 1 of the huntingtin gene. Cellular stress is a consequence of biological aging and plays a role in the pathogenesis of HD. Wildtype Huntingtin (wtHTT) acts in cellular stress responses, and mutant HTT (mtHTT) confers both a toxic gain-of-function, contributing to cellular stress, and a loss-of-function, leading to deficient stress responses. HTT lowering has shown preclinical therapeutic benefit, and multiple strategies are in clinical development. Because of the critical role of HTT in the stress response, loss of wtHTT may affect the stress resilience of cells. Preclinical HTT lowering studies have used cells and animals free from exogenous stress, thus the effect of HTT lowering on stress susceptibility has not been evaluated. In an effort to better model the cellular effects of HTT lowering in aging adults subject to various stressors, we treated mature primary neurons from HD mice and WT littermates with progerin, a truncated form of the Lamin A protein that causes Hutchinson-Gilford progeria syndrome, a disease of rapid aging. Subsequently, we used antisense oligonucleotides (ASOs) to suppress HTT either selectively or non-selectively, followed by induced oxidative stress. We found that in WT neurons, non-selective HTT lowering increased ROS and DNA damage. However, in induced-aged , stressed HD neurons, both pan-HTT lowering and allele-selective mtHTT lowering prevented stress-induced ROS and DNA damage. This suggests that the benefit of mtHTT suppression may outweigh the detriment of HTT loss in the disease state. However, pan-HTT lowering also increased susceptibility to age and stress-induced cell death. Together, these data suggest that allele-selective HTT suppression may provide enhanced tolerability in aged and stressed conditions. Considering the mechanistic overlap in mtHTT toxicity and HTT deficiency toxicity, this may translate to enhanced efficacy of selective suppression approaches.

Title: Use of a split AAV delivery platform for the evaluation of dxCas9 for allele-specific silencing in Huntington's disease

Authors: *J. WALDO, J. A. HALMAI, D. CAMERON, P. DENG, K. FINK;
Neurol. Department, Stem Cell Program and Gene Therapy Center, MIND Institute, Inst. for Regen, UC Davis Med. Ctr., Sacramento, CA

Abstract: Huntington's disease (HD) is a rare, autosomal dominant neurodegenerative disorder caused by a trinucleotide expansion in exon 1 of the Huntingtin gene (HTT), which leads to neuronal dysfunction and cell death. Healthy HTT is implicated in axonal trafficking and trophic factor regulation, making targeted mutant allele-specific reduction critically important. This study aimed to target single nucleotide polymorphisms (SNPs) in HD patient-derived cells to reduce expression of mutant HTT (muHTT) using CRISPR epigenome editing. Heterozygous SNPs near regulatory regions of the HTT promoter were confirmed in HD patient cells, allowing for the design of allele-specific sgRNAs. Our novel vector expressing dxiCas9 containing repressive effector domains has higher binding specificity and broader PAM site requirements compared to SpdCas9. CRISPR constructs were introduced to a HD patient fibroblast line and knockdown of total HTT transcript levels was assessed to screen for sgRNA selection. Knockdown was assessed at multiple loci in the HTT gene and significant downregulation was achieved using several of our allele-specific sgRNAs. Targeting SNP rs762855 or rs3856973 resulted in significant downregulation compared to a non-treated control. A sgRNA targeting rs762855 also showed significant downregulation in primary cortical neurons derived from YAC128 mice. The delivery of large proteins to the brain continues to be a barrier to success when using these gene-editing tools. By using a split AAV system, large proteins such as Cas9 can be split into two domains fused to inteins that are able to recombine and create a full-length Cas9 in target cells. Previously established sgRNAs targeting muHTT were cloned into the C terminus of the split AAV vector system containing dxiCas9 fused to KRAB. These AAV were injected into the striatum of YAC128 mice containing the full-length human HTT locus. Knockdown of HTT was assessed via qPCR, western blot, and immunohistochemistry (IHC). These studies support the potential of targeted allele-specific strategies paired with split AAV delivery for CNS disorders.

Title: Pharmacological modulation of UBE2K mitigates toxicity in Huntington's Disease patient-derived fibroblasts.

Authors: *K. M. ROSEN, J. RANJAN, A. REBELLO, C. S. LEE, V. K. VISHNUDAS, N. R. NARAIN, S. GESTA, R. SARANGARAJAN;
Berg, Framingham, MA

Abstract: Huntington’s disease (HD) is an autosomal dominant, progressive, neurodegenerative disorder caused by a polyglutamine (poly(Q)) triplet repeat expansion in the gene encoding the Huntingtin (Htt) protein. Huntingtin protein with pathologic poly(Q) expansion leads to a significant loss of neurons in the striatum, by mechanisms that are not clearly defined. The poly(Q) repeat sequence is localized to the N-terminal region of the very large (3144 amino acids) Htt protein. The N-terminal region of Htt is characterized by a high incidence of post-translational modifications and is the source of modified fragments that are commonly found as intracellular and intranuclear aggregates. Htt is known to be ubiquitinated in its N-terminal region and suggested to play a role in multiple sub-cellular systems and pathways. Htt interacts with many proteins but one of particular interest is the E2 ubiquitin-conjugating enzyme UBE2K, which had previously been identified through a yeast two-hybrid screen as Huntingtin-interacting protein-2 (Hip2) and shown to be involved in the ubiquitination of Htt. The ubiquitin proteasome system plays a critical role in protein quality control and is frequently disrupted in neurodegenerative disorders such as Huntington’s disease. HD patient derived fibroblasts display increased sensitivity to known chemical inducers of cellular stress via their actions on the proteasome and the endoplasmic reticulum. Interestingly, small molecule modulators allosterically targeting the function and activity of UBE2K demonstrate dose dependent decreases in the induction of chemical stressors. In addition, these UBE2K targeting compounds improve survival in differentiated neuroblastoma cell cultures exposed to the same chemical stressors in the absence of mutant Htt. The disease modifying role of UBE2K in HD and the therapeutic application of small molecule modulators to improve cell function and survival through in vitro and in vivo PoC studies is under active investigation.

Title: Elimination of Huntington disease-related phenotypes by expanded-CAG RNA-targeting CRISPR/Cas13d in HD models

Authors: *Q. WU[1,4], K. MORELLI[5], M. GOSZTYLA[5], C. ZHANG[1], H. LIU[1], J. CHEN[4], R. MARINA[5], K. LEE[5], K. L. JONES[5], G. W. YEO[5], W. DUAN[1,2,3];

Abstract: Currently incurable, Huntington's disease (HD) is a fatal, autosomal dominant neurodegenerative disorder caused by a CAG trinucleotide expansion (CAG^{EX}) in the first exon of the huntingtin (*HTT*) gene. Although the etiology of HD remains complex, many proposed mechanisms arise from the transcription and subsequent RAN translation of CAG-expanded HTT, ultimately causing disease through a toxic gain-of-function mechanism. Thus, therapeutic approaches that suppress mutant *HTT* at the RNA level are actively being pursued. We recently pioneered the repurposing of the Cas9 system to target and eliminate toxic repeat RNAs *in vitro* and *in vivo*, but for efficient *in vivo* delivery and clinical translation, Cas13d proteins are compact systems that can be packaged into a single adeno-associated viral vector (AAV9). Here, we engineered a AAV9 Cas13-based CAG^{EX} RNA-targeting CRISPR system to selectively target mutant *HTT* in patient iPSC-derived striatal neurons with minimal off-target effects from RNA-seq experiments. Intrastriatal delivery of CAG^{EX}/Cas13d in zQ175 mice, an established murine model of HD that expresses one copy of full-length human mutant *HTT* also mediates a significant and selective reduction of mutant HTT, and a sustained reversal of HD phenotypes, including a reduction of mutant HTT protein aggregates, attenuated striatal atrophy, and improved motor coordination in CAG^{EX}/Cas13d-treated zQ175 mice compared to control cohorts. Importantly, phenotypic improvements were durable for at least 8 months after

treatment without gross behavioral adverse effects, with minimal off-target interactions of CAG^{EX}/Cas13d in the mouse transcriptome. Future directions will be to determine potential off-target effects in the human transcriptome. Taken together, we demonstrate for the first time the proof-of-principle of CAG^{EX} RNA-targeting CRISPR/Cas13d as a potential therapeutic approach for HD, a strategy with broad implications for the treatment of other dominantly-inherited neurodegenerative disorders.

Abstract: Avocado oil prevents neurological and oxidative damage in a model of neurodegeneration induced by quinolinic acid.
González-Guevara Edith, Tristán-López Luis, Martínez-Gopar Pablo, Ángeles-López Quetzalli Dennise, López-Orozco Diego, El-Hafidi Mohammed, Alcaraz-Zubeldia Mireya, Sánchez-Mendoza Alicia, Morales-Martinez Adriana, Pérez-Severiano Francisca.

The intake of essential fatty acids (EFA) in both Huntington's disease (HD) patients and transgenic models has shown motor and cognitive improvement. Avocado oil contains different EFA and 60% is oleic acid, and its use through diet exerts important effects on the lipid composition of the neuronal cell membrane. The aim of this work was to study the effect of a fatty acid-rich diet included in avocado oil on the damage induced by quinolínic acid (QA). Male Wistar rats (250-280 g) were fed individually for 20 days with avocado oil (15% weight / weight). At the end of the diet, rats from the different groups were injured intrastriatally with QA (240 nmol/μL) and 2 hours after, striatal oxidative damage were measured through lipid peroxidation and the reactive oxygen species. Neurological changes were observed by counting of rotational turns in each animal after 3 days of QA lesion. We found that avocado oil diet for 20 days did not alter following parameters: the daily food intake, the body weight, and the biochemical parameters in blood. Interestingly avocado diet, diminished the ipsilateral turns (89%), and recovered the GABA levels (70%) and also the strital oxidative damage was prevented. Our data confirm the neuroprotective effect of a fatty acid-rich diet included in oil avocado.

Title: Neural dysfunction following Francisella tularensis infection

Authors: *A. TENA, R. HIGHTOWER, M. HOLGUIN, M. SANCHEZ, C. SPENCER; Univ. of Texas at El Paso, El Paso, TX

Abstract: *Francisella tularensis* is a gram-negative intracellular coccobacillus that is the causative agent of tularemia. Local, acute inflammation is beneficial since it can clear bacterial infections, remove cellular damage and promote the healing of tissue. However, *F. tularensis* is capable of bypassing the immune system and causing an overactivation of inflammation, known as a “cytokine storm”. This cytokine storm increases host cell damage, nutrient availability and serves an immune distraction allowing the bacterium to replicate. Other infections that cause cytokine storms include Ebola, pandemic influenza, hantavirus, and HIV, all BSL3 pathogens. The routes of transmission for *F. tularensis* are many and intertwined. Infection could be the result of inhaling air droplets containing infectious bacteria, coming into direct contact with an

infected animal or being bitten by an infected arthropod such as a tick, flea or mosquito. Eating and drinking contaminated meat and water can also lead to infection and different disease manifestations occur depending on the route of transmission.
While extensive research has documented infection of the spleen, liver and lung, there hasn't been any reports of *F. tularensis* productively infecting the brain, until now. This work focuses on characterizing the effects of *F. tularensis* infection of the brain. We hypothesize that damage caused by *F. tularensis* neural infection will have a negative effect on behavior. This work aims to identify these negative effects based on the anatomical location of the bacteria foci, regions containing numerous bacteria. With the use of brain mapping and behavioral assays, we seek to determine the impact of *F. tularensis* infection on behavior and cognition.

Title: Interactions with distinct MHC Class I molecules on brain endothelium differentially modulates CD8+ T cell entry and brain pathology during experimental cerebral malaria

Authors: *C. FAIN[1], K. AYASOUFI[1], J. ZHENG[2], F. JIN[1], R. H. KHADKA[1], Z. P. TRITZ[1], A. J. JOHNSON[1];
[1]Immunol., [2]Neurosci., Mayo Clin., Rochester, MN

Abstract: Malaria is a mosquito-borne disease caused by *Plasmodium* parasite that specifically infects red blood cells. *Plasmodium falciparu*m is the deadliest species of plasmodium in humans, namely due to its ability to cause severe encephalopathy; referred to as cerebral malaria. The mechanisms underlying brain involvement and subsequent fatality are not entirely understood. Using the animal model of experimental cerebral malaria (ECM), we sought to elaborate upon mechanisms of pathogenesis. We employ T1 and T2-weighted MRI as a novel diagnostic tool which confirms recapitulation of human data. In this etiology we confirm increased adhesion molecule expression, increased antigen (Ag)-presentation molecules and with two-photon we show extensive T cell interactions at the brain vasculature, resulting in CD8 T cell infiltration into brain parenchyma, brain pathology and neuronal death. While CD8 T cell interaction with MHC class I on cerebrovascular endothelial cells (CECs) has been put forward

as a putative mechanism for ECM, it has not been directly confirmed *in vivo*. We therefore hypothesized that removing Ag presentation by either H-2K^b or H-2D^b class I molecules specifically on brain endothelium would result in controlled modulation of activation and entry of parasite-specific CD8 T cells; attenuating pathology. To test this, we crossed endothelium-specific cre, CDH5-Cre mice with novel H-2K^b LoxP and H-2D^b LoxP mice to create endothelium-specific cKO of either or both class I molecules. In these mice we show differential class I dependent CD8 T cell infiltration and activation as well as subsequent changes in antigenic drainage and cervical lymph node involvement. Importantly, T cell interactions with cerebral vessels were modulated, and vascular permeability at the blood-brain barrier was attenuated, resulting in differentially improved survivals between the cKO strains. Together these data demonstrate that parasite-specific CD8 T cells undergo differential Ag-dependent engagement with H-2K^b or H-2D^b class I molecules on CECs in order to coordinate activation, entry and ECM development. Therefore, these studies indicate that specific modulation of these interactions may hold therapeutic benefit and reduce mortality following this severe complication. This work also provides much needed mechanistic insights into how this pathology develops.

Title: In vitro approaches to modulate neuroinflammatory astrocytes

Authors: N. HAGAN, ***F. RAPINO***, L. WOODWORTH, A. BLAZIER, J. SANCHO, D. OFENGEIM;
sanofi-aventis, Framingham, MA

Abstract: In vitro approaches to modulate neuroinflammatory astrocytes

Hagan N.[1], Rapino F.[1], Woodworth L.[1], Blazier A.[1], Sancho J.[1], Ofengeim D.[1]
[1]Rare and Neurologic Diseases Therapeutic Area, Precision Neurology Research Cluster, Sanofi, Framingham, MA.

Glia cells, such as microglia and astrocyte, are critical regulators of inflammation in the brain. Neuroinflammation can be a protective mechanism that helps maintain CNS homeostasis. However, sustained and prolonged inflammation is detrimental and contributes to the pathology of neurodegenerative diseases such as Alzheimer's Disease (AD), Parkinson's Disease (PD), and Amyotrophic Lateral Sclerosis (ALS). Because of the dual role that astrocytes play in

neuroprotection and neurotoxicity, a characterization of astrocyte states is needed to generate in vitro models to develop effective anti-inflammatory therapies. To characterize the molecular identity of reactive astrocytes, we performed bulk RNA sequencing on primary human astrocytes treated with A1 cocktail (C1q, IL1-α, and TNF- α) and compared them to untreated astrocytes. In addition to gene expression, we examined changes in cell surface markers using a panel of 361 antibodies in resting or activated conditions. We then used this system to investigate whether we could alter the transition of astrocytes into a pro-inflammatory phenotype using both a pharmacological and genetic approach. Finally, to mimic the complexity of the brain and to generate a robust system to study the effects of candidate targets in disease-relevant human cells, we implemented and characterized a novel triculture system using iPSCs derived neurons, microglia, and astrocytes. By using the tools we have generated, we aim to better understand the dynamic state of astrocytes with the ultimate goal of developing therapies to modulate their phenotypes to ameliorate neuroinflammation in neurodegenerative diseases.

Title: The temporal dynamics of brain invading monocytes following status epilepticus

Authors: *L. SHAPIRO, S. HUNTER-CHANG, R. DINGLEDINE, N. H. VARVEL;
Dept. of Pharmacol. and Chem. Biol., Emory Univ., Atlanta, GA

Abstract: Status epilepticus (SE) is a medical emergency that triggers a cascade of pathological events including neuron loss, blood-brain barrier breakdown, activation of brain-resident microglia, and infiltration of blood-borne monocytes into the brain, culminating in the development of epilepsy and cognitive decline. It is of great interest to develop novel therapeutic strategies to prevent the onset of epilepsy and cognitive comorbidities following SE. Previous work in our laboratory identified brain invading CCR2+ monocytes as pathogenic following SE in mouse models. Blocking monocyte brain invasion after SE via global knockout of *Ccr2* enhances weight regain, reduces neuron loss, prevents BBB erosion, and attenuates neuroinflammation, highlighting the potential for CCR2+ monocytes as a novel disease-modifying target. However, it remains to be determined how long these CCR2+ monocytes

remain in the brain following SE. To address this, we crossed mice expressing inducible CreER^{T2} under the CCR2 promoter to Ai9 reporter mice to allow for permanent fluorescent tagging of CCR2-expressing cells following tamoxifen administration. Tamoxifen (2mg, i.p.) was administered to male mice 8-10 weeks of age 48 and 24 hours prior to kainic acid-induced SE (30 mg/kg, i.p.) and the presence of CCR2+ cells in the brain was evaluated on a time course following SE. We observed peak engraftment of CCR2+ cells in the hippocampus and amygdala at 7 days post-SE (n=7), with virtually no cells encountered by day 14 (n=3). Ongoing work is being conducted to further immunophenotype the brain-invading cells and examine their inflammatory profile at each time point in order to better understand how they may contribute to the pathology observed following SE. Altogether, our results provide insight into the temporal dynamics of monocyte invasion into the brain following SE, which contributes to our understanding of how these cells may be used as a target for intervention in clinical populations.

Title: A novel model for paired epigenetic and transcriptomic studies of Müller glia with age related macular degeneration

Authors: *A. CHUCAIR-ELLIOTT[1], S. R. OCANAS[1], J. GURLEY[2], M. H. ELLIOTT[2], W. M. FREEMAN[1,3];
[1]Genes & Human Dis. Res. Program, Oklahoma Med. Res. Fndn., Oklahoma City, OK; [2]Ophthalmology, Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [3]Oklahoma City Veterans Affairs Med. Ctr., Oklahoma City, OK

Abstract: Aging is the major risk factor for age-related macular degeneration (AMD) but how ‘normal’ aging contributes to AMD pathogenesis is unclear. Epigenetic mechanisms, such as the DNA modifications of methylcytosine (mC) and hydroxymethylcytosine (hmC), affect DNA accessibility, regulate genomic organization and gene expression, and are altered with aging.

DNA methylation analyses of AMD patient blood and retinas suggest differential methylation resulting in gene expression changes during development/progression of AMD. In addition, Müller glia are activated in AMD patient retinas. The aim of this study is the validation of a cre/ERT2-NuTRAP mouse model for the parallel interrogation of differential mC/hmC genome-wide and transcriptome specifically in Müller glia with retinal aging. Female NuTRAP $^{flox/flox}$ were bred with male Aldh1l1-cre/ERT2$^{+/wt}$ to generate Aldh1l1-cre/ERT2$^{+/wt}$; NuTRAP$^{flox/wt}$ (Aldh1l1-cre/ERT2^{+}; NuTRAP^{+}). At 5 months old, female and male mice received intraperitoneal tamoxifen treatment or left untreated as controls. Mice were euthanized and their retinas harvested and processed for: 1) Immunohistochemistry of mCherry, EGFP, GS, and GFAP expressions on retina sagittal sections via confocal microscopy; 2) Ribosome bound RNA isolation via TRAP protocol, qPCR validation and stranded RNA-Seq profile, and 3) nuclei suspension preparation and DNA isolation via INTACT method for bisulfite amplicon sequencing (BSAS). A cohort of mice was subjected to the optic nerve crush model (ONC) to study the transcriptomic response of Müller glia at 72h post procedure. Specific co-localization of EGFP, mCherry, and the Müller glia marker GS was observed in the Aldh1l1-cre/ERT2^{+}; NuTRAP^{+} retinas. RNA-seq bioinformatic analysis revealed enrichment of Müller marker genes and pathways and depletion of other cell type markers in the positive TRAP fraction of Aldh1l1-cre/ERT2^{+}; NuTRAP^{+} retinas, compared to input profiles. qPCR validated enrichment and depletion of selected transcript expressions. BSAS showed a decrease of mC in the promoter region of selected Müller glia-specific genes in INTACT-DNA positive fraction relative to whole retina input. Over-representation analysis of differentially expressed genes in the ONC vs control group identified 7 biological processes related to inflammation with significant enrichment ratio. The selective recombination in Müller glia, enrichment of Müller glia genes, and the epigenetic findings support the Aldh1l1-cre/ERT2; NUTRAP model is suitable for the study of Müller glia-specific contributions to the transcriptome and epigenome of the retina in both acute stress and chronic aging settings.

Title: Changes to Astrocyte Activation Markers at Different Stages of Cuprizone Treatment

Authors: *L. FRANKLE, K. LI, C. LU, Q. GUAN, E. J. FREEMAN, R. CLEMENTS;
Kent State Univ., Kent, OH

Abstract: Cuprizone is a copper chelator that demyelinates neurons and is therefore frequently used to model multiple sclerosis as well as other demyelinating and degenerative diseases. Our previous work examining astrocyte dynamics using glial fibrillary acidic protein, or GFAP staining, confirmed a pattern of activation including increased process number and branching after one, two, and four weeks of cuprizone treatment. The current phase of the project aims to determine whether similar patterns are observed at one or two weeks of cuprizone treatment as well as when such changes begin. Animals were fed 0.3% cuprizone chow ad libitum for one or two weeks, sacrificed, dissected, and their brains halved with one half stained using GFAP and DAPI and imaged using confocal microscopy with astrocytes in the corpus callosum assessed for activation, and one half processed through Western blot. We used Western blots to measure levels of C3 or complement component 3, and Emp1 or epithelial membrane protein 1, in the whole-cell lysate of homogenized samples taken from the corpus callosum and/or cortex of control and experimental animals. C3 levels are measured because C3 is known to be upregulated in astrocytes that have an A1 reactive phenotype as well as by other cell types such as mast cells and macrophages in times of stress. Emp1 levels are assessed because Emp1 is upregulated in another type of activation phenotype less detrimental, A2. To confirm that the presence assessed by Western blot was representative of astrocyte protein levels of C3 and Emp1, immunofluorescence was done using these proteins on fixed tissue slides taken at one, two and four weeks of cuprizone treatment. The relative levels of A1 and A2 activation would therefore be relevant to the progression of cuprizone toxicity.

Abstract: Background: An important component of Alzheimer's disease (AD) is neuroinflammation. In the periphery, α7 nAChR activation inhibits macrophage production of pro-inflammatory cytokines. In the CNS, α7 nAChRs are enriched in brain regions affected early in AD. However, α7 nAChR expression is not restricted to neurons; these receptors are highly enriched within the CNS immune system. We have previously reported important roles for astrocytic α7 nicotinic acetylcholine receptor (nAChR)-Aβ interaction with subsequent effects on cognition. To refine these studies, we sought to test the hypothesis that astrocytic α7 nAChRs serve an analogous anti-inflammatory role to that in the periphery.Method: To test our hypothesis, we generated mice in which the fourth exon of the α7 nAChR gene (Chrna7) is flanked by loxP sites (α7nAChR^{flox}). We then crossed α7nAChR^{flox} mice with mice expressing Cre recombinase driven by the glial acidic fibrillary protein (GFAP) and studied neuroinflammatory responses and cognition following intracerebroventricular (ICV) injection of LPS (10 ng); a dose that induces transient neuroinflammatory responses without measurable peripheral inflammation. We studied hemizygous astrocytic α7nAChR (GFAP-A7$^{+/-}$) knockdown mice compared to α7nAChR$^{flox+/-}$ littermates.Result: Whereas sham and LPS ICV-injected α7nAChR$^{flox+/-}$ littermates performed similarly in hippocampus-dependent associative learning and memory, GFAP-A7$^{+/-}$ mice were impaired. Bio-Plex analysis of serum, hippocampus and cholinergic basal forebrain revealed that α7nAChR$^{flox+/-}$ littermates mounted both a pro- and anti-inflammatory response to ICV LPS; GFAP-A7$^{+/-}$ mice did not. However, GFAP-A7$^{+/-}$ mice exhibited pronounced microglia activation and tau hyperphosphorylation in hippocampal structures. Morphometric analysis showed that GFAP-A7$^{+/-}$ mice presented with blunted astrocyte response to LPS challenge. We used cultured astrocytes from hemizygous GFAP-Cre α7nAChR knockdown mice and α7nAChR^{flox} littermates to decipher mechanistic details and report that similar dysregulated inflammatory responses to LPS are detected in GFAP-A7$^{+/-}$ astrocyte cultures.Conclusion: Blunted astrocyte response, absence of an anti-inflammatory response, microglia activation and tau pathology resulting from ICV LPS injection suggests that knockdown of α7 nAChRs in astrocytes triggers a feedforward pro-inflammatory response to elicit AD-like cognitive deficits. Thus, similar to their role in the periphery, astrocytic α7 nAChRs serve an anti-inflammatory role in the CNS. This has significant implications for AD since Aβ binds α7 nAChRs to silence these receptors.

Title: Inhibition of the pentose phosphate pathway in anti-neuronal cytotoxic T lymphocytes preserves neuronal function and ameliorates neuroinflammatory disease

Authors: *E. GRUND[1], B. CLARKSON[2], C. L. HOWE[2];
[1]Mayo Clin. Grad. Sch. For Biomed. Sci., Rochester, MN; [2]Neurol., Mayo Clin., Rochester, MN

Abstract: Despite the presence of physical barriers and developmental immune tolerization, the CNS acts throughout life as a source of antigens that can induce aberrant auto-reactivity against neuronal and glial proteins. In diseases such as multiple sclerosis and the autoimmune limbic encephalitides, activated $CD8^+$ cytotoxic T cells infiltrate the brain and are found in clonally expanded clusters indicative of antigen-specific recognition. At present, the pathophysiological role of these cells is poorly understood and therapeutic strategies for neutralizing these cells are limited. T cells exhibit profound metabolic reprogramming in support of the energetic and proliferative demands of activation against autoantigens. Key metabolic pathways in this reprogramming include glycolysis and the pentose phosphate pathway (PPP). We have demonstrated that pharmacologic inhibition of the PPP reduces the acquisition of an effector phenotype and suppresses the secretion of proinflammatory cytokines in $CD8^+$ T cells. We have also found that limiting the metabolic flux of glucose-derived metabolites through the PPP rescues neurons from $CD8^+$ T cell-mediated cytotoxicity and preserves the electrophysiological function of primary neurons under stress. Finally, in the EAE preclinical model of multiple sclerosis, we found that pharmacologic inhibition of the PPP when administered at the onset of symptoms is sufficient to delay and ameliorate motor disability. These results demonstrate the potential of immunometabolic therapies to limit autoinflammatory and autoimmune injury to the CNS and to disrupt the progression and accumulation of neurologic deficits in patients with immune-mediated neurologic disease.

Abstract: Dysregulated immune signalling is implicated in disease and neuroinflammation has been linked to the pathogenesis of multiple neurodegenerative and psychiatric disorders. The establishment of effective and high-throughput preclinical models of neuroinflammation is required to advance drug development. LPS, a gram-negative bacteria outer membrane component, administered by peripheral (i.p.) or central (i.c.v.) injection has been used to model neuroinflammation, yet few studies have compared peripheral and central cytokine expression. Male C57BL/6J mice (n=24) received an i.p. injection of saline or one of 3 LPS doses (100, 250, 500 ug/kg). A second group of mice (n=16) received a stereotaxic unilateral i.c.v. infusion of artificial cerebrospinal fluid or one of 3 LPS doses (1, 5, 20 ug/mouse). In a third group of mice (n=50), the effect of minocycline (acute and sub-chronic, 100 mg/kg, i.p.) and dexamethasone (30 mg/kg, p.o.) administration prior to LPS (250 ug/kg, i.p.) was investigated. Plasma and brain were collected 4 hours after LPS administration and cytokines (TNF-α, IL-6, IL-1β) and chemokines (CCL2, CCL3, CCL4) were analysed using Meso Scale Diagnostics multiplexed assays.LPS (i.p.) increased all cytokines and chemokines analysed in plasma. In brain tissue, LPS (i.p.) increased IL-6, IL-1β and CCL2 in a dose-dependent manner. LPS (i.c.v.) increased all cytokines and chemokines in plasma except for CCL2. In brain tissue, 20 ug LPS (i.c.v.) induced an increase in all cytokines and chemokines analysed. TNF-α and IL-1β were increased in brain by 1 and 5 ug LPS (i.c.v.). Dexamethasone but not minocycline reduced all three cytokines and CCL4 expression in plasma and brain.Both i.p. and i.c.v. administration of LPS induced a robust peripheral inflammatory response. Similarly, both routes of administration induced neuroinflammation, although the specific cytokines and chemokines that increased in brain tissue differed between models. These data demonstrate that i.p. administration of LPS is sufficient to induce a model of neuroinflammation, responsive to anti-inflammatory drugs, and shows advantages over the i.c.v. model requiring surgical infusion. Neuroinflammation induced by i.c.v. administration was not contained within the brain at the doses tested here.

Title: Corticothalamic Functional Connectivity Post Traumatic Brain Injury

Authors: *H. KARBASFOROUSHAN[1], S. SIDDIQI[2], L.-L. WU[3], G. SWAMINATH[4], R. TOLL[5], J. L. TAYLOR[1], O. A. HARRIS[1], M. M. ADAMSON[6];
[1]Stanford Univ., Palo Alto, CA; [2]Harvard Med. Sch., Boston, MA; [3]Corporate Studies Program Coordinating Ctr., Mountain View, CA; [4]BronxCare Hlth. Syst., New York, NY; [5]Univ. of Texas, Dallas, TX; [6]WRIISC\Psychiatry, VA Palo Alto\Stanford Med. Sch., Palo Alto, CA

Abstract: Previous animal and human studies in traumatic brain injury (TBI) have frequently reported the thalamus' abnormalities post injury, as well as its role in recovery. There is a topographically organized pattern of functional connectivity between human cortex and thalamus, indicating parallel pathways linking distinct cortical areas to specific thalamic nuclei. However, the changes to corticothalamic connectivity network post traumatic brain injury is still unknown. The goal of this study was therefore to use advanced functional connectivity analysis methods to investigate the alterations in corticothalamic connectivity network in patients with traumatic brain injury. Thirty-one patients with TBI and 30 age-match healthy controls were recruited to this study. T1-weighted anatomical and functional MRI scans were collected on a 3T MRI scanner. T1-weighted images were acquired with isotropic resolution = 0.9 mm, flip angle = 12 degrees, and acquisition matrix = 256 × 256. The functional imaging scans had the following parameters: 42 axial slices, 2.9mm isotropic resolution, TR = 2s, TE = 30ms. Preprocessing and statistical analysis of the functional imaging data were performed using SPM12 software. Preprocessing steps included head motion correction, co-registration of the functional data to the T1-weighted scan, spatial normalization to MNI space, and smoothing with

a 2 mm kernel. The cortex was divided into 6 nonoverlapping regions of interest: the prefrontal cortex, motor cortex and supplementary motor area, somatosensory cortex, posterior parietal cortex, temporal lobe, and occipital lobe. The resting state preprocessed images were then used to create functional connectivity maps for each participant using Conn toolbox. The mean BOLD time series from each ROI was entered as a predictor in a multiple regression general linear model at each voxel. The variance related to head motion, the global gray matter signal, white matter and CSF were removed. Statistical analysis of functional connectivity proceeded by entering the individual subject connectivity maps into a two-sample t-test to create between group functional connectivity statistical parametric maps. All statistical maps for each ROI were then thresholded at $p<0.01$, cluster size corrected $p = 0.05$. Our results indicated increased functional connectivity between cerebral cortex and thalamus in patients with TBI, compared to healthy controls. Especially, the prefronto-thalamic functional connectivity had the greatest increase in these patients. These findings are aligned with the previous reports of increased global connectivity of thalamus post TBI.

Abstract: Different clinical assessments are used to identify specific post-concussion changes in athletes. The Standardized Assessment of Concussion (SAC) is a cognitive screening tool used to assess concussion. It was hypothesized that increased severity of concussive head impacts, and preinjury head impact exposure (HIE) can influence concussion severity, which may be reflected by a greater change in SAC score from baseline. We hypothesized that greater HIE and concussive impact accelerations would lead to decreased SAC assessment scores at the 24-48 hour timepoint in concussed athletes.

During the 2015-2017 NCAA Division I football competition seasons, athletes enrolled from 6 institutions were equipped with helmet-mounted accelerometer arrays that recorded each head impact exceeding a 10-g threshold and completed baseline clinical assessments, including the SAC. The SAC was scored out of a maximum of 30 points, which indicated no questions missed. HIE was compared between cohorts with decreased or increased/no change in SAC score at the 24-48 hr post-injury time point compared to baseline. HIE was assessed as either the total number of head impacts or risk weighted exposure (RWE), a cumulative injury risk function based on peak linear and rotational accelerations of repetitive impacts.

46 clinically diagnosed concussions were sustained by 41 players. As a group, athletes had significantly lower SAC scores at the 24-48 hour post injury timepoint when compared to baseline (U_{base}= 27, $U_{24\text{-}48hr}$= 25.7, p = 0.03). However, some athletes tested below (n= 28) and others tested at or above (n = 18) their baseline scores. Athletes that tested below their baseline SAC score sustained a higher number of head impacts on the injury date ($median_{below}$= 13 (95% CI [10.7,17.3])) compared to those that tested at or above their baseline scores ($median_{above}$= 8 (95%CI [6.13,14.3]), p = 0.095). This was also true for the two (p =0.03), four (p=0.08), and six (p =0.02) calendar days prior to injury plus the injury date. No difference was evident for RWE over any time prior to concussion. Between the two groups, there was no difference between linear (p =0.66) and rotational (p =0.19) accelerations of the concussive impacts.

These findings demonstrated that athletes with negative post-injury change in SAC score (i.e., decreased cognitive processing) had greater HIE leading up to concussion. Although injury date HIE was not statistically significant, HIE during the 3, 5, and 7 days leading up to concussion was significantly greater in athletes with negative SAC change. Therefore, accumulation of head impacts over time may be an important factor in producing post-concussion cognitive changes.

Title: Hyponatremia in TBI Patients

Authors: *A. RANO[1], S. UNDERWOOD[2];
[1]Build Exito, Portland State Univ., Portland, OR; [2]Div. of Trauma, Critical Care & Acute Care Surgery, OHSU, Portland, OR

Abstract: Background: Hyponatremia is frequently seen in patients with traumatic brain injuries (TBI). Hyponatremia (HN) is an electrolyte imbalance seen often in hospitalized patients. It occurs notably more frequently in patients who have suffered TBI (15%-20%). HN is defined as sodium levels less than 135 mmol/L. When TBI patients develop HN it can lead to serious neurological issues. Moderate to severe HN can increase the risk of death. This study looks at data in TBI patients who develop hyponatremia and variables such as medications, type of injury, demographics, etc. Methods: A retrospective analysis of 1232 patients treated at a level 1 trauma center from 2017 to 2020 was completed. Data was obtained from the local trauma registry and electronic medical records. Inclusion criteria were an injury severity score > 8, known age, and documented TBI. Patients with HN were identified as having serum sodium levels less than 135 mmol/L.Descriptive statistics were used to analyze the data. A p-value of < 0.05 was used to assign significance. Results: Of 1232 patients, 13.2% developed HN. The data was split into two groups, patients who developed HN and those who did not. There was no significant difference in admission vital signs. Patients who developed HN were older and had a lower GCS on admission. HN patients had significantly lower sodium levels on admission (136 mmol vs 140 mmol) and were more likely to be admitted to the ICU (92.1% vs. 79.3%). There was no difference in OR visits (5.3% vs. 4.6%). Patients in the HN group were more likely to receive saline-based fluids, especially 3% hypertonic saline (41.7% vs 8.3%) and 7% hypertonic saline (3.7% vs. 0.8%). Type of TBI did not appear to correlate with developing HN. Conclusion: Patients who develop HN are likely to have a lower GCS and sodium level on admission, be older, and receive more hypertonic saline. However, the type of TBI does not correlate with HN. Further studies are required to determine a specific profile of patients who may be at higher risk of developing HN after suffering a TBI.

Title: Binocular Coordination of Horizontal Saccades in mild TBI

Authors: *J. H. ANDERSON[1,2];
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Otolaryngology, Minneapolis VA Hlth. Care Syst., Minneapolis, MN

Abstract: Mild traumatic brain injury (mTBI) can result in significant problems affecting vision and oculomotor function (Armstrong, 2018; Mani et al., 2018; Stuart et al., 2020), vergence eye movements (Magone et al., 2014; Suhr et al., 2015), saccades (Samadani et al., 2015; Hunfalvay et al., 2019), spatial orientation, movement, and balance (Wallace and Lifshitz, 2016; Hoffer et al., 2010). These issues can result in problems with gaze control, eye-head-coordination, and visual-motor transformations underlying goal-directed movements. This can occur after multiple head trauma events, and in some cases after a single mild TBI event. Also, symptoms can persist years after the original trauma (Danna-Dos-Santos et al., 2018) and can become progressively worse over time. Effects of the natural aging processes probably interact with the pathophysiology resulting from TBI. The general aims of this study are to characterize the coordinated movement of the two eyes during changes in gaze in response to movement of a visual target and to relate the velocity trajectories of the two eyes to vergence dysfunction in mTBI. For this presentation, the horizontal position and velocity of the left eye versus the right eye were analyzed for the data from 18 control participants and 23 participants with mTBI. Saccade targets were presented 5 to 25 degrees left/right of center. Plots of left versus right horizontal eye velocity were quantified with polynomial regressions of eye velocity toward and away from zero velocity. Discriminant analyses of the regression coefficients identified those subjects with abnormal velocity trajectories. Some patterns included the following. For large saccade amplitudes there could be different velocities for the adducting eye versus the abducting eye in mTBI subjects who have convergence insufficiency or convergence excess. Furthermore, there were differences between the acceleration and deceleration phases of the saccades, with the acceleration phase of horizontal saccades being significantly different in mTBI compared to controls. Simulations of the velocity and acceleration profiles suggest deficits in the motor commands for adduction versus abduction movements. These results have identified eye velocity patterns and possible motor command deficits that show promise for characterizing binocular eye movements in mTBI. Further work will evaluate vertical and diagonal saccades and gaze in three dimensions where there are changes in vergence. The results could provide further insight into underlying the pathophysiology affecting the control of gaze in mTBI and suggest possibilities for vision therapy.

Title: Sensory functions and their relation to balance metrics: A secondary analysis of the LIMBIC-CENC multicenter cohort.

Authors: *S. M. VAN DER VEEN[1], R. PERERA[2], P. C. FINO[4], L. MANNING-FRANKE[2], A. A. AGYEMANG[2], K. SKOP[5], E. A. WILDE[6], S. R. SPONHEIM[7], A. STAMENKOVIC[1], J. S. THOMAS[1], W. C. WALKER[3];
[1]Virginia Commonwealth Univ., Richmond, VA; [2]Biostatistics, [3]Physical Med. and Rehabil., VCU, Richmond, VA; [4]Utah Univ., Utah, UT; [5]James A. Haley Veterans' Hosp., Tampa, FL; [6]Univ. of Utah, salt lake city, UT; [7]Univ. of Minesota, Minneapolis, MN

Abstract: Among patients with traumatic brain injury (TBI), symptoms of dizziness, nausea, and postural instability often persist. Besides balance impairments, blast related TBI has been associated with a loss of hearing (19%), vision (34%) or both (32%). When both hearing and vision were impaired, independent of TBI severity, poorer functional progress was found. The ability to regain premorbid balance and independent gait may be dictated by the ability to process, interpret, and combine, sensory information. Secondary analysis was performed on the complete CENC/LIMBI data set (N=1550 ,1346 male, mean 40±STD 10 age, 1248 TBI). Five imputed datasets were created using a fully condition specification. The estimates were then combined, and standard errors adjusted to account for the uncertainty due to missingness. Hierarchical regressions were performed, for each outcome on the separate items of sensory tests grouped in the following 5 steps: 1) the number of TBIs suffered, age, and sex, 2) the separate HHIA items, 3) separate BVMT items, 4) visual acuity, and 5) items of the SCAN3. Separate regression analyses were carried out for each of the balance assessment (i.e., different scores on the CDP). Sensory measures were removed from the regression equations when multicollinearity was found (VIF>10). Statistical significance determined using a Bejamin Hochberg correction. All sensory measures combined (demographics, hearing, reported by a hearing handicap questionnaire, visual memory, visual acuity, and auditory processing) accounted between 10.9% and 14.4% of the variability in the balance measures. Number of TBI was significantly related to CDP scores 2-6 ($p=.001$, $p<.001$, $p=.018$, $p=.005$, $p=.042$ respectively). When hearing (item on HHIA) was impaired lower scored on CDP 3, 5, and 6 were found ($p=.020$, $p=.003$, $p=.005$ respectively). Declines in auditory processing (SCAN3, competing words) was associated with worse CDP1-3 ($p=.001$, $p<.001$, $p=.021$ respectively). Better visual processing (SCAN3) was related to changes in CDP 2,5,6 scores (SCAN 3 Recall, sores CDP2 $p=.011$, Better CDP 5 and 6, $p=.010$, $p=.009$, Learning worse CDP 2 $p=.014$ and DCP6 $p=.013$, and Delayed recall better

CDP2 p=.003). TBI patients score as well as controls on static balance, but balance deficits may be unmasked when adjustments in weighting of theses sensory inputs are required due to various experimental perturbations, CDP2-6. In combination with very little associations with visual acuity and hearing deficits but stronger associations with sensory processing measures it is likely that processing of sensory information affects balance negatively and may increase fall risk in TBI patients.

Hosp., Boston, MA

Abstract: Background: American-style football players are likely to have experienced exposure to repetitive head impacts. Several studies suggested an association between traumatic brain injury (TBI) and risk of developing misfolded p-Tau protein identified in chronic traumatic encephalopathy (CTE) and Alzheimer's disease (AD). *In vivo* p-Tau positron emission tomography (PET) tracers with high binding affinity and selectivity were developed recently. This study's goal is to assess the ability of PET imaging to detect early stages of neurodegenerative disease in a population at increased risk of head injury. **Methods:** We recruited 28 former professional American-style football players who played from 1960 to 2019 and were between 33 and 60 years old at the time of testing. Each participant underwent imaging on GE Discovery MI PET/CT scanner using [^{11}C]-PiB for Amyloid-β and [^{18}F]-FTP for p-Tau. Reference region-based analysis was performed with in-house software quantifying [^{11}C]-PiB binding by distribution volume ratios (DVr) and [^{18}F]-FTP by standardized uptake value ratios (SUVr). Structural magnetic resonance imaging (MRI) was performed on a 3T Tim Trio Siemens and then processed with FreeSurfer. We compared the PET and MRI results of this population with 23 age-matched control subjects with no TBI exposure who underwent [^{11}C]-PiB and [^{18}F]-FTP scans on the same camera. **Results:** All subjects showed negative Amyloid-β burden (DVr<1.2) and no significant [^{18}F]-FTP uptake in CTE-related brain areas. However, we saw a notable uptake of [^{18}F]-FTP among football players compared to the control group in areas known for early AD stages (e.g., parahippocampal SUVr=1.01+/-0.03 vs 0.97+/-0.03; $p<0.01$ two-tailed t-test) with a significant age effect ($p<0.05$) for the football players. MRI showed decreased cortical thickness and increased white matter hyperintensities for football players with higher self-reported exposure to concussion related event. Cortical thinning could reduce the apparent uptake of PET tracers due to finite resolution of the camera, thus our findings of increased [^{18}F]-FTP binding cannot be explained by partial volume effects. **Conclusion:** p-Tau PET imaging with [^{18}F]-FTP may be useful in the investigation of repeated sport related concussion patients for early AD-like pathology. Further research is necessary to better characterize the potential and limitations of the technique.

Title: What about the children? Cognitive motor dissociation following pediatric brain injury

Abstract: Neuroimaging studies in adults have revealed that as many as 16% of those with severe brain injury retain high-level cognitive capacities not reflected in their clinical assessment; this has been designated cognitive motor dissociation (CMD). Pediatric medicine lacks both practice guidelines for identifying covert cognition, and epidemiologic data regarding the prevalence of CMD. To quantify cognitive function in children and adolescents diagnosed with disorders of consciousness (DoC), we developed a novel, hierarchical, pediatric-feasible, battery of quantitative neuroimaging assessments.
We evaluated cognitive function in two adolescents remaining chronically in DoC following severe brain injury. MRI and FDG-PET studies evaluated brain integrity. We assessed command-following using fMRI and EEG. We used EEG to assess selective attention to, and semantic processing of, auditory stimuli including spoken language.
Subjects were aged 15 and 18 (injured at 9 and 13 years respectively). Regional parenchymal volume loss and decreased resting cerebral metabolism were noted. Both subjects' EEG, and one subject's fMRI, provided evidence of the capacity to understand commands, make voluntary decisions to follow them, and sustain attention to the task. Both subjects' EEG demonstrated semantic processing of the meaning of words in context, and selective attention of narrative language.
Converging lines of evidence lead us to conclude that both subjects' cognitive function was dissociated from their motor output. The crucial gap in current clinical practice is vividly highlighted by the fact that, throughout the 5 years or more in which the subjects had remained in DoC, all attempts at communication and therapy had remained uninformed by any objective evidence of their cognitive abilities. Proper diagnosis of cognitive-motor dissociation is an ethical imperative. Without this, children who may have covert consciousness risk being abandoned to a lifetime of isolation. Emerging therapies and neuroprosthetics could re-establish self-determination, foster social integration, and improve interaction with caregivers to promote recovery.

Title: Event-related EEG markers of cognitive recovery following pediatric brain injury

Authors: *J. HILL[1,2], N. KIM[3], W. D. WATSON[5], E. CALIENDO[3], S. NOWAK[5], N. D. SCHIFF[4], S. A. SHAH[3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Stratton Albany VA Med. Ctr., Albany, NY; [2]Electrical & Computer Engin., State Univ. of New York at Albany, Albany, NY; [3]Dept. of Rehabil. Med., [4]Dept. of Neurology; Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [5]Blythedale Children's Hosp., Valhalla, NY

Abstract: Following brain injury, assessment of residual and emerging cognitive function is difficult and error-prone. In large part, this is because cognitive testing depends on motor output, which may be comorbidly impaired. In extreme cases, high-level cognitive function may be present but undetectable by conventional clinical testing—the term "cognitive motor dissociation" (CMD) has been used to denote such states. Identification of CMD has been associated with better clinical outcomes.
Accordingly, recent clinical practice guidelines recommend objective neuroimaging and neurophysiological measures to support diagnosis in adults. However, equivalent measures are lacking in pediatrics—an especially great challenge due to the combined heterogeneity of both brain injury and pediatric development. To address this gap, we aim to establish quantitative, objective, clinically practicable measures of cognitive function following pediatric brain injury. We recruited participants aged 8-18 with and without brain injury. Participants with brain injury were clinically classified according to cognitive recovery state: N=8 in disorders of consciousness (DoC), N=7 in confusional state (CS), and N=19 cognitively impaired (CI). In addition, N=13 typically-developing (TD) uninjured controls were included. We prospectively measured electroencephalographic (EEG) markers of sensory processing and attention in an auditory "oddball" paradigm, and of covert movement attempts in a command-following paradigm.
In three DoC participants, EEG markers of active attempted command-following revealed cognitive function that clinical assessment had failed to detect. These three individuals could also be distinguished from the rest of their group by two event-related potentials (ERPs): an auditory

evoked potential reflecting passive sensory processing, and the P3 reflecting rudimentary attention mechanisms. Across the whole cohort, the noise-corrected magnitudes of these two ERPs reflected cognitive recovery state (ANOVA: each $p < 0.001$); viewed jointly, they cleanly delineated the groups.
We conclude that objective EEG markers can be good indicators of individual cognitive recovery, even in a cohort in which there was great heterogeneity of both etiology and brain development. These markers could be measured at the bedside in a practicable way without requiring participants to make overt motor responses. They allowed us to identify, we believe for the first time in pediatrics, three individuals who meet the criteria for cognitive motor dissociation. To diagnose, prognose and track cognitive recovery accurately, such markers should be employed in pediatrics.

Title: Extracellular lactate as an alternative energy source for retinal bipolar cells

Authors: *V. CALBIAGUE[1,2], Y. CHEN[3,4], S. SCHEPERS[3,4], F. PAQUET-DURAND[3], O. SCHMACHTENBERG[1];

Training Ctr. of Neuroscience, Univ. of Tübingen, Tübingen, Germany

Abstract: Purpose: Metabolism is a fundamental issue for cell function. Interestingly, Warburg´s studies from 1924 pointed out that tumors cells and retina are the main tissues that use aerobic glycolysis, converting almost the 90% of consumed glucose into lactate. The aim of this study is a better understanding of energy metabolism in the inner retina and a possible consumption of lactate as an alternative energy source for rod bipolar cells (RBCs). **Methods:** We used immunofluorescence staining to determine the retinal expression of enzymes involved

in energy metabolism. Retinal explants obtained from P9 wild-type C57BL/6 and C3H mice were cultured and treated with selective drugs to alter energy metabolism. The percentages of TUNEL-positive cells in the INL was quantified. Finally, retinal slices from P30 mice were used to test the role of extracellular lactate in the neuronal activity in INL cells through calcium imaging and whole-cell patch-clamp. **Results:** The results showed that photoreceptors express MCT1 in the inner segment, and in the outer plexiform layer. Immunofluorescence indicated that MCT2 was exclusively expressed in cones and abundantly expressed in the INL. Co-immunostaining in the INL indicated that MCT2 colocalizes with RBCs markers, and with amacrine cells. Other key enzymes involved in aerobic glycolysis, such as PKM2 and LDHa, were also expressed in photoreceptors. Retinal explants treated with SR-13800 (MCT1 inhibitor), AR-C155858 (MCT1 and MCT2 inhibitor) and shikonin (PKM2 inhibitor) showed increased cell death in the INL. Additionally, under the three different treatments, the RBC number decreased significantly. Interestingly, the exposure of retinal slices to these drugs decreased neuronal activity. Specifically, the replacement of glucose by lactate maintained the membrane potential in RBCs, and the amplitude in both outward current and calcium currents. However, the replacement of glucose by mannitol and the treatment with MCTs inhibitor depolarized RBCs and decreased the amplitude of the currents. **Conclusions:** These results suggest that photoreceptors and cells in the INL have different expression patterns of the key enzymes involved in aerobic glycolysis. Our data support the notion that RBCs can consume a portion of the extracellular lactate liberated by photoreceptors to meet their physiological activity. This lactate can be used to produce energy through OXPHOS.

Title: G protein-coupled receptor 55 modulates the murine retinal function

Authors: *I. BACHAND, S. RAMDANE, B. CÉCYRE, J.-F. BOUCHARD;
École d'optométrie, Univ. de Montréal, Montréal, QC, Canada

Abstract: The G protein-coupled receptor 55 (GPR55) is mostly activated by lysophosphatidylinositols (LPIs), but also by endogenous and exogenous cannabinoids. The endocannabinoid ligands and enzymes, as well as the cannabinoid receptor type 2 (CB2) have

been shown to play a role in the mediation of murine retinal function and visual acuity. Moreover, GPR55 expression and effect on the retinal cell response have already been investigated in vervet monkeys. However, the expression and effects of the endocannabinoid system were shown to be very different in rodents and primates. To investigate the role of GPR55 in the mouse vision process, we evaluated the differences between knockout mice for the *gpr55* gene (*gpr55* KO) and their age-matched wild type controls (*gpr55* WT). We used a full field electroretinogram (ERG) of adult mice (n=20 mice, 3 to 4 months old) in scotopic and photopic conditions to reveal a significative difference between groups (mixed effect two-way ANOVA) for several of its graphical components. Scotopic a-wave latency and amplitude, scotopic b-wave and photopic a-wave amplitudes were significatively lower for *gpr55* KO mice. The first three main oscillatory potentials (OPs) were also lower for *gpr55* KO mice, as well as the sum of the four main OPs. Visual acuity differences during development from P15 to P50 (n=17 mice) were studied using the minimal spatial frequency capable of triggering an optomotor response. The spatial frequency threshold was also measured for adult mice between three and four months old. For both developing and adult mice, no significative differences between *gpr55* WT and KO groups were brought out. In summary, because the different components of the ERG are caused by different cell types depending on the experimental conditions, the ERG results show expression of GPR55 in a great diversity of retina cells in mice. As for the lack of effects on visual acuity, it opens the opportunity for the use of a GPR55 agonist to treat chronic photophobia without affecting vision quality otherwise.

Title: Unraveling the roles of $Ca_v1.4$ as an organizer of photoreceptor synapses.

Authors: *J. W. MADDOX[1], K. L. RANDALL[1], M. HOON[2], A. LEE[1];
[1]Neurosci., Ctr. For Learning & Memory, Univ. of Texas, Austin, TX; [2]Dept. of Ophthalmology and Visual Sci., Univ. of Wisconsin Madison, Madison, WI

Abstract: Photoreceptors capture and convert photon energy into a neuronal signal that is transferred to second-order neurons. The transfer of this visual information relies on the voltage-gated Ca^{2+} (Ca_v) channel $Ca_v1.4$ to trigger Ca^{2+}-dependent neurotransmitter release from highly

specialized ribbon synapses of rods and cones in the outer plexiform layer (OPL) of the retina. In mice that lack $Ca_v1.4$ expression, photoreceptor ribbons and synapse structure fail to develop, but whether this is due to the absence of $Ca_v1.4$ Ca^{2+} signaling or lack of $Ca_v1.4$ protein remains unknown. To dissect the synaptogenic requirements of $Ca_v1.4$, we generated mice that express a non-conducting $Ca_v1.4$ mutant (G369i KI). Remarkably, ribbons and the molecular composition of rod and cone synapses of these mice are largely intact; however, horizontal and rod bipolar neurites fail to invaginate into rod and cone terminals. Moreover, rod synapses of G369i KI mice are occasionally localized with horizontal and rod bipolar neurites that sprout into the outer nuclear layer (ONL). Although misshapen, cone photoreceptor terminals of G369i KI mice are properly localized in the OPL with little sprouting of cone bipolar cells into the ONL. Thus, while dispensable for the initial development and molecular organization of the photoreceptor synapse, $Ca_v1.4$ Ca^{2+} signaling enables the appropriate arrangement of postsynaptic partners and is differentially required for the localization of rod and cone synapses in the OPL. Our results support the hypothesis that $Ca_v1.4$ channels promote the development and function of the first synapse of the visual pathway by operating as both structural organizers and as conduits of Ca^{2+} ions.

Title: Gene expression in cone photoreceptors of adult zebrafish is plastic to external hormone treatment

Authors: *A. FARRE[1], J. HUANG[2], A. DUNCAN[1], R. POULSEN[3], D. L. STENKAMP[1]; [1]Univ. of Idaho, Moscow, ID; [2]Univ. of Washington Sch. of Med., Spokane, WA; [3]BYU-Idaho, Rexburg, ID

Abstract: Vertebrate color vision requires the differential expression of specific cone opsins in separate cone populations. One model for the regulation of the human long and medium wavelength sensitive (*LWS/MWS*) opsin tandem array suggests an upstream regulatory region interacts with replicated opsin genes at random, resulting in mutually exclusive expression of a

specific opsin. However, our prior investigations into the orthologous long wavelength sensitive (*lws1/lws2*) array in zebrafish suggest that thyroid hormone (TH) and retinoic acid serve as trans regulators of this gene array in larvae/juveniles (Mitchell et al., 2015, *PLOS Genetics*; Mackin et al., 2019, *PNAS*). This study investigates whether cone opsin expression remains plastic to TH treatment in adult zebrafish, where cone distribution is considered stable. Adult zebrafish were treated with NaOH (0.01%, control) or TH (386 nM) for 1 or 5 days. qRT-PCR was performed on homogenized eyes, and whole retinas and cryosections were analyzed by confocal imaging. In adult zebrafish, exogenous TH drastically increased *lws1* expression in both 1 and 5 day-treated groups ($p<0.001$, 0.01, respectively) while decreasing *lws2* expression ($p<0.01$, 0.001). Other phototransduction-related transcripts (*gngt2b, rh2-1*) also demonstrated expression changes following TH treatment. Transgenic *lws* reporter fish revealed a clear switch from *lws2* to *lws1* in dorsal retina, consistent with the qPCR data. Exogenous TH induced a drastic shift from *lws2 to lws1* in adult zebrafish, consistent with previous studies of larvae and juveniles. This shift occurs as rapidly as 1 day when exposed to TH, which shows that cones remain highly plastic even into adulthood. Plasticity in spectral sensitivity (to be sensitive to higher wavelengths) in response to TH suggest a role in visual system function well into adulthood.

Title: Human stem cell derived retinal organoid cone photoreceptors demonstrate robust intrinsic light responses mimicking primate foveal cones.

Authors: *A. SAHA[1,3], E. CAPOWSKI[2], M. A. F. ZEPEDA[2], D. M. GAMM[2,3,4], R. SINHA[1,4,3]; [1]Dept. of Neurosci., [2]Waisman Ctr., Univ. of Wisconsin, Madison, Madison, WI; [3]McPherson

Eye Res. Inst., [4]Dept. of Ophthalmology and Visual Sci., Univ. of Wisconsin Madison, Madison, WI

Abstract: Title: Human stem cell derived retinal organoid cone photoreceptors demonstrate robust intrinsic light responses mimicking primate foveal cones.
Abstract: In human and non-human primates, the high definition central vision originates at a highly specialized, tightly packed, dense pixel array of cone photoreceptors, called the fovea. Death of the foveal cone photoreceptors is the ultimate cause of vision loss in retinal degenerative diseases like age related macular degeneration – a leading cause of blindness in the world. Although there are no current treatment options available, 3D retinal organoids (ROs) derived from human pluripotent stem cells (hPSCs) show much promise to model and treat such diseases. However, RO photoreceptors haven't been able to elicit light evoked electrical responses comparable to primate cone photoreceptors to date. Here we used patch clamp electrophysiology to record light evoked responses from mature stage 3 organoid cones (OCs, differentiated 240-270 days in vivo) and compared their responses and membrane properties to primate foveal cones (FCs). 35% of OCs elicited robust, graded, wavelength-sensitive light-evoked responses across several hPSC derived organoids without the addition of any external chromophore. RO cones of different spectral sensitivities could be identified, with most of them being mid-wavelength sensitive. Light-evoked voltage responses of a RO cone displayed the key features of a typical photoresponse measured from primate FCs – hyperpolarization in response to onset of light stimulus and repolarization at the cessation of the stimulus. The OCs were also able to demonstrate adaptation at higher background luminance as well as to increasing intensities of light flashes, comparable to a primate FC. The size and kinetics of light evoked responses from OCs show variability within and across organoids we recorded from. OCs also replicate some of the membrane properties of primate FCs and express HCN channels in their outer segments, crucial for shaping the light evoked responses. Overall, our results provide evidence of intrinsic light responses of OCs at physiological light levels which helps to establish the hPSC OCs as important sources of functional human cone photoreceptors for use in stem cell-based transplantation therapies and as model system to study retinal degenerative disorders.

Title: The role of microRNA-150 (miR-150)-ETS transcription factor ELK1 (Elk1) axis in the diabetic retina

Authors: F. YU, *G. KO;
Vet. Integrative Biosci., Texas A&M Univ., College Station, TX

Abstract: Diabetic retinopathy (DR) is a leading cause of blindness in US adults, and retinal inflammation is observed in the development of DR. As microRNAs (miRs) represent a set of regulators that impact metabolism and inflammation and serve as possible biomarkers for DR, it is not clear how miRs might be involved in the pathogenesis of DR. Among the miRs, decreased miR-150 is observed in the diabetic patients and animals, and miR-150 is known as an endogenous inhibitor of inflammation and angiogenesis. We previously showed that deletion of miR-150 further exacerbates retinal inflammation and microvascular degeneration in obesity-associated type 2 DR. However, the link between miR-150 and retinal inflammation under diabetic insults is not clear. In this study, we used the 661W cells (a mouse photoreceptor cell line) and miR-150 knockout (miR-$150^{-/-}$) mice to decipher the downstream target of miR-150 in obesity-associated T2D. The mice were fed with a high fat diet (HFD) to induce T2D, and the 661W cells were treated with palmitic acid (PA) to mimic the HFD condition in mice. In cultured 661W cells, we found that knocking down miR-150 exacerbated the PA-induced increase of phosphorylated P65 (pP65), an inflammation marker. Using a functional assay with 661W cells, we found that ETS transcription factor ELK1 (Elk1), a bona fide target of miR-150, was consistently elevated while miR-150 was decreased in PA-treated cells, but other known miR-150 targets were not. Knocking down Elk1 alleviated the PA-induced increase of pP65. In miR-$150^{-/-}$ mice with HFD-induced T2DR, they had a significantly higher retinal inflammation that correlated with a higher retinal expression of pELK1 compared to the wild type (WT) mice with HFD-induced T2DR. Thus, decreased miR-150 exacerbates diabetes-induced retinal inflammation by upregulating Elk1.

Title: Cultured hiPSC-RPE cells exhibit increased resistance to oxidative stress triggers throughout differentiation and maturation

Authors: *A. GHOSH[1,2], O. VERGUN[3], J. HAKKARAINEN[3], S. KAJA[1,2];
[1]Loyola Univ. Chicago, Maywood, IL; [2]Res. & Develop. Div., Experimentica Ltd, Forest Park, IL; [3]Res. & Develop. Div., Experimentica Ltd, Kuopio, Finland

Abstract: Human induced pluripotent stem cell-derived retinal pigment epithelium (hiPSC-RPE) cells more closely exhibit the human RPE than existing RPE-derived cell lines, making them a promising tool for drug discovery and development for ophthalmic conditions affecting the RPE, including age-related macular degeneration and geographic atrophy. However, there is a lack of rigorous scientific data regarding the response of hiPSC-RPE cells to oxidative stress triggers. The purpose of this study was to determine the susceptibility of hiPSC-RPE cells to exogenously applied oxidative stress (*tert*-butyl hydroperoxide; *t*BHP) and an oxidizing agent (sodium iodate; $NaIO_3$) that triggers intracellular oxidative stress and to investigate their effects on hiPSC-RPE differentiation and maturation.HiPSC-RPE cells were seeded on Matrigel®-coated 96-well cell culture plates and differentiated according to the manufacturer's instructions. After varying amounts of differentiation time *in vitro* (days *in vitro*, DIV), cells were challenged with either *t*BHP (0.1 to 1.0 mM) or $NaIO_3$ (0 to 18 mM). Cell viability was assessed by resazurin assay and lactate dehydrogenase (LDH) release assay. Reactive oxygen species (ROS) generation was quantified by chloromethyl 2',7'-dichlorodihydrofluorescein diacetate (CM-H_2DCFDA) assay and vascular endothelial growth factor (VEGF) release was quantified by ELISA. HiPSC-RPE cells exhibited a dose-response to increasing doses of *t*BHP and $NaIO_3$. In *t*BHP experiments, IC_{50} values for tBHP from resazurin assay were ~0.4 mM from DIV13 to DIV19, ~0.7 at DIV26 and ~0.9 mM at DIV28. LDH release showed a similar shift (EC_{50} values for *t*BHP: range 0.4 mM to 0.9 mM). ROS generation was significantly attenuated at DIV26 and DIV28, which was positively associated with VEGF release. Similarly, $NaIO_3$ induced a dose-response in the cells with IC_{50} (resazurin assay) and EC_{50} (LDH assay) values of 7.8 mM. $NaIO_3$ elicited a significant 26-fold increase in ROS generation at the lowest dose of 2 mM $NaIO_3$, which slowly decreased with higher doses, likely attributable to a dose-dependent toxicity. Our data suggest that hiPSC-RPE cells continue to mature over time *in vitro*, manifesting as increasing resistance to exogenously-applied oxidative stress. Differences in the correlation between insult (tBHP *vs*. $NaIO_3$) and cell viability are likely due to mechanistic differences in the generation of intracellular *vs*. exogenously-applied oxidative stress. HiPSC-RPE cells exhibit a strong endogenous antioxidant system and potent VEGF response, making them a useful model for *in vitro* applications.

Title: Morphological homologies in diurnal and nocturnal Lepidopteran eyes

Authors: *D. PAUKNER[1], G. WILDENBERG[5], G. BADALAMENTE[2], P. LITTLEWOOD[2], N. B. KASTHURI[3], S. E. PALMER[4];

Abstract: The number of photons available during the day versus the night varies by orders of magnitude. It is therefore reasonable to hypothesize that there are evolved differences in eye structure of species active at different times of day. Ommatidial diameter, interommatidial angle, and resolving power have been measured in some species of bees and parasitic wasps. It was found that there was a square root relationship between the height of the eye and the diameter of the average ommatidium, and the ratio of the interommatidial angle to resolving power was between 0.4 and 1 in the regions of highest acuity in the eye. However, these finding only relate to diurnal species. We use different species of moths and butterflies that can either be grouped as diurnal, nocturnal, or crepuscular to determine if these metrics match those found in wasps and bees and whether they differ among species in different light environments. Surprisingly, using synchrotron x-ray data, we found that the relationship of the height of the eye to the ommatidial diameter matched the trend seen in wasps and bees except for diurnal species. We also found that the interommatidial angle to resolving power ratio was significantly greater than 1, regardless of the level of acuity, and the metrics we measured did not differ significantly between groups. These findings suggest the values measured are optimal for all Lepidopterans and that the correlation structure of natural scenes might set this general eye structure to support effective vision independent of light levels.

Title: Vamp1 immunoreactivity form ribbon-like structures in photoreceptor terminals in mouse retina

Authors: *A. A. HIRANO[1,2], C. SCHIETROMA[1], N. C. BRECHA[3,2];
[1]Neurobio., David Geffen Sch. of Med. at UCLA, Los Angeles, CA; [2]VAGLAHS, Los Angeles, CA; [3]Neurobiology, Ophthalmology & Med., David Geffen Sch. Med. at UCLA, Los Angeles, CA

Abstract: The cellular mechanisms and synaptic protein isoforms underlying synaptic vesicle release from the photoreceptor ribbon synapse remain incompletely understood. The mammalian photoreceptor releases the neurotransmitter glutamate in a continuous fashion onto bipolar and horizontal cells. The synaptic vesicle protein, VAMP1/synaptobrevin, forms part of the core SNARE complex that mediates vesicle fusion with the plasma membrane. The expression of VAMP1 was studied in lightly fixed mouse retina using immunohistochemistry, super-resolution confocal microscopy, conical EM tomography, and RNAscope *in situ* hybridization. VAMP1 immunolabeling formed crescents in the outer plexiform layer, where the photoreceptor synaptic terminals are located. The VAMP1 immunolabeling was observed in both rod and cone photoreceptor terminals. Double labeling with antibodies to PSD-95 confirmed that the ribbon-like VAMP1 immunolabeling occurred within photoreceptor terminals. Double labeling with CtBP2/ribeye antibodies showed that the VAMP1 label formed a nested crescent inside the arch of the synaptic ribbon. Double labeling with bassoon antibodies, which is thought to label the base of the ribbon, demonstrated that there was a significant overlap between VAMP1 and bassoon immunolabeling. To assess if VAMP1 co-localized with horizontal cells, double immunolabeling for calbindin indicated that VAMP1-immunoreactive structures were closely apposed to horizontal cell endings, but extended beyond the horizontal cell endings. Consistent with VAMP1 localization to photoreceptors, VAMP1 mRNA is expressed in the outer nuclear layer. Conical EM tomography of mouse rod photoreceptor terminals revealed a row of synaptic vesicles at the base of the synaptic ribbon. Taken together, we propose that the VAMP1 immunolabeling observed may correspond to this pool of synaptic vesicles at the base of the synaptic ribbon.

Abstract: Disruption of retinal layers by laser photocoagulation affects Visuospatial memory and visual functions. Priya Mehra[1, 2], Parul Bali [3], Jagtar Singh[1], Pradip Kumar Saha[4], Akshay Anand[2*1]Department of Biotechnology, Panjab University, Chandigarh, 160014, INDIA[2]Neuroscience Research Lab, Department of Neurology, Post Graduate Institute of Medical Education & Research, Chandigarh, 160012, INDIA[3]Department of Biological Science, Indian Institute of Science Education and Research (IISER), Mohali, INDIA[4]Department of Obstetrics and Gynecology, Post Graduate Institute of Medical Education and Research, Chandigarh-160012, INDIA
AbstractVisual pathway involves neuronal activity between presynaptic and post synaptic pathway to generate action potential to amplify the signal resulting in visual image formation. Although, various studies have been carried out to reverse the injury but these have not clinically translated successfully. This study was conducted to evaluate the effect of injury on visual spatial memory by establishing a laser injury model and performing neurobehavioral tests (Morris Water Maze and Passive Avoidance). *C57BL/6J* male mice were used for the study. The laser spots with defined parameters were given to the mice retina around the optic disc using laser photocoagulation that disrupted the RPE layer of the retina. Fundus Fluorescein Angiography confirmed the establishment of animal model. Subsequently, visual-spatial memory was analysed by neurobehavioral tests and short-term memory by using Morris Water Maze (MWM) and Passive Avoidance. In neurobehavioral experiments, we found that escape latency time in both healthy and eight laser groups was comparable. In the passive avoidance test, the latency time was non-significant between the healthy and laser groups. This shows that visuospatial memory may not get affected by retinal injury induced by laser photocoagulation. It may depend upon the intensity of the laser and the duration of the laser for

which additional experiments are required. **Ethical Statement-** Study was conducted after taking ethical approval from Institute Animal Ethical committee. The ethical approval number is 105/IAEC/720.**Conflict of Interest-** None

Title: Fmri-guided electrophysiological characterization of macaque orbitofrontal face patches

Authors: *E. MERGAN[1,2], Q. ZHU[3,1], X. LI[1,2], R. VOGELS[1,2], W. VANDUFFEL[4,2,5,1];
[1]Dept. of Neurosciences, KU Leuven, Leuven, Belgium; [2]Leuven Brain Inst., Leuven, Belgium; [3]CEA DRF/JOLIOT/NEUROSPIN, Univ. Paris-Saclay, Gif-sur-Yvette Cedex, France; [4]Radiology, Harvard Med. Sch., Boston, MA; [5]Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: fMRI studies in primates revealed face-category selective activations in prefrontal areas [Tsao et al., 2008]. Electrophysiological studies targeting orbitofrontal cortex reported neurons responding more to faces compared to objects. The latter face-selective neurons often convey social and emotional information [Barat et al., 2018]. However, the relationship of these orbitofrontal face selective neurons with respect to fMRI-defined face patches is not clear. Using fMRI-guided laminar recordings in macaques, we characterized the neuronal responses of 2 face patches within the orbitofrontal sulcus, i.e., face patch POa which is located rostro-lateral relative to a second orbitofrontal face patch POp. Extensive sets of images of bodies, animals, objects, and faces varying in position, viewpoint, and facial expression were presented to two

fixating rhesus monkeys. In both orbitofrontal face patches of both monkeys, we found on average only 1 out of 3 visually driven cells to be face selective (79/100 out of 217/265 cells in POp and 163/120 out of 504/406 cells in POa for monkey F and L, respectively). Surprisingly and contrary to previous studies in which face cells were recorded in orbitofrontal cortex without fMRI guidance [Barat et al., 2018], the face cells in POa and POp were not modulated by the emotional content of the images. However, many of the face cells in both areas were sensitive to the viewpoint of the faces. The selectivity of these neurons also showed a high degree of tolerance to changes in position of the faces. On population level the receptive fields of face neurons in both face patches covered large eccentricities, yet with a strong foveal bias, and a relatively small contralateral bias. Overall, our data provide a more comprehensive view on the properties of face-selective neurons within fMRI-defined orbitofrontal face patches POa and POp.

Title: Mapping Dynamic Body Patches in Macaque Inferotemporal Cortex

Authors: M. BEGHELLA BARTOLI[1,2], ***R. RAMAN**[1,2], N. TAUBERT[3], Y. ZAFIROVA[1,2], B. DE GELDER[4], M. GIESE[3], R. VOGELS[1,2];

Abstract: Visual information from body movements is an imperative element of non-verbal social communication and action recognition. Since previous fMRI studies employed static images to identify patches in the macaque inferotemporal (IT) cortex that were activated more strongly by bodies compared to faces and objects, the organization of patches that are activated by dynamic bodies is still unclear. In this fMRI study, we investigated the neural substrate underlying the visual processing of dynamic bodies in the macaque's brain. We measured the response to a set of 1 s long videos of dynamic monkey bodies, dynamic monkey faces, and

dynamic artificial objects. The body videos displayed natural actions of a monkey with its head blurred, while in the face videos a monkey displayed various expressions or turned its head. The actions and objects were presented on a dynamic white noise background. In addition, we presented mosaic scrambled versions of these videos, keeping the local motion of the full video displays. For scanning, we employed a block design during passive fixation. Dynamic body patches (bodies – objects) were present in the dorsal bank, fundus and upper bank of the superior temporal sulcus (STS), and ventral to the rostral STS. The dynamic body and face (faces – objects) patches were close to each other. The most posterior body patch was located in or close to the Fundus of the Superior Temporal (FST) area. More anterior ones coincided with the patches previously defined with static images of bodies: MSB and ASB in the ventral bank of STS (Kumar et al., Cerebral Cortex, 2019), and one in ventral IT, dorsal to face patch AM (Bao et al., Nature, 2020). In addition, several body patches were present in the fundus and dorsal bank of the rostral STS, neighboring face patches MF, MD and AF. Dynamic body patches were also observed in the frontal cortex and in 2/4 animals weakly in the parietal cortex. In some monkeys, weak activations to the scrambled body videos were present in the dynamic body patches, suggesting responses to local features. This fMRI mapping study provides a roadmap of the network of dynamic body patches in the macaque brain, which are currently targeted with single-unit recordings.

Title: Hemisphere-specific coding of left vs. right viewpoint for perception of the human body in lingual gyrus.

Authors: *G. MARRAZZO[1], M. VAESSEN[1], F. DE MARTINO[1,2], A. LAGE-CASTELLANOS[1,3], B. DE GELDER[1,4];

Col. London, London, United Kingdom

Abstract: Visual information from body movements conveys crucial information about emotions, intentions and actions of conspecifics. Our current understanding of body posture and movement shows a gap between processing of low-level features and high-level semantic categories (de Gelder & Poyo Solanas 2021). An important intermediate level processing stage in models of object perception is viewpoint (in)tolerance. Viewpoint sensitivity is of special importance for body perception because self vs. other oriented body images may have a very different behavioral impact on the viewer which stresses the importance of maintaining viewpoint tolerant representation. Previous studies showed that EBA, but not the FBA, is sensitive to the orientation of the body (Lawson et al. 2009; Kumar et al. 2019). In this fMRI study we investigated the brain representation of differences in viewpoint on body perception. Stimuli were generated using a variational autoencoder (VAE), via a random sampling of the latent space parameters, depicting 3D rendered body poses. We used 108 randomly generated unique poses from 3 different viewpoints (frontal view, 45° rotation to the right and to the left respectively), for a total of 324 stimuli. In a behavioral experiment participants (N=54) evaluated (using a Multi-arrangement method, RSA and features survey) the similarities between all stimuli including triplets (same stimulus from 3 viewpoints). For the fMRI experiment participants were scanned using a 7T (T2*-weighted Multi-Band accelerated EPI 2D BOLD sequence, MB = 3, voxel size = 1.6 mm^3, TR = 1000 ms, TE = 20 ms) in a fast event-related design over 12 separate runs. Each run consisted of 54 unique stimuli (18 unique poses x 3 viewpoints) which appeared on the screen for 750 ms. Participants were asked to fixate and attention was controlled with a one-back task (6 trials per run) in which a button press was required if following a specific visual cue, the current stimulus was the same as in the previous trial. For the univariate analysis, data were combined in a fixed effect GLM in which 3 regressors of interest were generated representing the 3 viewpoints conditions. The contrast between opposite viewpoints (-45 vs +45) showed activation in the lingual gyrus with opposite pattern in left and right hemisphere as higher activation was found for the left rotated stimuli from the observer point of view in the right hemisphere whereas higher activation for the right rotated stimuli from the observer point of view in the left hemisphere. These results have implications for understanding the importance of viewpoint specific perception of human bodies and its special role in hierarchical models of object perception.

Title: Physiologically-inspired neural model for the visual recognition of dynamic bodies

Authors: P. KUMAR[1], N. TAUBERT[1], R. RAMAN[2,3], R. VOGELS[2,3], B. DE GELDER[4,5], *M. A. GIESE[1];
[1]Section for Computat. Sensomotorics, Dept. of Cognitive Neurology, Hertie Inst. for Clin. Brain Res. & Ctr. for Integrative Neuroscience, Univ. Clin. Col. London, London, United Kingdom

Abstract: The recognition of bodies and body movements is essential for the survival of many social species. The detailed underlying neural circuitry is not yet fully understood. We present a physiologically-inspired hierarchical neural model for the recognition of body movements for comparison with electrophysiological data from monkeys and human fMRI data. METHODS: The model combines a feed-forward deep neural network (VGG-19) with a neurodynamical model that reproduces responses at the single-cell level in the superior temporal sulcus (STS) and premotor cortex (Giese and Poggio, 2003). The initial parts of the visual pathway were modeled by the layers up to the MaxPool4 layer of VGG-19 (pre-trained on the ImageNet database). Output features were reduced by eliminating features with low variance and applying PCA. The reduced feature detector responses provided input to RBF units (snapshot neurons) which were trained with individual keyframes of the actions, and which were embedded in sequence-selective recurrent neural networks (neural fields) with asymmetric lateral connections (Giese and Poggio, 2003; Fleischer et al., 2013). Neural fields encoding different actions mutually inhibit each other, resulting in a competition between the different learned actions. The outputs of the individual neural fields are summated by motion pattern neurons that are activated by only one of the learned actions. We tested the model using videos of macaques and humans performing different types of actions. Similar movies of macaques are presently being used in physiological experiments and fMRI experiments on body motion encoding. RESULTS: The model successfully recognizes the actions from real videos. The snapshot neurons show a traveling pulse of activity that encodes the corresponding pattern. The motion pattern neuron responses clearly differentiate between the different encoded actions. Consistent with the behavior of real neurons in the inferior temporal cortex (IT), the model trained with naturalistic stimulus movies generalizes spontaneously to silhouette stimuli. The model makes predictions about the responses of different neuron classes along the hierarchy, which are presently being compared to recordings from the macaque visual cortex and to human fMRI data.

Title: Investigating the mental representation of observed grasp movements through similarity judgements

Authors: *L. J. ETTENSOHN, K. WOODARD, L. G. UNGERLEIDER, C. I. BAKER, M. VAZIRI PASHKAM;
Lab. of Brain and Cognition, NIH, Bethesda, MD

Abstract: Hand grasp movements constitute a large portion of human's everyday activities. In addition to performing hand grasp movements ourselves, we regularly observe others grasping objects and can judge these grasps by their similarity. What are the core features relevant for similarity judgements of observed grasp movements? Do people's similarity judgements of grasp movements match objective grasp similarities based on kinematics of the movement? To answer these questions, we first conducted a hand grasp movement experiment. We placed 16 sensors on each participant's (n=14) hand and measured their movements in 3 dimensions as they grasped a set of 58 naturalistic 3D printed objects (e.g. spoon, teapot, teddy bear). Using these kinematic data, we calculated the similarity between grasp movements and constructed a similarity matrix based on objective measurements. Next, we used the kinematic data to create point-light videos to serve as stimuli in our second experiment. Our second experiment was an odd-one-out similarity judgement task. Participants on Amazon Mechanical Turk identified the most distinct grasp among triplets of the grasp videos (130 data points were collected for each pair). These judgements were used to construct a subjective similarity matrix. Both the objective and subjective similarity matrices had high reliabilities ($r^2 > 0.7$). Surprisingly, the correlation of these two matrices was ~0.37: significantly above zero ($p < 0.001$) but also significantly below the noise ceiling ($p < 0.001$). These results demonstrate that humans rely on systematic features when judging the similarity of grasp movements, but these subjective judgements do not mirror the objective similarity of grasp kinematics. These results suggest that distinct neural representations may support action observation and action execution.

Abstract: Like face perception, body recognition is a fundamental social skill for many animals including primates. While several body-selective regions have already been identified in both humans and nonhuman primates, there is no comprehensive picture of which regions are specifically involved in dynamic body perception and whether they are species specific. Interestingly, homologous face and body patches mainly along the superior temporal sulcus (STS) have been observed in monkeys (Tsao et al. 2003) leaving open questions about species specificity of social signals (Qi et al. 2012). This high-field fMRI 7T ($1.6mm^3$ isotropic, TR = 1s) study investigated the neural correlates of dynamic human and monkey bodies and faces in human participants. Stimuli consisted of 1-s videos of dynamic faces and bodies of both monkeys and humans (neutral, face information removed), as well as dynamic artificial objects (e.g. machine parts). A scrambled version of each category was used to control for motion and low-level visual features. The experiment used a block design and a fixation change based oddball task. Several body patches were found when contrasting human bodies to objects including the extrastriate body area, STS, fusiform body area, occipito- and temporal-parietal junction, premotor cortex, inferior frontal cortex and anterior cingulate extending previous findings (de Gelder & Poyo Solanas 2021). The STS patches were clearly separated into anterior, middle and posterior parts. A contrast between human faces and objects revealed a large overlap between the STS body patches and face patches, especially for posterior and middle parts. Human bodies compared to monkey bodies elicited more activity in the ventral and dorsal premotor cortex, inferior frontal cortex, extrastriate body area and fusiform body area. In addition, we saw higher sensitivity to human bodies in the middle and posterior STS, even after controlling for low-level features. The STS patches corresponded to those found in monkey studies (Beghella Bartoli et al. 2021) suggesting a species continuity in the representation of social stimuli in the brain. However, here, the STS body patches were more selective for human bodies than monkey bodies indicating a species-specific coding in those areas.

Title: Face neurons see Waldo

Authors: M. J. ARCARO[1], *M. LIVINGSTONE[2];
[1]Dept. of Psychology, Univ. Of Pennsylvania, Philadelphia, PA; [2]Harvard Med. Sch., Boston, MA

Abstract: Inferotemporal cortex (IT) contains neurons that respond selectively to complex visual images. These neurons are thought to be critical for our ability to detect and classify things (e.g., faces) in our environment. The speed and accuracy with which we recognize faces is impaired when faces are embedded within cluttered environments. Here, we explored the impact of clutter on response properties of IT neurons.
We recorded from microelectrode arrays implanted in fMRI-defined posterior, middle, and anterior lateral face patches across four adult monkeys. We probed responses to faces embedded within visually cluttered and uncluttered scenes. Cluttered scenes comprised either non-faces (e.g., a face within a pile of rocks) or other faces (e.g., a monkey face within an array of human faces). To measure spatially specific responses across each scene, we presented each image centered at different positions relative to each neuron's receptive field such that the neuron's receptive field sampled all parts of each image across the experiment. We assessed perceptual awareness of the cluttered faces with a preferential looking paradigm. Neurons responded strongly when faces in both cluttered and uncluttered scenes were presented within their receptive fields. Responses were spatially focal to faces across a variety of retinal sizes and even when presented briefly (32-100ms). Only when faces were embedded within a dense array of other faces did responses become erratic. Together, these results demonstrate that cluttered environments had a minimal impact on the spatial and feature specificity of these neurons. In contrast to the neural recordings, the monkeys did not appear to be aware of faces in clutter. When presented in isolation or in uncluttered scenes, the monkeys preferentially looked at faces. In contrast, the monkeys did not look at faces in cluttered scenes where the clutter comprised non-faces, even for presentations several times longer in duration (500ms) than the neural

recordings. Only when scenes were presented for even longer epochs (2000ms) where they were able to scan the image, did the monkeys look at the cluttered faces. These results indicate that cluttered environments impaired the monkeys' ability to perceive faces without substantially affecting the response properties of face-selective neurons in IT. The spatial and feature tuning of IT neurons under visual clutter illustrates the strong tie of these neurons to the retinal input. Thus, while IT neurons may be necessary for and modulated by the perception and recognition of faces and objects, our results indicate that downstream areas that receive input from IT may be the 'secret sauce' to perception.

Abstract: Primates use vision to guide their interactions with objects and conspecifics in the three-dimensional physical world. However, study of object related areas of the ventral visual pathway of the cerebral cortex have focused on questions regarding spatially invariant object recognition. Relatively few studies have asked how neurons in object-specialized areas are affected by geometric properties of a scene, including the absolute sizes and distances of objects. Here, we asked to what extent the brain is sensitive to the 'real-world' 3D geometry of objects, as opposed to their 2D retinal subtense. We recorded from isolated neurons in the macaque anterior fundus face patch while stereoscopically presenting 3D faces and objects, which permitted systematic variation of virtual object size and distance. The results revealed neural sensitivity to properties of real-world geometry, while retinal subtense accounted for relatively less variation in neural response. Neurons were tuned for the absolute size of heads. Surprisingly, while real macaque heads are typically ~13 cm in width, 45.5% of face patch neurons responded most strongly to most extreme sized heads, which in our stimulus set were very small (~1cm) or

very large (~26 cm). Across the population, 70.5% of neurons responded most strongly to faces in the largest or smallest quartile. This sensitivity to for extreme sizes was not unique to faces but also observed for a variety of non-face objects. Together, these results demonstrate that object-selective neurons in ventral visual cortex are highly sensitive to the 3D geometry of objects within an environment. The findings suggest that high-level visual object representations in the brain are not abstracted from physical space but integrated with it, rendering them directly useful for a range of actions and judgements.

Title: Assessing finger individuation abilities in cerebral palsy using a 3-dimensional force device

Authors: *B. CRABTREE[1], O. A. KHAN[1], S. V. WILHOITE[1], J. PASCAL[1], P. R. IYER[1], G. COLQUITT[2], C. M. MODLESKY[1], J. XU[1];
[1]Dept. of Kinesiology, Univ. of Georgia, Athens, GA; [2]Dept. of Hlth. Sci. and Kinesiology, Georgia Southern Univ., Statesboro, GA

Abstract: Children with Cerebral palsy (CP) often demonstrate impairments in fine motor ability that are associated with poor selective motor control (SMC). Existing clinical assessments of SMC in CP are often subjective, require highly experienced examiners, and lack the granularity of functional kinematics/kinetics to precisely identify fine motor control deficits. Here we used a novel device, Hand Actuation Neuro-training Device (HAND, JHU reference #C14603), that tracks subtle isometric forces at all five fingertips in three dimensions (3D). We tested CP and typically developed (TD) children's finger individuation, the ability to move one finger without moving others. The purpose of the study was to accurately assess individuation deficits for children with CP.
Sixteen children with CP (ages 5 -16) and seven age-matched TD children participated in the study. Participants placed their hand in the device (more affected for CP, dominant for TD) in a comfortable, pronated, resting posture. They were instructed to control a dot's movement along each axis of a virtual 3D space on a computer screen by exerting isometric forces with one finger

(max=10N) while keeping all the other fingers immobile. Movement of the dot along the virtual XYZ axes reflected forces exerted by metacarpophalangeal (MCP) ab/adduction, proximal interphalangeal joint (PIP) flexion/extension, and MCP flexion/extension, respectively. Force trajectories were recorded from all five fingers during the task. From these trajectories, Individuation Indices were derived as the -log(slope) of the function relating non-instructed finger forces and forces in the instructed finger's target direction.
Linear mixed effect models were used to test the difference across CP and TD groups. Overall, we found that the average Individuation Index was higher for TD children (M = 0.16, SD = 1.08) than CP children (M = -0.42, SD = 1.14) ($\chi 2$ = 24.38, p = 7.9e-07). The Individuation Index among all participants was the highest in digit F1 (M = 0.384, SD = 1.08) and the lowest in F4 (M = -0.87, SD = 0.86); this had an interactive effect with the patient group ($\chi 2$ = 141.81, p = 2.2e-16). Individuation in movement across participants was the highest in finger flexion (M = -0.10, SD = 1.17) and the lowest in finger ab/adduction (M = -0.55, SD = 0.94); movement direction also interacted with group ($\chi 2$ = 83.21, p = 2.2e-16). These results suggest the device and paradigm are highly sensitive in detecting the distinct impairment patterns of finger individuation in CP children. This approach has the promise of providing detailed and precise assessment of the hand function in children with CP to inform future evidence-based targeted treatment.

Title: Identifying mechanical biomarkers of peripheral neuropathy via machine learning method in carpal tunnel syndrome applications

Authors: *W. ZHANG[1], Y. WEI[3], F. GU[2];
[2]Computer Sci., [1]Col. of Staten Island / City Univ. of NY, Staten Island, NY; [3]Univ. of Technol. of Compiègne, Compiègne, France

Abstract: Peripheral neuropathy that interrupts sensorimotor integration in the motor control process will lead to hand and upper limb motor function deficits in daily life. However, behavioral biomechanics and motor functions have never been considered in available diagnosis and clinical evaluation. Previous studies that investigate behavioral biomechanics to delineate

specific peripheral neuropathy and its severity have shown evidences that certain biomechanical parameters have the potential to be identified as biomarkers for the detection of the neuropathy from an early stage. Nevertheless, datasets formed by behavioral biomechanical parameters are often characterized by high dimensionality, small sample size, and high redundancy, which brings us challenges for making binary classification between patients and healthy controls. In this study, we propose a two-step machine learning protocol using random forests for early variable screening and (K)PCA-SVM system for final variable interpretation and classification prediction. We suggest determining the hierarchy between feature groups by analyzing the distribution of the variable importance for early elimination of redundancy. The result of the application of our protocol in the carpal tunnel syndrome dataset show better rationality in the interpretation of variable selection and higher accuracy in prediction when compared to a single application of random forests. The final prediction accuracy reaches 90.3% when 6 variables are selected. The choice of variables implies that kinetic variables from all three-dimensional directions possess an aspect of importance in the reflection of disease. It also suggests that digits should be grouped for future studies and analysis according to their major function in grasping or lifting. Further experiments and tests should be designed with specifications to collect supplement biomechanical parameters so that better classification could be made for the detection of diseases in an early stage. The result of its application in our example dataset provides us guidelines and directions for future clinical test designs in the aim of optimizing disease diagnosis.

Title: A Novel Method for the Assessment of Precision Force Control in Children

Authors: *V. L. ROSE[1], A. R. AJOY[1], G. R. GOGOLA[2], P. J. PARIKH[1];
[1]Univ. of Houston, Houston, TX; [2]UT Physicians, The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Hand sensorimotor function depends on intact sensory and motor systems, but also on sensorimotor integration to successfully handle objects. Sensorimotor integration is responsible for critical aspects of manual function such as precise control of force magnitude and direction exerted by each digit on an object. This is important during daily tasks which require dexterity.

Clinically, the measurement of hand function identifies children with developmental pathology, guides treatments, and quantifies post treatment progress. Current tests are time-based measures and thus assess only a subset of functional abilities needed for manual activities. Therefore, these tests might not be sensitive enough to detect subtle changes in dexterity following an intervention. There is a need for a test designed specifically for children to measure the quality and control of movement (i.e., precision force control). To meet this challenge, we developed a novel device to comprehensively assess hand sensorimotor function by considering precision control of digit forces (i.e. total force) exerted on the object in addition to a time-based measure (trial duration). Children are asked to move a small object from one location to another and perform this task under three difficulty conditions: low, medium, and high. Our aim is to assess interrater reliability of the device. We have recruited 9 typically developing children aged 4-15 years. To assess interrater reliability, two independent researchers analyzed the output of the new device, and a third researcher calculated intraclass correlation coefficients (ICC). For the trial duration measure, we found that the ICC (2,1) between the 2 raters (absolute agreement) was 0.97 for the low difficulty condition, 0.99 for the medium difficulty condition, and 0.99 for the high difficulty condition. For the total force measure, we found that the ICC (2,1) between the 2 raters was 0.99 for the low difficulty condition, 0.99 for the medium difficulty condition, and 0.98 for the high difficulty condition. Our findings provide preliminary evidence of high interrater reliability for our new device that measures precision force control for a wide age range of children and adolescents.

Title: Assessing the control of residual muscles in children with congenital upper limb deficiencies

Authors: *J. FITZGERALD[1], M. BATTRAW[2], A. BAGLEY[3], M. JAMES[3], J. SCHOFIELD[2], W. M. JOINER[1];
[1]Neurobiology, Physiology, and Behavior, [2]Mechanical and Aerospace Engin., UC Davis, Davis, CA; [3]Shriners Hosp. for Children Northern California, Sacramento, CA

Abstract: Recently, ultrasound imaging coupled with machine learning has been used to quantify spatiotemporal tissue deformation patterns of the residual muscles in adults with acquired below-the-elbow limb loss. However, the pediatric population is more likely to present with a congenital upper limb deficiency (ULD). Currently, it is unknown to what extent these

methods can be applied to the pediatric population. Furthermore, there is a lack of understanding on the extent to which pediatric patients can volitionally contract residual muscles to a desired state, at will and reproducibly. This includes both static states (e.g., power grasp or index pinch) and proportional control where the hand is partially closed. Here, we investigated the sensorimotor control capabilities of residuum muscles in children with unilateral congenital below-the-elbow ULDs. We examined whether their control was sufficiently robust and reliable for a machine learning algorithm to accurately classify multiple tissue deformation patterns when children attempted to perform distinct hand or wrist movements. Patients performed a minimum of 5 trials of six hand or wrist motions with both their affected and unaffected limb. A K nearest neighbors (KNN) algorithm was used to classify the spatiotemporal tissue deformation patterns. We found that all patients were able to execute unique tissue deformation patterns with some reliability (classification accuracy > 60%) when simultaneously classifying 4 grasp patterns, and some were able to reliably perform all six motions. To further study the extent of patients' motor control, we examined the intra-grasp variability by comparing the similarity of spatiotemporal tissue deformation patterns within each motion. This enabled us to examine in depth the variability of executed tissue deformation patterns. Interestingly, we found that intra-grasp variance did not correlate with grasp classification accuracy in most patients. Collectively, these results suggest that children with congenital below-the-elbow ULDs have significant control of their residual muscles. Future systems that fully utilize this control could provide prostheses with greater functionality than current pediatric interfaces.

Title: Classifying hand grip and release events in object grasping with Granger Causality features extracted from scalp electroencephalography

Authors: *A. Y. PAEK, J. L. CONTRERAS-VIDAL;
Electrical and Computer Engin., Univ. of Houston, Houston, TX

Abstract: Objective: Brain machine interfaces (BMIs) are systems that allow users to control assistive devices through motor intent detected from the brain. Such systems can be used to help

restore hand-based motor function to paralyzed individuals. Most BMI studies have utilized scalp electroencephalography (EEG) to predict motor intent with spectral features that are extracted from individual sensors. Few studies have explored predicting motor intent with functional connectivity, a metric that estimates the magnitude of communication between different cortical areas. This intercortical communication is a fundamental aspect of cortical activity that is found to be modulated in motor tasks and shows potential to be used as a feature for predicting motor intent. In this work, we assessed if Granger Causality, a functional connectivity measure, can be used to predict when able-bodied participants held or released a grasped object. Methods: Eleven able-bodied volunteers participated in an experiment where they grasped and lifted a sensorized object. The object contained load cells that measured the grip forces exerted by the thumb and index finger. EEG signals were recorded simultaneously with the grip force recordings. Utilizing the force trajectories, we found time regions in trials when subjects were either holding the object or not touching the object. These "hold" and "release" periods were designated as the classes we aimed to predict with EEG signals. 5-fold cross validation was used to train and test a classifier that used Gaussian Mixture Models to model the classes and Local Fisher Discriminant Analysis to reduce the dimensionality of the data. For predictive features, we tested lowpass filtered delta band potentials (<1 Hz), spectral power in six frequency bands (4-8 Hz, 8-13 Hz, 13-30 Hz, 30-50 Hz, 70-110 Hz, 13-200 Hz), and Granger Causality. The features were extracted from 8 bipolar EEG sensors that were mostly centered on sensorimotor areas. Results: While classification accuracies were modest (median balanced accuracies ranged from 52%-58%), we found that Granger Causality features performed significantly better than the other features used in the study. The results demonstrate that functional connectivity may be a promising feature that can improve future EEG-based BMIs. Acknowledgement: We note that this work is new analysis on data that was previously collected and published in collaboration with Dr. Pranav Parikh, Dr. Alycia Gailey, and Dr. Marco Santello from Arizona State University.

Title: Influence of grip force magnitude on temporal structure of electrocortical variability

Authors: *N. RAO[1], A. PAEK[2], J. L. CONTRERAS-VIDAL[2], P. J. PARIKH[1];
[1]Hlth. and Human Performance, [2]Electrical and Computer Engin., Univ. of Houston, Houston, TX

Abstract: Fine grip force adjustments in routine tasks such as holding a coffee-mug allows one to adapt to task requirements. The temporal structure of grip force variability that underlies such adjustments is known to be modulated with the magnitude of force required to hold an object. Furthermore, neuroimaging evidence suggests that spatial activation in fronto-parietal brain regions is also driven by the grip force magnitude. However, it remains unclear whether the temporal structure of neural variability is influenced by the magnitude of grip force exerted on a hand-held object. To this end, we hypothesized that the temporal structure in neural variability assessed using electroencephalography (EEG) over sensorimotor regions would modulate with the force magnitude during a moment-to-moment grip force control task. We recruited 11 right-handed healthy young adults (age range: 18-40 years) and recorded their cortical activity using 64-channel EEG during performance of an isometric force production task. For each trial, the subject was cued to exert 5, 10, or 15% of their maximum voluntary contraction (MVC) for 8 sec. Subject's grip force was displayed on a computer screen and each subject performed 100 trials during the session with ~33 trials per force level. We used sample entropy to assess temporal structure in the EEG signal variability. Consistent with previous reports, our preliminary findings (n=7) show an increase in sample entropy of the grip force with the increase in grip force magnitude. Interestingly, sensor-level analysis of EEG channels depicts a modulation in sample entropy of the electrocortical activity with grip force magnitude. The sample entropy of EEG time series recorded using a channel over the hand sensorimotor cortical regions was lower for 10% versus 5% MVC. There was a trend for an increase in sample entropy of EEG signal between 10% and 15% of MVC. However, there was negligible difference in sample entropy of the EEG signal between 5% and 15% MVC. Such a modulation in sample entropy was not observed in the EEG signals captured from an electrode placed closer to the midline. These findings are suggestive of non-linear and spatially constrained modulation in the temporal structure of electrocortical variability with grip force magnitude. Findings from this study could contribute to mechanistic underpinnings of moment-to-moment force control with applications in neurorehabilitation.

Title: Pre-movement interhemispheric synchronicity of sensorimotor activities is associated with the sustained anti-phase bimanual tapping

Authors: *S. IWAMA[1], T. YANAGISAWA[3], J. USHIBA[2];
[1]Grad. Sch. of Sci. and Technol., [2]Dept. of Biosci. and Informatics, Keio Univ., Kanagawa, Japan; [3]Dept. of Neurosurg., Osaka Univ., Osaka, Japan

Abstract: Coherent coupling of neuronal oscillation represents perception, sensorimotor control and ongoing actions. However, its impact on subsequent behavior remains to be explored. Here, to test whether the coherence of scalp EEG over bilateral sensorimotor cortices (SMC) at pre-movement period is associated with subsequent unstable behavior, we developed experiment setup that cued in participants in a brain-state dependent manner. Because the anti-phase bimanual tapping spontaneously alters into in-phase putatively due to the interaction of interhemispheric sensorimotor activities (Aramaki et al., 2006), we hypothesized the initiation of finger tapping at the trough of spontaneous fluctuation of functional connectivity between bilateral SMCs prolongs the duration and vice versa.Fifteen participants participated in the study. Each participant underwent 96 trials of anti-phase tapping task using bimanual index and middle fingers during recording whole-head scalp EEG. The first 16 trials were served as "No-triggered" session in which cues of motor task were given independent from EEG. Parameters for online estimation of coherence of bilateral SMC were determined from the data; For EEG signals around bilateral SMC that exhibited sensorimotor event-related desynchronization (ERD) in beta frequency band (14-30 Hz), phase-locking value (PLV) was predicted using autoregressive model in the following trials. During ready period (1 ± 0.5 s before movement onset), if online calculated PLV exceed or inferior to the 75/25 percentile of distribution from resting-state EEG, the auditory cue of finger tapping was presented to the participant (High and Low PLV condition, respectively). The duration of anti-phase bimanual tapping was quantified from the online acquired keyboard data. The pre-movement PLV and duration were subjected to Spearman's rank correlation test unless the normality of both variables were confirmed by the Shapiro-Wilk test.We found significant negative correlation between PLV in beta-band and duration (Spearman's rank correlation test, $p < 0.001$, $\rho = -0.70$), while the difference of the magnitude of bilateral ERD was not confirmed between high and low conditions (Two-way repeated measure ANOVA, $p = 0.61$, 0.59 main effect for "Condition" and "Hemisphere", respectively). Moreover, the correlation between the ERD magnitude and duration was not observed for the bilateral hemisphere (Right: $p = 0.95$, Left: $p= 0.81$, respectively). Collectively, not the local excitability but the inter-regional coupling would be the substrate to execute the bimanual asynchronous behavior, that underlies our sophisticated performance such as piano playing.

Title: Neuromuscular control of smartphone manipulation - selfie strain?

Authors: *P. ACHARYA[1], S. A. WINGES[2], A. W. VAN GEMMERT[3];
[1]Illinois Col., Jacksonville, IL; [2]Sport and Exercise Sci., Univ. of Northern Colorado, Greeley, CO; [3]Kinesiology, Louisiana State Univ., Baton Rouge, LA

Abstract: Taking 'selfies' has become common behavior among smartphone users. Such self-portrait photography requires individuals to hold their arm either in a fully extended position or slightly flexed at an elbow compared to the regular texting position. One study has shown that smartphone users maintain such posture frequently until a good photo is taken (Khanal et al. 2019). Such repetitive arm position for selfies could put excessive loading on the upper limb muscles and strain the elbow and wrist joint. The primary goal of this study was to understand the muscle loading generated when a smartphone was held and manipulated at two comfortable arm heights: shoulder and abdomen, by recording the 14 muscles of the upper limb. Participants pressed instructed keys in these two arm positions (heights) and moved at self-defined walking speeds (movement conditions). This study examined interaction effects among movement conditions and arm height on the muscle activity of the upper limb involved in this smartphone manipulation. It was hypothesized that when manipulating a smartphone device at the shoulder, there would be an increase in arm muscle activity to stabilize the arm and overcome the moment. Likewise, a significant increase in hand muscle activity when the device was manipulated at the shoulder compared to the abdomen was expected. Lastly, walking was expected to result in greater muscular activation patterns across both hand and arm muscles compared to standing when the device was held at the shoulder compared to the abdomen. We found that there was an effect of arm height on the muscle activity of the upper limb. The mean amplitude of surface EMG recorded for ECU, EPL, ED, BIC, TRI, ADEL, MDEL, PDEL, and RTRAP increased significantly when the hand was held at the shoulder position. In contrast, FDI, FCR, and LTRAP had higher amplitudes at the abdomen position. There was an absence of significant interaction effects of arm height and movement conditions for twelve muscles out of fourteen recorded muscles except for ECU and TRI muscles. From our observations, we concluded that the neuromuscular system generates a 'simple motor control strategy' specifying the necessary muscle activity to accomplish smartphone manipulation.

Title: The positive dimension of schizotypy is associated with both an impaired attenuation and discrimination of self-generated touch

Authors: *E. ASIMAKIDOU, X. JOB, K. KILTENI;
Dept. of Neurosci., Karolinska Inst., Stockholm, Sweden

Abstract: Self-generated touch feels weaker compared to externally generated touch of identical intensity (Bays and Wolpert 2008; Kilteni, Engeler, and Ehrsson 2020), and prevalent theories of motor control posit that attenuation arises because the brain predicts the sensory consequences of our voluntary movements (McNamee and Wolpert 2019; Wolpert and Flanagan 2001). Although somatosensory attenuation has been shown in 98% of healthy adults in a population-based cohort (Wolpe et al. 2016), it appears greatly reduced in patients with schizophrenia (Blakemore et al. 2000; Shergill et al. 2005, 2014) suggesting a failure to accurately predict self-generated touch. Here, we tested whether somatosensory attenuation in non-clinical individuals is related to schizotypy, a premorbid phenotype associated with increased liability for schizophrenia (Ettinger et al. 2014). One hundred volunteers participated in a psychophysics force discrimination task that quantified the perceived magnitude and discrimination ability of self-generated and externally generated tactile stimuli applied on their left index finger. Afterwards, participants completed the Schizotypal Personality Questionnaire (SPQ) (Raine 1991).
A significant negative relationship was found between the participants' somatosensory attenuation and their total SPQ score (Spearman's rho = −0.207, $p = 0.039$). This association was driven by the Cognitive-Perceptual SPQ factor (Spearman's rho = −0.256, $p = 0.010$), a factor that represents the positive dimension of schizotypy. Moreover, the Cognitive-Perceptual SPQ factor was associated with a reduced sensitivity for discriminating self-generated touches from externally generated touches (Spearman's rho = 0.331, $p < 0.001$). Furthermore, individuals with high scores in the Cognitive-Perceptual factor displayed significantly reduced somatosensory attenuation (Mann-Whitney test, $W = 775.5$, $p = 0.030$) and sensitivity for their self-generated touches (Mann-Whitney test, $W = 763.5$, $p = 0.042$) compared to those with low scores in the Cognitive-Perceptual factor.
Our results suggest that the Cognitive-Perceptual factor and by extension the positive dimension of schizotypy is associated with a reduced ability to attenuate and discriminate self-generated tactile stimuli compared to externally generated stimuli. Given that the positive dimension of schizotypy represents the analogue of positive psychotic symptoms, deficits in processing self-

generated tactile information could potentially serve as a bio-cognitive marker for early diagnosis and prevention of schizophrenia.

Title: Failure to Compensate: Nerve Injury Patients Use Their Injured Dominant Hand, Even When Their Non Dominant is More Dexterous

Authors: *B. A. PHILIP[1], M. R. THOMPSON[2], N. A. BAUNE[4], M. HYDE[1], S. E. MACKINNON[3];
[1]Occup. Therapy, [2]Psychiatry, Washington Univ. Sch. of Med., Saint Louis, MO; [3]Plastic and Reconstructive Surgery, Washington Univ. Sch. of Med., St. Louis, MO; [4]Rehabil. Med., Emory Univ., Atlanta, GA

Abstract: Compensation with the non-dominant hand (NDH) is critical for patients with irreversible chronic impairment of the dominant hand (DH) due to nerve injury, orthopedic injury, or stroke. However, it remains unknown how performance and behavior change after unilateral impairment of the DH, even among individuals with a healthy brain (i.e. peripheral nerve injury). We hypothesized that compensatory use of the NDH would depend on performance of the DH rather than the NDH, because current rehabilitation is not designed to encourage compensation. We addressed this question by studying adults with unilateral upper extremity peripheral nerve injury to the DH (n = 22, 15 female). This sample was recruited from all individuals with significant injury-related disability (Quick Disabilities of the Arm, Shoulder, and Hand score ≥ 18) in one outpatient rehabilitation clinic and one nerve surgery clinic. We measured hand usage (% of actions with each hand) via an unconstrained reach-to-grasp block building task, and dexterity via four subtests of the Jebsen-Taylor Hand Function Test. Most participants were more dexterous with their uninjured NDH than their injured DH (77%; mean laterality index -0.10 ± 0.26), but hand usage patterns did not differ from typical adults (p = 0.08). Compensatory use of the NDH was associated only with DH dexterity; not NDH dexterity, nor any other factor including rehabilitation, sex, injured nerve, or injury location. In other words, we confirmed our hypothesis that compensation would depend only on performance of DH, not NDH. Specifically, patients only compensated with their NDH if their DH was severely

injured, and compensation did not depend on whether their NDH was their more dexterous hand post-injury. Overall, most peripheral nerve injury patients with DH injury did not engage in compensatory use of the NDH, even when they might benefit from compensation, i.e. because their NDH became more dexterous. This demonstrates a persistent influence of hand preference despite peripheral nerve injury, and indicates the need to understand (and support) the neural mechanisms that could potentially allow people to compensate with the NDH.

Title: Bilateral reorganization of upper limb kinematics after traumatic brachial plexus injury

Authors: *L. A. LUSTOSA[1], A. L. SILVA[2], R. P. CARVALHO[3], C. D. VARGAS[1];
[1]Inst. of Biophysics Carlos Chagas Filho, Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [2]Grad. Program in Neurol. and Neurosci., Univ. Federal Fluminense, Niterói, Brazil; [3]Inst. of Hlth. and Society, Univ. Federal de São Paulo, Santos, Brazil

Abstract: Traumatic brachial plexus injury (TBPI) causes a sensorimotor deficit in upper limb (UL) movements, usually compromising shoulder muscle force. We hypothesized that the hand kinematics of both the injured UL and uninjured UL would be disturbed through changes in the arm-forearm intersegmental coordination. Individuals with TBPI (n=12) and controls (n=9) matched in age, gender, and anthropometric characteristics were recruited. Participants kept a standing position and held an empty cup with the UL relaxed beside the body. The movement of transport of the cup to the mouth and return to the starting position was recorded with the Vicon System. Reflexive markers were positioned in the shoulder, elbow, wrist and index finger. Hand kinematics was calculated based on index finger movement, and the arm-forearm dynamics (angular displacement and angular velocity) was measured by extracting the polar phase angle. Intersegmental coordination was measured as the relative phase (RP) between the arm and the forearm phase angles. Five TBPI participants scoring 3/5 in MRC in the injured UL biceps were

able to execute the task. TBPI participants exhibited a longer movement duration for both UL ($p<0.05$) and a lower peak velocity for uninjured UL when compared to controls ($p<0.05$). Shorter time to peak velocity was observed during transport in comparison to return ($p<0.01$). Area under the arm phase angle curve presented a difference for the injured UL during transport ($p<0.001$), and for the uninjured UL during return ($p<0.05$). We analyzed the RP in three different time windows based on hand movement (start, peak velocity, ending). RP analysis indicated more forearm use during the transport to mouth phase in the hand peak velocity for all groups ($p<0.001$). Furthermore, a greater arm use was found in the injured UL as compared to controls and to the uninjured UL ($p<0.001$). During the transport deceleration phase, a negative correlation was found between the time to peak velocity and the area under arm phase angle curve for the injured UL ($p<0.05$), contrasting to controls and the uninjured UL, in which time to peak velocity correlated with that of the forearm phase angle curve ($p<0.001$). In the return deceleration, the area under arm phase angle curve of the uninjured UL correlated positively with movement duration ($p<0.05$) and negatively with the peak velocity ($p<0.05$). These results suggest a more active control of the arm in the injured UL, modifying the natural UL coordination and causing a disturbance in the control of hand kinematics. Furthermore, the uninjured UL presented modifications in hand kinematics and arm dynamics, indicating that motor control of this limb is also affected by TBPI.

Title: A common template for neural reinforcement of finger individuation

Authors: *J. KILMARX[1], E. OBLAK[3], J. S. SULZER[1], J. A. LEWIS-PEACOCK[2];
[1]Mechanical Engin., [2]Psychology, Univ. of Texas at Austin, Austin, TX; [3]RIKEN Ctr. for Brain Sci., Wako, Japan

Abstract: Stroke is the leading cause of serious long-term disability and often results in lasting deficiencies in the strength and control of individual fingers. Functional MRI neurofeedback may

provide a useful tool to guide neuroplastic changes in the brain after injury to restore fine motor function. However, identifying an individualized neural training target in the presence of a neurological injury may not be possible. To address this issue, we have investigated the use of functional alignment, or *hyperalignment*, of brain data across healthy individuals to create an idealized neural template that can be used as a surrogate training target for new participants. We conducted an offline study of 17 healthy young adults who were engaged in a finger individuation task during an fMRI localizer session. For each individual, a support vector machine classifier was trained on the functionally aligned data of the 16 other participants. We found that the classification accuracy of individual finger presses significantly improved ($p < 0.001$) when group data was aligned based on function (88.8%) rather than conventional anatomy (46.0%). Furthermore, we have demonstrated that our functionally aligned template is robust to impaired finger presses. If a participant has a deficit in their ability to individuate a movement for one or two fingers, it is possible to infer the proper neural representation for those fingers from the surrogate template. To assess this, the data for one or two fingers was completely removed when aligning the left-out individual to the neural template. The neural representations for the removed finger(s) were then obtained by applying the transformation matrices from subject space to the common template space to the entire dataset with all fingers included. We found that the classification accuracy when one finger (80.6%) or two fingers (66.5%) were removed during functional alignment was still significantly better ($p < 0.001$) than anatomical alignment with all fingers included (46.0%). These results indicate that our functionally aligned template can provide an effective substitute neurofeedback training target for patients following neurological injury.

Title: The development of efficient communication in the human connectome

Authors: *D. VAN BLOOIJS[1,2], J. F. VAN DER AAR[1], G. J. M. HUISKAMP[1], G. CASTEGNARO[1], M. DEMURU[1], W. J. E. M. ZWEIPHENNING[1], N. E. C. VAN KLINK[1], P.

VAN EIJSDEN[1], K. J. MILLER[2], F. S. S. LEIJTEN[1], D. HERMES[2];
[1]Brain, UMC Utrecht, Utrecht, Netherlands; [2]Mayo Clin., Rochester, MN

Abstract: The development of rapid communication between different brain regions is essential for brain function. Post-mortem studies have shown that the myelination of white matter pathways starts in the late prenatal period and continues in late adolescence. MRI measurements have shown that pathways develop at different rates in different areas, often reaching a plateau around 30-40 years of age. These indirect measurements do not give quantitative information about how the transmission speed develops throughout development. Quantitative neurophysiological measurements of transmission speed in the developing human brain are essential to understand the maturation process of efficient communication that is necessary for brain functions like cognition and behavior. We collected data in 75 subjects, age 4 to 51 years, who were implanted with intracranial electrodes (electrocorticography - ECoG) to evaluate epilepsy surgery. The electrodes were positioned in MNI space and categorized in either frontal, parietal, temporal or sensorimotor sites. Adjacent electrode pairs were stimulated with ten consecutive pulses (1ms, 4-8mA, 0.2Hz), and we measured cortico-cortical evoked potentials (CCEPs) throughout the other electrodes. These CCEPs expose the underlying physiological networks. We calculated the latency of the initial negative potential deflection (N1-response) that occurs within 100ms after stimulation. We fitted distributions of latency as a function of age for all 16 combinations of these four brain regions. We found that the latency of the N1 decreased significantly with age, from ~40ms at age 4 years to ~25ms in adulthood. More detailed fits indicated that the transmission delay between cortical areas decreases with 0.23-0.88ms each year, until it plateaus around age 15-29 years old. These increases in speed were observed in both long and short range connections between and within frontal, parietal and temporal areas. The decreases in the N1 latency reveal that transmission speed in the human brain connectome increases about two-fold from childhood to adulthood. These measurements provide quantitative estimates of the development of efficient communication and can be used in large scale models of the human brain that bridge structural and functional development. With this study, we facilitate the construction of growth curves with velocities in the brain. This could be helpful in diagnosing abnormal development in cognition and behavior.

Abstract: Uncovering the neural basis of anesthesia calls for direct brain recordings. However, the most commonly used tool, electroencephalography, is largely driven by synchrony in widespread ensembles and may miss different types of local cortical activity. Simultaneous recordings from both scalp (EEG) and intracranial (iEEG) electrodes could provide a unique opportunity to understand combined local and ensemble neural activity underlying anesthesia. This opportunity presents itself in epilepsy patients undergoing invasive monitoring for seizure localization. Simultaneous EEG and iEEG activity was captured from 13 epileptic patients as they emerged from anesthesia. Spectral and complexity measures were calculated and compared before, during, and after emergence from anesthesia in both EEG and iEEG signals. Topological maps of spectral and complexity changes demonstrate the extent and timing by which different brain areas exhibit changes in activity during emergence from anesthesia. These findings provide a unique signature of the neural basis of anesthesia and may offer insights into mechanisms of human consciousness.

Abstract: Responsive neural stimulation (RNS) delivers electrical stimulation in a brain region in response to brain activity to treat neurological disorders. RNS directed at seizures and abnormal epileptiform activity proved to be successful in reducing seizures in drug resistant epilepsy, but efficacy optimization can be slow. There is ongoing interest in systems where stimulation paradigms and network targets are optimized adaptatively over time. Here we present a system where a cascade of detectors in implanted neural sensing and stimulation (INSS) device and a handheld device enabling machine learning seizure detection algorithms to adaptively control stimulation parameters and brain targets. We developed a system for multi-stage control over adaptive neurostimulation paradigms. The system utilizes an INSS with continuous real-time intracranial EEG (iEEG) recording and bi-directional communication with a handheld for off-device programmable control. The adaptive RNS settings on the INSS device engage multiple different network targets. In this application, the initial electrical stimulation targets detected hippocampal seizures. If the seizure activity continues despite the responsive stimulation for a specified time interval, the algorithm adaptively switches to a second network target with different stimulation parameters. The detected events are further evaluated by detection algorithms running on the handheld device and can alter the stimulation paradigm. We tested the detector cascade system in benchtop settings on 200 seizures and 6 interictal days using hippocampal iEEG previously recorded from 6 patients undergoing evaluation for epilepsy surgery. We measured performance of the second cascade detector which is engaged after initiation of the first detector and achieved 96% sensitivity and 99.5% specificity with 10.62 seconds average detection lag from seizure onset. The off-device detector was developed on large dataset from the NeuroVista study (5 dogs and 10 humans with more than 10 years of data). The detector was tested using data from 4 patients (181 seizures over 496 days in total). Our off-device detector improved the specificity up to 99.9% which enables more control over adaptive network stimulation. We developed and tested the RNS system with multi-stage control loop for

adaptive network stimulation. The system enables hypersensitive RNS targeting abnormal epileptiform activity that runs concurrently with a second INSS cascade detector for detecting seizures of a specified length and triggers RNS of a different network target. Deployment of the system to an INSS might prove useful in disrupting epileptogenic networks.

Title: Cortec brain interchange in freely behaving canine

Authors: *S. WORRELL[1], F. MIVALT[2], I. KIM[2], A. BELSTEN[5], P. BRUNNER[5], S. MESSINA[3], T. KAUFMAN[3], N. STAFF[2], D. HERMES[4], G. A. WORRELL[2], G. SCHALK[1], K. MILLER[1];
[1]Dept. of Neurosurg., [2]Dept. of Neurol., [3]Dept. of Neuroradiology, [4]Dept. of Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN; [5]Dept. of Neurosurg., Washington Univ., St. Louis, MO

Abstract: ***Objective:*** We report our initial experience with the CorTec Brain Interchange, a fully implantable bi-directional system for chronic nervous system tracking and interaction. Because

canines are large enough to accommodate devices designed for humans, they are a good model system for the preclinical research required to develop an implantable bi-directional system for tracking electrophysiology, implementing algorithms, and adaptive stimulation.
Methods: A healthy 24-month-old beagle (*canis familiaris*) named Laika was implanted with the CorTec Brain Interchange system. The CorTec Brain Interchange device features up to 32 channels for local field potential recording and electrical stimulation. Two grids (20 total channels) were implanted through bilateral craniotomies into the subdural space spanning frontal and parietal canine cortex. The subdural grid electrode tails were tunneled to the shoulder, adjacent to the scapula, and connected to the internal electronics unit. The internal electronics unit in the shoulder inductively couples via a telemetry wand to an external interchange box for data streaming onto a computer using BCI2000 (1kHz Sampling Rate, Dynamic Range 0.5 - 450 Hz). Local field potentials were obtained in three different activities as ascertained by simultaneous video: 1) quiet wakefulness 2) movement and 3) sleep. The power spectral density in the three activities were analyzed. The LFP signals were segmented into 10-second-long epochs. The data were then filtered by a 0.5-200 Hz band-pass filter, and power spectral density (PSD) was estimated using Welch's method for each 10-second-long epoch.
Results: The CorTec Brain Interchange system provided continuous data streaming that was only limited by the ability to maintain a physical connection between the magnet in the implant and the magnet in the coupling device of the telemetry wand. Recordings of up to 30 minutes in duration were obtained. The PSD for the 3 activities showed spectral changes enabling differentiation of wake, movement, and slow-wave sleep.
Conclusions: These preliminary results demonstrate the feasibility of continuous streaming of cortical electrophysiology in a behaving canine with the CorTec Brain Interchange. Simple spectral measures were shown to identify behavioral state, wake, and sleep. Future plans include further engineering refinements for reliable coupling of the device, reduction of artifact, and the ability to stimulate. All of these are required for a clinical brain computer interface trial in humans, and this technical experience represents a meaningful step toward this.

Title: A case study for tracking verbal memory performance during anterior nucleus of the thalamus stimulation in patients with epilepsy

Authors: *V. S. MARKS[1], V. KREMEN, JR[2,6], V. SLADKY[3,7], J. DOLEZAL[6], B. BRINKMANN[4], T. PAL ATTIA[4], M. T. KUCEWICZ[2,8,5], G. A. WORRELL[3,5];
[1]Mayo Clin. Grad. Sch. of Biomed. Sci., Rochester, MN; [2]Neurol., [4]Dept. of Neurol., [5]Dept. of Physiol. and Biomed. Engin., [3]Mayo Clin., Rochester, MN; [6]Czech Tech. Univ. in Prague, Prague, Czech Republic; [7]Intl. Clin. Res. Ctr., St. Anne's Univ. Hosp., Brno, Czech Republic; [8]Gdansk Univ. of Technol., Gdansk, Poland

Abstract: Verbal memory complaints are common in patients with temporal lobe epilepsy (TLE). The impact of therapeutic electrical brain stimulation on memory can be difficult to disentangle from seizures. Verbal memory encoding and recall abilities can be probed with a simple free recall task and can provide objective measures of memory function. The purpose of this study was to investigate the changes in human verbal memory performance while receiving chronic electrical stimulation to bilateral anterior nucleus of the thalamus (ANT) as a therapy to reduce seizures in a patient with drug resistant TLE. Recordings were obtained from a patient with drug resistant epilepsy implanted with an investigational Medtronic Summit RC+S™ sensing and stimulation device. As patient seizure diaries are notoriously inaccurate, the patient's intracranial electroencephalography (iEEG) was analyzed for seizures to create a gold standard seizure diary. The verbal memory tasks were performed by the ambulatory subject living in their home environment with iEEG and behavioral data streamed to a handheld device and cloud repository. The participant was presented with lists of words on a handheld tablet screen for a delayed test of free recall. Lists were composed of 12 randomly chosen nouns. After a distractor task, the participant was asked to recall as many of the words as possible. The participant completed 33 independent sessions over 18 months with 15 lists per session for 5940 total word presentations. We were then able to compare changes in verbal memory score to the patient's seizure frequency changes during therapy. Using Pearson's Correlation Coefficient, we found that memory performance and seizure frequency had a significant negative correlation (Pearson's Correlation Coefficient $r = -0.4396$, $p = 0.0105$). While these results are for one patient, they are promising, and they demonstrate the feasibility of dense cognitive tracking in ambulatory patients. Emerging devices for electrical stimulation of the brain enabling smart sensing and continuous streaming of the iEEG data enable long-term investigation of underlying brain dynamics during cognitive tasks. This case study shows that a simple verbal memory task may provide a suitable measure for tracking a therapy's impact on memory and it's relationship with seizures.

Title: New Depths in Human Brain-Computer Interfacing

Authors: *K. MILLER[1], D. HERMES[1], A. BELSTEN[2], P. BRUNNER[2], G. A. WORRELL[1], G. SCHALK[1];
[1]Mayo Clin., Rochester, MN; [2]Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Implanted brain-computer interfaces (BCIs) have, to date, measured from the brain's convex surface to identify control signals. However, the circuitry of cognition and behavior is distributed throughout the brain volume. Nuanced applications for BCI will need to engage circuit nodes from the depths of the brain where they are located. Intracranial implanted electrode monitoring for epilepsy with penetrating stereoelectroencephalography (SEEG) has enabled our team to study the electrophysiology of behavior and BCI from the brain's depths. We recorded SEEG electrophysiology during movement and movement imagery of the tongue, foot, and hand of 5 epilepsy patients, aged 6 to 36 (2 females). Movement and imagery associated broadband spectral changes from the SEEG measurements were used for simple ball-target BCI feedback and imagery-based application control of the video game Galaga. Robust maps of movement and imagery-based brain activity were identified in primary, premotor, insular, and supplementary motor cortical areas. Recordings from the sulcal depths were used for robust control of the BCI feedback task (peak accuracies 92-100%) and the Galaga video game.

A) SEEG measures from motor sites at sulcal depths. **B)** Power spectrum from the sulcal base of primary motor cortex (pink arrow in E) during hand movement and rest. **C&D)** Low frequency beta (12-20Hz) power decreases (C) and high frequency broadband power increases (D). **E)** Sagittal slice with electrodes within 6 mm of this slice allows viewing broadband power increases on the surface and at depth. Abstract: Objective: Seizures are a consequence of abnormal brain network excitability. Two fundamental electrophysiologic biomarkers of epilepsy and network excitability, interictal epileptiform spikes (IES) and seizures, show circadian patterns supporting behavioral state modulation of brain excitability. The circadian patterns of seizures and IES in mesial temporal lobe epilepsy (mTLE), however, differ as seizures show daytime peaks and IES show nocturnal peaks in occurrence. Methods: We investigated this paradox in mTLE brain excitability using a chronically implanted device enabling continuous intracranial EEG (iEEG), wireless data streaming, and electrical stimulation in four patients with electrodes targeting two key mTLE network nodes, the hippocampus (Hc) and anterior nucleus of the thalamus (ANT). Automated sleep staging, IES rates, and seizure detection iEEG classifiers provided dense behavioral state and brain excitability tracking. The Hc evoked responses to continuous ANT electrical stimulation were used to track ANT-Hc network excitability over multiple months in ambulatory subjects living in their natural environments. Results: Consistent with prior literature, seizure probability was highest during the day and average IES rates were highest at night. In particular, seizures had a daytime bimodal peak, increased in the morning and evening whereas IES had a unimodal nocturnal peak during non-REM slow wave sleep. Using continuous behavioral state, IES, seizure, and ANT-Hc evoked potential tracking, we show that mTLE seizures are increased in wakefulness, while IES are increased in slow-wave sleep. Tracking ANT-Hc evoked potentials we show that the ANT-Hc evoked responses have shorter latency in wakefulness relative to slow wave sleep, suggesting that limbic network excitability and connectivity are reduced in slow-wave sleep. Conclusion: We hypothesize that increased local Hc excitability in slow-wave sleep, as demonstrated by increased spike rates, is not associated with increased seizure probability due to reduced long-range limbic (ANT-Hc) effective connectivity. This reduced limbic effective connectivity in slow wave sleep may suppress the broader network activation required for initiation and propagation of mTLE seizures. These results help clarify a standing paradox of Hc excitability and seizure occurrence in mTLE and provide insights to the mechanism of therapeutic electrical brain stimulation. Furthermore, the ability to effectively track brain network connectivity and excitability in behaving humans may prove useful for adaptive electrical brain stimulation to improve electrical brain stimulation efficacy.

Title: Signatures of electrical stimulation driven network interactions in the human limbic system

Authors: *A. OJEDA VALENCIA[1], N. M. GREGG[2], G. A. WORRELL[3], B. N. LUNDSTROM[2], B. H. BRINKMANN[2], J. J. VAN GOMPEL[4], K. J. MILLER[4], D. HERMES[1]; [1]Physiol. and Biomed. Engin., [2]Neurol., [4]Neurologic Surgery, [3]Mayo Clin., Rochester, MN

Abstract: The human limbic network is involved in emotional and memory processing. Understanding its dynamics is important to better understand several clinical conditions, such as epilepsy and related psychiatric co-morbidities, and it is often targeted with therapeutic brain stimulation. To further understand the basic dynamics in this network, single-pulse electrical stimulation (SPES) can be delivered to various limbic substructures, and cortico-cortical evoked potentials (CCEPs) can be measured in other regions to assess network effective connectivity. Typical CCEP responses have been described as either an early surface negative deflection within 10-50 ms (N1) or as a later slow-wave within 80-250 ms (N2). We investigated whether the limbic network evoked responses after SPES follow the same profile. Seven patients with drug-resistant focal epilepsy who had stereotactically-targeted invasive EEG electrodes implanted for clinical purposes participated in the study. SPES was delivered through pairs of adjacent electrodes to limbic network substructures (hippocampus, amygdala, thalamus, posterior and anterior cingulate, and parahippocampal gyrus) ~10 times every 3-5 sec with 200 microsec square wave pulses of 6 mA. The electrodes studied were not involved in spontaneous seizure generation. Robust CCEPs were observed throughout the limbic system. Many evoked potentials had profiles outside the typically reported N1/N2 deflections. Stimulation of hippocampus and amygdala elicited prominent CCEPs in the posterior cingulate gyrus (PCG) across all patients, and responses in the PCG were more often observed and had larger amplitudes compared to responses in the anterior cingulate gyrus. However, these responses in the PCG did not follow typical N1/N2 shape, but showed a unique electrophysiological signature of 3 to 4 repetitive deflections within ~500-600 milliseconds. These data demonstrate that limbic network CCEPs cannot be fully described by amplitude and latency of one particular feature, but that different networks may show complex response patterns and interactions. Characterizing these different CCEPs waveforms can be relevant to better understand the dynamics of the limbic system and its implication in clinical states such as epilepsy.

Title: A framework to characterize sources of stereotactic error in neurosurgical electrode implantation

Authors: *M. JENSEN[1], K. J. MILLER[2];
[2]Neurosurg., [1]Mayo Clin., Rochester, MN

Abstract: Title: A framework to characterize sources of stereotactic error in neurosurgical electrode implantation Michael A. Jensen and Kai J. Miller **Introduction:** Understanding the sources of error in stereotactic systems is paramount to the progression of functional neurosurgery. A centralized framework is a necessary component to identify these sources. **Objectives:** In order to define sources of error, we identified common sources of error, categorized them, and applied them to the different stereotactic systems used by modern neurosurgeons. That is, each system has a unique set of sources of error derived from this framework, but not each source of error will apply to each system. No such framework currently exists. **Methods:** We created a list of targeting systems reported in the recent neurosurgical literature: ROSA®, Mazor Renaissance™, Starfix (FHC) ™, Nexframe®, Clearpoint®, and Leksell®. We reduced each system to its most basic description (such as entry versus target deviations), and subsequently identified common sources of error (table 1). Within this framework, sources of error were categorized as stochastic or systematic. For systematic errors, we attempted to describe the source of error and how this error will manifest intraoperatively and in post-operative imaging. **Results:** We describe and illustrate the details of this framework applied to each of the stereotactic system. Each system is individually characterized and we discuss the unique framework-based score held by each. This framework describes each error type, and we discuss what might be done by surgeons to limit this error in their practice. We discuss why a generalized framework is crucial to driving both innovation in these systems' designs and improvement in stereotactic accuracy. **Conclusion:** This framework provides a simple rubric by which to analyze the sources of error for each of the most prominent stereotactic systems in use. This allows for ease and continuity of analysis between systems, across surgical centers, as well as a shared means to describe stereotactic error.

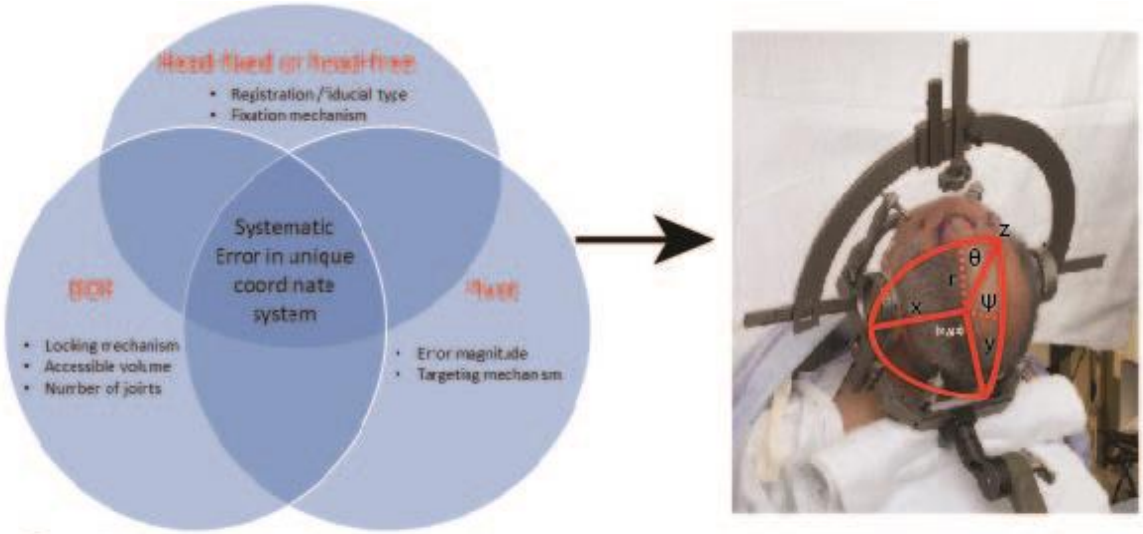

Figure 1. Left: Ven diagram demonstrating the three fundamental questions of our framework along with which fundamental characterstics that can contribute directly to systematic error. Answering all three qestions leads to a coordinate system(s) of best fit for the system being analyzed. Right: Leksell frame with superimposed Cartesian and Spherical Coordinate Systems.

Title: The interplay between oxytocin and CB1 receptors within the mesolimbic and limbic brain structures of rats followed by the effects of chronic oxytocin intranasal administration in acute exercise and stress

Authors: *P. MUÑOZ-RODRÍGUEZ, J. M. PADILLA-ESCALONA, L. RODRÍGUEZ-SANTOS, A. P. RAMOS-ROLÓN, W. NORZE, V. M. SCHLEIER, M. C. APONTE-REYES, A. I. RODRÍGUEZ-LEÓN, A. ACEVEDO-JETTER, C. S. MALDONADO-VLAAR;
Univ. of Puerto Rico, Rio Piedras Campus, San Juan, PR

Abstract: Oxytocin (OT) is a neuropeptide associated with social behaviors, stress responses, and drug addiction. A previous study showed a cross-talk between the cannabinoid Type 1 receptor (CB1R) of the endocannabinoid system (ECS) and oxytocin receptors (OTR) within the mesolimbic system to modulate anxiety-like behaviors. Several studies support that intranasal oxytocin administration and voluntary wheel running are treatments endowed with anxiolytic properties. Other studies demonstrated that ECS is crucial for voluntary wheel running performance. OTR and CB1R within the limbic, mesolimbic, and endocrine systems are associated with anxiolytic responses. The purpose of this study was to examine whether OT intranasal pretreatment enhances voluntary wheel running behaviors and potentiates the anxiolytic properties of exercise in Sprague-Dawley male rats. Animals were divided into two groups, the first group received intranasal infusions of OT 0, 1 μg, 20 μl before being exposed to the running wheel two hours daily for 10 consecutive days. The second group received the same dose of OT or vehicle and was not exposed to the running wheel. The results indicated that the rats treated with OT exercised more than those that received the vehicle. Using the Light and dark box as a behavioral paradigm to measure responses related to anxiety, we found that rats treated with OT and acute exercise showed a decrease in anxiety-like behavior. We measure the OTR and CB1R expression within the paraventricular nucleus (PVN), amygdala (AMG), nucleus accumbens (NAc), and the ventral tegmental area (VTA) in order to examine the potential cross-talk between oxytocinergic and the endocannabinoid systems as mediators of the anxiolytic response and exercise performance. Biochemical assays showed a co-expression between the CB1 and OT receptors within the NAc. Additionally, the trend of the CB1Rs expression in each group remained the same for all the areas we examined (AMG, VTA, NAc, and PVN). Studying the physiological and behavioral changes of each of these groups allows us to have a better understanding of which would be the most effective anxiolytic treatment for people with a sedentary or physically active lifestyle. Future biochemical studies are required to examine the potential cross-talk between OT and the ECS as mediators of the anxiolytic response and exercise performance and, the implications it can have as a treatment for drug addiction, sedentary lifestyle, and anxiety disorders.

Title: Swimming exercise counteracts acute stress-induced neurobehavioral impairments via hippocampal FNDC5/BDNF pathway

Authors: *M. JODEIRI FARSHBAF[1], A. KUMAR MONDAL[1], T. IYER[2], K. GOLDINAK[2], P. KEYEL[1], K. ALVINA[2];
[1]Texas Tech. Univ., Lubbock, TX; [2]Univ. of Florida, Gainesville, FL

Abstract: Stress is a powerful stimulus that can change the structure, function, and activity of the brain. Depending on the type of stress—acute or chronic—the CNS shows a wide range of behavioral and physiological changes. The hippocampus is one of the most vulnerable regions of the brain to stress, as hippocampal functions such as emotion, spatial navigation, and memory are heavily influenced by stress. On the contrary, physical exercise has wide beneficial effects on physical and mental health, including minimizing the symptoms of neurological diseases such as Alzheimer's and Parkinson's diseases (AD and PD). Myokines, which are secreted from skeletal muscles during exercise, are thought to strengthen the muscle-brain axis. One example is Fibronectin Type III Domain Containing 5 (FNDC5), myokine that is abundantly expressed in skeletal muscle and brain, and that induces brain derived neurotrophic factor (BDNF) expression in the hippocampus after exercise. BDNF has crucial role in memory formation and decreased by psychological stress. Based on our previously published data showing that FNDC5/Irisin can counteract stress, we now tested the hypothesis that swimming exercise can suppress acute stress-induced neurobehavioral impairment by impacting hippocampal FNDC5/BDNF pathway. To test our hypothesis, we exposed male mice to daily swimming exercise for 20 days. 24h after last swimming session, mice were subjected to acute restraint stress for 3h while being probed in our combined OFT/NOR test. Our analysis showed that acute stress had no impact on anxiety-like behavior and short-term memory in exercised male mice, while the sedentary group showed increased anxiety-like behavior and short-term memory impairment after acute stress. We also found that swimming exercise increased FNDC5 expression in skeletal muscle and hippocampus. Furthermore, BDNF as downstream target of FNDC5, showed higher expression in the hippocampus of exercised mice. We also revealed an important connection with the Akt pathway in the hippocampus, all changes that were not observed in the prefrontal cortex. Taken together our results showed swimming exercise can promote resilience against acute stress in male mice. Also, our result support the idea that exercise has the potential to stimulate the maintenance of healthy neural function.

Title: Differential cortical monoamines release during exercise in rats chronically implanted with microdialysis probes

Authors: *C. G. GERIN[1,2];
[1]Neurosci., SOM-UTRGV, Edinburg, TX; [2]Physiologie, CNRS, Faculté de Médecine Grange-Blanche, Lyon, France

Abstract: Physical exercise is known to positively influence mood, to reduce anxiety and to improve reaction to stress. Cerebral monoaminergic systems are thought to underly the neurochemical influence of exercise on mood and behavior. We hypothesized that beneficial effects of exercise can be shown by variations of neurotransmitters release in the cerebral cortex. We aimed at demonstrating that there is a temporal relationship between release of plasma and cerebral monoamines (A, NA, 5-HT, DA) and spontaneous running exercise in rats.Ten Spague Dawley rats (250 g) were chronically implanted (for up to 39 days) with a left common carotid cannula and a bilateral fronto-parietal transverse microdialysis probe. Blood and microdialysate were sampled 7 and 15 days after surgery. Sampling occurred for a total 180 minutes (divided in 20 minutes samples) during a one hour each period: Rest, treadmill exercise (80%V_{O2}max), and post-exercise rest. One animal was used for *in vivo* microdialysis recovery study. Seven animals were used for monoamines studies. Results showed: (1) that the development of the rat head device allowed sampling in an unrestrained running rat; (2) the permeability and functionality of carotid cannulas and microdialysis probes for up to 39 days in chronic implantation; (3) NA release increase at the end of exercise (100-120 min) and during the post-exercise rest period (120 to 180 min); (4) a significant DOPAC increase of 36% during exercise and of 58.3% during post-exercise rest when compared to rest. Post-exercise DOPAC increase was of 15.5% when compared to exercise; (5) that 5-HIAA did not vary at any time point. These findings indicate that spontaneous exercise specific stress induces DOPAC extracellular increase resulting from DA neuronal terminal release in layers IV and V of the fronto-parietal terminal field cortex. Differences between DA, NA, 5-HT release might be due to synaptic arrangements or to differences in the actual release of NT and in neural paths evoked during acute exercise. Abbreviations: A: Adrenaline, NA: Noradrenaline, DA: Dopamine, DOPAC: 3,4-Dihydroxyphenylacetic acid, 5-HT: 5-Hydroxytryptamine or Serotonin, 5-HIAA: 5-hydroxyindoleacetic acid, NT: Neurotransmitter. Acknowledgement: Author thanks Dr. L. Peyrin for advising this experimentation.

Title: Effects of environmental enrichment on emotional regulation in C57BL/6J mice

Authors: *A. C. BASU, M. E. CRONIN, L. AMEZCUA, E. R. MONTANARI, R. M. PRICE, V. D. VU;
Col. of the Holy Cross, Worcester, MA

Abstract: Etiological studies of neuropsychiatric disorders depend on the use of animal model systems to experimentally test the effects of putative risk factors. Environmental Enrichment (EE) affects behavior, cognition, neuroanatomy, and physiology in laboratory rodents, a fact that has implications for the design and interpretation of studies, and the ability to detect subtle effects of genetic manipulations. Previous findings by our research group (Hendershott et al., 2016) suggested that EE reduces anxiety-like behavior in mice, but did not conclusively rule out confounding effects on locomotor activity. In this study, we attempt to further characterize the effects of EE on emotional regulation in 72 male and female C57BL/6J mice by administering a battery of behavioral tests that implicate neural systems associated with emotional response and for which there are benzodiazepine-validated anxiety-like outcome measures: open field, grooming assay, marble bury, stress-induced hyperthermia, social ethogram, and novelty suppressed feeding. There were no significant effects of sex or housing in the benzodiazepine-validated outcome measures in the open field, grooming, or marble bury tests. There was a sex difference in novelty suppressed feeding, with females exhibiting significantly shorter latencies to feed than males. The stress-induced hyperthermia assay revealed a significant effect of sex with males exhibiting high hyperthermic responses to females, and a significant effect of housing with mice reared with EE exhibiting high hyperthermic responses relative to standard housed mice, suggesting that HPA axis regulation is affected by environmental enrichment. The interpretation of this result as an anxiety-like outcome would not be consistent with the negative results of the tests of anxiety-like behavior in the same animals. Analysis of the social ethogram is still underway.

Title: Cortical thickness in patients with Obsessive Compulsive Disorder: a study by Magnetic Resonance Imaging

Authors: *C. ROSALES MONDRAGÓN, E. H. PASAYE ALCARÁZ, S. ALCAUTER SOLORZANO, A. REYES AGUILAR;
Inst. De Neurobiología, UNAM Inst. De Neurobiologia, Queretaro, Mexico

Abstract: Introduction: Traditionally, OCD has been described as a pathological condition in which the patient experiences intrusive, repetitive and uncomfortable thoughts that can become disabling (obsessions). Later, they resort to certain behaviors or rituals that tend to reduce the feeling of anxiety caused by these thoughts (compulsions). Worldwide, they have found alterations in the amount of gray matter of different structures of patients with obsessive compulsive disorder. The present study aims to measure the cortical thickness and the morphometry of the gray matter, focusing mainly on the cortico-striato-thalamus-cortical circuit in OCD patients with washout and revision dimension and a control group. **Material and methods:** A comparative study was carried out between 23 patients with OCD (10 scrubbers and 13 reviewers) and 23 HC. The images were acquired by means of a G.E. 3.0 T magnetic resonator. In order to carry out the measurement of cortical thickness and the statistical comparison, FreeSurfer and its statistical tool QDEC were used. To perform the morphometry, the structural data were analyzed with FSL-VBM. For the analysis of the volumetric the statistical program IBM SPSS Statistics was used. The comparison of means was carried out by means of the one-way ANOVA, subsequently, a Pearson correlation test was used, in order to identify a linear relationship between the severity index and the volume variable in the different structures under study. **Results:** We found a statistically significant reduction in the density of gray matter in the ventral face of the occipital lobe was found bilaterally, decrease in the density of the anterior lobe of the cerebellum at the level of the predominantly left bilateral quadrangular lobule. A significant increase in the density limited to the medial aspect of the left postcentral gyrus was also found. Also we found a statistically significant linear association was moderately and inversely proportional ($r_P = -0.513$, $p < 0.05$) between the score of the severity index of the patients and the volume gray matter of the left globe pallidus. **Conclusions:** The present results suggest an important role of the cerebellum in the pathophysiology of OCD. In addition, it would link the condition of the globe pallidus within the cortico-striato-thalamus-cortical circuit with the severity of the symptoms, forming part of the anatomical abnormalities involved in the pathophysiology of OCD. However, studies with larger samples are still needed to corroborate these findings. **Acknowledgments:** to the CONACyT, to the Institute of Neurobiology, to the National Laboratory of Magnetic Resonance Imaging (LANIREM).

Title: Interaction between the hypothalamic pituitary adrenal (HPA) and thyroid (HPT) axes during immobilization stress

Authors: H. J. KADHIM[1], **P. J. STRAIGHT**[2], *W. J. KUENZEL[2];
[1]Vet. Med. Col., Univ. of Thi-Qar, Nasiriyah, Iraq; [2]Poultry Sci. Dept., Univ. of Arkansas, Fayetteville, AR

Abstract: Food deprivation (FD) and immobilization (IM) stress have been utilized to determine the sequence of gene activation within the avian HPA axis that includes the septal nucleus of the hippocampal commissure (NHpC), hypothalamic paraventricular nucleus (PVN), anterior pituitary (APit), and adrenal gland. FD or IM stress resulted in an upregulation of corticotropin releasing hormone receptor 2 (CRHR2), located on thyrotropes within the chicken APit, suggesting that stressors not only activated the HPA axis, but stimulated the thyroid axis as well. Therefore, an experiment was designed to study the effect of an IM stressor on gene expression of thyrotropin-releasing hormone (TRH) and its receptors (TRHR1 and TRHR3), urocortin (URO3), deiodinase 2 (DIO2), and a recently discovered second type of CRH named CRH 2 within the neural component of the avian HPA axis. Additionally, TRHR1 and TRHR3, TSHβ and DIO2 mRNA expression were determined in the APit. Male broiler chicks, 5 weeks of age, were divided into six groups, n = 10/trt. Group one was unstressed controls, while 5 groups formed stress groups immobilized for different time periods: 15m (m=minutes), 30m, 60m, 90m, and 120m. Immediately after IM, blood, brain and APit were sampled. Brains were cryosectioned, and the NHpC and PVN were dissected. Total RNA was extracted from the NHpC, PVN, and APit, and cDNA was synthesized for qPCR. Results showed significantly increased CORT levels in all stressed groups. TRH gene expression data displayed significant increases at 90m and 120m of IM in the PVN and at 120m of IM in the NHpC. Of interest, URO3 mRNA showed no significant increase in the PVN, however, a 3-fold increase occurred at 15m in the NHpC. Importantly, CRH2 mRNA showed a 3-fold increase in the NHpC at 60m, 90m, and 120m of IM while the PVN displayed a modest increase only at 120m. TRHR1 mRNA at 15m and TRHR3 mRNA at 60m and 90m were significantly elevated in the NHpC with no significant increases displayed by either receptor in the PVN. DIO2 mRNA was significantly upregulated solely at 60m of IM in the NHpC. At the APit level, TSHβ, TRHR1 and TRHR3

gene expression were significantly upregulated from 15m to 120m treatments of IM stress. Results suggest that an activation of the avian HPA axis using IM stress also stimulates the HPT axis based primarily upon significantly increased gene expression of TSHβ in the APit. However, it appears not due to increased TRH mRNA from two neural structures examined: the NHpC nor PVN. A prime neuropeptide is CRH that showed a significant increase in gene expression following IM that was associated with increased CRHR2 expression within the APit. Other candidates included CRH2 and URO3 peptidergic neurons.

Title: The neural circuit of enhanced post-traumatic threat detection

Authors: *A. RITTER, O. KLAVIR;
Sch. of Psychological Sci., Univ. of Haifa, Haifa, Israel

Abstract: Anxiety disorders in general and posttraumatic stress disorder in particular are associated with heightened levels of arousal. The current work is aimed at investigating the neural networks which regulate threat detection, and their malfunctioning after traumatic experiences. Specifically, we are interested in the neural activity in the cortico-basal ganglia related circuits which may facilitate threat detection by inhibiting the nigro-tectal pathway including the substantia nigra and its connection to the superior colliculus (SC). The striatum as the main input of the basal-ganglia receives dense projections from the medial prefrontal cortex (mPFC). Trauma-related mPFC activity potentially allows the introduction of affective information into the basal-ganglia to modulate the threat detection system and the behavioral responses to threat. Thus, we are investigating alterations in threat detection top-down control as executed by the mPFC, both as it projects directly onto the SC, and indirectly via the striatum and the nigro-tectal pathway. We combine in-vivo electrophysiology and optogenetics together with a behavioral assessment of threat detection in a mouse, 7 days and 21 days after an inescapable electric foot shock. We use a newly developed task, involving a randomly moving robotic bug (robo-beetle), creating incidental interactions with the mouse in a testing arena. In this exploratory investigation, we found, significant differences in fear related behaviors, such as altered timing and distance of avoidance and escaping onset, higher fleeing velocities following an anticipated contact with the robo-beetle and overall, more instances of fear related actions

following the inescapable foot shock. This was measured before the shock, 7 days, and 21 days post shock. Most SC recorded neurons (n=1730) show a firing pattern change which precede fleeing onsets by a few milliseconds, suggesting direct involvement. This change is correlated with both the magnitude and temporal nature of fleeing behavior. Additionally, SC neurons, receiving the different routes of mPFC inputs, respond to different types of fear behavior, suggesting a complex circuit of control and balance, involved in changing threat detection and provoked action after a traumatic event.

Title: Stress-mediated cellular mechanisms of allostasis regulate mitochondrial bioenergetics

Authors: *N. KANYUCH[1], J. CHAN[3], C. P. MORGAN[6], C. MANNELLA[4], N. YADAVA[5], T. L. BALE[2];

Abstract: Reproductive and developmental outcomes are impacted by parental lifetime experiences including stress, trauma, and infection. In males, cellular reprogramming of reproductive tissues in response to stress poses an intriguing model to examine cellular allostatic mechanisms contributing to lasting post-exposure effects. At the epididymis, sperm receive essential maturation signals via extracellular vesicles produced by epididymal epithelial cells (EECs). Our previous work in mice demonstrates that the content of these signals is altered following chronic stress and that these persisting changes are causal in post-conception neurodevelopmental outcomes. However, the mechanism by which past stress experiences alter the basal EEC set point to maintain these lasting changes is unclear. The glucocorticoid receptor (GR) is a key regulator of the stress response and known target involved in allostasis. To test the hypothesis that stress-dependent EEC programming involves GR, we exposed mice with EEC-

targeted reduction of GR (GR^{Het}) to chronic stress followed by 12 weeks of recovery and evaluated the intergenerational transmission of stress by assessing offspring. In fact, GR^{Het} expression in sire EECs eliminated the offspring neurodevelopmental phenotype. Transcriptomically, genes differentially expressed between wildtype and stress GR^{Het} EECs accounted for two very large clusters of co-regulated genes (over 400 and 1200 genes, respectively) related to chromatin-modifying and mitochondrial processes identified by functional annotation analysis. To further investigate the impact of stress on allostasis, we utilized corticosterone exposure in an *in vitro* EEC model of stress. We identified significant transcriptional downregulation by RNA-sequencing six days after recovery from stress treatment suggesting the involvement of a repressive mark. Using CUT&RUN sequencing, a high efficiency epigenetic profiling approach, we probed the distribution of the transcriptional repressor, H3K27me3. Indeed, we found a robust increase in H3K27me3 at over 7000 peaks following stress treatment. Gene set enrichment analysis of the associated genes revealed associations with mitochondria. Given these data, we assessed the capacity of GR to program basal mitochondrial respiration by cell-based respirometry. While prior stress treatment decreased basal respiration after recovery, GR reduction by targeted shRNA protected against this change. Together, these studies demonstrate a vital role for GR at the intersection of the epigenetic and metabolic consequences of stress to regulate a sustained change in the cellular allostatic set point.

Title: Programming the postnatal mitochondrion: long-term effects of prenatal stress on brain metabolism and behavior

Authors: *B. ROBERTSON[1], E. GORMAN-SANDLER[1], A. CROCKETT[1], J. CRAWFORD[1], D. JOYNER[1], F. HOLLIS[1,2];

Abstract: Mitochondria are dynamic, energy-supplying organelles that utilize 20% of the body's energy to support critical brain processes. Thus, deficits in mitochondrial energy could have detrimental effects on an individual's health. Indeed, mitochondrial deficits have been associated with several neuropsychiatric disorders including depression and anxiety. Furthermore, we have previously identified a link between individual differences in adult brain mitochondrial function, trait anxiety, and social behavior. However, it is unclear how these individual differences in brain mitochondrial function develop. We hypothesized that experiences in early life might induce long-term alterations in brain mitochondrial function that drive behavioral responses in adulthood. To test this hypothesis, we investigated whether early life experiences can program mitochondrial brain function through exposure to prenatal stress. We exposed pregnant outbred Wistar rats to chronic mild unpredictable stress or control conditions during gestational days 10 through 20. Following birth, we assessed offspring for social, anxiety- and depressive-like behaviors at different developmental timepoints beginning at postnatal day 4 through adulthood. Using high-resolution respirometry, we measured mitochondrial function in the cortex immediately following behavioral assays such as ultrasonic vocalizations, play behavior, and the forced swim test. Our findings indicate that exposure to prenatal stress had notable and sex-specific effects on the postnatal mitochondrion that correlate with differences in offspring behavior, highlighting interactions between prenatal experiences and long-term mitochondrial development.

Title: Prenatal stress: comparing three models on embryonic cortical interneuron outcomes

Authors: *S. V. MAURER, B. A. KELVINGTON, B. HING, H. E. STEVENS;
Univ. of Iowa, Carver Col. of Med., Iowa City, IA

Abstract: Background: Prenatal stress is associated with increased risk of autism and schizophrenia, disorders in which abnormal development and function of cortical interneurons are implicated. Prenatal restraint stress as well as other rodent models of stress lead to broad activation of maternal stress physiology and are translatable to human psychosocial stress. However, consistency across models in impacts on cortical interneurons, which would be expected from common mechanistic pathways, has not been demonstrated. The current work compares three prenatal stress models and their effects on cortical interneuron development.

Methods: CD1 female mice were mated with GAD67-GFP+ CD1 males. Dams were randomly assigned to four experimental groups: control without stress (Ctrl), restraint stress (RS), chronic unpredictable stress (CUS), or foot shock stress (FS). Stress was administered for 45 minutes, 3-4 hours apart, three times daily on embryonic days 12 and 13 (E12 & E13), and once more on the morning of E14. Embryo tissues were collected on E14 one hour after the last stress session. One male and one female per litter was assessed for each outcome. GFP+ offspring brains were fixed, sectioned, immunostained for GFP, and assessed with digital microscopy blind to condition. GAD67GFP+ interneuron progenitor migration was measured as the length of the GFP+ cell migratory path in the cortical pre-plate as a proportion of total cortical surface length. RNA was isolated from GFP- ventral forebrains, cDNA was synthesized, and qPCR performed for genes related to interneuron development. Results: General effects on E14 placental and fetal weight differed by stress model; CUS decreased placental and fetal weight while FS increased placental and fetal weight across both sexes ($p < .01$ for both placental and fetal weight). Interestingly, only RS and CUS decreased E14 interneuron migration across both sexes (86.0% in RS, 87.3% in CUS versus 92.2% in Ctrl, $p < .05$). Surprisingly, in female ventral forebrain, CUS increased expression of *Erbb4*, a gene for a critical receptor underlying chemoattraction of interneurons to the cortex (fold change = 5.1, $p < .05$). Differential effects of these three stress models on other interneuron developmental outcomes will also be reported. Conclusion: Different models of stress lead to some similar and some distinct offspring outcomes, relevant to understanding the underlying mechanisms of risk for neurodevelopmental disorders. Further work is required to assess the underpinnings of these differences.

Title: Preconception stress impacts metabolic signaling in maternal extracellular vesicles and sex-specific offspring neurodevelopment

Authors: *Y. CISSE[1], W. HUANG[2], M. A. KANE[2], T. BALE[1];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Univ. of Maryland Sch. of Pharm., Baltimore, MD

Abstract: Preconception lifetime adversity is a strong predictor of adverse perinatal outcomes and offspring neurodevelopment. Cumulative stressful life experiences precipitate a state of allostatic load; however, little is known about the biological mechanisms involved in storing and perpetuating this signal across generations. In our mouse model of maternal preconception stress (MPS), stress exposure prior to conception programs offspring-sex specific sensitivity to stress and metabolic insults in adulthood. We hypothesize that preconception allostatic load interacts with the incredible energetic demands of pregnancy, unmasking latent programming affecting highly metabolic tissues such as the placenta, and ultimately affecting offspring development. We first investigated changes in the cargo of circulating extracellular vesicles (EVs) in MPS females. EVs are secreted lipid-bound nano particles that mediate intercellular communication via transport of bioactive compounds, the composition of which is sensitive to cellular stress. Proteomic analysis revealed increased abundance of proteins involved in cellular metabolism in circulating EVs from females 4 weeks post-stress. During pregnancy, control females robustly increased abundance of proteins involved in cellular metabolism, a rise absent in MPS dams suggesting a ceiling effect or diminished response to pregnancy. As the largest contributor of circulating EVs during pregnancy and a sex-specific determinant of offspring growth, we examined the mid-gestation placenta. Although male placentas had a larger transcriptional response to MPS than females, both increased cellular metabolic gene expression, and decreased trophoblast differentiation genes, suggesting disruption in metabolic signaling and placental development. To better understand interactions with the maternal compartment, we examined the transcriptome of the uterus apposing these placentas. In contrast to the placentas, there were robust sex differences in the uterine transcriptome where tissue apposing male placentas showed changes in genes involved in cellular metabolism, but tissue apposing female placentas showed changes in genes involved in innate immunity. Finally, we characterized the mid-gestation fetal brain transcriptome and determined MPS offspring reduced expression of genes involved in neuronal development relative to controls. Together, these data suggest a lasting effect of preconception stress on maternal physiology, detected in circulating EVs that may play an important role as both a peripheral biomarker of maternal state and mode of transmission of MPS effects via changes in their cargo.

Title: Stress-induced dysregulation of the hypothalamic extracellular matrix shapes HPA axis development

Authors: *K. R. MONTGOMERY, M. S. BRIDI, L. M. FOLTS, T. L. BALE;
Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Lifetime maternal exposure to chronic stress and adversity represent significant risk factors for neuropsychiatric disorder development in their offspring. However, the exact mechanisms by which preconception experiences are transmitted to the next generation and influence neurodevelopment are not well understood. We established a novel mouse model of maternal preconception stress (MPS) where female, but not male, offspring of MPS dams show heightened stress reactivity in adulthood, a hallmark of many neuropsychiatric disorders. To examine the hypothesis that the sex-specific effects of MPS on stress responsivity involve lasting changes to the paraventricular nucleus of the hypothalamus (PVN), the master regulator of the hypothalamic-pituitary-adrenal (HPA) axis, we performed PVN Sim1 neuron-specific RNA sequencing in control and MPS postnatal day 21 (PN21) offspring. Remarkably, differential gene expression analysis showed more than 2200 genes differed in PVN neurons between MPS and control female offspring at PN21. Subsequent analysis revealed only 63 differentially expressed genes between MPS and control male offspring, suggesting that the observed female-specific adult stress phenotype may result from altered PVN neuron development. Functional analysis of the PN21 MPS female differentially expressed genes revealed significant enrichment of genes involved in the production and remodeling of the extracellular matrix (ECM). We then compared gene expression patterns using RNA sequencing in PVN neurons from MPS and control offspring in adulthood and found that female MPS offspring again had the highest enrichment of differentially expressed genes related to the extracellular matrix. Taken together, these data suggest that MPS imparts enduring sex-specific changes to the formation and maintenance of neuronal extracellular matrix in the PVN. The ECM undergoes considerable maturation during development, transitioning from a juvenile state to the adult state beginning in the second postnatal week. This transition coincides with the closure of plasticity windows in specific brain regions, though the majority of this work has been conducted solely in males and in non-hypothalamic regions. Our results suggest that dysregulation of either the developmental rate or the composition of the ECM could lead to lasting effects on PVN circuitry formation that persist into adulthood. Ongoing pharmacological and chemogenetic manipulations will examine the role of hypothalamic ECM in shaping the adult HPA response and how perturbations to neuronal activity during critical developmental windows alter ECM formation and HPA axis organization.

Title: Extracellular vesicles as novel stress signals altering placental and fetal development

Authors: *H. ZIERDEN[1], K. E. MORRISON[2], B. M. NUGENT[1], T. L. BALE[3];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]West Virginia Univ., Morgantown, WV;
[3]Pharmacol., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Maternal stress is linked to a variety of adverse fetal and pregnancy outcomes. In our well-established mouse model of early prenatal stress (EPS), we observe impaired cognitive function, alterations in metabolic programming, and heightened stress sensitivity, specifically in male offspring. A novel contribution to this stress signaling during pregnancy is extracellular vesicles (EV) largely secreted by the placenta. EVs are cell-derived nanoparticles that participate in intercellular communication by transporting signaling factors, including proteins and noncoding RNA, between cells and tissues. We first examined the role of EVs in stress signaling by isolating circulating EVs from pregnant mice, comparing control and EPS-exposed groups and performing small RNA-sequencing and proteomic analyses to analyze the content of these EVs. We injected labeled EVs into naïve dams, and utilized *in vivo* imaging (IVIS) to identify changes in EV trafficking to maternal and fetal compartments, and to detect transcriptomic changes in placental and fetal tissues. We observed that EVs from control and EPS-exposed dams were similarly trafficked to the placenta and did not appear to enter the fetal compartment. In determination of changes in EV characteristics, we found that the size of circulating EVs remains consistent over the course of gestation (~120 nm), but the concentration of EVs decreases as gestation progresses. Additionally, we observed that the surface charge (zeta potential) of EVs isolated over the course of pregnancy trended towards becoming more neutral. In addition, we found a reduction in overall EV concentration from stress dams compared to controls, and observed differences in the cargo signatures of EVs isolated from the two groups. We hypothesize that vesicle size, concentration, and surface charge of circulating EVs could influence signaling and EV interactions with fetal tissues. Together, these studies provide insight into the role EVs play in promoting stress signals in both maternal and fetal circulation, their interaction at the level of the placenta, and the impact of prenatal stress on important signaling dynamics between maternal and fetal compartments during gestation.

Title: Exposure to a low resource environment alters rat maternal care

Authors: *J. FLOWERS[1], C. ARDEKANI[3], A. JEAN-LOUIS[1], N. SEKHAWAT[1], D. A. BANGASSER[2];
[2]Dept. of Psychology and Neurosci. Program, [1]Temple Univ., Philadelphia, PA; [3]Univ. Of California Davis, Davis, CA

Abstract: Growing up in a low resource environment can induce effects on offspring that endure through adulthood. However, few studies investigate how raising offspring in a low resource environment affects parental brains and behavior. Therefore, our lab utilized the limited bedding/nesting (LBN) manipulation in rodents to mimic this environment. In LBN, dams and pups are put in a cage with a barrier to prevent access to bedding, no enrichment, and only one paper towel for nesting materials from post-natal (PND) days 2-9. This contrasts with control dams who have ample bedding, nesting, and enrichment. The LBN manipulation shifts maternal care such that dams spend more time engaged in pup-directed behavior (e.g., nursing, grooming pups) and less time engaged in self-care (e.g., self-grooming, resting outside the nest). This increase in pup-directed behavior does not prevent ill effects in offspring. This study extends the characterization of LBN dam behavior by assessing pup retrieval. We observed the dams' retrieval latency for each pup and the latency to crouch over the pups once they were all retrieved. Our preliminary results suggest that both LBN (n=5) and control dams (n=4) retrieve their first pup at similar times, but the LBN dams were quicker to retrieve all of their pups to the nest [$t(2)=.30$, $p=.11$]. Once retrieved, both LBN and control dams crouched over the nest at a similar rate. Ongoing studies are also assessing whether LBN dams are more defensive. When combined with our prior findings that LBN dams engage in more pup-directed behaviors, these data suggest that a low resource environment drives dams to be more focused on their pups, suggestive of a hyperarousal phenotype.

Title: Early life adversity causes sex-specific transcriptional changes in the basolateral amygdala of rats

Authors: *A. CUARENTA[1], C. C. BAVLEY[4], R. KARBALAEI[4], S. FAMULARO[4], M. E. WIMMER[2], D. A. BANGASSER[3];
[2]Psychology, [3]Dept. of Psychology and Neurosci. Program, [1]Temple Univ., Philadelphia, PA; [4]Temple, Philadelphia, PA

Abstract: Early life trauma can increase risk for the development of a variety of psychiatric disorders later in life including depression, anxiety, and substance use disorder—all disorders where dysregulation of the basolateral amygdala (BLA) is reported. However, early life stress that is not overwhelming can have an "inoculating" effect that promotes the development of resilience in adulthood. To understand how early life adversity impacts the basolateral amygdala, we used a rodent model of early life stress called the limited bedding and nesting model (LBN), which mimics a low resource environment by restricting a dam's access to nesting materials during the pups first week of life. Previously we found this manipulation produces a resilient-like phenotype against addiction-related behaviors. For example, LBN reduces impulsive choice, a BLA-mediated behavior, particularly in male rats. We therefore sought to delineate possible molecular underpinnings that promote stress-induced resilience. RNA sequencing was conducted to delineate the effect LBN had on the transcriptional profile of the BLA in adult rats (male control, $n = 4$; female control, $n = 5$; male LBN, $n = 5$; female LBN, $n = 4$). We used rank-rank hypergeometric overlap (RRHO) analysis to compare overall gene expression pattern in males and females induced by LBN. We found that LBN induced sex-specific changes in transcription. Specifically, we see significant distinction between genes upregulated in males and downregulated in females due to LBN. We narrowed our analysis to genes showing a significant difference between control and LBN and found 209 differentially expressed genes (DEGs) in females and 149 DEGs in males. These gene expression changes were predominantly sex specific as only 11 genes were altered by LBN in males and females. Heatmaps organized by fold change of LBN DEGs displayed different patterns of upregulated and downregulated genes in males and females. Of interest *Grin1*, the gene for the glutamate ionotropic receptor NMDA type subunit 1, was downregulated by LBN in females and pathway analysis found LBN - induced changes in glutamate pathways in females. In males, pathway analysis found LBN-induced changes in the MAPK pathways and several MAPKs, such as *MAPK10*, were

upregulated in LBN compared to control males. These analyses highlight unique patterns of gene expression LBN induces within the BLA in a sex-specific manner. Future work will focus on validating top targets with RNAscope and manipulating them in a cell-type specific manner to link changes to addiction-related behavior. Altogether, this work furthers our understanding of the neurobiological underpinnings of stress inoculation.

Title: Dynamic changes in stress-induced PVN-CRF neuron activity during juvenile development

Authors: *M. S. BRIDI, T. L. BALE;
Pharmacol., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Stress dysfunction and HPA axis dysregulation are associated with vulnerability to neuropsychiatric disorders. Adverse events or trauma experienced during vulnerable developmental periods such as during pubertal maturation increase disease risk across the lifespan. The paraventricular nucleus of the hypothalamus (PVN) integrates critical information regarding stressful stimuli, and the output of PVN corticotropin-releasing factor (CRF) neurons regulates hormonal and autonomic stress responses required for survival. While adult PVN CRF neurons are highly plastic and quickly return to baseline activity during stress recovery, determination of when this homeostatic setpoint is established during postnatal development is not understood. Further, despite the vulnerability of adolescents to stress-related neuropsychiatric disease, juvenile PVN anatomy and function has received limited attention. To examine how CRF neurons mature relative to HPA axis function over a juvenile period of development, and how adversity experience, modeled as social isolation stress exposure in mice, during this vulnerable period alters this trajectory, we utilized *in vivo* fiber photometry to measure PVN-CRF neuron activity while mice were exposed to acute or chronic stressors, with concurrent collection of tail blood to assay corticosterone levels. Stress-induced CRF calcium activity is

examined in younger animals and compared with their corticosterone response that decreased with age. The impact on this trajectory will be examined in juvenile mice while exposed to chronic social isolation stress following weaning. Our studies are focusing on a developmentally-programmed trajectory of PVN activity and HPA axis activation that is vulnerable to disruption by stress challenge during a specific maturational period. Further investigation must determine the relative contributions of afferent input and intrinsic CRF neuronal properties.

Title: Accelerated aging associated with a history of early stress: role of mitostasis and neuroinflammation

Authors: *P. R. CHAUDHARI[1], A. SINGLA[1], S. E. FANIBUNDA[2], P. TIWARI[1], S. SURYAVANSHI[1], U. KOLTHUR-SEETHARAM[1], A. D. B. VAIDYA[3], V. A. VAIDYA[1]; [1]Dept. of Biol. Sci., Tata Inst. of Fundamental Res., Mumbai, India; [2]Kasturba Hlth. Society-MRC and Vaidya Lab-TIFR Alliance, Mumbai, India; [3]Med. Res. Centre, Kasturba Hlth. Society, Mumbai, India

Abstract: Early life stress can evoke life-long alterations in anxiety and depression-like behaviour, and accelerate neuronal aging and cognitive decline. However, the molecular and cellular changes evoked by early trauma that contribute to these persistent phenotypes remain only partially understood. Maintaining a fine balance of mitostasis (mitochondrial biogenesis and mitophagy) is essential to the health of neurons. Mitochondrial dysfunction and neuroinflammation are implicated as a key precursor events that can drive neurodegenerative changes in the aging brain, and are linked with increased risk for stress-related psychopathology. Here, we sought to address the influence of a history of early stress on mitochondrial biogenesis, function, and mitophagy, as well as the consequences on both peripheral and central inflammation, focussing in the brain on the hippocampus which is particularly susceptible to neuroinflammation. A history of maternal separation (MS), an early stress model in rodents, results in enhanced adult anxiety, depression-like behaviour, accelerated aging, and perturbed neuroendocrine stress responses that endure across the life span. We carried out the MS paradigm in Sprague Dawley rats, which involved separation of the entire litter from the dam,

once daily for 3 hours from postnatal day 2 (P2) to P14. The influence of MS was then assessed at multiple time points across the life-span in key limbic neurocircuits, in particular in the hippocampus, prefrontal cortex and the hypothalamus of both male and female rats using cellular, molecular, neuropharmacological, imaging, and behavioural approaches. We provide evidence that a history of MS is associated with a dysregulation of multiple mitochondrial measures in key limbic brain regions of middle-aged MS rats. We noted a robust dysregulation in mitostasis, with a reduction in mitochondrial biogenesis and an increase in mitophagy, associated with a deterioration of mitochondrial function, accompanied by an inflammatory state evoked in the hippocampus and prefrontal cortex as MS animals age. We also analysed serum for circulating proinflammatory signatures and observed a robust induction in proinflammatory molecules, commencing as early as 6 months and noted to worsen as animals hit middle-age. These studies motivate future investigation to address whether strategies that intervene and ameliorate the inflammation associated changes can also reverse the mitochondrial and inflammatory changes that we observe following early stress.

Title: Goal-directed decision making is disrupted during morphine withdrawal

Authors: *B. HALBOUT, Z. A. SPRINGS, C. R. HUTSON, K. K. BODINAYAKE, S. B. OSTLUND;
Univ. of California, Irvine, Irvine, CA

Abstract: Drug-related cues are known to play several distinct roles in regulating drug-seeking and drug-taking behaviors. Drug-related cues can directly motivate drug use and relapse. Moreover, growing evidence shows that these cues can be distracting and may therefore disrupt ongoing cognitive control processes that support adaptive, goal-directed decisions, which might pave the way for maladaptive drug-seeking behavior. While clinical research on this subject has gained traction, there have been few such preclinical studies. We developed a novel rodent behavioral model to study the disruptive influence of morphine-related cues on goal-directed

action selection. Adult male Long Evans rats (n = 7-8 / group) were first trained with two different action-outcome contingencies (e.g., left press --> grain & right press --> sucrose). This was followed by a cue learning phase, during which separate multimodal contextual cues were paired with repeated morphine ($CS_{MORPHINE}$) or saline (CS_{SALINE}) administration. We then tested the rats' ability to choose between the two actions based on expected reward value using a well-established outcome devaluation task. This test took place in the presence of $CS_{MORPHINE}$ or CS_{SALINE}, immediately after morphine administration (Early Withdrawal) or following 21 days of withdrawal (Late Withdrawal) allowing us to determine the tendency of the morphine-paired cue to transiently interfere with goal-directed behavioral control (i.e., sensitivity to outcome devaluation). We found that morphine-exposed rats were insensitive to devaluation when tested in Early but not Late Withdrawal and that this effect was not dependent on $CS_{MORPHINE}$ or CS_{SALINE}. Brief re-exposure to morphine in Late Withdrawal also re-instated insensitivity to outcome devaluation. On the other hand, control groups that received saline administration in the presence of both contextual cues remained sensitive to outcome devaluation. Together, these data suggest that acute morphine withdrawal is associated with a deficit in goal-directed decision making. Ongoing experiments using sucrose licking tasks are assessing the influence of withdrawal and morphine-paired context on the motivational and hedonic processes that govern reward consumption.

Title: Evaluation of Oliceridine as a high selectivity, low potency μOR radioligand for molecular imaging

Authors: *E. VENTRIGLIA[1], S. LAM[1], Y. SHAHAM[1], J. BONAVENTURA[2,3], M. MICHAELIDES[1];
[1]Natl. Inst. on Drug Abuse, Baltimore, MD; [2]Univ. of Barcelona, Barcelona, Spain; [3]Inst. de Neurociències - UB, Barcelona, Spain

Abstract: A μOR radioligand with a low potency— compared to that of currently available fentanyl derivate radioligands— would reduce the pharmacological activation of the radioligand during molecular imaging studies, ideally without compromising affinity and selectivity of the

μOR. In this research, we investigate the biased μOR agonist Oliceridine (TRV-130) as a potential radioligand candidate via molecular imaging and behavioral paradigms. Using *in vitro* competition and *ex vivo* GTPγS binding assays in rodents, we have demonstrated Oliceridine's high affinity and low efficacy for brain μOR across both sexes. Similarly, using *in vivo* ARG, we found that pharmacological doses specifically bind to μOR rich areas of the rat brain. On the other hand, [^{3}H]Oliceridine appears not to enter the brain at trace doses and is instead sequestered within ventricles. This suggests that trace doses but not larger, pharmacological doses of Oliceridine are actively excreted from the brain by efflux pumps expressed throughout endothelial cells of the blood brain barrier. To overcome this, we found that co-injection of 1mg/kg Tariquidar, a P-glycoprotein efflux pump blocker, increased [^{3}H]Oliceridine brain uptake in μOR rich areas of the brain in *in vivo* ARG. To characterize the addiction-relevant behavioral response towards Oliceridine in an enhanced uptake condition, we are employing transgenic P-glycoprotein 1 knock-out mice in a conditioned place preference paradigm. Our results serve to facilitate the utilization of Oliceridine as a radioligand when co-administered with a P-gp blocker, enabling trace doses to bind to brain μOR with minimal G-protein recruitment.

Title: Calcium permeable AMPA receptors in the nucleus accumbens core and shell mediate the incubation of oxycodone craving

Authors: J. R. NOWLIN[1], B. W. C. WONG[1], A. R. ZIMBELMAN[2], K. CONNESS[1], B. O'BRIEN[1], J. GREENBERG[1], M. VOGEL[1], ***M. T. STEFANIK**[1];
[1]Psychology and Neurosci., North Central Col., Naperville, IL; [2]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: The enduring craving for drugs of abuse is a major contributing factor to the relapse to drug seeking. Cue-induced craving progressively intensifies ('incubates') over weeks of forced abstinence or withdrawal. This 'incubation of craving' has been observed during withdrawal from many different classes of abuse in rodents and humans, yet relatively little is known about this phenomenon or its mechanisms regarding the widely-prescribed prescription opioid, oxycodone (Oxy). Incubation for psychostimulants depends on time-dependent strengthening of AMPA receptor (AMPAR) transmission onto medium spiny neurons in the nucleus accumbens

(NA) through the accumulation of high-conductance, GluA2-lacking, Ca^{2+}-permeable AMPARs (CP-AMPARs). Recent studies have shown that oxycodone craving incubates, and our lab has identified CP-AMPAR emergence in the NA during this timeframe. However, it is not known if these receptors are functional contributors to the incubation of oxycodone craving. In the current study, we microinjected NASPM, a selective CP-AMPAR antagonist, directly into the nucleus accumbens core (NAcore) or shell (NAshell) subregions immediately before a seeking test. We hypothesized that Oxy craving would incubate and that if Oxy incubation was neurobiologically similar to incubation for other drugs of abuse, drug-seeking behavior would be significantly reduced in rats that received NASPM microinjections directly into the NA. Male Sprague Dawley rats underwent 10 days of extended-access Oxy or saline self-administration (6hr/day, 0.15mg/kg/infusion). In a counterbalanced design, immediately before 30-minute cue-induced seeking tests on withdrawal day 1 (WD1; when craving is low) and withdrawal day 15 (WD15; when craving has incubated), animals received bilateral microinjections of either NASPM (40 µg/side) or aCSF. Results show that NASPM microinjections into either subregion significantly reduced the incubation of drug craving in oxycodone self-administering animals on WD15 but not on WD1, and had no impact on saline animals. Together, these studies provide critical insight on the anatomical locus for CP-AMPAR action and its functional role in driving incubated oxycodone craving.

Title: Enhancement of compulsive-like opioid self-administration, and seeking, that persists despite two different forms of punishment-induced abstinence.

Authors: *S. HONEYCUTT, M. PALADINO, A. MUKHERJEE, G. LONEY;
Univ. at Buffalo, Buffalo, NY

Abstract: Nicotine and opioid use disorders (OUDs) are highly comorbid. Critical to the formation and maintenance of OUDs are drug-associated memories (e.g., contextual cues). Contextual cues can become associated with the reinforcing and aversive properties of drugs, which then coordinate later motivated behaviors. Our lab previously demonstrated that systemic and intra-insular cortex treatment with nicotine modulates contextual opioid conditioning and

enhances opioid intravenous self-administration (IVSA), supporting the role of nicotine in modulating opioid-associated contextual learning in a manner that facilitates OUDs. Here, we employed a model of punishment-induced abstinence wherein remifentanil (RMF) IVSA was explicitly unpunished in one context while infusions in a different context resulted in contingent punishment. These models are often used for their translational value because they model the self-imposed abstinence observed in humans which can follow experience with the deleterious consequences of drug use. We examined the effect of nicotine (0.4 mg/kg) or saline treatment, in rats, prior to RMF (3.2 µg/kg/infusion) IVSA sessions. RMF IVSA occurred in two alternating contexts. One context was unpunished, and, in another context, infusions were punished by one of two forms of punishment. In one group, we used an interoceptive punisher (escalating histamine adulteration). In the second group, we used an exteroceptive punisher (escalating foot-shock intensity). Subsequently, we examined the motivation to obtain RMF in progressive-ratio and extinction sessions in both contexts. We found that, regardless of punisher, rats treated with nicotine, relative to saline, took more RMF regardless of punishment and had higher breakpoints in both the unpunished and punished contexts. Additionally, nicotine treated rats displayed decreased latencies to first RMF infusion and first earned foot-shock. Similarly, nicotine treatment slowed extinction of RMF seeking and increased the propensity for cue exposure to induce relapse to RMF seeking within the punished context. Comparisons of the two forms of punishment revealed differential effects such that histamine adulteration was less effective than footshock and did not support measures of contextual discrimination between unpunished and punished contexts. In summary, nicotine enhances compulsive-like opioid seeking, and bolsters against negative consequences of drug taking in punishment associated contexts. However, the form of punishment differentially effects the continued abstinence from opioid seeking.

Title: Effects of clonidine on the expression of morphine withdrawal symptoms precipitated by naloxone in the mouse and in the rat

Authors: G. FROGET, C. FROGER-COLLEAUX, ***D. PUSHETT**, B. PEAN, C. PERRAUDEAU, V. CASTAGNE;
Porsolt SAS, Le Genest-Saint-Isle, France

Abstract: Naloxone is widely used to treat opioid overdose, although it induces serious side effects. Clonidine, an alpha-2-adrenergic agonist, is frequently prescribed to attenuate symptoms

of opioid detoxification. In this study, we aimed to evaluate the effects of clonidine in two rodent models of morphine withdrawal, precipitated by naloxone administration. Male and female Swiss mice (ten per group) were made morphine-dependent following seven administrations over two days. Two hours after the last morphine administration, withdrawal (assessed by jumping behavior) was precipitated by the injection of naloxone. The effect of clonidine on the number of jumps was observed over a 10-minute period. Male Sprague Dawley rats (four per group) were made morphine-dependent with twice daily administrations of escalating doses over ten days. Two hours after the last morphine administration, withdrawal was precipitated by naloxone injection and the effects of clonidine on body weight, body temperature, behavioral symptoms and stool consistency, were assessed. Clonidine significantly reduced the number of jumps induced by naloxone injections in morphine-dependent mice. The effects were more marked in female (-73%, $p < 0.01$) than in male mice (-55%, $p < 0.05$). In morphine-dependent rats, clonidine reduced the fecal output (-100%), did not affect the loss of body weight and potentiated hypothermia (-1.5°C max). Conversely to its effects in the mouse, clonidine increased naloxone-induced jumping behavior (+ 5262%). The naloxone-precipitated withdrawal model in the mouse using jumping as the main endpoint is a good screening tool to evaluate pharmacological treatments, potentially alleviating the side effects of opiate detoxification. The rat model using fecal output as the main endpoint, while less amenable to screening studies, allows for the evaluation of a broader range of potential symptoms associated with the opiate detoxification.

Title: Sex differences in distress-related behavior and reinstatement of opioid seeking in mice that witness a conspecific under predatory threat

Authors: T. MATVEEVA[1,2], Z. L. MATTI[2], C. W. COLLINGE[2], E. H. TRESSLER[4], ***J. C. GEWIRTZ**[2,3];
[1]Psychology, Cornell Univ., Itheca, NY; [2]Psychology, [3]Neurosci., Univ. of Minnesota, Minneapolis, MN; [4]Biol., U. Minnesota, Minneapolis, MN

Abstract: Witnessing other people in distress ("observational distress") is a significant source of pathogenic stress in human populations. We have shown in male mice that witnessing a conspecific mouse under predatory threat induces a variety of distress-related behaviors in the observer, including observational distress-induced reinstatement (ODIR) of opioid seeking. Here, we investigated whether male and female mice showed divergent responses following the observation of a conspecific under predatory threat.Male and female C57/Bl6 mice were trained in a conditioned place preference (CPP) paradigm, in which one chamber was paired with morphine (15mg/kg), and the opposite chamber with saline. Animals underwent 4 days of conditioning in each chamber, followed by extinction. Mice then observed the distress of a same-sex conspecific exposed to a male Sprague-Dawley rat. Distress-related behaviors (freezing, escape, burrowing, etc.) were recorded. In separate groups, we also investigated the role of oxytocin, which we and others have found to be critically important in the expression of observational distress. The exogenous neuropeptide was administered intranasally (20 μg/kg) either acutely or chronically, and the oxytocin antagonist L-368,899 hydrochloride was administered systemically (IP; 10 mg/kg). In male mice, observational distress induced reinstatement of CPP, as well as aggression towards a conspecific, primarily when the observer and demonstrator were familiar with each other. Moreover, the degree of reinstatement in the observers was predicted by the number of defensive and aggressive behaviors shown by their respective demonstrators. Female showed distress and reinstatement irrespective of their familiarity with their dyadic partner. In further contrast to males, they exhibited huddling behavior, not aggression, when returned to their home cage. Administration of oxytocin increased observational distress in male unfamiliar observers, thereby eliminating the familiarity bias. In both sexes, administration of the oxytocin antagonist rescued observational distress-related behavior.These data reveal sex-related differences in responding to the distress of another. Our paradigm may offer a means of further investigating sex differences in the induction of psychosocial stress and in stress-induced reinstatement in mice.

Title: Fentanyl self-administration by rats engages the central nucleus of the amygdala

Authors: *E. CHALOUX-PINETTE[1], M. CASTRO[1], P. H. JANAK[2,1];
[1]Dept. of Neurosci., Johns Hopkins Universtity Sch. of Med., Baltimore, MD; [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Opioid use disorders (OUD) can be conceptualized as maladaptive 'wanting' or craving of opioids, regardless of potential consequences or alternative reinforcers. The central nucleus of the amygdala (CeA) has been demonstrated to modulate motivation for natural and drug reinforcers, but there has been limited exploration of its role in self-administration models of OUD. To assess the role of the CeA in opioid self-administration, we trained male (n=20) and female (n=10) Sprague-Dawley rats to self-administer the synthetic opioid, fentanyl (0.5μg/i.v. infusion), on an FR1 schedule in 2-hr daily sessions. Rats achieved robust and stable intake after training for 28 sessions. Using GABA agonists, baclofen and muscimol, we found that CeA inactivation attenuated the mean number of fentanyl infusions, supporting a role for this region in fentanyl reinforcement. To probe the role of specific CeA transmitters previously implicated in appetitive processes, we microinfused either the opioid receptor antagonist, naltrexone, the 5-HT_2 receptor agonist, 2,5-dimethoxy-4-iodoamphetamine (DOI), or the dopamine receptor antagonist, flupenthixol, prior to self-administration sessions. Blockade of CeA opioid receptors by naltrexone increased intake and decreased inter-response intervals, consistent with CeA opioid receptors being key mediators of fentanyl reward. DOI reduced fentanyl intake, particularly during the first 15 minutes of the session when motivation to take drug was likely highest, indicating that 5-HT_2 receptors in the CeA modulate drug consumption when motivation to consume drug is high. While flupenthixol administered to the CeA failed to alter mean intake, it did shift the distribution of inter-response intervals, increasing the frequency of intervals under 120 seconds. None of these effects interacted with sex. Taken together, these results demonstrate that the CeA is engaged by fentanyl self-administration when subjects have been trained under conditions that do not typically induce strong dependence.

Title: Differential rearing effects on the gut-brain axis after oxycodone precipitated withdrawal in adolescent rats

Authors: A. G. TORRES[1], Z. SIMSEK[1], S. RIVERA[2], T. RICHARDSON[2], S. ASSEFA[3], G. KOEHLER[3], *D. VAZQUEZ SANROMAN[1];
[1]Anat. and Cell Biol., [2]Col. of Osteo. Med., [3]Microbiology and Biochem., Oklahoma State Univ. Ctr. for Hlth. and Sci., Tulsa, OK

Abstract: Chronic use of opioids leads to the development of dependence. Environmental enrichment (EE) prevents oxycodone-induced withdrawal in adult rats. After chronic oxycodone use, adolescents are more susceptible to gastrointestinal disorders (nausea, constipation) compared to adults, with effects on intestinal homeostasis. However, opioid effects on the gut-brain axis activity during oxycodone withdrawal remain unknown. Brain-derived neurotrophic factor (BDNF) plays important roles in controlling cell survival in the nervous system and enhancing gastrointestinal motility. Hence, 1) we will investigate correlations of differential rearing with changes in the adolescent gut microbiome and 2) determine the effects of oxycodone-induced withdrawal in brain/gut BDNF levels. **Methods:** Adolescent male Sprague-Dawley rats were raised in isolated condition (IC), standard social condition (SC), or enriched condition (EC). On postnatal day 51 oxycodone dependence was initiated using a passive injection model (1, 2, 3, and 5 mg/kg) every 12 h for 5 days. Chronic oxycodone administration facilitated tolerance and physical dependence, demonstrated by withdrawal symptoms. On the 6th day of administration, rats received a naloxone injection (1 mg/kg) precipitating withdrawal. Brains were collected for proBDNF and mBDNF immunoassay analyses. Gut microbiota compositions were analyzed using 16S rRNA gene amplicon sequencing in baseline and time-course fecal samples as well as in intestinal samples contents. **Results:** IC rats showed an increase in sniffing, grooming, and rearing, while all withdrawal features were not observed in the EE rats. Social isolation followed by oxycodone withdrawal enhanced proBDNF and mBDNF expression in the Prefrontal Cortex. Differential rearing conditions correlated with compositional changes in the gut microbiota.

Title: Neural and behavioural signature of the compulsive relapsing nature of heroin addiction in the rat

Authors: *M. FOUYSSAC[1], A. BELIN-RAUSCENT[1], M. SIDDLE[2], M. PUAUD[1], B. J. EVERITT[1], D. J. BELIN[1];
[1]Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [2]Developmental Neurosciences, Univ. Col. London, London, United Kingdom

Abstract: Addiction has been hypothesised to result from a transition from volitional drug use to the compulsive seeking and taking of drugs that occurs only in a subset of recreational users. The neural and behavioural factors underlying the vulnerability to switch to compulsive drug seeking are increasingly being understood for stimulant drugs, but less so for opiates. Here we present a novel procedure in the rat that has enabled the identification of behavioural and molecular markers of the vulnerability to develop compulsive heroin seeking behaviour. In this novel procedure, the individual tendency to persist in seeking heroin in a drug-free state despite contingent punishment (mild footshock) was revealed in 25 individuals from a large cohort of 89 Sprague Dawley rats with an extended history of heroin seeking maintained by heroin-associated cue presentations. In a series of longitudinal studies, drug naive rats were tested for several addictive behaviour-relevant traits including anxiety, decision making, sensation and novelty seeking as well as reward (sweetness) preference, prior to being trained to seek heroin under the influence of the conditioned reinforcing properties of heroin-paired cues for several weeks (a second-order schedule of reinforcement). The compulsive nature of heroin seeking behaviour was then measured over several sessions during which mild footshock punishment was delivered contingent on seeking responses prior to, but not during, the administration of heroin. The individual tendency to persist in seeking heroin in the face of punishment was shown to be predicted by a sign-tracking phenotype while that to relapse after punishment-induced self-abstinence was associated with a high anxiety trait. This individual vulnerability was associated with an alteration in the adenosinergic system in the nucleus accumbens in that rats identified as highly compulsive had higher mRNA and protein levels of the adenosine 2A receptor in the ventral striatum as compared to low compulsive rats. These adaptations were further shown to predict compulsive heroin seeking at the population level. Together, these data indicate that high anxiety and a propensity to ascribe incentive value to conditioned stimuli predict the vulnerability to express the compulsive relapsing nature of heroin addiction that may be mediated by the adenosinergic system in the ventral striatum. These data offer new avenues to developing therapeutic strategies to target the compulsive relapsing nature of heroin seeking that represents a hallmark feature of addiction.

Title: Taste Reactivity to Sucrose in Differentially Reared Rats Altered by Mu Opioid Receptor Functioning

Authors: *D. LAUX[1], T. J. MOSER[2], M. C. AZUMA[1], J. K. GOMENDOZA[1], M. CAIN[3]; [2]Dept. of Psychological Sci., [1]Kansas State Univ., Manhattan, KS; [3]Psychological Sci., Kansas Sate Univ., Manhattan, KS

Abstract: It is well established that rearing in isolated environments during adolescence increases incentive salience for reinforcers, compared to animals reared in enriched environments. Our current research suggests that isolated rats emit less hedonic responses ('liking') to sucrose in a taste reactivity paradigm, despite their increased operant responding ('wanting') for sucrose. Interestingly, Mu (μ) opioid receptors (MORs) are critical for determining hedonic value. While it is established that MOR function is critical for hedonic responding, MOR function during hedonic responding has not been investigated in differentially reared rats. In the current experiment, we examine changes in hedonic responding for sucrose in differentially reared rats, while enhancing MOR function via morphine injections. Male and female Long-Evans rats arrived on postnatal day 21 and were randomly assigned to rear in isolated (IC), standard (SC) or enriched (EC) conditions for 30 days. Post-weaning, rats were implanted with indwelling intraoral fistulas. Following recovery, rats underwent taste reactivity trials for sucrose, utilizing a within-subjects design with a counterbalanced order for morphine injections (0, 2 and 4 mg/kg, sc) and sucrose concentrations (0, 0.1M and 0.5M). Taste reactivity data collected via video recording was analyzed frame by frame to quantify orofacial hedonic and aversive responses. Our data suggests that high doses of morphine reduces hedonic responding for sucrose only in IC rats. Comparatively, EC rats with high doses of morphine display increased hedonic responding for sucrose. These data indicate that activation of MORs may decrease 'liking' in isolated rats, and increase 'liking' in enriched rats. These results suggest that isolation rearing may alter MOR function to change incentive salience for reinforcers.

Title: Dopamine facilitates associative memory coding in the lateral entorhinal cortex

Authors: *J. LEE[1], H. JUN[1], S. SOMA[2], T. NAKAZONO[3], K. IGARASHI[1];
[1]UC Irvine Sch. of Med., Irvine, CA; [2]Kyoto Prefectural Univ. of Med., Kyoto, Japan;
[3]Fukushima Med. Univ., Fukushima, Japan

Abstract: Dopamine plays a central role in motivation and reward. Accumulating evidence shows that dopaminergic inputs in the ventral tegmental area (VTA)-striatum circuit are critically involved in reward-based learning. However, it remains unclear how dopamine reward signals control the entorhinal-hippocampal circuit, another brain network critical for learning and memory. Here we show that dopaminergic inputs from the VTA/substantia nigra to the lateral entorhinal cortex (LEC) are critical for cue-reward associative memory. Optogenetic inhibition of LEC dopamine inputs, or inhibition of LEC layer 2a fan cells, impaired the learning of olfactory cue-reward association, although the retrieval of pre-learned memory was spared. Photometry recordings revealed that LEC dopamine transmits novelty-induced reward expectation signals. Using optogenetic-assisted electrophysiological recording during associative learning, we found a cue-reward association coding of LEC fan cells, where representations of newly learned rewarded cues gradually overlapped with that of a pre-learned rewarded cue while separating them from the representation of a pre-learned unrewarded cue. This coding of LEC fan cells was disrupted by the inhibition of LEC dopamine inputs. These results indicate that dopamine functions as a powerful memory gatekeeper for the entorhinal cortex to encode cue-reward associative memory, pointing to the involvement of the entorhinal cortex in dopamine-mediated reinforcement learning.

Title: Medial prefrontal cortex routes relevancy of ongoing events to the nucleus reuniens

Authors: *X. YU[1], K. TAKEHARA-NISHIUCHI[2];
[1]Cell and Systems Biol., [2]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Established literature suggests the medial prefrontal cortex (mPFC) works concertedly with the hippocampus (HPC) during the consolidation and retrieval of event memories; however, their interaction during encoding remains unclear. By using a HPC-dependent differential associative learning task, we have shown that the mPFC changes its network activity patterns depending on whether a neutral conditioned stimulus (CS) is predictive of an upcoming aversive stimulus. Moreover, augmenting this relevancy-selective activity facilitated the formation of stimulus associations. This neural signal could thus be a mechanism through which the mPFC enhances the contrast between relevant and incidental events and facilitates the encoding of the former in the hippocampus. Since the mPFC lacks direct projections to the HPC, the exact pathways through which this relevancy signal reaches the HPC remains unknown. To address this point we used fiber photometry to monitor mPFC axon terminals in the nucleus reuniens (RE) and mediodorsal thalamus (MD), the former of which possess direct HPC projections. Terminal calcium activity was recorded as subjects were trained in a differential trace eyeblink conditioning task wherein one CS was paired with a mild eyelid shock (CS+) and the other was presented by itself (CS-). Before conditioning, presentations of the CS by themselves elicited comparably small increases of calcium activity in terminals within the RE and MD. Once stimulus pairings started, mPFC terminals in the RE began exhibiting significantly larger calcium responses to the CS+ compared to the CS-. Responses to the CS+ also increased in magnitude across conditioning sessions. Conversely, in terminals within the MD, both the CS+ and CS- elicited more comparable calcium responses. Furthermore, the magnitude of the responses to either CS type did not significantly increase across sessions. These findings suggest that mPFC output to the RE differs based on the predictive qualities of the CS, and that this differentiation was much less apparent with output to the MD. The relevancy signal is thus likely to be routed to the RE, whilst information more related to the physical sensory aspects of a stimuli are routed to the MD. We therefore propose that the mPFC exerts executive control over hippocampal encoding by signaling the relevance of ongoing events via RE.

Abstract: *Introduction:* Previous studies suggested that resting state functional connectivity is affected by experiences preceding resting state. Little is known about the impact of memory task performance on subsequent functional connectivity within and between resting state networks in individuals with and without depressive disorders (DD). Characterizing this relationship is important for understanding aberrant memory consolidation in depression. *Methods:* 52 individuals with DD (age=28.2±0.9, 42 female*)* and 45 healthy controls (HC, age=29.0±1.0, 33 female*)* completed clinical interviews, and a food and object encoding task followed by a forced-choice recognition test. A 5-min resting state fMRI scan was administered immediately after the forced-choice task. Resting-state data were preprocessed using *fmriprep* and band-pass filtered (0.01Hz-0.1Hz). Resting state networks were determined using ICA across all 97 participants and were cross-correlated with the 7-network solution from Yeo (2011) using *fslcc*. The resulting networks served as inputs to *dual-regression* for within-network analyses and *FSLNets* for between-network analyses. We tested how diagnostic status moderated the relationship between memory accuracy and connectivity measures within and between resting state networks. *Results*: There was no significant effect of diagnosis-by-memory interaction on within-network connectivity. *FSLNets* revealed that the correlation between functional connectivity in the default mode network (DMN) comprised of the medial prefrontal cortex, posterior cingulate cortex and hippocampal formation, and functional connectivity in the dorsal attention network (DAN) comprised of the inferior temporal, parietal, and prefrontal cortices, was significantly associated with the interaction between recognition accuracy and diagnostic status (p=0.02). Specifically, a stronger positive correlation between these two networks was observed in individuals with DD who showed higher memory accuracy prior to resting state. No such effect was observed for HC. *Conclusion:* The DMN and DAN typically anticorrelate. Our findings that individuals with DD, but not HC, showed stronger positive correlation between these two networks in the context of accurate memory performance preceding resting state, suggests aberrant post-task memory consolidation processes. Such aberrant memory consolidation may lead to continuous “play back” of previously learned information and underlie rumination on negative thoughts and experiences in depression. Previous findings that DMN activity is related to the level of detail in thoughts partially supports this account.

Title: The role of sleep in the formation of indirect memory associations

Authors: *T. TADROS[1], M. V. BAZHENOV[2];
[1]UCSD, La Jolla, CA; [2]Dept. of Med., Univ. of California San Diego, La Jolla, CA

Abstract: Relational memory, the ability to make and remember associations between objects remains an essential component of mammalian reasoning. In relational memory tasks, it has been shown that periods of offline processing, such as sleep, are critical to improving one's ability to make indirect associations or transitive inferences. For example, one may learn to associate two items (A and B) and later learn to associate B with a new element (item C) during the wake state. After briefly learning these associations, a subject can recall item B (also called "linking" item) when presented with item A or C, but is less adept at recalling item C. Behavioral research has shown that the duration of slow-wave sleep (SWS) following such is significantly correlated with the subject's ability to recall item C when presented with item A. Based on the empirical evidence that sleep improves relational memory, in this study, we built a Hodgkin-Huxley-based model of the thalamo-cortical network to understand how SWS can lead to improvements in an unordered relational memory task. The cortical network was composed of two layers, both including and excitatory and inhibitory neurons; the first layer represented the perception of an individual object (e.g. visual cortex) and the second layer represented higher-order processing (e.g. associative cortex). Feedforward connections from the first layer to the second layer and recurrent connections within the second layer were plastic and modified through spike-timing dependent plasticity (STDP) rules during training and sleep. The model was first trained on a paired associate inference task, where four pairs of items (e.g., A+B, B+C, X+Y, Y+Z) were presented to the network. After which, the model was able to recall direct associations (e.g., A->B, B->C) learned during the waking state. However, the indirect relational association (e.g., A->C) was not learned or was unreliable. After a period of SWS, the model's ability to recall these indirect associations was significantly improved, highlighting the importance of SWS in relational memory. In agreement with empirical data, we found that the duration of SWS significant correlates with the improvement in relational memory after sleep. Importantly, we found that replay during sleep increases synaptic connections between neurons representing the linking (common) item (B) and neurons representing the unlinked associations (A, or C). This change in synaptic connectivity led to a greater ability to recall the unlinked items when its

indirect pair was presented. Our study predicts that sleep can reactivate pathways to and from the linking item to the unlinked objects to form indirect associations.

Title: Predicting real-world mathematical proficiency and learning from brain activity

Authors: *Q. LIN[1], N. SHAIKH[1], N. B. TURK-BROWNE[1,2];
[1]Psychology, [2]Wu Tsai Inst., Yale Univ., New Haven, CT

Abstract: Mathematics are an integral part of all levels of education and useful in many aspects of everyday life, yet mathematical abilities vary dramatically across individuals. Mathematicians can reason through a sea of complex equations while some struggle with simple arithmetic like calculating the tip at a restaurant. What neural mechanisms explain such individual differences in math proficiency and learning? Here we test the hypothesis that how the brain responds to math instructional videos will reveal an individual's existing understanding of advanced concepts and their readiness to learn new concepts. We recruited 15 participants with a range of expertise, from novices with little college-level math exposure (e.g., first-year students not intending to major in STEM) to experts with extensive quantitative training (e.g., PhDs in a quantitative STEM field). After completing a written baseline exam on various topics in college-level math (linear algebra, calculus, probability) on Day 1, participants watched Khan Academy videos about these topics while undergoing fMRI on Day 2. On Day 3, participants completed another exam on these topics with a new set of questions. By projecting fMRI activity evoked during the videos into a common space using shared response modeling, an algorithm for functional alignment, we were able to predict baseline test performance on Day 1 in a cross-validated manner. Shared responses in default mode network regions such as the angular gyrus and precuneus carried the most predictive power. In addition to predicting baseline math proficiency, fMRI activity during the videos enabled us to predict who would improve the most after watching the videos in terms of test performance on Day 3. After identifying template voxel activity patterns linked to baseline math proficiency, we showed that the emergence of these patterns during learning predicted the magnitude of behavioral improvement. Taken together, our study demonstrates how combining advanced fMRI analysis methods with naturalistic stimuli can uncover the neural architecture supporting the acquisition of abstract concepts. This approach holds promise for identifying neural templates that could be targeted for cognitive

training of mathematical expertise through real-time neurofeedback. More generally, this study adds to a growing literature that grounds education and pedagogy in the brain.

Title: Targeted Prefrontal Projections Drive Feature Recognition and Memory Recall

Authors: *N. YADAV[1,2], C. NOBLE[2], J. NIEMEYER[2], A. TERCEROS[2], J. D. VICTOR[1], C. M. LISTON[1], P. RAJASETHUPATHY[2];

Abstract: The neural basis underlying the relationship between a contextual memory and its constituent features is not well understood; in particular, where features are represented in the brain and how they drive memory recall. To gain insight into this question, we developed a virtual reality based behavioral task where mice learned to associate multisensory contexts with rewarding or aversive outcomes. During retrieval sessions, they were presented with partial features of the original multi-modal context and challenged to recall the associated contextual memory. We performed longitudinal imaging in hippocampus as mice performed this task and identified robust representations of global context but not of individual features (9% conjunctive vs 1.1% feature-selective neurons, n=3 mice, 9 sessions). By studying cortical inputs to hippocampus, we found that inhibition of anterior cingulate cortex (AC) led to silencing of a substantial proportion of context-selective neurons in CA1 and to behavioral deficit in feature-based memory recall. Single neurons in AC displayed feature-selectivity as well as mixed-selectivity to combinations of features, in contrast to the strong conjunctive tuning that was observed with CA1 neurons. These multiplexed single neuron activity gave rise to robust population level representations of features. Interestingly, we observed that AC feature representations lag hippocampus context representations during training, but dynamically reorganize to lead and target recruitment of context ensembles in hippocampus during recall (CDF as a function of latency, KS test, $p<0.001$). This AC-CA1 interaction is further enhanced

by the saliency of the memory, as suggested by tight coupling of feature-context ensembles in reinforced compared to non-reinforced contexts (ACfeature-CA1context correlations, $c_{Aversive}$ =0.43, $c_{Neutral}$=0.23, $p<0.05$). Together, we provide neurophysiological insights into how feature representations access long-range episodic representations to drive memory recall. Ongoing work is aimed at understanding how feature representations are selected and stabilized during learning.

Title: Dissociation between left inferior frontal cortical thickness and encoding-related fMRI activity in temporal lobe epilepsy

Authors: *S. S. KAFAFI[1], P. F. HILL[1], B. C. LEGA[2], M. L. RACENSTEIN[1], D. R. KING[1], M. D. RUGG[1];
[1]Ctr. for Vital Longevity and Dept. of Brain and Behavioral Sci., Univ. of Texas at Dallas, Dallas, TX; [2]Neurosurg., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Cross-sectional and longitudinal studies have established that patients with temporal lobe epilepsy (TLE) show accelerated cortical thinning in comparison to healthy adults. However, the impact of these structural differences on memory function in TLE patients is under-explored. The purpose of the present study was to examine whether global or regional cortical thickness moderates the neural correlates of successful memory encoding in TLE. Male and female TLE patients (N=16) and age-matched healthy controls (N=20) were scanned with fMRI while they studied a series of word lists. Following the presentation of each list and a brief distractor task, participants attempted to recall as many of the study items as possible. The scanning session was followed by a post-scan test of recognition memory that employed a mixture of studied and novel words. Thus, we were able to identify fMRI 'subsequent memory effects' (greater encoding-related activity for later remembered than later forgotten items) based on two different memory tests. There were no significant differences in recall performance between the patients and controls, although recognition memory performance was significantly lower in the patients. Highly robust subsequent memory effects predictive of later free recall and recognition were evident in the left inferior frontal gyrus, among other regions. These effects did

not significantly differ in magnitude between the two groups. For each participant, we extracted estimates of global and left IFG cortical thickness, and left and right hippocampal volume, from their T1-weighted MRIs. Both of the thickness metrics were significantly lower in the TLE patients, while there were no group differences in hippocampal volume. Across participants, neither estimate was reliably associated with recall or recognition memory performance. The findings suggest that cortical thinning in TLE has little or no impact on memory performance or the neural correlates of successful memory encoding, at least as these correlates are manifest in the LIFG.

Title: Increased prefrontal cortex gamma power in a rat model of Fragile X Syndrome

Authors: *J. W. MOORE[1], L. KOSTRZEWA[1], A. ASIMINAS[1,2], D. E. ARKELL[1,2], P. A. DUDCHENKO[3], P. C. KIND[1,2], E. R. WOOD[1,2];

Abstract: Fragile X Syndrome (FXS) is one of the most common inherited forms of intellectual disability and autism spectrum disorder. Mouse and rat models of FXS have been produced through knockout (KO) of the *Fmr1* gene, and numerous learning and memory deficits have been observed in these models. Previous data from our lab suggest that the *Fmr1*$^{-/y}$ rats fail to show memory for object-place-context associations in a spontaneous object exploration recognition memory task, which is reliant on intact connections between medial prefrontal cortex (mPFC) and hippocampus (Till et al. 2015, Hum Mol Genet, Asiminas et al. 2019, Sci Trans Med). More generally, interactions between these areas are important for adaptation to novelty and cognitive flexibility, which have been shown to be affected in FXS patients (Schmitt et al. 2019, Brain Sci). The current study aimed to investigate whether differences in network activity within, or functional connectivity between, mPFC and hippocampus could underlie such deficits. Tetrodes were implanted into the mPFC and hippocampus of adult male *Fmr1*$^{-/y}$ and littermate

wild-type (WT) rats, to record single units and local field potentials (LFP) from both areas simultaneously, while the animals freely explore familiar and novel environments and object configurations, including an object-in-place task that is dependent on mPFC-hippocampus connections. Our analysis of LFPs indicates that power of gamma (30-80 Hz) oscillations in the mPFC was significantly increased in KOs compared to WTs, in both familiar and novel environments, while mPFC theta power, and power of oscillations in the hippocampus, were no different between genotypes. Further analyses of interaction mechanisms, such as coherence, phase-amplitude coupling, and spike-phase locking are currently ongoing. Elevated cortical gamma power has been observed previously using surface EEG in the mouse *Fmr1*$^{-/y}$ model (Lovelace et al. 2018, Neurobiol Dis), and in FXS patients (Wang et al. 2017, J Neurodev Disord). Our translation of this finding to *Fmr1*$^{-/y}$ rats indicates increased cortical gamma power as a robust preclinical biomarker, and suggests mPFC network dysregulation which could underlie cognitive inflexibility.

Title: Distinct deficits of short-term versus extremely long-term repetition priming following lateral versus anteromedial frontal cortex damage

Authors: S. C. MILLEVILLE[1], ***S. J. GOTTS**[1], J. H. WITTIG, JR[2], S. K. INATI[3], K. A. ZAGHLOUL[2], A. MARTIN[1];
[1]Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD; [2]Surgical Neurol. Br., [3]Office of the Clin. Director, Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Object repetition commonly leads to long-lasting improvements in identification speed and accuracy, a behavioral facilitation referred to as “repetition priming”. Neuroimaging and transcranial magnetic stimulation (TMS) studies have most often implicated the involvement of left lateral frontal cortex in repetition priming, although convergent evidence from neuropsychological studies is lacking. In the current study, we examine the impact of surgical

resection for the treatment of epilepsy on the magnitude of repetition priming at relatively short-term (30-60 minute delay) and extremely long-term (3 months) delays in 41 patients with varying seizure foci and resection locations (17 left anterior temporal, 10 right anterior temporal, 5 frontal, and 9 other). Overall, patients exhibited significant repetition priming at both short-term and long-term delays. However, patients with frontal resections (largely anterior and medial frontal) differed significantly from those with right anterior temporal resections in showing fully intact short-term priming but absent long-term priming. Supplementing this sample with a set of 10 recovered aphasic patients (having previously suffered a left hemisphere stroke), we further compared priming magnitudes in patients with damage that included versus spared left lateral frontal cortex. Priming following left lateral frontal damage was indeed significantly reduced at the short-term delay (30-60 minutes) for these patients, consistent with the results of previous neuroimaging and TMS studies. Taken together, the results suggest the differential involvement of lateral and anteromedial frontal regions in mediating repetition priming at short-lag and long-lag timescales, respectively.

Title: Topological inference of stimulus space reveals low-dimensional geometry in fly and mouse olfaction.

Authors: M.-C. WU[1], ***Y. BERCHENKO-KOGAN**[1], M. WACHOWIAK[2], V. ITSKOV[1]; [1]Mathematics, Pennsylvania State Univ., University Park, PA; [2]Neurobio., Univ. of Utah, Salt Lake City, UT

Abstract: Sensory coding in olfaction remains poorly understood. Unlike vision, where the stimulus and receptor code can be simply defined, the complexity of the “odor space” as well as the complexity of the odorant receptor (OR) repertoire has hindered our understanding of odor coding and processing. For example, there is no consensus on key defining features of odor sensation such as the dimensionality of odor perceptual or odor receptor space. It is commonly conjectured that the ORs transform a high-dimensional “chemical space” to a relatively low-dimensional space of neuronal representations.

We developed a novel mathematical method for the inference of basic geometric features of a stimulus space from neural activity. This method makes no substantial assumptions on the underlying stimulus space, instead it assumes that the receptive fields are *convex* in some natural coordinate system in the underlying olfactory space. The convexity of sensory receptive fields is well-documented in many other sensory modalities, such as vision and spatial navigation. The key feature of this method is that it is insensitive to the inherent (and usually unknown) monotone non-linearities of neuronal responses.
It turns out that it is possible to infer basic geometric features of the underlying stimulus space, such as the *non-linear* dimension, based on a noisy and sparse data that is available for the activity of olfactory receptors in flies and mice. Our method converts the activity of each OR into a combinatorial summary that records relative rankings of neuronal responses to odorants per each OR. This data preserves basic information about the geometry of the underlying stimulus space, such as the dimension. We then use topological methods to infer the *non-linear* dimension of the underlying space.
We used our methods to estimate basic geometric features of OR representations in two distant species: Drosophila and mice. We compared the geometric features of neural representations in Drosophila antennal odorant receptors with those in the mouse olfactory bulb, using previously published datasets as well as newly collected data from the mouse. We found that the non-linear dimension of the olfactory coding space is low in both species. Our results indicate that the dimensionality on per-receptor basis is significantly different between these species, as the fly has substantially smaller olfactory receptor repertoire, than the mouse. Our findings establish that the non-linear transformation performed by the olfactory receptors compresses the high-dimensional chemical space into a low-dimensional olfactory space, at the level of the olfactory receptor neurons.

Title: Topological data analysis of spontaneous activity in the zebrafish optic tectum

Authors: *J. PAIK[1], E. HANSEN[2], G. SUMBRE[2], C. P. CURTO[1];
[1]Mathematics, The Pennsylvania State Univ., University Park, PA; [2]Ecole Normale Superieure, Paris, France

Abstract: Techniques using topological data analysis can help us find structure in correlation matrices that traditional linear algebra techniques cannot. One cause of this problem is that notions like rank and spectra are not numerically robust to nonlinearities upon entries. An attempt to address this problem are through Betti curves, introduced in [1], which are matrix statistics that are invariant to monotone nonlinearities upon entries. In this study, we use Betti curves (β_k) to analyze spontaneous activity from the zebrafish optic tectum, data collected using two-photon light sheet microscopy. The calcium imaging signal from ~4,000 neurons are clustered into functional assemblies and a correlation matrix is computed. From there, we calculate Betti curves on submatrices induced by assemblies using Ripser. What we find are identically zero β_k for $k > 0$, which are clearly different to the Betti curves for a random assembly, which have nontrivial β_k. In [2], the authors showed that an all-positive symmetric matrix with an underlying rank of one has identically zero Betti curves β_k for $k > 0$. Hence the correlation matrices are consistent with that of a rank one matrix. We note that in contrast to Betti curves, the singular values of the correlation matrix induced by both the assembly and the random assembly are consistent with that of a full rank matrix. We propose that this low rank structure is a signature of the attractor-like dynamics observed in the zebrafish optic tectum.

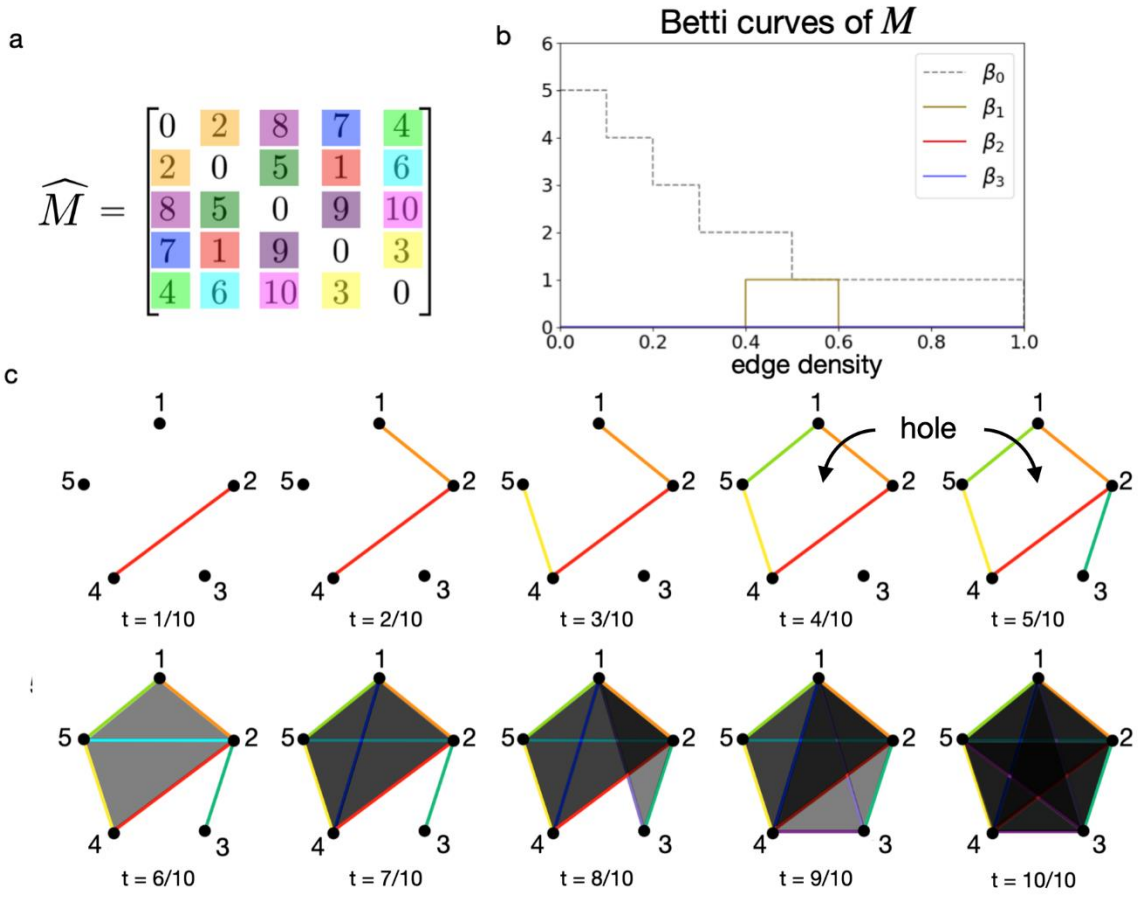

Fig. 1. In (a), we see the ordering matrix of a rank four matrix. (b) The Betti curves induced by which are the same for any matrix with the same relative ordering of entries as . (c) We depict the construction of Betti curves, by adding edges one by one relative to their weight in

Title: Sparc: enhanced microscopy image analysis tools for the production of fair neuromorphological data

Authors: M. L. HEAL, A. E. SULLIVAN, C. R. BATES, M. GULENKO, *S. TAPPAN, P. J. ANGSTMAN, J. R. GLASER;
MBF Biosci. - Microbrightfield LLC., Williston, VT

Abstract: Microscopy image analysis techniques have been constantly evolving with the onset of new microscope devices, advanced histological preparations, and cutting-edge computational technologies. Though the output of such image analysis software often allows for robust qualitative and quantitative analysis, the data files are frequently absent of file-level metadata about the subject and anatomical region from which the data was derived. Moreover, the use of cross-species anatomical ontologies (e.g., UBERON, FMA) have seldom been used in neuroanatomical reconstruction pipelines due to a lack of software tools that serve anatomical terms from these ontologies directly to the user at the time of neuron reconstruction. As public-access data portals (e.g., sparc.science), open science, and collaborative academic ecosystems become more common, the need for this rich machine-readable metadata at the file level becomes more crucial. To help prepare researchers for this shift in paradigm, we have developed tools for findable, accessible, interoperable, and reusable (FAIR) reconstruction of multi-species, multi-organ, and multi-scale neuroanatomical regions. Unlike any other software, this toolset supports the use of anatomical ontologies at the time of data creation through a direct API

connection to the SciCrunch knowledge infrastructure for accessibility of current, FAIR, and organ-specific terminology lists curated by anatomical experts. It is also equipped with verification methods to ensure all annotations have globally unique and persistent identifiers. The output file format produced by this toolset has a comprehensive and publicly available specification that richly characterizes all elements of the neuromorphological data. The amalgamation of these novel tools will facilitate scientific discovery by producing meaningful and sustainable data that can be searched for, shared, and repurposed.

Abstract: Stimulating the autonomic nervous system (ANS) to modulate organ physiological function holds enormous therapeutic promise, but the underlying mechanisms are poorly understood. The NIH Stimulating Peripheral Activity to Relieve Conditions (SPARC) program

aims to improve targeted therapies by providing public access to high value datasets, maps, tools, and predictive simulations to support the development of new, safe, and effective neuromodulation devices. Over 100 SPARC teams world-wide work on ANS mapping, manipulation/observation tools, and therapeutic translation. To assure an integrative approach and facilitate collaborative open science, SPARC has established the Data Resource Center (DRC). It i) stores, organizes, and disseminates data generated by the SPARC program, ii) establishes standards (e.g., on minimal metadata and formats) and provides curation and knowledge management services, iii) generates interactive visualizations of nerve-organ anatomy and function, and iv) offers a modelling, simulation, and data analysis platform. The SPARC Portal (https://sparc.science/) hosts data (currently > 30Tb) and computational studies, which can be found through knowledge-base and map-driven search, viewed, downloaded, or executed. The SPARC Portal provides unified access to the SPARC platform comprising: 1) Pennsieve, a cloud-based data management platform to manage, curate, and publish large scientific datasets,offers dynamic, interactive, and modular visualizations of nerve, organ and body anatomy, and function across a range of species; 2) SciCrunch, a dynamic vocabulary management system used to develop community-driven ontologies and organize curation metadata into graphs to power smart queries; 3) technology from MBF Bioscience that supports image segmentation, co-registration, annotation, and visualization; 4) the ApiNATOMY framework to define relationships between anatomy components and the nervous system; and 5) Flatmap/Scaffold views that provide multi-scale visualization of relationships and data; 6) o^2S^2PARC, an online, cloud-based, open, extensible platform for computational (neuro-)sciences, serves to predict the effects of ANS neuromodulation on organ function. Computational models and data analysis pipelines can be hosted, shared, executed, documented, and coupled. These infrastructure and approaches ensure that datasets are scientifically interpretable, reproducible and FAIR (Findable, Accessible, Interoperable and Reusable). The integration of these resources in the SPARC platform will accelerate progress in the field of bioelectronics medicine, the wider life-sciences and beyond.

Title: The Allen Cell and Structure Segmenter: An open source toolkit and Napari plugin for segmenting 3D intracellular structures in microscopy images

Authors: *K. A. GERBIN, J. CHEN, .. ALLEN INSTITUTE FOR CELL SCIENCE TEAM, S. M. RAFELSKI;
Allen Inst. for Cell Sci., Seattle, WA

Abstract: The Allen Institute for Cell Science uses high-replicate live cell imaging to understand the principles by which cells reorganize in health and disease. We aim to predict cell behavior by building a state space of structural signatures in human induced pluripotent stem cells (hiPSCs) to differentiated cell types, while building open source image analysis tools and reproducible datasets.
Towards this goal, we generated a dynamic imaging pipeline using endogenous fluorescently-tagged hiPSC lines. Each line expresses a monoallelic EGFP-tagged protein that represents a major cellular structure or organelle, including neuron-relevant structures such as the nuclear envelope (Lamin B1), nucleolus (Fibrillarin and Nucleophosmin), mitochondria (Tom20), endoplasmic reticulum (Sec61 beta), peroxisomes (PMP34), cell membrane (CAAX), actin filaments (Beta-actin), microtubules (alpha-tubulin), and more. Thousands of high-resolution 3D images are acquired for each structure and used to develop quantitative image-based assays and computational models. However, accessible cell and structure segmentation tools remain a challenge in the field, limiting the extraction of meaningful information from imaging data.
With this in mind, we developed the Allen Cell and Structure Segmenter, a Python-based open source toolkit and Napari plugin for 3D segmentation of intracellular structures. This toolkit combines classic and iterative deep learning workflows to streamline the identification of successful 3D segmentation algorithms for a wide range of intracellular structures. To make this tool broadly applicable across diverse cell types and structures, we 1) formulated a classic image segmentation workflow based on a minimal number of selectable algorithms and tunable parameters, 2) successfully applied this workflow to over 30 intracellular structures; whereby the workflows can be selected via a lookup table, 3) developed this workflow and lookup table into a user-friendly plugin for the open source image viewer Napari, and 4) implemented an iterative deep learning workflow using the results of these classic segmentation algorithms with minor manual inspection to generate a ground truth for training deep learning models.
This open source segmentation toolkit facilitates quantitative single-cell cell biology in cell types from pluripotent stem cells to neurons, leveraging state-of-the-art algorithms in computer vision for specific image segmentation needs and challenges. The Allen Cell and Structure Segmenter, as well as our suite of open source tools, methods, data, and other resources are available free to the public on our website allencell.org.

Title: In silico analysis on the stability of calpain-10

Authors: *L. M. ARRATIA-CORTÉS[1], A. V. VEGA[2], A. ZAMORANO-CARRILLO[3]; [1]Biochem. Res. Lab., PhD of Sci. in Biotech. ENMH- Inst. Politécnico Nacional, Mexico, Mexico; [2]Fes-Iztacala, UNAM, Tlalnepantla, Mexico; [3]Biochem. Res. Lab., ENMH- Inst. Politécnico Nacional, Ciudad de México, Mexico

Abstract: Calpain-10 is a non-lysosomal calcium-sensitive cysteine protease that has been proposed to play an important role in the development of diabetes mellitus and neuropathic pain as some of its potential targets are voltage-gated sodium channels (Nav). Calpains hydrolyze their substrate by separating domains from target proteins and, consequently, activate or inhibit their targets. Although multiple proteins have been identified as targets for calpains, how they recognize and interact with their targets and how they recognize the hydrolysis site remains a mystery. Here we use a bioinformatic approach to obtain a full-length molecular model of Calpain-10. The 3D structure of mouse Calpain-10 (666 aa) was constructed to visualize different conformations adopted over to 250 ns time lapse, by molecular dynamics (MD), in a simulated environment at 310 and 400 K. Calpain-10 is gradually denatured, especially the α-helix in domain I that loses its conformation throughout DM. The unfolding of the α-helix in domain I may be relevant to regulate the activation of Calpain-10 since, in contrast to calpains 1 and 2, domain I remains bound to Calpain-10 after activation. Domain III also exhibit conformational changes that could be involved in calcium binding for subsequent protease activation. This description helps us understand the functionality and stability of Calpain-10 and better understand its activation mechanisms and will help us develop more models of interactions with target proteins.

Title: Generative adversarial networks for parameter inference in populations of neuroscience models

Authors: *T. RUMBELL[1], S. SAGHAFI[2], C. O. DIEKMAN[2], J. KOZLOSKI[1], V. GUREV[1]; [1]IBM - TJ Watson Res. Ctr., Yorktown Heights, NY; [2]Dept. of Mathematical Sci., New Jersey Inst. of Technol., Newark, NJ

Abstract: In computational neuroscience, parametric families of mechanistic models are often employed to simulate neural activity from a set of recordings. In population of models (PoM) scenarios (a.k.a. stochastic inverse problems (SIP)), the parametric family is fit to a population of observed data from the model output domain, transferring a dataset of real-world observations collected across a population of individuals into the latent space of mechanistic parameters. Neural systems exhibit striking heterogeneity within populations at all scales, while at the same time multiple model parameter sets can result in equivalent activity, rendering the models noninvertible. Furthermore, these models typically have an intractable likelihood, making parameter inference challenging and inaccessible to traditional techniques. Recent advances in deep learning have enabled development of new approaches to related problems. Deep learning networks for amortized inference in likelihood-free settings have been applied in several neuroscience modeling problems [1]. However, deep learning methods have not been applied in SIP to construct parametric families of models. We present a generative adversarial network (GAN) approach to solve SIP formulated as a constrained optimization problem. We developed these methods to be generically applicable to mechanistic model parameter inference across domains, and designed them with flexible configuration that can incorporate prior information directly into the network architecture [2]. Here, we apply our GAN methods for parameter inference in neuroscience modeling problems, using models at several scales for demonstration. First, we used the Morris-Lecar model of neuronal spiking and inferred diverse populations of parameters that exhibit either Hopf or saddle-node on invariant cycle bifurcations. Second, using a Hodgkin-Huxley (HH) model [3], we inferred a population of ionic conductance parameters that are coherent with a distribution of measured rebound spike delays after hyperpolarization. Third, using a large network of HH models, we inferred distributions for global excitation and inhibition parameters that result in activity across the network matching network spiking statistics. Across these examples, we demonstrate several advanced parameter inference methods facilitated by our GAN framework, such as amortized SIP using a conditional GAN, and our constrained optimization formulation of SIP using either a neural network surrogate model to recreate the mechanistic model function, or a differentiable implementation of the mechanistic model ODEs directly incorporated into the inference architecture.

Abstract: Electrical brain stimulation techniques take advantage of the intrinsic plasticity of the nervous system and may have a wide range of therapeutic applications. In this context, vagus nerve stimulation (VNS) is an approved treatment for refractory epilepsy and drug resistant depression. Among the different modalities of VNS, a non-invasive form of VNS, auricular transcutaneous VNS (atVNS), is under investigation for different applications, including cognitive improvement. Brain regions relevant for memory performance are sensitive to vagal nerve afferents, although the impact of atVNS in brain activity has not been fully elucidated. We aimed to study the efficacy of atVNS in modulating memory persistence and brain connectivity in CD-1 male mice. Using a previously described atVNS device (Brain Stimulation 13:494, 2020), we targeted the left *cymba con*chae. We performed acute atVNS with a standard stimulation protocol under light isoflurane anesthesia. We found that novel object-recognition memory persistence was enhanced when atVNS was delivered just after, but not 3 h after, the familiarization phase. We obtained brain samples for bilateral c-Fos analysis, performing the electrostimulation protocol immediately after the familiarization phase, in various brain areas of the brainstem, hippocampus, amygdala, frontal cortex, thalamus and cortical regions of the default mode network (DMN). We first observed that atVNS did not modify overall c-Fos density in any of the brain regions analyzed. Then, correlation analysis was performed between c-Fos densities in each pair of regions to obtain matrices of significant relations in activity under non-stimulated and electrostimulated conditions. Such analysis revealed that atVNS coupled the activity of left and right *locus coeruleus*, increasing also its connection with the dentate gyrus (DG). Furthermore, the electrostimulation reinforced the relation in activity of all subregions of the hippocampus (DG, CA1 and CA3), and revealed a marked enhancement in the correlated activity between hemispheres both in prelimbic and infralimbic cortex, although it did not have marked effects on the prefrontal-retrospenial axis of the DMN. Moreover, evaluation of global brain network metrics showed a marked increase in integrity, segregation and strength properties

in the stimulated brain. Indeed, overall connectivity was found significantly increased in atVNS-exposed brains. In conclusion, our results provide new insights in the effects of atVNS on memory performance and brain connectivity, and open the possibility to extend our knowledge of the biological mechanisms of bioelectronics in medicine.

Title: Fast neural EIT for imaging of the spontaneous neural traffic of the cervical vagus nerve and its validation by spatially selective neuromodulation and MicroCT (SPARC).

Authors: *E. RAVAGLI[1], S. MASTITSKAYA[1], N. THOMPSON[1], J. PERKINS[2], A. GOURINE[1], K. ARISTOVICH[1], D. HOLDER[1];
[1]Univ. Col. London, London, United Kingdom; [2]Royal Vet. Col., London, United Kingdom

Abstract: Introduction: Fast neural EIT is a novel imaging tool which allows imaging of impedance changes caused by neuronal depolarisation. It was validated in rat sciatic nerve [1] but never used for autonomic nerves. The purpose of this work is to perform EIT imaging of spontaneous and evoked neuronal activity in cervical vagus nerve to assess the presence of fascicles with organ-specific functions. We validate the images with spatially selective neuromodulation (SSN) [2] and demonstrate the possibility of future use of EIT and SSN for precise closed-loop neuromodulation.
Methods: In N=4 pigs, multi-electrode cuff arrays for SSN (2 rings, 14 electrodes each) and EIT (1 ring, 14 electrodes) were applied on the left cervical vagus nerve. End-Tidal CO2, heart rate and EMG were recorded to monitor SSN-evoked changes in pulmonary, cardiac, and laryngeal activity, respectively. SSN was performed as in [2]. Biphasic pulses were applied at 50µs, 20Hz for recurrent laryngeal and pulmonary fascicles, and 1ms, 20Hz for cardiac fascicles. Amplitude required to evoke or modulate laryngeal, pulmonary and cardiac activity was 238±102µA, 355±105µA and 1038±634µA, respectively. EIT measurements (200µA, 6KHz) were performed over 14 pairs, 10min each. Spontaneous EIT was performed for pulmonary and cardiac activity, whereas laryngeal activity was evoked by recurrent laryngeal nerve stimulation at 50µs, 20Hz, 1.5mA. EIT data were subject to coherent averaging and image reconstruction. Vagus nerves

were dissected post-mortem for MicroCT tracing of organ-specific fascicles.
Results: EIT allowed reconstruction of three spatially separated images for laryngeal, pulmonary and cardiac fascicles. In all four animals, cross-sectional positions of laryngeal, pulmonary and cardiac SSN peaks followed the same order. For EIT, angular distances of pulmonary and cardiac activation peaks from laryngeal were 118±32° and 126±77°, respectively. For SSN, they were 125±36° and 158±57°, respectively.
Conclusions: EIT and SSN results suggest organotopic or function-specific fibre organisation in the cervical vagus nerve. EIT enables imaging of spontaneous activity within the cervical vagus nerve and evoked activity of large myelinated fibres. Together with SSN, this enables the possibility of closed-loop neuromodulation. Work in progress is analysis of MicroCT data to fully validate EIT, as well as translation of EIT and SSN to human applications.

Title: Protective anti-inflammatory reflex caused by electrical stimulation of the splenic neurovascular bundle

Authors: *C. KAISER, E. HAAG, I. SONDH, D. ZACHS, M. NEWHOFF COLLINS, H. LIM; Univ. of Minnesota, Minneapolis, MN

Abstract: Systemic inflammation is decreased by activation of the neuro-immune mechanism termed the Cholinergic Anti-inflammatory Pathway (CAP), providing a promising treatment for chronic and acute inflammatory conditions including rheumatoid arthritis, Crohn's disease, inflammatory bowel disease, sepsis, and acute kidney injury. In CAP, efferent vagus and splenic nerve activity leads to release of norepinephrine in the spleen, triggering a signaling cascade involving CD4 T-cells and macrophages that leads to inhibition of pro-inflammatory cytokine release. CAP activation by electrical stimulation of the cervical vagus nerve (VNS) in animal models decreased pro-inflammatory cytokines such as TNF-alpha, IL-1beta, and IL-6. Nearly all published research on CAP targets the vagus nerve for stimulation. However there remains

disagreement in the field about the direct anatomical pathway from the vagus nerve to the splenic nerve. To characterize the effects of CAP activation directly associated with the splenic nerve near the end-organ, our group designed a study using electrical stimulation of the splenic nerve (SNS) at its central branch proximal to innervation into the spleen, where it is embedded in a neurovascular bundle (NVB). Results demonstrated the effect of direct SNS in the absence of VNS. We assessed efficacy of SNS for treatment of acute inflammation in anesthetized rats injected with lipopolysaccharide endotoxin (LPS), a model of sepsis. LPS stimulates macrophages to heighten secretion of pro-inflammatory cytokines. Inflammation state was monitored for up to two hours post-LPS injection. Cytokine levels were assessed within circulating blood every 30 minutes and within the spleen hourly. Immunohistochemistry was performed on splenic nerve and whole spleen tissue to verify location of the splenic nerve within the neurovascular bundle using neurofilament and tyrosine hydroxylase antibodies and to assess tissue damage. Additionally, electrophysiology was performed to characterize nerve activation in response to SNS therapy. Central branch SNS provided a protective effect against LPS-induced inflammation. Cytokine levels for TNF-alpha and IL-1beta were decreased in animals that were treated with SNS compared to LPS positive controls, indicating lower systemic inflammation. Compound action potentials were successfully recorded along the splenic neurovascular bundle, providing near-organ neural activity verification of SNS therapy. No significant tissue damage was observed on the stimulated NVB compared to controls in histology. These results confirm the safety and efficacy of SNS as an alternative to VNS for activation of CAP.

Title: A Potential Novel Treatment for Hypoglycemia Utilizing Sub-Diaphragmatic Vagus Nerve Stimulation: Demonstration of a Rapid Increase in Plasma Glucose in Rat and Swine Models of Diabetes with Vagal Stimulation

Authors: *J. J. WAATAJA[1], D. GAL[1], S. M. GOETZ[2], R. K. NIHALANI[1];
[1]ReShape Lifesciences Inc., San Clemente, CA; [2]Medtronic Inc., Minneapolis, MN

Abstract: Over thirty (34.2) million Americans are diabetic w/ 1.5 million new cases per year. Hypoglycemia negatively affects diabetics. The average type 1 diabetic experiences two episodes

of symptomatic hypoglycemia/week. Severe hypoglycemia (need for a 3rd party assistance) has an annual incidence of 1.0 - 1.7 episodes per patient per year. Every year 73% of insulin dependent type 2 diabetics experience hypoglycemic episodes and 15% have severe episodes. Hypoglycemia can cause loss of consciousness, stroke, coma or death. Repeated hypoglycemic episodes have been linked to cardiovascular disease. Treatments typically involve consuming 15 grams of a fast-acting carbohydrate. However, this treatment is not ideal for nocturnal hypoglycemia & contraindicated for severe hypoglycemic episodes. Use of insulin pumps for insulin dependent diabetics is limited to ~1% of insulin dependent diabetic population. Insulin pump therapy in conjunction w/ continuous glucose monitor (CGM) technology decreases the risk of hypoglycemia, but still remains a meaningful problem in insulin dependent diabetics. Thus, there is opportunity for bio-electronic treatment modalities for management of hypoglycemia. The vagus nerve innervates organ systems that regulate plasma glucose (PG). It has been demonstrated that vagus nerve stimulation increases pancreatic endocrine hormone release and in some circumstances will induce an increase in PG; likely due to glucagon secretion. Here we tested different bio-electronic stimulation parameters delivered to the sub-diaphragmatic posterior vagus nerve (containing celiac fibers innervating the pancreas) in rat and pig diabetic model systems. First, 1 Hz stimulation demonstrated a significant 43±14 mg/dL rise in PG within 15 min in type 2 diabetic Zucker rats compared to sham. Next, we tested stimulation in an alloxan treated type 1 diabetic swine model following insulin induced hypoglycemia. Fasting PG was 446±30 mg/dL. IV injection of insulin caused a dramatic decrease in glucose to levels below 60 mg/dL. One to 2 IV injections of dextrose were required to induce a sustained increase in PG. In experimental conditions stimulation was applied following a 33% drop in PG. Responses were demonstrated with frequencies of 5 and 10 Hz; yielding a significant 38±13 mg/dL rise in glucose by 10 min. Following experiments histopathology was performed of the liver, pancreas, nerve and brain. All tissues were healthy. This methodology has the potential to work in concert with CGM technology to trigger stimulation on demand as a treatment for hypoglycemic episodes.

Title: Effects of non-invasive trigeminal nerve stimulation on visuomotor adaptation

Authors: *D. E. ARIAS, C. A. BUNEO;
Arizona State Univ., Tempe, AZ

Abstract: Trigeminal nerve stimulation (TNS) is a novel neuromodulation technique where low-intensity electrical stimulation is delivered to branches of the trigeminal nerve to modulate brain activity. The rationale behind TNS is the activation of ascending trigeminal pathways to brain stem nuclei known to influence activity in cortical structures. TNS has been shown to improve the symptoms of major depression, drug-resistant epilepsy, migraine, and other disorders. Stimulation of the vagus nerve, which has similar therapeutic profiles and projections as the trigeminal nerve, has shown the ability to enhance plasticity in motor areas. However, it is unknown whether TNS can exert similar effects. For this reason, this study explored the effects of TNS on visuomotor adaptation. Fifty-six (56) right-handed healthy subjects (26 women, 30 men; 18-36 y/a), were randomly assigned to 3 groups based on the stimulation frequency used: 120 Hz (n=19), 60 Hz (n=19) and sham (n=18). Participants performed a visuomotor rotation task that involved center-out reaching movements to eight targets arranged in a vertical plane. Four blocks of trials were performed as follows: two baseline blocks with veridical visual feedback, one adaptation block involving a 30° CCW rotation of hand visual feedback, and one washout block where the rotation was removed. TNS was applied for 20 min before the 2nd baseline block using two electrodes placed on either side of the forehead, thereby targeting the ophthalmic branches of the trigeminal nerve. Each participant set the intensity to a sub-maximum tolerable level (mean currents; 120 Hz: 3.01 ± 0.76 mA, 60 Hz: 3.43 ± 0.83 mA). No current was applied to the sham group. To minimize variations in emotional states across subjects, during the stimulation phase participants viewed images of neutral valence and arousal obtained from the International Affective Picture System. Visuomotor performance was quantified by the directional error (DE), defined as the angular difference between the hand position and the virtual feedback at peak velocity. DE across the adaptation block was fitted to a double exponential model to capture the fast and slow learning processes that drive motor adaptation. Preliminary analyses showed that the 60 Hz group had the slowest adaptation among groups. In addition, learning rates were initially similar between the 120 Hz and sham groups, but gradually diverged, with the 120 Hz group exhibiting slightly faster rates than sham later in the adaptation block. The results suggest that TNS is associated with frequency-dependent effects on visuomotor adaptation, which provides new information on the potential use of TNS in motor applications.

Title: Using vagus nerve stimulation to shape neuromodulation of the neocortex

Authors: Z. H. MRIDHA[1,3], J. W. DE GEE[1,3], ***S. LEE**[2,3], S. ALEEM[1,3], E. NEYHART[1], J. REIMER[1], M. THOMPSON[1,3], K. JASPE[1,3], M. J. MCGINLEY[1,3,4];

Abstract: It is now known that neuromodulators are responsible for dynamically adjusting the functional brain state to changes in the environment. Dysfunction of neuromodulator signaling is central to many neurological and psychiatric disorders, including Parkinson's disease, depression, epilepsy and addiction. We have recently reported that electrical stimulation of the mouse vagus nerve activates cholinergic axons in neocortex (Mridha et al. 2021). Acetylcholine is heavily involved in modulating neuronal excitability, plasticity, cortical state and cognitive tasks such as attention and memory. Vagus nerve stimulation (VNS) thus provides a promising avenue to treat a broad range of disorders and perhaps shape brain state.
Here, we leverage a combination of two-photon (2P) advanced imaging techniques and genetically encoded fluorescent sensors to characterize the dynamics of VNS-evoked changes in acetylcholine concentration with high spatiotemporal resolution. The sensors were developed by coupling neurochemical-sensing G protein-coupled receptors (GPCRs) with a circularly-permuted fluorescent protein (Jing et al. 2018). We injected the specific $GRAB_{ACH}$ sensors to the auditory cortex (A1) and recorded the VNS-evoked acetylcholine concentration as well as the pupil dilatation. Corroborating our previous cholinergic axon results, we here find that VNS parametrically increases cholinergic concentration in neocortex.
We also show that pupil dilation is a reliable and convenient biosensor for successful VNS. Pupil size is widely used as a non-invasive metric of brain state. Previous studies, including ours, have shown links between pupil size and the activity in major neuromodulatory systems including the basal forebrain acetylcholine system (Reimer et al., 2016; Mridha et al. 2021). Exploiting this relationship, we are working on closed-loop applications based on real-time pupil detection in combination with VNS. Applications range from "clamping" the brain's arousal state at the optimal level to perform a certain cognitive task, to guide VNS parameter selection for more targeted neuromodulation in a range of disorders.

Title: Differential activation of locus coeruleus neurons by vagus nerve stimulation bursting parameters

Authors: *A. FARRAND[1], V. JACQUEMET[2,3], R. VERNER[4], E. BEAUMONT[1];
[1]Biomed. Sci., East Tennessee State Univ., Johnson City, TN; [2]Pharmacol. and Physiol., Inst. of Biomed. Engineering, Univ. of Montreal, Montreal, QC, Canada; [3]Res. Ctr., Sacred Heart Hosp. of Montreal, Montreal, QC, Canada; [4]Neuromodulation division, LivaNova PLC, Houston, TX

Abstract: Vagus nerve stimulation (VNS) is used to treat epilepsy and depression, and additional uses such as heart failure and rheumatoid arthritis are under investigation. The noradrenergic center locus coeruleus (LC) is a key mediator for effects of VNS in the brain; however, the optimal stimulation parameters for ideal neuromodulatory effects remain unknown. Therefore, the current study examines neuronal response profiles during 11 VNS paradigms for ideal LC activation. Extracellular activity was recorded in left LC for chloralose-anesthetized rats (n=12) using stereotaxically-placed, high-impedance tungsten electrodes. VNS paradigms were delivered in a pseudorandom fashion for 5 consecutive cycles via a bipolar cuff electrode around the left cervical vagus nerve. These 11 predetermined VNS paradigms utilized variable standard frequencies and bursting characteristics to alter LC activity. Recorded neurons (n=83) were divided into categories based on firing rate changes from baseline during VNS: non-responders, negative, positive, and super responders. Additionally, timing response profiles of neurons were assessed: correlation of firing to VNS on periods, changes in synchrony between LC neurons during VNS, and latency/spike density during bursting VNS paradigms. Responses to stimulation are reliable and have expected latency, which implies causation by VNS. Overall, standard VNS paradigms drive greater responders initially, while bursting paradigms yield more positive responders across the 5 VNS cycles ($p<0.05$). Increasing VNS frequency yields higher super responders ($p<0.05$). For bursting paradigms, shorter intervals and fewer pulses per burst show more responders ($p<0.05$). Furthermore, standard paradigms show more cells negatively correlate with VNS ($p<0.01$). Greater numbers of cells are positively correlated with VNS with

more pulses per burst (p<0.05), with shorter intervals between bursts, and as standard VNS frequencies increase (p<0.01). LC synchrony is increased during VNS for the majority of bursting paradigms (p<0.05), but not for standard paradigms. For standard paradigms, 20 Hz is ideal for driving positive LC activation, while 5 Hz best negatively activates LC. Increased synchrony during bursting VNS suggests common input/network recruitment that may be ideal for nuclei like LC with strong phasic response profiles, with median frequencies and pulse numbers/short intervals having the strongest positive response. Stronger negative LC responses are observed with longer bursting intervals and lower frequencies. These results may provide insight into ideal parameters that will help maximize clinical efficacy of VNS.

Title: Electrical stimulation of subdiaphragmatic vagal trunk slows development of hypertension in the SHR

Authors: *E. W. DIRR[1], K. J. OTTO[2], J. ZUBCEVIC[1];
[1]Physiol. and Pharmacol., Univ. of Toledo, Toledo, OH; [2]Univ. of Florida, Gainesville, FL

Abstract: Introduction: The vagus nerve facilitates bidirectional communication between the gut and brain. A low vagal tone has been described in many conditions characterized by inflammation and gut dysbiosis, including hypertension (HTN). However, the role of the sub-diaphragmatic gut-projecting vagal nerve branches in control of blood pressure (BP) remains unclear. This study examines the effects of augmenting subdiaphragmatic vagal signaling on development of HTN in spontaneously hypertensive rat (SHR), a rodent model of neurogenic age dependent HTN characterized by gut dysbiosis. **Methods**: Juvenile male SHR (N=10, 8 wo) were implanted with telemetric BP transducers and either a silicone cuff electrode (STIM, N=5) or sham cuff devoid of electrode sites (SHAM, N=5) on the ventral subdiaphragmatic vagal

trunk. Following recovery and baseline BP recordings, STIM rats were connected to a stimulus generator and subjected to biphasic (600 μA, 500 us/phase, 25 Hz) vagus nerve stimulation (10 minutes/ session, 3 sessions/ day, 5 days/ week). SHAM rats were subjected to similar handling but with no stimulation. 24 hr continuous BP recordings were obtained once per week for six weeks in all rats. Analysis of cecal bacterial abundance and composition was completed using the Illumina platform 16s bacterial sequencing at endpoint. **Results**: Starting at five weeks after stimulation onset, diastolic BP in SHAM rats was significantly higher compared to baseline (ΔDBP= +26.7 mmHg, $p < 0.001$). This was not observed in STIM rats (ΔDBP= +15.2 mmHg, $p = 0.15$). Four weeks after the onset of stimulation, we observed a significantly elevated systolic (ΔSBP= +22.5 mmHg, $p = 0.002$) and mean BP (ΔMBP= +16.7 mmHg, $p = 0.009$) in SHAM rats alone when compared to baseline. Both SHAM and STIM groups showed a significantly elevated SBP and MBP at weeks five compared to baseline, which remained elevated for the duration of the study. Gut bacterial sequencing showed no significant differences in diversity or abundance of big bacterial phyla between groups. However, the abundance of bacterial orders of *Anaeroplasma*, *Anaeroplasmataceae*, and *Anaeroplasmatales* was higher in the SHAM versus STIM group. **Conclusions**: Bioelectric restoration of sub-diaphragmatic vagal signaling may be beneficial in reparation of gut-brain neural axis and cardiovascular homeostasis. This is demonstrated through alleviated increase in DBP and delay in increase in SBP and MBP in the SHR following chronic vagal stimulation. These changes may be due to effects on afferent vagal signaling and/or gut microbiota induced by subdiaphragmatic vagal stimulation.

Abstract: Advancements in bioelectronic medicine have enabled the treatment of various disorders through neuromodulation. However, existing approaches often require invasive surgeries to reach therapeutic nerve targets and implantation of centimeter-sized devices. Here we demonstrate that it is possible to stimulate peripheral nerves from within blood vessels using a millimeter-sized wireless stimulator that can be delivered minimally invasively through a percutaneous catheter. By taking advantage of the vascular system that accompanies nerves as part of the neurovascular bundle, stimulation leads can be directed through the blood vessels to specific nerve targets that are difficult to reach with traditional surgeries. This would significantly lower the barrier to entry for neuromodulatory treatment approaches because of the reduced risk. These mm-sized implants are achieved through the use of magnetoelectric materials to deliver data and power to a digitally programmable 0.8 mm^2 CMOS system-on-a-chip. As a proof-of-principle, we demonstrate that these MagnetoElectric powered Bio-ImplanTs (ME-BITs) can stimulate peripheral nerves both directly and from within the blood vessels in rodent and porcine models. The wireless endovascular nerve stimulator (EVNS) shown here opens the door for the possibilities of a new class of low risk and highly precise endovascular bioelectronic medicine with direct access to difficult to reach nerve targets and analytes within the blood for fully closed-loop systems without the need for open surgery.

Title: The role of KIF11 in modulating microtubule dynamics and dendritic transport

Authors: *J. WINGFIELD[1], S. V. PUTHANVEETTIL[2];
[1]Scripps Res. Inst., JUPITER, FL; [2]Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: During mitosis the cell relies on a several different microtubule motors to dynamically manipulate the microtubule architecture for proper cell division. Interestingly, several of these motors are expressed in postmitotic neurons, including KIF11 (kinesin-5) which walks on antiparallel microtubules to separate the spindle poles. A recent study from our lab found that knockdown of KIF11 in mouse primary hippocampal cultures leads to increased dendritic

arborization, the number of synapses, and synaptophysin and piccolo expression (Swarnkar et al. 2018). We sought to investigate the mechanism by which KIF11 regulates dendritic arborization by first examining how KIF11 modulates microtubule dynamics in dendrites. We expressed Dendra-EB1 in primary hippocampal cultures and utilized two different KIF11 inhibitors: one that prevents KIF11 from binding to microtubules (Ispinesib) and one that locks KIF11 in the rigor state, bound to microtubules (BRD9876). Ispinesib treatment significantly increased the frequency of retrograde EB1 comets compared to both the vehicle (~330%) and BRD9876 (~480%). However, BRD9876 had no significant effect on the frequency of EB1 comets in either the anterograde or retrograde direction. Curious if a change in microtubule dynamics would broadly impact microtubule-based transport, we visualized trafficking of mitochondria in primary hippocampal cultures by employing MitoTracker© Green. Intriguingly, Ispinesib treatment led to a significant decrease in anterograde transport compared to the vehicle (~240%) and BRD9876 (~380%); as well as an increase in retrograde transport of mitochondria compared to the vehicle (~260%) and BRD9876 (~180%). Again, we found BRD9876 had no significant effect on the trafficking of mitochondria compared with the vehicle. Given that BRD9876 prevents KIF11 from walking on microtubules and addition of this drug had no impact on EB1 comets of mitochondrial transport, we suspect KIF11 is already in the rigor state and acts to stabilize microtubules in dendrites. We reason that the observed increase in dynamic minus-end-out microtubules upon KIF11 inhibition is what ultimately leads to increase in arborization, and synapse number seen with KIF11 knockdown. We propose a new model for dendritic arborization in where dynamic minus-end-out microtubules initiate the formation of a new dendritic branches.

Title: The chaperonin CCT is required for dendritic elaboration through cytoskeletal regulation

Authors: *E. N. LOTTES, B. TETE, D. N. COX;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Neuronal proteostasis is integral to the growth and maintenance of intricate and polarized cellular architectures. Chaperones are a key part of proteostatic maintenance

machinery, and ensure proper conformation of other proteins. While chaperones are particularly important in neurons, they have been under-studied in dendrites. Chaperonin-containing tailless complex polypeptide-1 (CCT) is an ATP-dependent chaperonin comprised of eight subunits which come together to form a barrel-shaped complex. CCT is thought to fold anywhere from 1-15% of the cellular proteome. Two of its most notable clients are actin and tubulin - major cytoskeletal components essential to the development and maintenance of dendritic arbors. Although CCT has been studied in axons, especially in conjunction with Hereditary Spastic Paraplegia, a genetic disease marked by advancing neuropathy, the potential function of CCT is not well understood in dendrites. Therefore, we investigated the role of CCT in the dendrites of *Drosophila melanogaster* multidendritic (md) sensory neurons of the peripheral nervous system using neurogenetics; *in vivo* imaging; and neuromorphometric quantitative analyses. Loss-of-function (LOF) genetic analyses support recently published work showing that disruption of each of the eight CCT subunits results in dendritic hypotrophy in dendritically complex Class IV (CIV) sensory neurons. Dendritic complexity plateaus in early third instar stage in CCT LOF conditions, revealing a failure of elaboration due to LOF of the chaperonin. Despite findings in CIV neurons, a LOF screen of simpler Class I, II and III neurons did not reveal any hypotrophy due to loss of CCT. Transcriptomic analyses of these neuron classes reveal highest levels of expression in CIV neurons and lowest in CI neurons. Together, these findings suggest that different neuronal types have differential reliance on CCT function. This is bolstered by our cytoskeletal investigations, which have revealed that homozygous mutation of CCT5 leads to decreased levels of stable microtubules in CIV but not CI neurons. Through live multi-channel imaging we have confirmed that loss of CCT results in both decreased stable MT and F-actin signal throughout the dendritic arbor. Polarity of MT EB1 comets is preserved in CCT LOF conditions, though the comets are fewer and slower. Early work on the CCT co-chaperone, Prefoldin (PFD), suggest that PFD LOF results in phenotypically similar but milder hypotrophy and reductions in cytoskeletal signal. Together, our findings indicate that CCT is necessary for the elaboration of dendritic arbors through regulation of the cytoskeleton in complex CIV md neurons.

Title: Fat3 acts through independent cytoskeletal effectors to coordinate asymmetric cell behaviors during polarized circuit assembly

Authors: *E. AVILES[1], A. KROL[1], S. J. HENLE[1], J. BURROUGHS-GARCIA[2], M. R. DEANS[2], L. V. GOODRICH[1];

Abstract: The correct localization of neurons, their processes, and their synapses is crucial for the proper flow of information within a neural circuit. This polarity emerges sequentially in development, starting with directed migration of neuronal precursors, which subsequently elaborate neurites that form synapses in specific locations. Although several molecules required for synapse formation between specific partners have been identified, less is known about the molecular mechanisms that control where synapses form relative to other neurons in the circuit. The retina offers an excellent example of the link between the morphology of an individual neuron and its position in the circuit. In the retina, synapses occur exclusively in the outer and the inner plexiform layers (IPL). Amacrine cells (ACs), whose cell bodies reside either in the inner nuclear layer or retinal ganglion layer, make connections with other retinal cells in the IPL. Thus, developing ACs must extend processes that are oriented towards the IPL, regardless of where their cell bodies are positioned. We focused on AC development to study the molecular mechanisms that govern neural circuit polarity. In other organs, Fat cadherins sense position and polarize individual cells by inducing localized changes in the cytoskeleton that are coordinated across the tissue. Similarly, the polarized organization of the retina depends on Fat3, an atypical cadherin that controls where neurons migrate, which processes they retract, and where their synapses form. Here, we show that Fat3 acts through discrete modules in its intracellular domain (ICD) to coordinate these diverse features of circuit assembly. We found that Fat3-ICD interacts with cytoskeleton regulators, including Kif5B, Ena/VASP proteins, and the WAVE regulatory complex (WRC). By using CRISPR/Cas-9 to delete specific modules from the Fat3-ICD in mice, we found that neuronal migration, neurite retraction, and synapse localization are controlled by independent sets of effectors. Removal of binding motifs to WRC and Kif5B, but not Ena/VASP, affected AC migration. Consistently, the WRC is mislocalized in Fat3-deficient ACs, and deletion of Abi1 - a critical component of the WRC - resulted in AC migration defects. On the other hand, all three Fat3-ICD motifs are required for neurite retraction and, in their absence, synapses occur outside of the IPL. Unexpectedly, upon deletion of most of the Fat3-ICD, extra neurites were retained but they did not form ectopic synapses, suggesting that Fat3 acts in an independent pathway for synapse localization. Thus, Fat3 serves as a molecular node to coordinate different asymmetric cell behaviors across development.

Title: The kpc-1 3'UTR promotes dendritic transport and local translation of mRNAs to regulate dendrite branching and self-avoidance of a nociceptive neuron

Authors: *M. SHIH[1], Y. ZOU[2], H. CHIU[3], T. FERREIRA[4], N. SUZUKI[1], W. ZOU[5], C.-F. CHUANG[1], C. CHANG[1];

Engin. and HHMI, California Inst. of Technol., Pasadena, CA; [4]Div. of Developmental Biology, Cincinnati Children's Hosp. Res. Fndn., Cincinnati, OH; [5]The Fourth Affiliated Hospital, Zhejiang Univ. Sch. of Med., Yiwu, China

Abstract: Mechanical stimuli on the skin of *C. elegans* are detected by the dendritic arbors of PVD nociceptive neurons, which provide uniform sensory coverage outside the head region across the entire animal. Through genetic screens, we isolate three mutants that display profound dendrite self-avoidance defects in PVD neurons. Studying dendrite self-avoidance in *C. elegans* is likely to provide new mechanistic insight into the process as the well-known self-avoidance molecule Dscam is absent from the *C. elegans* genome. Through whole genome sequencing, we identify the responsible mutations in the *kpc-1* gene. Compared to wild-type animals, a strong *kpc-1* mutant allele exhibits secondary dendrite branching defects whereas a weak *kpc-1* mutant allele displays tertiary dendrite self-avoidance defects. Here, we show that the *kpc-1 3' UTR* is required for *kpc-1*'s functions in both dendrite branching and dendrite self-avoidance. The *kpc-1* 3'UTR facilitates *kpc-1* RNA localization to branching points and contact points between sibling dendrites. Using fluorescence recovery after photoconversion, we show that the *kpc-1* 3'UTR promotes local protein synthesis in the distal segment of PVD dendrites. We identify an important secondary structural motif in the *kpc-1* 3'UTR required for tertiary dendrite self-avoidance. We demonstrate that over-expression of *kpc-1* leads to greater self-avoidance without limiting initial dendrite outgrowth, supporting a direct role of *kpc-1* in self-avoidance. Animals with *dma-1* receptor over-expression display similar secondary dendrite branching and tertiary dendrite self-avoidance defects that are suppressed with *kpc-1* over-expression, which suggests that DMA-1 is a potential KPC-1 target that is down-regulated by KPC-1. Our results support a model where KPC-1 proteins are synthesized locally at branching points and contact points between neighboring dendrites to locally down-regulate DMA-1 receptors to promote dendrite branching and self-avoidance.

Title: The PP2A serine/threonine phosphastase complex regulates cell-type specific cytoskeletal organization to promote dendritic diversification

Authors: *S. BHATTACHARJEE[1], E. N. LOTTES[1], S. NANDA[2], G. A. ASCOLI[2], D. N. COX[1];
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Ctr. for Neural Informatics, Structures & Plasticity, Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Uncovering the molecular mechanisms that regulate dendritic diversification is essential to understanding the formation and modulation of functional neural circuitry. Transcription factors (TFs) have been widely implicated in regulating dendritic diversity but the molecular mechanisms by which this is achieved remain incompletely understood. Previous studies in our lab have demonstrated that the TF Cut regulate cell-type specific dendritogenesis through cellular pathways that converge on cytoskeletal architecture in *Drosophila* multi-dendritic (md) neurons. Neurogenomic and phenotypic analyses identified the highly conserved PP2A serine/threonine phosphatase complex as a downstream effector of Cut. The PP2A complex is composed of a catalytic subunit encoded by *microtubule star (mts),* a scaffolding subunit encoded by *PP2A-29B* and one of four alternate regulatory subunits encoded by *widerborst (wdb), twins, well-rounded (wrd)* and *CG4733.* Mutant analyses of *mts* and *PP2A-29B* reveal severe reductions in dendritic arborization with *wdb* functioning as the relevant regulatory subunit in Class IV (CIV) md sensory neurons. In contrast, mutations in *mts* and *PP2A-29B* leads to increased dendritic complexity via *de novo* filopodia formation in Class I (CI) md sensory neurons. Mechanistically, while Mts and PP2A-29B are also part of the STRIPAK complex, our data indicate that the PP2A and STRIPAK complexes function in parallel to regulate dendritic architecture. Cellularly, live imaging reveals that *mts* mutations leads to microtubule (MT) destabilization and increased MT turnover. In addition, dynamic EB1::GFP imaging reveals Mts is required to maintain both dendritic and axonal MT polarity. In contrast to its effects on MT, *mts* knockdown leads to F-actin reorganization with a proximal shift towards the soma and actin hyperstabilization. Loss of *mts* has distinct effects on organelle trafficking in these neurons. In CIV neurons, *mts* knockdown leads to reductions in dendritic

localization of organelles including mitochondria and satellite Golgi outposts while CI neurons show increased Golgi outpost trafficking along the dendritic arbor. Further, *mts* mutant neurons exhibit defects in neuronal compartmentalization with selective markers of dendrites and axons being detected in opposing compartments. At a regulatory level, phenotypic and immunohistochemical analysis reveal that β-tubulin subunit 85D is a common PP2A target in CI and CIV md neurons while the TF FoxO may be a target of the complex in CI neurons. Collectively, these studies provide novel insights into the functional roles of the PP2A phosphatase in promoting dendritic diversity.

Title: Initiation vs. elongation: determining the specific contribution of Ca_V1 channels to activity-dependent neurite outgrowth in cerebellar granule neurons

Authors: *A. L. PARKER, B. MEADE, H. WEN, A. J. WILLIAMS;
Dept. of Psychiatry, Univ. of Iowa, Iowa City, IA

Abstract: The neuropsychiatric disease-associated Ca_V1 channels are critically involved in neurodevelopment. It has been shown in multiple neuronal subtypes that KCl-induced activity induces dendritic growth through Ca_V1 channels. These measures of dendritic growth have largely used global measurements of dendritic growth, such as total dendritic length and dendritic branching. While these data are useful for identifying general phenotypic changes due to Ca_V1 channels, they combine the output of multiple biological processes, namely dendritic initiation and elongation. Dendritic initiation is the process by which actin-derived processes are extended from existing structures. Conversely, dendritic elongation is the microtubule-driven invasion and stabilization of dendrites. These two processes are mediated by different cell signaling pathways yet existing studies of Ca_V1 channels have not distinguished between them. Therefore, the underlying mechanism for how Ca_V1 channels specifically impact activity-dependent dendritic growth is not yet known.
In this study, I use sparsely labelled cerebellar granule neurons to specifically measure the number and length of the neurites for each individual cell to determine how activity-dependent neurite initiation and elongation are respectively impacted. I measured both primary neurites

(directly from the soma) and secondary neurites (branching from existing neurites) to determine how each of these components are impacted.
This study shows that KCl-induced activity is significantly associated with increased dendritic number and not dendritic length. Therefore, KCl-induced activity impacts dendritic initiation, not dendritic elongation. I next assessed the contribution of Ca_V1 channels to KCl-induced neurite initiation through the use of both a Ca_V1 channel antagonist and agonist. I showed that Ca_V1 channels impact the number of primary neurites induced by KCl without affecting the number of secondary neurites. This indicates that Ca_V1 channels are specifically involved in activity-dependent primary dendrite initiation, not secondary dendrite initiation.
These data clarify existing knowledge on the relationship between Ca_V1 signaling and dendritic growth and provide a framework for connecting the neurodevelopmental function of these channels to long-term changes in neuronal structures and function. The next steps of this research will be to identify the downstream signaling pathways and mechanisms for how Ca_V1 channels affect primary neurite initiation in cerebellar granule neurons.

Title: Activation of the G protein-coupled estrogen receptor (GPER) promotes neural development in rat embryonic (E18) hippocampal neurons

Authors: *F. XU[1], M. ROSATO[1], K. PEMBERTON[1], C. DELEON[2], C. ARNATT[2];
[1]Biol., [2]Chem., St. Louis Univ., Saint Louis, MO

Abstract: Accumulating evidence has proven that the steroid hormone estrogen plays a pivotal role in the nervous system, ranging from its development and function to neuroprotection after injury. The mechanistic actions of estrogens in the nervous system were originally restrained to classical, nuclear estrogen receptors (ERs), ERα and ERβ, which regulate gene transcription processes. Recently, the seven transmembrane domain of G protein- coupled receptor 30 (GPR30) has been identified to be a third estrogen selective receptor, namely the G protein-coupled estrogen receptor (GPER). Although mounting evidence has suggested GPER's

profound roles in neural survival and protection, a caveat is that most studies have primarily looked at the effects of estrogen and GPER in mature neurons derived from postnatal to adult animals or after neural network has been established. GPER's roles and working mechanisms in early neuronal development, especially the development of neurites (axons and dendrites), is severely lacking. In this study, we investigated the role of GPER activation in neural development of the primary rat embryonic (E18) hippocampal neurons. Our preliminary data revealed that activation of GPER by selective agonist G1 and non-selective agonist 17β-estradiol (E2) significantly increased neurite outgrowth. GPER activation also increased neuronal excitability and intracellular calcium (Ca^{2+}) in hippocampal neurons. All these effects were significantly inhibited by GPER selective antagonist G15, implicating GPER's specific effects. The rise in Ca^{2+} involved extracellular entry via Ca^{2+} channels and phospholipase C (PLC)-mediated intracellular Ca^{2+} store release. RNA sequencing data revealed the significant upregulation of transcripts for protein kinases such as Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and Akt (known as Protein Kinase B), as well as axonal/dendritic proteins such as the collapsing response mediator protein (CRMP) and growth associated protein 43 (GAP 43). Future studies
of these signalling pathways and neuron cytoskeletal proteins in GPER action will advance our mechanistic understanding of estrogen' effects in the nervous system and provide new knowledge for promoting nervous system development.

Title: Neurochemical dissection of the complex micro-structure of the stria terminalis in infant and adult macaque monkey

Authors: *M. SAKHARKAR[1], K. S. ROCKLAND[2], A. DUQUE[3];
[1]Boston Univ., Boston, MA; [2]Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [3]Neurosci., Yale Univ. Sch. Med., New Haven, CT

Abstract: The stria terminalis (ST) is a bidirectional fiber tract anchored in the amygdala and bed nucleus. While the general C-shaped trajectory is well-established, there is much less known about the micro-organization, especially in macaque monkeys, the subject of the present study.

In parallel histological series reacted for antibodies against fiber or cellular elements, we addressed this question in five brains from one adult (8 years) and 4 infants (2.5 months old). Brains were frozen sectioned at 50μm in the coronal plane, with 1 mm within series spacing. Both the dorsal and ventral ST (dST, vST) were investigated, standardized to the anterior-posterior (AP) extent of the lateral geniculate nucleus (~7 mm). This gave several specific results: 1) In the dST and vST, myelin-poor bands or patches were evident and coincided with dense fiber bundles positive for calbindin (CB), calretinin (CR), or tyrosine hydroxylase (TH). These were medially biased, dorsal-ventrally oriented in the vST, but more medio-lateral in dST. In vST, fibers positive for neuropeptide Y (NPY) or somatostatin (SOM) were laterally biased, avoiding the ventralmost edge of the ST. Fibers positive for choline acetyltransferase were preferentially located dorsolateral (vST). 2) Large thalamostriatal blood vessels bordered and partly invaded the dST (medially) and vST (laterally and ventral) and were often associated with TH and NPY fibers. 3) Small clusters and scattered neurons, visualized by neuronal nuclei protein (NeuN), occurred across the AP extent. Neuron number was larger for dST than vST; and dST and vST counts, averaged over 5 sections per brain, were less numerous in the adult brain (dST: 70.4 ± 25.6 (SD), vST: 34.4 ± 17.7) than in the 2.5M infant brains (dST: 105.8 ± 3.9 (SEM), vST: 67.9 ± 3.4). 4) Subgroups of neurons were verified as positive for CR (the largest number), NPY, CB, or SOM. For the infants and adult respectively, the average number of neurons per section (vST) was CR (14.6 ± 1.9; 7.0 ± 1.0), NPY (5.1 ± 1.0; 2.5 ± 1.3), CB (3.9 ± 0.9; 4.0 ± 1.9), and SOM (n=2 infants: 3.8 ± 1.6; 2.8 ± 1.5). For dST, equivalent counts were CR (19.8 ± 2.6; 6.2 ± 1.6), CB (9.9 ± 0.5; 5.6 ± 6.0), NPY (8.6 ± 0.8; 3.0 ± 1.2), and SOM (for n=2 infants: 6.9 ± 0.7; 3.0 ± 1.6). 5) Cell size and shape are heterogeneous within each subpopulation. Neurons have previously been reported in the ST (rodent: Alheid et al., 1998; primate: Martin et al., 1991), and considered part of the extended amygdala. However, the conspicuously lower numbers in the adult brain recall the developmental cell loss typical of telencephalic white matter neurons (Kostovic and Rakic, 1980), raising the possibility that these neurons are intrinsic to the ST.

Title: White matter connectivity patterns in tool-using primates

Authors: *A. MURPHY[1], K. A. PHILLIPS[3,4], S. F. BROSNAN[5,6,7,8], E. E. HECHT[2];
[1]Human Evolutionary Biol., [2]Dept. of Human Evolutionary Biol., Harvard Univ., Cambridge, MA; [3]Psychology, Trinity Univ., San Antonio, TX; [4]Texas Biomed. Res. Inst., San Antonio, TX; [5]Psychology, [6]Language Res. Ctr., [7]Ctr. for Behavioral Neurosci., [8]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Extensive tool-use is one of the hallmark features of human behavior. While human tool-use exceeds that of other species in complexity, other primates have shown the ability to utilize tools. Chimpanzees and bonobos (last common ancestor (LCA) with humans of 6-7 million years ago (Ma)) show tool-use behaviors in the wild. Other species, such as Rhesus macaques (LCA with humans of 25Ma), can use tools in captive settings but do not do so extensively in the wild. A group of even more distantly related primates, capuchins (LCA with humans of 40Ma), show convergent evolution of percussive stone tool use with humans and chimpanzees. Like humans, capuchins show high relative brain to body mass as well as sophisticated social behaviors including cooperation. Previous work comparing humans, chimpanzees and rhesus macaques has suggested that greater tool-using ability corresponds to more distributed patterns of temporal-parietal and fronto-parietal white matter connectivity. However, it is currently unclear whether similar neurological changes underly the ability to use tools in Old World and New World primate lineages. To address this question, 20 capuchins (*Sapajus apella*) were scanned at 3T. T1 images were acquired at a voxel size of 0.5mm isotropic, and diffusion-weighted imaging was acquired at 1.0mm isotropic at 128 directions with 11 B0s. Probabilistic tractography was performed using TRACULA. Seed regions-of-interest were areas of the brain associated with the social learning of tool use, including the ventral premotor area, ventrolateral prefrontal cortex, intraparietal lobule, superior temporal sulcus, and inferior temporal cortex. The thresholded extent of projections from these regions were compared both to humans and to other tool-using non-human primates. By comparing connectivity across distantly related primates who have displayed tool-using behavior, it may be possible to pinpoint specific patterns of connectivity that are associated with tool-use. This can allow for a better understanding of what changes in the brain may underly the evolution of this ability.

Title: Neuroanatomical asymmetry in the canine brain

Authors: *S. A. BARTON[1], D. A. GUTMAN[3], T. M. PREUSS[4], M. KENT[5], E. E. HECHT[2]; [1]Human Evolutionary Biol., [2]Dept. of Human Evolutionary Biol., Harvard Univ., Cambridge, MA; [3]Dept Psychiatry & Behavioral Sci., Emory Univ. Dept. of Psychiatry and Behavioral Sci., Atlanta, GA; [4]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA; [5]Univ. of Georgia, Athens, GA

Abstract: In the brains of both humans and our ape relatives, research has documented left/right asymmetries in gray matter morphology, white matter connections, and functional activations. These asymmetries have been linked to specialized behavioral adaptations including language, gestural communication, handedness, and tool use. Meanwhile, left/right asymmetries in behavioral tendencies have been recognized across the animal kingdom, suggesting a deep evolutionary origin for the lateralization of physiological mechanisms underlying behavior. However, it is unknown to what extent brain asymmetries underlying lateralized behaviors are a general feature of large, complex brains or a unique adaptation of the primate lineage. Canids and other carnivores evolved large, complex brains independently and convergently with primates, and therefore offer an opportunity to address this question. We examined T1-weighted MRI images of 62 domestic dogs from 33 breeds, opportunistically collected from a veterinary MRI scanner from dogs who were referred for neurological examination but were not found to show any neuropathology. Images were segmented into gray matter, white matter, and CSF. Gray matter segmentations were registered to a bilaterally symmetric, study-specific template using ANTS and then modulated by the Jacobian determinant of the warpfield, an index of where and how much each subject's scan had to deform to come into alignment with the template. We then left/right flipped these images and computed original-flipped and flipped-original maps. Finally, we applied one-sample t-tests for the two subtraction images using Monte Carlo permutation testing. Volumetrically asymmetric regions of gray matter include portions of temporal, frontal, and piriform cortex. We additionally assessed the relationship between these gray matter asymmetries and historical functional specializations across breeds such as herding, guarding, and companionship. These results help inform our understanding of the neural basis of behavior in dogs, and more generally, suggest that asymmetry may be a common feature underlying the evolution of large brains and complex behavior across clades.

Abstract: Determining the unique specializations of the human brain requires an understanding of how the long distance connectivity has been modified and reorganized since our evolutionary divergence from other primates. Recent work by our group (Bryant et al., 2020) elucidated putative human and chimpanzee white matter specializations that arose since our divergence from our recent common ancestor with chimpanzees, by comparing the major white matter bundles of those two species using macaques as an outgroup. However, to identify which specializations are unique to hominids (great apes) and which are unique to hominoids (great and lesser apes) requires the characterization of hylobatid (lesser ape) white matter organization. We produced a white matter atlas using probabilistic diffusion tractography on an ex vivo diffusion-weighted scan of a lar gibbon (Hylobates lar) brain from Copenhagen Zoo. The brain was formalin-fixed within 24 hours, stored in phosphate buffered saline, and scanned in fluorinert. Diffusion-weighted resolution was 0.6 mm * 0.6 mm, b-value = 4000 s/mm2. Protocols seeding in the bodies of 24 major white matter tracts, originally derived from protocols designed for humans and macaques (De Groot et al., 2013; Mars et al., 2018) were adapted based on our previous comparative investigations (Bryant et al., 2020). Tractography was carried out in native space using FSL's XTRACT (Warrington et al., 2020) and thresholded to produce maps of 24 major white matter tracts (fig. 1). Tracts were projected to the surface by multiplying the tracts with a matrix describing the tractography of the grey/white matter boundary to the whole brain (O'Muircheartaigh & Jbabdi, 2017), creating a cortical termination maps. Ongoing work will use exploit this map to create a formal comparison of great ape, lesser ape, and Old World monkey connectional anatomy to offer insight into the evolutionary trajectory of white matter organization in hominoid evolution (cf. Mars et al., 2018).

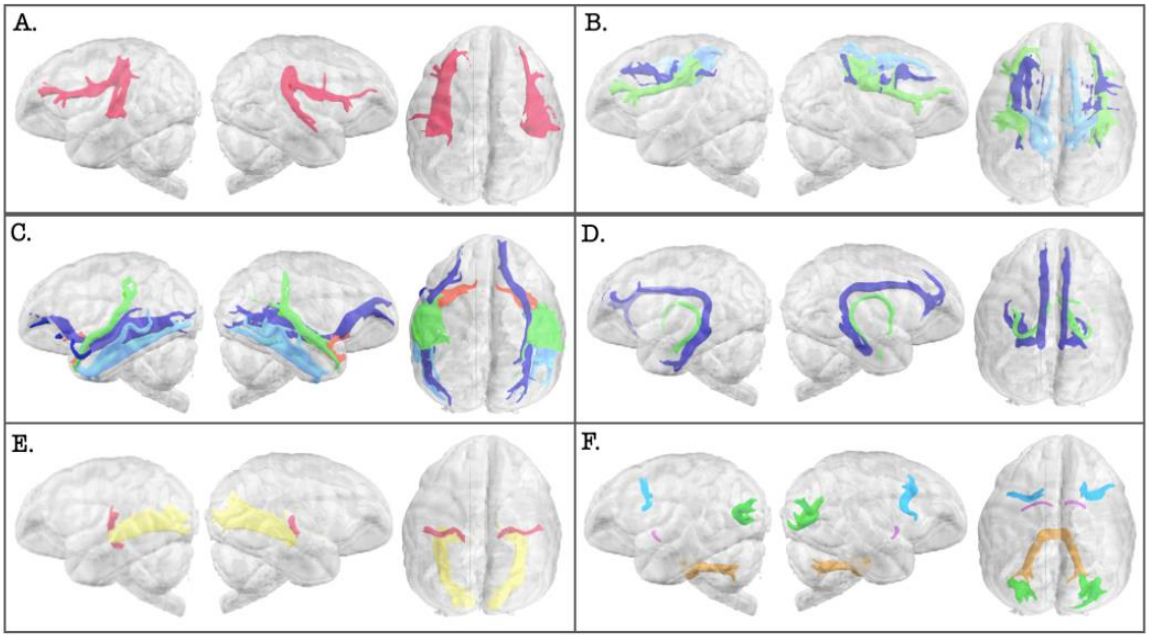

Figure 1: Thresholded probabilistic tracts in the lar gibbon. A: arcuate fasciculus; B: superior longitudinal fasciculi; C: temporal tracts (inferior longitudinal fasciculus, inferior fronto-occipital fasciculus, uncinate fasciculus, middle longitudinal fasciculus; D: cingulum and fornix; E: acoustic and optic radiations; F: short tracts - middle cerebellar peduncles, vertical occipital fasciculus, frontal aslant, anterior commissure.

Title: Individual variation in chimpanzee white matter connectivity, gray matter morphology, and behavior.

Authors: *S. VIJAYAKUMAR[1], W. D. HOPKINS[2], T. M. PREUSS[3], E. E. HECHT[1]; [1]Dept. of Human Evolutionary Biol., Harvard Univ., Cambridge, MA; [2]Dept. of Comparative Med., Univ. of Texas MD Anderson Cancer Ctr., Bastrop, TX; [3]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA

Abstract: In order to explain how evolved differences in brain anatomy give rise to behavioral adaptations, comparative neuroscience researchers have primarily focused on inter-species comparisons of the large-scale organization of the brain. However, within-species analyses of variation in behavior and brain anatomy can also provide valuable information toward this topic. Interestingly, comparative studies suggest that the degree of variability in the gray matter morphology and sulcal anatomy of association regions is not only higher in humans as compared to chimpanzees, but also less heritable, putatively indicating that these regions evolved to support experience-dependent, culturally-transmitted behaviors. Given that the white matter pathways connecting the association regions have expanded in humans as compared to other primates, the underlying white matter connectivity seems likely to be driving these individual differences. To address this possibility, we studied 65 adult chimpanzees, ages ranging from 9 to 51 years (mean = 22, s.d. = 8.75, 41 female) that were housed at the Yerkes National Primate Research Center. Ethical approval was obtained from The Institutional Animal Care and Use Committee. T1 scans ($0.7 \times 0.7 \times 1.0$ mm^3) and diffusion scans ($1.8 \times 1.8 \times 1.8$ mm^3) in 60 directions were acquired using a Siemens 3T Trio scanner. To delineate the individual differences driven by white matter connectivity, we performed probabilistic tractography between all gray matter voxels and constructed a voxel-wise connectivity matrix. Coefficient of variation mapping of voxel-based connectivity showed the most variation in the orbitofrontal cortex, cingulate cortex, precentral gyrus, postcentral gyrus, anterior temporal lobe, lateral parietal lobe, and lateral occipital cortex. In order to identify individual variation in cortical grey matter organization, we used voxel-based morphometry. Grey matter images were registered to a symmetric study-specific template and modulated by Jacobians to account for local differences due to non-linear spatial transformations. Regions that showed the most individual variation included the orbitofrontal cortex, motor cortex, posterior parietal cortex, and parts of the visual cortex. We additionally analyzed associations between individual variation in connectivity and gray matter morphology and behavioral metrics of tool use, handedness, and communicative gesture. Because individual variation is the foundation on which natural selection acts, these findings have relevance for our understanding of how human-specialized behavioral skills might have evolved via adaptations to brain organization.

Title: Description and characterization of the adult gray short-tailed opossum (Monodelphis domestica) brain: Focus on tyrosine hydroxylase-expressing neurons in the midbrain

Authors: *C. M. BOTELLO[1], J. L. VANDEBERG[2], M. GIL[3];

Abstract: Description and characterization of the adult gray short-tailed opossum (*Monodelphis domestica)* brain: focus on tyrosine hydroxylase-expressing neurons in the midbrain
Cristian M. Botello, John L. VandeBerg, and Mario Gil.
Mus musculus is one of the most widely used animal models to study central dopamine systems (Phifer-Riley & Nachmann, 2015). However, the research community needs alternatives to rodents to study the mammalian brain. The *Monodelphis domestica* is a marsupial, their pups are born underdeveloped and easily accessible, and are thus excellent models for tracking neurodevelopment (Baggott & Moore, 1990). The present study includes three objectives. The first was to consider the similarities and differences between the *Mus Musculus* and the *Monodelphis* brains. This was done by viewing Nissl-stained brain sections from each animal and comparing neural structures. We observed major species differences in the forebrain. The corpus callosum in the mouse brain is prominent, whereas it is absent in the Opossum. There are also differences in the general structure of the hippocampus and ventricles. As expected, posterior brain structures are similar between the two species. Further research is needed to determine what these differences could mean in behavior and cognition.The second objective was to characterize tyrosine hydroxylase (TH), a marker for dopamine neurons, expression in the *Monodelphis* brain. However, research is needed to see if commercially available TH antibodies, which are well researched in mice, can also be used to study the *Monodelphis* brain. Based on our preliminary results, we observed a stronger signal from the Pelfreeze TH antibody when compared to the EMD Millipore antibody. The final objective was to look at the differences in TH expression in the Ventral Tegmental Area (VTA) and the Substantia Nigra (SN) of Opossums that were exposed to a social stimulus compared to animals that were not exposed to a social stimulus. Animals in the experimental group were exposed to another animal for 10 minutes, then were sacrificed, and perfused 60 minutes after the social stimulus. Those in the control group were not exposed to social stimulus. We are currently processing brain tissue from these different groups to test the hypothesis that a social stimulus increases TH protein in the midbrain of the *Monodelphis*. Given that *Monodelphis* is a model for neurodevelopmental research and that there is not a lot of literature on their use in neuroscience, our work can contribute to the characterization of central dopamine systems in this innovative animal model.

Title: Translating time from transcriptomics and structural variation in great apes reveals old age as a distinctive human trait.

Authors: *K. OFORI[1], J. SCHWARTZ[1], B. RIGBY DAMES[2], C. BAUCUM[3], A. VAN DER KOUWE[4], E. TAKAHASHI[4], C. J. CHARVET[1];

Abstract: How the unique capacities of human cognition arose in evolution is an enduring question of interest. Yet, we still lack appropriate procedures to align ages across primates, and this lacuna has hindered progress in understanding the evolution of biological programs in humans. We found corresponding ages across humans and five non-human primates (e.g., orangutan, gorillas) by collecting 379 time points from abrupt and gradual changes in behavior, anatomy, and transcription. In addition, we collected high-resolution diffusion MR scans of mammals close to birth (e.g., mouse, marmoset), which we used to track the relationship between brain growth and pathway maturation. We used these data to identify how schedules of development and aging vary across species. We found that the lifespan is extended in humans relative to apes after ages are aligned in different species. The extended lifespan of humans is concomitant with biological processes (e.g., brain atrophy) observed in aged humans that are difficult to detect in studied great apes. This dataset identifies corresponding ages across primates species, and accounts for the observation that biological pathways in aged humans are difficult to detect in great apes. Our study prompts a reevaluation of the use of model systems to understand aging, given that very old age is a period of life that has no counterpart in great apes.

Title: White matter connectivity of the cerebellum in the Russian farm-fox experiment

Authors: *C. N. ROGERS FLATTERY[1], S. VIJAYAKUMAR[1], J. LEVINE[2], J. MCENEANEY[2], L. N. TRUT[3], A. V. KUKEKOVA[4], J. B. SMAERS[5], E. E. HECHT[1]; [1]Dept. of Human Evolutionary Biol., [2]Harvard Univ., Cambridge, MA; [3]Inst. of Cytology and Genet. of the Siberian Br. of Russian Acad. of Sci., Novosibirsk, Russian Federation; [4]Dept. of Animal Sciences, Col. of ACES, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [5]Dept. of Anthrop., Stony Brook Univ., Stony Brook, NY

Abstract: Above and beyond its classical association with motor coordination and motor learning, the cerebellum is thought to play a role in cognition. In particular, the lateral hemispheres of the cerebellum have been implicated in attention, executive function, language,

and social cognition. Most of this research has been done in humans and non-human primates, and little is known about cerebellum-cortical connectivity in clades that independently evolved large brains, such as canids. Here, we examined cortico-cerebellar connectivity in silver foxes (Vulpes vulpes) from the farm-fox domestication experiment. These foxes have been bred to create strains displaying divergent social behavior, thus they provide an excellent model for understanding how strong selection pressure for social behavior shapes neural circuits. We looked across strains of silver foxes for variation in cerebellum structure and connectivity. Previous research revealed volumetric differences in the cerebellum across these strains. In our study, we used diffusion tensor imaging (DTI) tractography in 10 tame, 10 unselected, and 9 aggressive/avoidant foxes to examine cortico-cerebellar connectivity across strains. Images were collected with 60 diffusion directions at a resolution of 300 cubic microns using a Bruker 9.4T MRI. We defined five cerebellar regions of interest: the anterior lobe; lobule HVI; lobule HVII; lobules HVIII, HIX, and HX; and the vermis. Among these ROIs, the anterior lobe was the best predictor of total brain size. In general, aggressive and conventional foxes had greater overlap in their patterns of connectivity compared to tame foxes. In all strains, the vermis showed the most extensive connectivity with the frontal cortex, in contrast to previous results from primates showing frontal connectivity with the lateral cerebellar hemispheres. This may be related to the frontal cortex in canids being more limbic-associated than in primates. Additionally, we also used a data-driven approach to divide the cerebellum into five clusters based on connectivity patterns with the cerebrum. These clusters corresponded moderately well to our a priori anatomical ROIs. In the tame foxes, clusters putatively corresponding to HVI and HVII were shifted more laterally compared to the conventional and aggressive foxes. Overall, our results suggest a congruence between anatomically defined lobules in the cerebellum and connectivity patterns. Our results also suggest that strong selection pressure on social behavior can affect cortico-cerebellar connectivity and that adaptive change in cerebellar morphology may be linked at least in part to connectivity changes.

Title: Japanese and rhesus macaques differ in amygdala cannabinoid 1 receptor-immunoreactive axon density

Authors: *D. N. JONES[1], H. N. SMITH[1], K. N. HIRTER[1], E. L. MUNGER[1], P. R. HOF[2], C. C. SHERWOOD[3], M. RAGHANTI[1];

Abstract: Japanese and rhesus macaques differ in amygdala cannabinoid 1 receptor-immunoreactive axon density
Endogenous and exogenous cannabinoids signal through the cannabinoid 1 receptor (CB1R) to modulate various aspects of social behavior, including aggression and anxiety. In rodents and primates, CB1R expression in the basolateral amygdala is dense and cannabinoid signaling in this region has been reported to influence social behavior. Little is known about how endocannabinoid signaling in the amygdala contributes to primate social diversity. The behaviorally diverse and species-rich cercopithecoid monkey genus *Macaca* is an ideal model for addressing this topic. Japanese (*Macaca fuscata*) and rhesus macaques (*M. mulatta*) display similar social styles in some respects; however, there is evidence to suggest they differ in their stress response, amygdala structure, and monoaminergic signaling. To further assess the molecular basis of social style in Japanese and rhesus macaques, we used immunohistochemistry and stereological methods to compare CB1R-immunoreactive (CB1R-ir) axon density in the basolateral amygdala, which is comprised of the lateral, basal, and accessory basal nuclei. Our study sample included 6 Japanese and 5 rhesus macaques. Repeated-measures ANOVAs were used to evaluate species differences, with amygdala region as the within-subjects measure and species as the between-subjects factor. This revealed significant main effects for species and area (p values < 0.05) with no interaction. Post hoc tests revealed higher CB1R-ir axon density in the basal and accessory basal nuclei of rhesus macaques compared to Japanese macaques. Our results suggest that CB1R-mediated signaling in the lateral nucleus of the amygdala is comparable between the two species, while the differences we observed in the basal and accessory basal nuclei may contribute to the nuanced behavioral differences observed between them.

Title: Neurodevelopmental scaling is a major driver of brain-behavior differences in temperament across domestic dog breeds

Authors: *E. E. HECHT[1], I. ZAPATA[2], *C. E. ALVAREZ[3], D. A. GUTMAN[4], T. M. PREUSS[5], M. KENT[6], J. SERPELL[7];
[1]Dept. of Human Evolutionary Biol., Harvard Univ., Cambridge, MA; [2]Rocky Vista Univ., Parker, CO; [3]The Ohio State Univ., Columbus, OH; [4]Sch. of Med., [5]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA; [6]Col. of Vet. Med., Univ. of Georgia at Athens, Athens, GA; [7]Dept. of Clin. Sci. and Advanced Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Dog breeds vary in temperament, including traits like aggression, anxiety, and trainability. These breed differences are both significant and highly heritable. However, the underlying neural bases are unknown. In this study, we analyzed breed-average scores for the 14 major dimensions in the Canine Behavioral Assessment and Research Questionnaire, a well-validated measure of canine temperament, in relation to structural MRI scans of 62 dogs of 33 breeds. We observed significant relationships between several behavior categories and brain morphology. Source-based morphometry analyses revealed that morphologically covarying gray matter networks involved in the flight-or-fight response and social processing were significantly linked to stranger-directed fear and aggression - putatively, the main behavioral responses under selection during wolf-to-dog domestication. Additionally, voxel-based morphometry analyses revealed that expansion in broad regions of cortex was significantly associated with higher scores for trainability. Conversely, expansion in distributed subcortical regions were significantly linked to C-BARQ categories for fear, aggression, and other “problem” behaviors. In striking correspondence with models of developmental constraint on brain evolution, these results overlapped closely with regional volume changes associated with changes in total brain size. These results suggest that disproportionate enlargement of later-developing regions in larger-brained dogs is at least partly responsible for the well-established link between dog body size and behavior.

Title: Serotonin innervation of the ventral pallidum and nucleus accumbens is conserved among primates.

Authors: *H. N. SMITH[1], D. N. JONES[1], E. MUNGER[1], P. R. HOF[2], C. C. SHERWOOD[3], M. RAGHANTI[1];
[1]Kent State Univ., Kent, OH; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]George Washington Univ., Washington, DC

Abstract: Previously identified differences in serotonin innervation have been proposed to underlie differences in behavior, such as personality style and sociability. Contrasting serotonergic fiber densities have been found in the amygdala of chimpanzees versus bonobos, and humans and apes are known to have more serotonin than monkeys in the dorsal and medial caudate nucleus and dorsal putamen. Our present work builds on earlier results by examining serotonergic axon innervation density in the nucleus accumbens and ventral pallidum, two important nodes in the reward system. The present sample included humans (n = 6; NIH NeuroBioBank), pigtailed macaque monkeys (n = 5; National Primate Research Center, University of Washington), and capuchin monkeys (n = 6; Alpha Genesis). All individuals were adult and free of neuropathological alterations. Brain sections were immunohistochemically processed for serotonin transporter (SERT) (Millipore, MAB 5618), and stereological methods (SpaceBalls probe, MBF Bioscience) were used to quantify the length density of SERT-immunoreactive axons and neuron densities from adjacent Nissl-stained sections. Repeated measures ANOVA was used to evaluate differences of SERT-immunoreactive axon densities and neuron densities among species. The main effect of brain region was significant ($F_{1,2}$ = 12.25, p = 0.004) with greater SERT innervation in ventral pallidum compared to the nucleus accumbens in all species. The main effect of species and the interaction of species x brain region were not significant. Based on these results, the serotonergic system in the nucleus accumbens and ventral pallidum appears to be evolutionarily conserved in the amount of innervation supplied to neurons among human and other anthropoid primates.

Title: Learning differentially increases the synaptic levels of AMPA receptor subunits (GluA1-GluA4) in the rodent hippocampus: a single-synapse approach

Authors: *G. A. PRIETO[1], C. J. RODRIGUEZ-ORTIZ[2], M. KITAZAWA[3], C. W. COTMAN[2]; [1]UNAM, Inst. de Neurobiología, Juriquilla, Mexico; [2]UC Irvine, Irvine, CA; [3]Med., Univ. California, Irvine, Irvine, CA

Abstract: Decades of experimental work support the idea that synapses are the anatomical substrate for experience-dependent plasticity in the brain. Changes in the synaptic strength underlie learning and memory via the accumulation of glutamate AMPA receptors (AMPAR) at the surface of excitatory synapses. AMPAR are tetrameric receptors constituted by multiple combinations of four subunits: GluA1 GluA2, GluA3, and GluA4. However, the relative contribution of each AMPAR subunit on learning and memory is relatively unexplored. Here, we introduce Fluorescence Analysis of Single-Synapse Potentiation induced by Learning (FASS-PiL), a flow cytometry-based method to quantify surface levels of all four GluA-AMPAR subunits, in parallel, in isolated synaptosomes after a learning episode in rodents. We evaluated surface levels of all four AMPAR subunits in synaptosomes of mice trained in a learning protocol commonly used for studying episodic memory in the hippocampus (e.g., Object Location Memory (OLM) and Object Recognition Memory (ORM) tasks). Briefly, after exploring novel objects in a novel environment for 10 min, mice were returned to their home cage for 60 min. After hippocampus dissection, synaptosome isolation and immunostaining, samples were analyzed via flow cytometry. We first demonstrated that FASS-PiL is a simple and sensitive method to track all four GluAs at the synaptosome surface (each GluA subunit was paired with the presynaptic marker Neurexin-1beta to focus on synaptosome particles containing both pre- and postsynaptic compartments). Notably, by profiling hundreds of events, our data showed that training increases the number of hippocampal synaptosomes expressing high levels of GluA1 and GluA2, but not GluA3 and GluA4 (vs control animals). This result indicates that plasticity-related mechanisms underlying learning are AMPA-subunit-specific in hippocampal synapses. Our approach could provide the basis for protocols to study behavioral-relevant mechanisms of plasticity directly at the synapse, with single-event resolution.

Title: α2δ-1 Promotes Synaptic Expression of Calcium Permeable-AMPA Receptors by Disrupting Heteromeric GluA1/GluA2 Assembly in the Hypothalamus in Hypertension

Authors: *J.-J. ZHOU, S.-R. CHEN, J.-Y. SHAO, H. CHEN, H.-L. PAN;
Ctr. for Neurosci. and Pain Research, Dept. of Anesthesiol. and Perioperative Med., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: The native AMPA receptors (AMPARs) in the brain are calcium impermeable and mainly composed of GluA1/A2 heteromers. AMPARs lacking GluA2 are highly calcium permeable (CP-AMPARs) and their currents show inward rectification at positive membrane potentials. Increased prevalence of CP-AMPARs in the paraventricular nucleus (PVN) of hypothalamus augments sympathetic outflow in hypertension. However, the molecular mechanisms underlying this AMPAR synaptic plasticity in hypertension remain unknown. In this study, we determined the role of α2δ-1 in regulating AMPAR phenotype in the hypothalamus in spontaneously hypertensive rats (SHR). Co-immunoprecipitation analysis showed a significant reduction in GluA1/GluA2 heteromers in the synaptosome and endoplasmic reticulum (ER)-enriched fractions of the hypothalamus in SHR compared with normotensive Wistar-Kyoto rats (WKY). Whole-cell recordings in brain slices showed an inward rectification of current-voltage (I-V) relationship of AMPAR-mediated excitatory postsynaptic currents (AMPAR-EPSCs) in retrogradely labeled, spinally projecting PVN neurons in SHR. Inhibition of α2δ-1 with gabapentin increased GluA1/GluA2 heteromers in ER-enriched fractions of the hypothalamus and abolished the inward rectification of AMPAR-EPSCs in labeled PVN neurons in SHR. Co-immunoprecipitation analysis revealed that α2δ-1 physically interacted with both GluA1 and GluA2 in the hypothalamus in rats and humans. The protein levels of α2δ-1-GluA1 and α2δ-1-GluA2 complexes in the hypothalamus were significantly greater in SHR than in WKY. Furthermore, disruption of the α2δ-1-AMPAR interaction with an α2δ-1 C terminus peptide restored heteromeric GluA1/GluA2 in the ER and normalized the inward rectification of AMPAR-EPSCs in labeled PVN neurons in SHR. These findings indicate that α2δ-1 is an important AMPAR-interacting protein that promotes synaptic predominance of CP-AMPARs in the PVN via disrupting heteromeric GluA1/GluA2 assembly in hypertension.

Title: The differential role of auxiliary subunits in the assembly of AMPA receptors

Authors: *N. CERTAIN[1], Q. GAN[3], L. P. WOLLMUTH[2];
[1]Pharmacol. Sci., [2]Neurobiol & Behavior, Stony Brook Univ., Stony Brook, NY; [3]Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: AMPA receptors (AMPARs) are ionotropic glutamate receptors that transmit the majority of fast excitatory synaptic transmission. Regulation of the number and composition of AMPARs at the postsynaptic membrane is essential for the process of learning and memory, and AMPAR dysregulation is implicated in various brain disorders. In the brain, AMPARs associate with auxiliary subunits that can affect their functional activity, however auxiliary subunit regulation of AMPAR assembly is unclear. Here, we addressed the role of auxiliary subunits in the assembly of AMPARs using a combination of blue native gel-electrophoresis, immunocytochemistry, and electrophysiology. We find that AMPARs co-expressed with cornichon-2 (CNIH-2) and cornichon-3 (CNIH-3) enhance the tetramerization process, whereas co-expression with other auxiliary subunits including stargazin (TARP-2), TARP-8, and GSG1-L does not. To study the basis for this, we mutated key residues in the AMPAR transmembrane domain which attenuates tetramerization and co-expressed these AMPARs with auxiliary subunits. Destabilized tetramerization leads to increased receptor dimers and significantly reduced tetramer formation. We found that when AMPAR mutants are co-expressed with CNIH-2 or CNIH-3, the tetramer fraction was efficiently rescued compared to co-expression with other auxiliary subunits. Our results suggest that auxiliary subunits influence receptor tetramerization through the transmembrane domain with CNIHs capable of stabilizing the transmembrane region and rescuing disrupted receptor assembly. In contrast, other auxiliary subunits demonstrate a much weaker influence on tetramerization compared to CNIHs. We conclude that CNIHs differ from other auxiliary subunits in their ability to influence the stages of AMPAR biogenesis.

Title: Neto proteins differentially modulate the gating properties of Drosophila glutamate receptors

Authors: *T. HAN, M. SERPE;
NICHD/NIH, Bethesda, MD

Abstract: *Drosophila* neuromuscular junction (NMJ) is a glutamatergic synapse similar in composition and physiology to excitatory synapses in the mammalian CNS. In flies as in humans, synapse strength and plasticity are determined by the interplay between expression of different ionotropic glutamate receptor (iGluR) subtypes, *Drosophila* NMJ utilizes two distinct postsynaptic complexes that co-exist within individual postsynaptic densities; they are heterotetrameric complexes composed of three shared subunits, GluRIIC, -IID and -IIE, and either -IIA (type-A) or -IIB (type-B). We have previously discovered Neto (Neuropillin and Tolloid-like) as an obligatory subunit of the fly NMJ iGluR complexes, essential for receptors recruitment and function at the *Drosophila* NMJ. Neto belongs to a family of highly conserved auxiliary proteins that have an ancestral role in the formation and modulation of glutamatergic synapses. *Drosophila* neto encodes two isoforms, Neto-α and -β, that share highly conserved extracellular motifs and have different cytoplasmic domains, generated by alternative splicing. Either isoform could confer functionality to NMJ iGluR complexes reconstituted in heterologous systems, indicating that *Drosophila* Neto is required for iGluR function. To examine the role of Neto isoforms on the modulation of NMJ iGluRs gating properties, we expressed both recombinant receptors in HEK293T cells and measured their properties using outside-out patch-clamp technique. Here we report for the first time the biophysical properties of fly NMJ iGluRs of defined subunit composition. We found that Neto is absolutely required for the function of both type-A and -B receptors; in the absence of Neto, these receptor complexes are expressed on the cell surface, but do not elicit any detectable currents. Both of Neto-α and -β have similar effects on single channel conductance and deactivation rates for both receptor subtypes. However, the two Neto isoforms differentially modulate the desensitization rates of type-A and -B receptors. Pre-treatment with Concanavalin A increases the single channel open times, whereas extracellular PhTx blocks the channels to various extents. In outside-out patches the IV relationship is linear but shows biphasic rectification in the presence of intracellular spermine. Finally, we compared the deactivation kinetics of receptor channels in outside-out patches and larval muscle membrane and found that native, extrajunctional channels have a slower decay kinetics than the reconstituted channels. Our study reveals that Neto is not only required for functional channels but also increases the diversity of the receptor properties.

Title: Kainate and AMPA receptors control error correction during navigation along chemosensory gradients

Authors: *P. MALDONADO-CATALA[1], P. J. BROCKIE[2], J. E. MELLEM, JR[3], D. MADSEN[1], A. V. MARICQ[4];
[2]Dept. of Neurobio. & Anat., [1]Univ. of Utah, Salt Lake City, UT; [3]Neurobio. & Anat., [4]Biol., Univ. of Utah, Salt Lake Cty, UT

Abstract: Understanding how the nervous system controls behavior across vastly different timescales has been a challenge in neuroscience. During navigation, animals must perform moment to moment corrections as well as long-term modulation of their behavior to navigate efficiently. The nematode *C. elegans* suppresses backwards locomotion and performs corrections in steering during navigation towards chemical attractants. However, how this simple nervous system can control behavior at short timescales (steering) and longer timescales (reversals) is unknown. In this study, we show how a single pair of key interneurons called RIA, in the nematode control error-correction during navigation by adjusting steering and suppressing reversals. Interestingly, this is achieved by expressing two classes of ionotropic glutamate receptors, the AMPAR and Kainate receptor are expressed in RIA. These two classes of receptors differentially regulate behavior during navigation by 1) controlling moment to moment corrections in steering and 2) long-term suppression of reversals. Electrophysiological analysis reveals a mechanism for this neural control of error-correction. The AMPAR provides large-rapid activation of the interneuron that acts as a negative-feedback to control steering during navigation in the timescale of hundreds of milliseconds. The Kainate receptor provides small-amplitude but long lasting activation that allows for the suppression of reversals which occur in the timescale of tens of seconds. In this study, we tie the physiology of different classes of glutamate receptors to information processing and behavior. Taken together, our results provide a fundamental mechanism for how a simple neural circuit can control behavior across different timescales by expressing different classes of glutamate receptors which confer different properties to the activation of the neuron.

Title: Activation of extrasynaptic kainate receptors drives hilar mossy cell activity

Authors: *C. RAMOS[1], S. LUTZU[2], M. YAMASAKI[3], Y. YANAGAWA[4], K. SAKIMURA[5], S. TOMITA[6], M. WATANABE[7], P. E. CASTILLO[8];

Ins Niigata Univ., Niigata, Japan; [6]Yale Univ., New Haven, CT; [7]Hokkaido Univ. Sch. Med., Sapporo, Japan; [8]Albert Einstein Coll Med., Bronx, NY

Abstract: Mossy cells (MCs) of the dentate gyrus (DG) are key components of an excitatory associative circuit established by reciprocal connections with dentate granule cells (GCs). MCs are implicated in place field encoding, pattern separation and novelty detection, as well as in brain disorders such as temporal lobe epilepsy and depression. Despite their functional relevance, little is known about the determinants that control MC activity. Here, we examined whether MCs express functional kainate receptors (KARs), a subtype of glutamate receptors involved in neuronal development, synaptic transmission and epilepsy. Using mouse hippocampal slices, we found that bath application of submicromolar and micromolar concentrations of the KAR agonist kainic acid induced inward currents and robust MC firing. These effects were abolished in GluK2 KO mice, indicating the presence of functional GluK2-containing KARs in MCs. In contrast to CA3 pyramidal cells, which are structurally and functionally similar to MCs, and express synaptic KARs at mossy fiber (MF) inputs (i.e., GC axons), we found no evidence for KAR-mediated transmission at MF-MC synapses, indicating that most KARs at MCs are extrasynaptic. Immunofluorescence and immunoelectron microscopy analyses confirmed the extrasynaptic localization of GluK2-containing KARs in MCs. Finally, blocking glutamate transporters, a manipulation that increases extracellular levels of endogenous glutamate, was sufficient to induceKAR-mediated inward currents in MCs, suggesting that MC-KARs can be activated by increases in ambient glutamate. Our findings provide the first direct evidence of functional extrasynaptic KARs at a critical excitatory neuron of the hippocampus.

Title: Mechanisms of kainate receptor regulation of AMPA receptor surface expression and function

Authors: *B. P. YUCEL, J. D. NAIR, K. A. WILKINSON, R. SEAGER, A. FLETCHER-JONES, J. M. HENLEY;
Univ. of Bristol, Bristol, United Kingdom

Abstract: Kainate receptors (KARs) and AMPA receptors (AMPARs) are tetrameric glutamate-gated ion channels that play critical roles in neuronal excitability, signal transduction and synaptic plasticity. Their dysfunction has been strongly implicated in neurological and neurodegenerative disorders including Alzheimer's disease, autism spectral disorders (ASD), and epilepsy. However, the precise inter-relationship, relative synaptic localisations of KAR - AMPAR complexes, and crosstalk between their signalling pathways, are not well understood.Our lab recently demonstrated that different patterns of KAR activation can bidirectionally regulate AMPAR surface expression and synaptic strength. Depending on the KAR stimulation protocol used, we observe either KAR-mediated LTP (long-term potentiation) or LTD (long-term depression) of AMPARs. To explore the molecular pathways that underpin KAR regulation of AMPARs we are now investigating whether the receptor complexes and/or individual subunits interact using co-immunoprecipitation techniques both in HEK293T cells by exogenously expressing KAR and AMPAR subunits, and in rat cortical neurons overexpressing KARs. Our data show that in both HEK293T cells and neurons the AMPAR subunit GluA1 co-immunoprecipitates with the KAR subunit GluK2. Furthermore, contrary to some previous reports, using high resolution confocal microscopy and immunolabelling we show that KARs and AMPARs can localise to the same dendritic spines at the same time. Building on these initial data we are testing the hypothesis that, at least at some synapses, KARs regulate AMPARs either by binding of individual AMPAR and KAR subunits or, perhaps more likely, through common interacting proteins.

Title: Noradrenaline excites serotonin dorsal raphe neurons via glutamate delta 1 receptor-dependent ionic current

Authors: *S. C. GANTZ[1], K. MOUSSAWI[2], H. S. HAKE[3];
[1]Mol. Physiol. and Biophysics, Univ. of Iowa, Iowa City, IA; [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [3]Psychology, Univ. of Washington, Seattle, WA

Abstract: *In vivo* studies using rodent models have shown that the dorsal raphe - the largest serotonergic nucleus and the predominant source of serotonin in the brain - is controlled by noradrenaline afferents. In this brain region, noradrenaline activates $G\alpha_q$-coupled α1-adrenergic receptors (α1-A_R), causing action potential firing and serotonin release. In the absence of noradrenaline, dorsal raphe neurons are either silent or fire slowly and erratically demonstrating necessity of α1-A_R signaling. Despite this crucial role, the ion channels responsible for α1-A_R-mediated depolarization were unknown. Here, we show in adult C57BL/6J male and female mouse brain slices that α1-A_R-mediated excitatory synaptic transmission was mediated by the ionotropic glutamate receptor homolog cation channel, glutamate delta 1 receptor ($GluD1_R$). $GluD1_R$-channels were constitutively active under basal conditions carrying tonic inward current and synaptic activation of α1-A_Rs augments tonic $GluD1_R$-channel current. The mechanism underlying this coupling has not been resolved but was GTP-dependent. We found that α1-A_R-mediated excitatory synaptic transmission was inhibited by the amino acids D-serine and glycine, the glutamate receptor antagonist, kynurenic acid, and completely blocked by the calcium-permeable glutamate receptor-channel blocker, NASPM. Provided the limitations of pharmacological strategies, we then used a CRISPR/Cas9 viral strategy to introduce a deleterious mutation to the gene encoding $GluD1_R$ (*Grid1*) and functionally deleted $GluD1_R$ channels from dorsal raphe neurons. Following functional deletion of $GluD1_R$, the α1-A_R-dependent inward current was eliminated. Further, loss of dorsal raphe $GluD1_R$-channels produced an anxiogenic phenotype. Thus, $GluD1_R$-channels are responsible for α1-A_R-dependent induction of persistent pacemaker-type firing of dorsal raphe neurons and regulate dorsal raphe-related behavior. Given the widespread distribution of these channels, ion channel function of $GluD1_R$ as a regulator of neuronal excitability is proposed to be widespread in the nervous system.

Title: Standing current by the delta-1 glutamate receptor is independent of g protein activity in central neurons

Authors: *D. S. COPELAND, S. C. GANTZ;
Univ. of Iowa Carver Col. of Med., Iowa City, IA

Abstract: G protein-coupled receptors (GPCRs) have grown to be large targets for therapeutics due to their versatility. As the pool of pharmaceuticals targeting these receptors expands, a deeper understanding of the actions of GPCRs has become more relevant. One of the many functions of GPCRs is action on ion channels to influence membrane potential and, ultimately, neurotransmitter release. The glutamate delta-1 receptor ($GluD1_R$) showcases this mode of action, where activation of $G\alpha_q$PCRs produces current through the $GluD1_R$ ion channel pore in a G protein-dependent manner. The $GluD1_R$ channel also carries a standing inward current, henceforth referred to as a tonic current (Gantz et al. 2020). The aim of this study was to investigate constitutive $G\alpha_q$PCR activity by manipulating G protein activity and monitoring changes in this tonic current. Brain slices were collected from male and female C57bl/6j mice and whole-cell patch-clamp recordings were made from dorsal raphe serotonin neurons at 35° C. After blocking NMDA, AMPA and kainate receptors, inhibitors or activators of G protein activity were delivered internally via the patch pipette. Tonic $GluD1_R$ currents were then measured by bath application of the pore-blocker NASPM. This produced apparent outward currents by blocking inward sodium flow and allowed us to quantify the amplitude of tonic current. Neurons treated with standard GTP-based internal solutions, as a control, had a -19.3±2.7 pA tonic current (n=8), consistent with our previous study. Neurons dialyzed with a non-hydrolyzable GTP analog (Gpp-NHp) produced a sizable potassium leak current through GIRK channels (49.7±8.2 pA, n=16). But Gpp-NHp had no effect on the tonic $GluD1_R$ current (p=0.72, Mann-Whitney test). We next targeted the alpha1-adrenergic receptor (alpha1-A_R), as our previous work demonstrated activation of alpha1-A_R augments $GluD1_R$ channel currents. Bath application of the alpha1-A_R inverse agonist prazosin had no effect on the tonic $GluD1_R$ current (n=7, p=0.50, Mann-Whitney test), suggesting a negligible role of on-going alpha1-A_R activity in the tonic $GluD1_R$ current. Lastly, following dialysis with a non-hydrolyzable GDP analog (GDPβS) which arrests G protein activity, there was no change in the tonic $GluD1_R$ current (-28.7±4.9 pA, n=13, p=0.27, Mann-Whitney test). This result held true after depleting $G\alpha_q$ responses via bath application of noradrenaline, and after multiple applications of NASPM. These data suggest that if present, constitutive $G\alpha_q$PCR activity has minimal impact on the tonic $GluD1_R$ current. Further, our results call into question the primary form of gating this mysterious, clinically-relevant receptor-channel.

Title: Fluorescent lifetime imaging of CAMKII during behavioral time scale plasticity at CA1 synapses

Authors: *A. JAIN[1], R. YASUDA[2];
[1]Florida Atlantic Univ., Jupiter, FL; [2]Max Planck Florida Inst., Jupiter, FL

Abstract: Hippocampal place cells, once formed, are stable for a given environment and can last for many days suggesting that an activity dependent synaptic plasticity underlies the induction/modulation of place cells. A recent study by Bittner et al showed that a novel non-hebbian form of plasticity induces CA1 place cell formation, where seconds long calcium plateau integrates with CA1 inputs to induce place cells. In our study, we characterized this behavioral time scale plasticity (BTSP) at single synapses in CA1 neurons. Using glutamate uncaging in hippocampal slices, we paired 5 uncaging pulses at 1 Hz frequency to somatic depolarization (induced by 600 pA current injection for 300 ms) with a 750 ms delay between them and found that potentiation can be induced in a synapse specific manner whether uncaging pulses were given before or after depolarization. In these experiments, when uncaging pulses precedes the depolarization, excitatory postsynaptic potential (EPSP) potentiation occurred by 76 ± 23% in stimulated spines and when depolarization was induced before the uncaging pulses, EPSP amplitude increased by 93 ± 26% in stimulated spines. As CA1 synapses receive inputs from different brain regions, we induced BTSP at different types of CA1 synapses using the same protocol and found that BTSP occurred specifically in the proximal apical dendrites and not in basal dendrites or distal dendrites. Generation of seconds long calcium plateau likely occurs via inputs from entorhinal cortex (EC) and provides instruction to the CA3-CA1 synapses during place cell formation. It is unknown what biochemical pathway transduces the signal from EC-CA1 synapses to CA3-CA1 synapses. Previous two-photon fluorescent life time imaging (2pFLIM) of CAMKII sensor showed stimulus locked CAMKII activity during long-term potentiation that lasts for 1-3 seconds, making it an ideal candidate to integrate EC and CA3 inputs during BTSP. We first confirmed the requirement of CAMKII in BTSP by doing experiments in slices made from T286A transgenic mice, where we failed to induce BTSP. However, surprisingly, preliminary 2pFLIM of CAMKII sensor during BTSP at single synapses showed no activation of CAMKII at single synapses and found a delayed CAMKII activity almost 30-40 second following BTSP induction. This suggests that maybe CAMKII is not the biochemical signal that integrates EC inputs to CA1 neurons. Further experiments will confirm

the CAMKII activity and identify the protein that integrates inputs during BTSP. Understanding activation profiles of kinases in behaviorally relevant plasticity mechanisms will provide insights into their specific functions during behavior

Title: Exploring the role of SENP3 in kainate receptor trafficking

Authors: *K. TALANDYTE, J. HENLEY, K. WILKINSON, R. SEAGER;
Univ. of Bristol, BRISTOL, United Kingdom

Abstract: SUMOylation is a protein based post-translational modification involving the conjugation of a small protein, SUMO, to substrate proteins to alter their stability, function or activity. The most common SUMO paralogues, SUMO-1-3, are attached to the substrate proteins through a three-step enzymatic cascade and can be removed by SUMO proteases (SPs). The biggest family of SPs are sentrin specific proteases (SENPs), which include SENP1-3 and SENP5-SENP7. There are multiple SUMO substrates identified in neurons, both in the nucleus, where SUMO is mostly localised, as well as in the cytosol, mitochondria and plasma membrane. Excitatory neurotransmission in the brain is mainly mediated by the neurotransmitter glutamate, which binds to three types of ionotropic receptors: AMPA, NMDA and kainate receptors (KARs). KARs are present pre-synaptically, where they regulate neurotransmitter release, post-synaptically, where they mediate synaptic transmission and plasticity and extra-synaptically, where they regulate neuron excitability. KARs seem to function both in a similar manner to AMPARs, by mediating synaptic plasticity and neurotransmission, and analogous to NMDARs, by inducing changes in surface expression of AMPARs to drive synaptic plasticity.
A widely expressed KAR subunit in the brain, GluK2, has been identified as a SUMO substrate in neurons. GluK2 C-terminus SUMOylation plays a role in GluK2-containing KAR trafficking in neurons. Moreover, phosphorylation of S868 on the GluK2 C-terminus by PKC in response to agonist stimulation leads to increased SUMOylation at K886 and GluK2 endocytosis. The aim of my work was to investigate the potential role of SENP3 in KAR stability as well as different functions of SUMO-1 and SUMO-2/3 in KAR trafficking.
I performed co-immunoprecipitation experiments to show that SENP3 interacts with the GluK2 subunit of KARs. Furthermore, I showed that phosphomimetic mutant S868D and WT GluK2

are SUMOylated with both SUMO-1 and SUMO-2/3 and that SENP3 is able to deSUMOylate WT GluK2 but has no effect on the phosphomimetic SUMO-1ylated GluK2. I am currently investing how SENP3 affects GluK2 stability, by using cycloheximide and MG132. My work has identified a novel role of SENP3 in GluK2 trafficking in neurons under basal conditions and suggests that different SUMO paralogs may have varying effects on GluK2.

Title: Rates of amyloid deposition indicate widespread simultaneous accumulation throughout the brain

Authors: *M. R. LAPOINT[1], S. L. BAKER[2], S. M. LANDAU[3], T. M. HARRISON[1], W. J. JAGUST[3];
[1]Helen Wills Neurosci. Inst., Univ. Of California, Berkeley, Berkeley, CA; [2]Mol. Biophysics and Integrated Bioimaging, Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Helen Wills Neurosci. Inst., Univ. of California, Berkeley and Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: β-Amyloid (Aβ) plaques are a hallmark pathology of Alzheimer's disease (AD). Aβ begins to aggregate long before cognitive deficits. However, the progression of amyloid throughout the brain is not well understood. Using Pittsburgh Compound B (PIB)-PET imaging, we investigated the progression of regional Aβ accumulation in cognitively normal older adults (N = 195, mean age = 75.5 years). In cross-sectional analyses, elevated amyloid was found most often in frontal and parietal regions, and least often in occipital, medial temporal, and sensorimotor regions. Overall, however, individuals typically showed deposition in all or most regions or low levels throughout the brain. In a subset analysis of participants with longitudinal PIB-PET scans (N = 106, mean follow-up time = 4.71 years), we leveraged the well-known "inverted U" characteristic of amyloid-PET accumulation rates, where accumulation is fastest at intermediate levels, and slower at high and low levels of amyloid. By fitting longitudinal PET data to quadratic functions, we found that all examined regions reached their peak accumulation rates 24-28 years after an estimated initiation corresponding to the mean baseline PIB-PET signal in amyloid-negative older adults. We also found that individuals with the apolipoprotein-E (APOE) ε4 allele had faster amyloid accumulation in all brain regions, adjusting for baseline levels of amyloid. Finally, we focused on the association between amyloid accumulation and tau pathology, another hallmark of AD, in a further subset of participants who had a Flortaucipir-PET scan to measure tau (N =88). In all regions excluding the temporal lobe, faster Aβ

accumulation was associated with greater tau burden. The pattern of regions showing higher tau related to greater Aβ accumulation was similar regardless of the amyloid region being investigated. Overall, these results indicate that amyloid accumulates near-simultaneously in most brain regions, and that accumulation is associated with increased genetic risk of AD and higher tau pathology.

Title: Effect of congruency and ambiguity on memory performance across the adult lifespan

Authors: *L. VARGHESE[1], X. CHEN[1,2], W. JAGUST[1,2];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: This study examines how stimulus properties, specifically the congruency and ambiguity between an object and a scene in a picture, affect memory of the picture in aging. A total of 273 participants from MTurk (aged 22-70 yrs old) completed a memory task online. They were first presented pictures depicting an object in a scene and judged if the object is likely or unlikely to be in the scene. Following a delay, participants were asked to identify pictures as old or new, with new items comprised of similar lures. Each studied picture was associated with two indices based on participants' likely/unlikely judgment during the study phase: congruency was based on whether participant judged the object-scene pair to be likely (congruent) or unlikely (incongruent); ambiguity was determined by the proportion of participants with a congruency judgment different from the majority, where higher values indicate the pair was perceived more ambiguous. Mixed-effects logistic regressions examined the effect of age, congruency/ambiguity, and their interaction on memory. We found that higher congruency predicted higher hit rates ($p < 0.001$): people were more likely to correctly identify an old image as old if they considered it a congruent pair. But congruency also led to more false memories ($p < 0.001$): people more often incorrectly identified a lure as an old image if they considered the initial stimulus congruent. A significant interaction between congruency and age was found for memory accuracy where older adults were more negatively affected by congruency ($p = 0.02$, Fig 1a). Ambiguity predicted both higher hit and false alarm rates ($p < 0.001$), and overall negatively affected memory accuracy ($p = 0.01$), with similar effects across ages (Fig 1b). In summary, congruency and ambiguity proved to be both harmful and beneficial for memory (high hit rates and high false alarm rates), with an overall negative influence on memory quality.

Interestingly, older people's memory is more influenced by congruency than young adults, likely suggesting that older adults rely more on schema for memory retrieval.

Title: Mechanistic contributions of memory to decision-making impairments in Alzheimer's disease

Authors: *Z. ZHANG[1], S. MABOUDIAN[1], A. J. JACKSON[2], S. NGO[2], M. MANIVANNAN[2], A. S. KAYSER[2,1], M. HSU[1], W. CHIONG[2];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Life is not a multiple-choice test. Because real-world decisions are often open-ended, with choice options conceived by decision-makers themselves, the quality of decisions may heavily rely on the retrieval of options, as failure to generate promising options limits, and often eliminates, the opportunity for choosing them (Zhang et al., 2021, PNAS). Because of the

demand on memory retrieval, such decisions may pose substantial challenges to patients with Alzheimer's disease (AlzD), the hallmark of which is substantial and worsening memory deficits. Our sample included Alzheimer's disease patients (N = 13), along with healthy controls (N = 16) and behavioral-variant frontotemporal dementia (bvFTD) patients (N = 13) as a dementia control group. The experiment consisted of (1) a semantic fluency condition, where subjects recalled as many items as possible from a category, (2) an internal-menu choice (IMC) condition, where subjects chose their two most preferred items from a category without a menu, and (3) an external-menu choice (EMC) condition, where subjects made the same choice with a predefined menu. The order of fluency and IMC was counterbalanced and EMC was always the last. Of primary interest is choice switches between IMC and EMC in the same category, with the rationale being that memory constraints in IMC would be lifted in EMC due to the provision of a menu. By examining the occurrence and nature of such switches and linking them with performances in fluency, we could characterize the extent and causes of decision impairments in different groups. As expected, Alzheimer's disease patients recalled fewer items in fluency than both control ($p < 0.005$) and bvFTD groups ($p < 0.01$) across categories. Importantly, this difference in memory retrieval capabilities were related to IMC to EMC choice switches: the Alzheimer's disease group made more switches than both bvFTD ($p < 0.05$) and controls ($p < 0.01$), and a significant correlation was observed across all groups between the average number of items recalled in SF and the average choice switches. In parallel, at the item level, we also found that subjects tended to switch to more difficult to recall items. Furthermore, Alzheimer's disease patients made higher memory-driven switches than controls, while bvFTD patients showed more value-driven switches.
These findings provide novel evidence for an overlooked source of decision impairments in Alzheimer's disease and connect models of open-ended decisions with longstanding findings of memory impairments in Alzheimer's disease. They bear implications for new interventions that help improve decision quality in Alzheimer's disease and related dementia.

Title: Abnormal neural oscillations reveal excitatory-inhibitory imbalance are distinctly associated with amyloid and tau depositions in Alzheimer's disease

Abstract: Excitation-to-inhibition (E/I) imbalance is believed to be a key contributor of synaptic and network degeneration in Alzheimer's disease (AD). Extensive preclinical research on transgenic animal models of AD have demonstrated neuronal and circuit level E/I imbalance mediated by amyloid-beta (Aβ) and abnormally phosphorylated tau proteins. However, the mechanisms of E/I imbalance leading to disrupted networks and their relationships to Aβ and tau in humans remain poorly understood. In this multimodal imaging study in patients with AD (n=20 AD patients; n=35 age-matched controls), we first examined the spectral changes in oscillatory brain rhythms using magnetoencephalography and their relationships to tau and amyloid-beta (Aβ) accumulation in PET imaging (flortaucipir and ^{11}C-PiB, for tau and Aβ, respectively). Next, we estimated parameters of a linear neural mass model that best fit the observed spectra, and examined the relationships between model parameters for excitatory and inhibitory neural sub-populations, and tau and Aβ accumulations. We found that neuronal hypoactivity was associated with tau while hyperactivity was associated with Aβ. We also demonstrated E/I imbalance in patients with AD, depicted as abnormal excitatory and inhibitory neuronal parameters in a linear neural mass model that reproduced the empirical macroscopic power spectra (Figure 1). The abnormal excitatory and inhibitory neuronal parameters showed distinct associations with tau and Aβ—higher tau correlated with a longer excitatory time-constant, whereas higher Aβ correlated with a longer inhibitory time-constant. The current study demonstrates how abnormalities in the oscillatory power spectrum in AD is mechanistically linked to impaired function of excitatory and inhibitory neuronal populations that are in turn associated with tau and Aβ accumulations. The multimodal neuroimaging in AD patients in the current study demonstrate how different frequency oscillations are distinctly affected by Aβ and tau, and offer new perspectives for network stabilizing therapies.

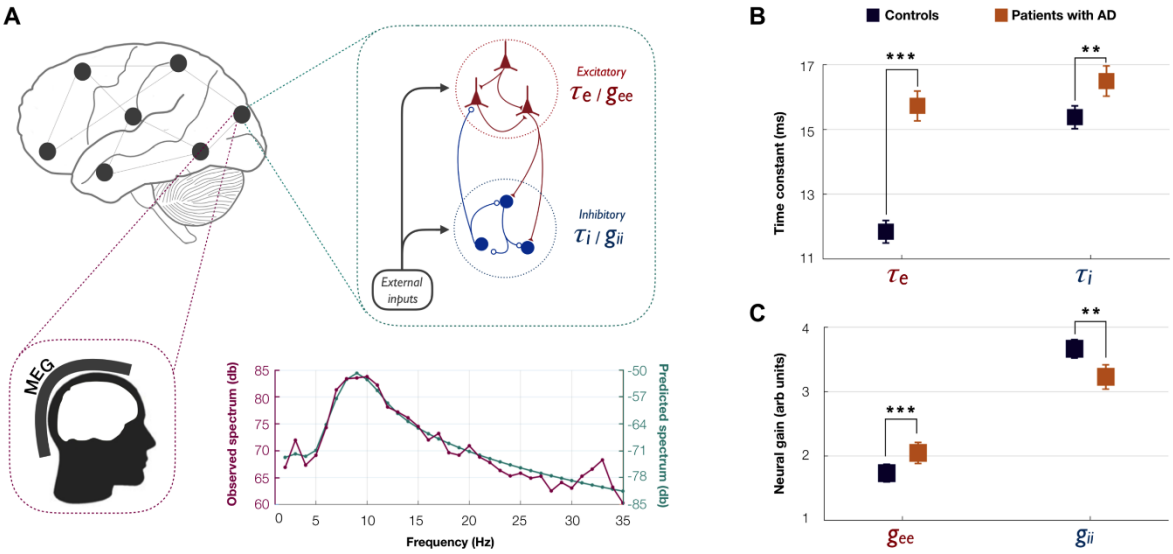

FIGURE 1
Linear neural mass model and its predictions of excitatory and inhibitory neuronal deficits in patients with AD. Schematic representation of the linear neural mass model and an example model prediction (A). Spectral graph model represents the local assemblies of excitatory and inhibitory neurons into lumped linear systems, at each region-of-interest (ROI). External inputs and outputs are gated through both excitatory and inhibitory neurons. The recurrent architecture of the two pools within a local area is captured by the neuronal time constants, τ_e and τ_i , and neural gain terms, g_{ee} and g_{ii}, indicating the loops created by recurrents within excitatory, inhibitory and cross-populations. At each ROI, the model delivers these parameters as it predicts the broad-band spectrum (1-35 Hz) optimized to the empirical spectrum derived from MEG. Patients with AD showed significantly increased neuronal time constants, τ_e and τ_i compared to age-matched controls (B). Patients with AD also showed increased excitatory neural gain (g_{ee}) and reduced inhibitory neural gain (g_{ee}) than controls (C). The markers and error-bars depict the least-square means and 95% confidence intervals. Abbreviations: AD, Alzheimer's disease; MEG, magnetoencephalography.

Title: Sex Modulates the Pathological Age Effect on Caudate Functional Connectivity in Mild Cognitive Impairment

Authors: *Z. YANG[1,2], J. Z. K. CALDWELL[1], J. L. CUMMINGS[2], J. KINNEY[2], D. CORDES[1,2,3];
[1]Cleveland Clin., Las Vegas, NV; [2]Univ. of Nevada Las Vegas, Las Vegas, NV; [3]Univ. of Colorado, Boulder, CO

Abstract: Introduction: Brain aging is characterized by considerable heterogeneity, including the variability induced by demographic factors and symptomatic or presymptomatic pathology, such as mild cognitive impairment (MCI). While episodic memories are established and maintained by an interplay between medial temporal lobe and other cortical regions, the degradation of the frontostriatal system is suggested to be a driving factor of episodic memory decline in old adults, which dismisses a uni-factorial view of neurocognitive aging. In this study, we focused on evaluating whether and how sex mediates the pathological age effect on caudate functional topology in MCI. **Materials and Methods**: 277 functional magnetic resonance imaging (fMRI) sessions from 163 cognitive normal (CN) older adults and 309 fMRI sessions from 139 subjects with MCI were included in our analysis. Pearson's correlation was used to characterize the functional connectivity (FC) between caudate and each brain region, then caudate nodal strength was computed to quantify the overall caudate FC strength. Association analysis between caudate nodal strength and age was carried out in MCI and CN separately using linear mixed effect (LME) model with covariates (education, handedness, sex, Apolipoprotein E4 and intra-subject effect). Then LME model was applied to women and men separately within MCI group to evaluate age effect on caudate nodal strength and each region's FC with caudate. Finally, Pearson's correlation was used to assess the association of neuropsychological scores with age and caudate nodal strength. **Results**: MCI group had significantly stronger age-related increase of caudate nodal strength compared to the CN group. Analyzing women and men separately revealed that the age effect on caudate nodal strength among MCI participants is significant only for women (left: P=6.23x10^{-7}, right: P=3.37x10^{-8}), but not for men (P>0.3 for bilateral caudate). Caudate connectivity with ventral prefrontal cortex substantially contributed to the positive age effect on caudate nodal strength in women with MCI. Both positive and negative age effects on individual region's connectivity with caudate were observed in men with MCI. While both women and men with MCI demonstrated worse cognitive performance with older age, higher caudate nodal strength is significantly related to worse cognitive performance only in women but not in men with MCI. **Conclusion**: Stronger age-related increase of caudate nodal strength in MCI over CN is sex-dependent. Caudate nodal strength may be a sensitive biomarker of pathological aging in women with MCI.

Title: Advantaged family and higher social position associated with better memory and delayed memory aging separately

Authors: *X. CHEN[1,2], L. VARGHESE[1], W. J. JAGUST[1,2];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: Lower socioeconomic status has been shown to have life-long effects on cognition. In the present study, we investigated how social position of one's original family, as well as current social position, may influence an individual's memory ability across the adult lifespan. A total of 271 participants recruited from MTurk (aged 22-70 years old) completed a memory experiment online. During the experiment, they were presented pictures depicting an object in a scene, and later tested for their memory of the pictures. During the recognition phase, if a participant responded that the exact picture was not previously seen, they were asked whether the picture differed by object, scene, spatial relation, or entire picture (Fig 1a). The response accuracy for this question was used to index memory (i.e., source memory accuracy). Participants also reported their highest education and the occupation class of their most recent job. The same information for their original family was also collected. Using the education and occupation information, Hollingshead index of their current social position (self social position) and their original family (parents' social position) were calculated. We used mixed-effects logistic regressions to examine the effect of age, age^2, parents' social position, self social position, and their interactions on source memory accuracy. We found that memory performance decreases with age quadratically: older people exhibited significantly faster memory ability drop with increasing age (Fig 1b). Moreover, higher parents' social position was constantly associated with better memory performance (Fig 1c), whereas higher self social position was associated with a delayed performance drop in older age, which occurred later than those with lower social position (Fig 1d). The findings suggest that an advantaged family social position appears to be associated with an age-invariant benefit for memory across the lifespan; having a higher social position as an adult, on the other hand, may help "slow down" memory aging in later life.

Title: Subjective cognitive self-appraisal correlates with cortical thickness and tauopathy in aging

Authors: *K. ZHUANG[1], X. CHEN[1,2], K. E. CASSADY[1,2], S. L. BAKER[2], W. J. JAGUST[1,2]; [1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Mol. Biophysics and Integrated Bioimaging, Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: Self-awareness of cognitive decline is often impaired in patients with Alzheimer's Disease (AD). In normal aging, it is also common to observe inaccurate self-appraisal of cognitive ability. Understanding this phenomenon in cognitively healthy older adults (OA), especially those with early AD pathologies, is imperative to early detection of behavioral alterations related to AD. A total of 151 cognitively healthy OA (male = 62, mean age = 76.09) from the Berkeley Aging Cohort Study underwent neuropsychological testing and 1.5T structural MRI. A subset of 66 OA (male = 29, mean age = 78.36) further received amyloid-PET with [11C] PiB and tau-PET with [18F] AV-1451. Additionally, we included longitudinal cognitive data (mean (sd) follow up = 6.95 (3.48) years, 6.68 (3.09) sessions) of all subjects with PET. Self-appraisal rating was recorded after each task to estimate performance relative to peers of the same age, sex, and education. Average appraisal discrepancy was calculated by subtracting objective performance from self-appraisal rating (positive discrepancy = overestimation). We found that worse performers had lower self-appraisal ratings than better performers ($r = .323$, $p < .001$), but they still overestimated their abilities by having higher appraisal discrepancy ($r = -.621$, $p < .001$). Whole-brain vertex wise analyses revealed that greater overestimation was associated with thinner inferior-lateral temporal, fusiform, and rostral anterior cingulate cortices. Multiple linear regression models examined the relationship between amyloid, tau, and self-appraisal measures. Higher entorhinal tau was related to lower self-appraisal ratings regardless of amyloid status ($p = .019$). Higher entorhinal tau was also associated with higher appraisal discrepancy, or overestimation, in amyloid negative OA ($p = .018$). In addition, linear mixed effect models were used to explore longitudinal effects of biomarkers and objective performance on changes in self-appraisal measures and showed no significant longitudinal effects. In summary, the behavioral results were consistent with the previously described Dunning-Kruger effect. OA with AD pathology had lower self-appraisal ratings, consistent with the suggestion of subjective cognitive decline prior to objective deficit in AD. Additionally, performance overestimation was related to greater atrophy and higher entorhinal tau in OA with low amyloid. These results suggest that overestimation could implicate structural differences in medial and temporal regions in OA and that reduced performance appraisal could be an early indicator of AD pathology.

Abstract: Prior work has documented short and long term improvements in higher cognitive function caused by deep brain stimulation of the cholinergic basal forebrain. In this work, we explored whether these findings extended to two senescent male Rhesus monkeys. Animals were pre-trained in on-cage touchscreen behaviors that tested working memory and sustained attention. Then, animals were implanted with electrodes in the nucleus basalis of Meynert targeting the region 2 mm posterior to the anterior commissure. Electrodes were coupled to wire leads and tunneled to an implantable pulse generator. The working memory behavior was a two AFC color discrimination, and delay length was set each day using adaptive tracking. Over 9-12 weeks of unilateral stimulation, working memory delays increased two to four-fold. Over the following 12 week period with no stimulation, working memory delays continued to be similarly elevated. Sustained attention was tested before and after, but not during, the first stimulation period. The behavior followed a continuous performance task design in which animals were rewarded for touching each white square in a stream of squares of difference colors. Hit rates and errors of commission both increased, with the balance favoring improved detection. Brains were processed post-mortem for histological reconstruction of stimulation site, and protein analysis from the stimulated vs the unstimulated cortical hemispheres. The results demonstrate that deep brain stimulation of the basal forebrain can cause improvements in working memory and sustained attention in aged male macaques, and that these changes are sustained for at least months after cessation. Senescent female monkeys are entered in a parallel study.

Title: Alterations in resting-state functional connectivity in individuals with HIV: Parallels with aging

Authors: *M. C. MCCUSKER[1,2], B. J. LEW[3], J. O'NEILL[3], B. MORSEY[3], S. SWINDELLS[3], H. S. FOX[3], T. W. WILSON[2,3], G. E. DOUCET[2];

Abstract: The increasing incidence of age-related comorbidities in people with HIV (PWH) has led to accelerated aging theories. Functional neuroimaging research, including functional connectivity (FC) using resting-state functional magnetic resonance imaging (rs-fMRI), has identified neural aberrations related to HIV infection. Yet little is known about the relationship between aging and resting-state FC in PWH. This study enrolled 121 PWH and 133 demographically matched controls spanning 22-72 years old who underwent rs-fMRI. We computed FC within and between the major resting-state networks in each sample. ANCOVA models were used to identify independent and interactive effects of HIV and aging. We also performed network-based statistical (NBS) analyses to characterize group differences in FC between multiple regions (n = 512). We found independent effects of age and HIV in between-network FC. The age-related increases were widespread, while the PWH displayed further increases above and beyond aging, specifically between the default-mode (DMN), executive control (ECN), and limbic networks. The NBS analyses showed similar results: PWH showed a significant reduction in FC primarily within the DMN, especially in the frontal and parietal regions, but also between the DMN and ECN irrespective of aging compared to uninfected controls. Meanwhile, PWH showed significant increases in FC between the DMN and ECN, especially in the frontal lobes, irrespective of aging relative to uninfected controls. Since both HIV infection and aging are associated with independent increases in between-network FC, HIV infection may be associated with a reorganization of the major brain networks and their functional interactions in a manner similar to aging.

Abstract: In Parkinson's disease (PD) there is a preferential degeneration of neuromelanin (NM)-containing neurons, especially neurons from the Substantia Nigra (SN) but also from the Ventral Tegmental Area (VTA) and Locus Coeruleus (LC). We generated a new NM-producing mouse model, based on the tissue-specific constitutive expression of human tyrosinase (hTyr) under the tyrosine hydroxylase (TH) promoter (tgNM), that mimics the distribution and age-dependent accumulation of NM in the human brain (i.e. catecholaminergic groups A1-A14). TgNM mice exhibited major PD features, including both motor and non-motor behavioral alterations, inclusion body formation, neuronal degeneration in lower brainstem areas (LC) together with neuronal dysfunction in higher brainstem areas (SN and VTA). In order to understand the mechanisms by which NM accumulation in specific brain areas ultimately interferes with the normal functioning of cells, we characterized genome-wide transcriptomic changes linked to the intracellular presence and progressive accumulation of NM in two NM-accumulating neuronal subpopulations (SN and VTA) that are known to be differentially susceptible to PD pathology. We selectively isolated single dopaminergic NM-containing neurons by laser capture microdissection from male and female wild-type and tgNM animals at 3 months, 12 months and 20 months of age (n=4-6 mice per group). We performed differential expression analysis, resulting in statistically significant differentially expressed genes at all ages (p-value<0.01 and $\log_2$FC><0.5). Gene-set enrichment analysis (GSEA) with Reactome Pathway Database led to the identification of altered biological pathways in tgNM related to

neuroinflammation, vesicle-mediated transport and lipid metabolism, transcription and translation, mitochondrial function and cell cycle (senescence) (False Discovery Rate<0.05). Targeted-based validation of candidate RNA species was performed in microdissected samples by quantitative real-time PCR and candidate biological pathways were validated at the protein level by western blot in dissected ventral midbrain tissues from biological replicates. The transcriptomic profiles identified in this project contribute to our understanding of selective vulnerability in PD and brain aging, and points to key biological pathways and molecular targets in prodromal and early PD.

Title: Pak6 regulates tfeb to enhance autophagy in neurons

Authors: *F. AGOSTINI[1], N. PLOTEGHER[1], R. AGOSTINIS[2], F. DE LAZZARI[1], S. COGO[3], M. BISAGLIA[1], E. GREGGIO[1];
[1]Univ. of Padova, Padova, Italy; [2]Telethon Inst. of Genet. and Med., Napoli, Italy; [3]Univ. of Reading, Reading, United Kingdom

Abstract: Autophagy is a degradation and recycling mechanism which is essential for maintaining cellhomeostasis. This process is mainly controlled by the activity of the transcription factor EB (TFEB),that modulates the expression of several genes involved in the autophagic-lysosomal machinery.TFEB regulation and subcellular localization are mainly controlled by the binding of 14-3-3 proteins,which prevent its nuclear translocation.Accumulating evidence links autophagy dysregulation to the onset and progression of severalneurodegenerative diseases. Therefore, activation of TFEB and induction of autophagy areconsidered promising therapeutic approaches for the treatment of these pathologies. For thisreason, the major aim of this project is to characterize and validate a novel mechanism to enhanceautophagy and lysosomal function in neurons.Considering that the neuronal-enriched kinase PAK6 has been recently demonstrated to regulatethe interaction of 14-3-3 proteins with their binding partners, we hypothesized that PAK6 mayinduce TFEB nuclear translocation by phosphorylating 14-3-3s and promoting their dissociation fromTFEB.Taking advantage of both *in vitro* and *in vivo* models we assessed the

effect of PAK6 kinase activityon TFEB. First, we revealed that cells transfected with a hyperactive mutant form of PAK6 displayan increased TFEB nuclear translocation. We then tested whether PAK6 affects autophagy in SH-SY5Y neuroblastoma cells overexpressing wild type PAK6. We observed that PAK6 stimulatesautophagy, as assessed by the analysis of several autophagic markers and the level of TFEB.To explore whether PAK6 can activate autophagy also *in vivo*, we used *Drosophila melanogaster*downregulating *mbt*, the fly orthologue of mammalian PAK6. By performing western blots,lysosomal activity assays and immunofluorescence analysis, we found that neuronal-specificsilencing of *mbt* results in a reduction of autophagic activity and lysosomal function.Taken together, these results show a novel and conserved mechanism by which the kinase activityof PAK6 enhances autophagy/lysosome pathways through the activation of TFEB.Moreover, our data point to PAK6 as a potential key target to regulate autophagy specifically inneurons.

Title: Increased D1/D5 receptors to Kv1.3 channel signaling causes striatal cholinergic interneurons hyperexcitability in parkinsonism and dyskinesia

Authors: *C. TUBERT[1], R. M. PAZ[2], A. M. STAHL[3], L. RELA[4], M. G. MURER[5];
[1]IFIBIO-HOUSSAY-CONICET-University of Buenos Aires, Capital Federal, Argentina; [2]IFIBIO Houssay, Ciudad Autonoma Buenos Aires, Argentina; [3]IFIBIO Houssay - CONICET - UBA, Buenos Aires, Argentina; [4]Physiol. and Biophysics, IFIBIO Houssay CONICET UBA, Buenos Aires, Argentina; [5]Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: Striatal cholinergic interneurons (SCIN) are the main source of striatal ACh. In Parkinson´s disease (PD), dopaminergic neurons that innervate the striatum degenerate, leading to a relative increase of cholinergic function that contributes to the generation of PD symptoms (Barbeau A, 1962, *C Med Ass J*). The gold standard therapy for PD is levodopa (L-dopa) administration, but prolonged treatment may result in adverse effects like dyskinesia (Kalia LV & Lang AE, 2015, *Lancet*). This highlights the need for the development of alternative therapies

for patients with advanced PD. Previously, we found that SCIN are hyperexcitable in a mouse model of PD as a result of a reduction in a current mediated by Kv1.3 channels, which is not explained by reduced channel expression (Tubert C *et al.*, 2016, *Cell rep*). Contrary to expectations, in a recent study we report that L-dopa administration at doses that induce dyskinesia not only does not revert the hyperexcitability observed in SCIN of parkinsonian mice but instead exacerbates the already increased excitability of these cells through undetermined mechanisms likely involving stimulation of the D1/D5 receptors in SCIN (Paz RM *et al*., 2021, *Mov dis*). Our aim is to identify these mechanisms. Because this enhanced hyperexcitability is observed in the off L-dopa medication condition, 24 hs after the end of a chronic L-dopa treatment, we hypothesize that physiologic activation of D1/D5 receptors results in a reduction of Kv1.3 current and a consequent increase in excitability, and that an alteration in D1/D5 signaling contributes to the enhancement of hyperexcitability observed in the off L-dopa medication condition. With *ex-vivo* electrophysiological recordings and classic pharmacology, we found that, in physiological conditions, activation of D1/D5 receptors increases SCIN excitability by reducing Kv1.3 current through a signaling pathway involving cAMP and Erk1/2 kinase. Moreover, in parkinsonian and dyskinetic mice, antagonizing cAMP signaling in SCIN restores normal excitability. Finally, preliminary results suggest that the cAMP pathway overactivity is due to an increased ligand-independent activity of D1/D5 receptors that entails a cAMP-dependent reduction in Kv1.3 current. Our results suggest that the design of new strategies for restoring or preventing the changes that occur in the D1/D5 receptors to Kv1.3 signaling pathway in SCIN may prove beneficial both in PD and in dyskinesia.

Title: Loss of Bmal1 drives cell-autonomous dopaminergic neuron degeneration

Authors: *M. KANAN, P. SHEEHAN, J. PATTERSON, A. G. DAVIS, E. MUSIEK; Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Circadian disturbances are among the most common and disabling non-motor symptoms of Parkinson’s disease (PD), affecting as many as 90% of patients. While disruptions in circadian rhythms are a known symptom of PD, the relationship between molecular timing mechanisms and the dopaminergic neurodegeneration of PD is poorly understood. Previous data has indicated a connection between circadian clock machinery and increased neuronal oxidative

stress, which is a known risk factor for PD-related neurodegeneration. To examine the relationship between circadian clock machinery and health of dopamine containing neurons in the substantia nigra pars compacta (SNpc), we examined the effect of tissue-specific deletion of the critical circadian clock transcription factor BMAL1 (BKO) on dopaminergic neuron degeneration. We performed stereological counts of tyrosine hydroxylase expressing (TH+) cells in the SNpc and found that global inducible BKO mice exhibited a significant reduction in dopaminergic neurons, suggesting Bmal1 may regulate dopaminergic neuron longevity. Global Bmal1 deletion also exacerbated dopaminergic neuronal loss in response to striatal injection of alpha-synuclein fibrils. Neuron-specific BKO mice showed a significant reduction of TH+ cells in the SNpc, while the astrocyte specific BKO mice did not, suggesting a cell-autonomous effect. We are currently examining transcriptional regulation of glutathione transferases and other oxidative stress pathways by BMAL1 as a possible mechanism. These findings suggest that neuronal BMAL1 may directly regulate the homeostasis of dopaminergic neurons, potential through upregulation of oxidative stress gens controlled by Bmal1.

Title: Neurotoxic astrocyte secreted-exoDrp1 causes excessive mitochondrial fragmentation and neurodegeneration in Parkinson's disease.

Authors: *B. SEO, H. KO;
Inst. for Cell Engineering, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Emerging evidence suggests that neurotoxic astrocytes play a role in the onset of neurodegenerative disorders including Parkinson’s disease (PD). However, it is still unclear how neurotoxic astrocytes contribute to neurodegeneration in PD. It speculates that toxic factors produced by the neurotoxic astrocytes may play a role in neurotoxicity, yet the toxic factors that mediate neurotoxicity are unknown. In order to identify neurotoxic factors secreted by neurotoxic astrocytes, we conducted mass spectrometry (MS) analysis combined with SILAC (Stable Isotope Labeling with Amino acids in Cell culture) using conditional medium collected from neurotoxic astrocytes (ACM) induced by conditional medium (MCM) collected from α-synuclein preformed fibrils (α-syn PFF)-activated microglia. Intriguingly, dynamin related protein 1 (Drp1) was identified from the MS analysis. Our preliminary studies indicate that Drp1 is secreted from neurotoxic astrocytes via exosomes (**exoDrp1**) and exoDrp1 is uptaken by

neurons. We also found transported exoDrp1 leads to mitochondrial fragmentation and neurotoxicity in neurons. More importantly, exoDrp1 aggravates human α-syn PFF-induced Lewy bodies (LBs) pathology. Based on our preliminary results, we have investigated the contribution of exoDrp1 in human dopaminergic neurodegeneration using both H9-human embryonic stem cell (hESC)-derived midbrain dopaminergic neurons and PD patient's induced pluripotent stem cells (hiPSCs)-derived midbrain dopaminergic neurons. The investigation will provide a new insight into the pathogenesis of PD and new strategy for the treatment of PD.

Title: Activating transcription factor-4 mediated inhibition of mTOR signalling results in PUMA/Bax-dependent neuronal apoptosis in models of parkinson's disease

Authors: *M. D. DEMMINGS, K. C. HURLEY, E. TENNYSON, S. P. CREGAN;
Robarts Res. Institute, Univ. of Western Ontario, London, ON, Canada

Abstract: Parkinson's Disease (PD) is the second most common neurodegenerative disorder and results from the progressive loss of dopaminergic (DA) neurons in the substantia nigra. The underlying disease pathology is characterized by alpha-synuclein aggregates, which form Lewy body inclusions and increase oxidative and ER stress. Unfortunately, the mechanisms by which DA neurons die remain to be fully understood and current treatments for PD only mitigate some of the clinical symptoms of the disease. Previously we have demonstrated that ATF4, a key mediator of the Integrated Stress Response (ISR), is upregulated in dopaminergic neurons following exposure to MPP+, 6-OHDA, or humanized alpha-synuclein pre-formed fibrils (PFFs). Specifically, we determined that ATF4 induction promotes neuronal death through transcriptional activation of known death genes including pro-apoptotic BH3-only protein PUMA. Interestingly, despite ATF4 being required for PUMA activation, chromatin immunoprecipitation experiments have revealed that ATF4 does not interact directly with the PUMA promoter. Given this, in the current study, we aim to characterize the indirect mechanism by which ATF4 activation signals PUMA-dependent neuron loss. Using mouse primary neurons,

we demonstrate that ectopic ATF4 expression results in activation of Trib3, SESN2, and DDIT4, which have previously been implicated to have inhibitory activity on mTOR. Indeed, ectopic expression of ATF4 in neurons also results in downregulation of mTOR signalling and increases in neuronal apoptosis. Importantly, our current investigations, show that ATF4-deficient neurons are resistant to mTOR inhibition induced by exposure to a-syn PFFs or PD toxins as compared to wild-type littermates. In addition, we describe that pharmacological inhibition of mTOR results in significant increases in PUMA activation and promotes PUMA-dependent dopaminergic neuron loss. Lastly, we demonstrate that both PD toxins and a-syn PFFs activate the PUMA/Bax intrinsic mitochondrial apoptotic pathway as marked by cleaved-caspase activation and subsequent neuronal loss. Ultimately, these results provide a novel signalling mechanism by which ATF4 indirectly promotes PUMA/Bax-mediated cell death through suppression of mTOR signalling and provides further evidence for targeting the ISR for the development of therapeutics for PD.

Title: Defective mitochondria-lysosome contact site dynamics in Parkin PD iPSC-derived dopaminergic neuronal models

Authors: *W. PENG, L. SCHRÖDER, P. SONG, Y. WONG, D. KRAINC;
Northwestern Univ., Chicago, IL

Abstract: Autosomal recessive mutations in in the E3 ubiquitin ligase PARK2 (Parkin) are associated with early-onset Parkinson's disease (PD). Although previous studies have implicated Parkin in the regulation of mitochondrial homeostasis via mitophagy, whether Parkin alters additional forms of mitochondria-lysosome interaction, and how loss-of-function mutations in Parkin lead to neurodegeneration remain incompletely understood. Here, we show that loss-of-function mutations in Parkin alter mitochondria-lysosome contact site dynamics in multiple cell types independent of mitophagy. Parkin regulation of mitochondria-lysosome contacts is dependent on its ubiquitination activity and occurs via stabilization of active, GTP-bound Rab7. Importantly, these defective mitochondria-lysosome contact site dynamics are recapitulated in Parkin PD patient iPSC-derived dopaminergic neurons, and can be rescued by modulating levels

of mitochondria-lysosome contact site tethering proteins. These findings highlight a novel role of Parkin in mitochondrial and lysosomal homeostasis and suggests Parkin regulation of mitochondria-lysosome contact site dynamics as an important pathway in both cellular homeostasis and disease.

Title: Deletion of Lag3 in the Microglia Prevents Neuropathology in Mouse Model of Parkinson Disease

Authors: *X. YANG[1], S. HA[1], H. LIU[2], N. WANG[2], S.-U. KANG[2], T. DAWSON[3], V. DAWSON[3], X. MAO[3];

Abstract: Parkinson's disease (PD), the accumulation of aggregated α-synuclein (α-syn) is the typicalpathological hallmark disease. Substantial evidence has indicated that pathological α-syn canspread from cell to cell. The neuroinflammation induced by the spreading of pathological α-synsubsequently leads to progressive neurodegeneration and behavioral deficits. Previously, wehave identified a major receptor of the neuron that mediates the spreading of pathogenic α-synperformed fibrils (PFF), named lymphocyte activation gene 3 (Lag3) (Mao et al., Science. 2016).In the neuron, Lag3 mediates the endocytosis of pathogenic α-syn and contributes to theneuron-to-neuron transmission. Based on the previous study, we generated the Lag3 neuronalconditional knock out (LL-Nestin-Cre) mice (Zhang et al., Sci. Immunol. 2017), and found thatthe pathogenic α-syn transmission was reduced. The role of Lag3 in the neuron is wellestablished, however, the underlying mechanism of how α-syn pathology in the microgliainduces neuroinflammation is not clear. In our current study, we have explored the role of Lag3in microglia mediated neuroinflammation. To study the role of Lag3 in microglia, we havegenerated the microglial Lag3 conditioned knockout mice (LL-CX3CR1-ERT-Cre). In these mice,we evaluated how the absence of the Lag3 receptor in the microglia influence PD pathology.We performed intra-striatal injection of α-syn PFF in these mice and evaluated diseasepathology at varying time intervals. Our results indicate that deletion of Lag3 in the microgliaprevents α-syn mediated neuropathology abnormalities. Moreover, deletion of Lag3 in microgliaresulted in significant rescue of motor deficit compared to wild type (WT) mice. To

understandthe disease mechanisms, we performed our in-vitro experiments in the primary microglia culturefrom WT vs Lag3 KO mice. In-vitro study results show that deletion of Lag3 in the microgliainhibit release of pro-inflammatory cytokines and thereby reduce the reactive astrocytes.Furthermore, when the neurons are exposed with the conditional media from the stimulated glia
cells, it leads to significant attenuation of neurotoxicity. Overall, this study demonstrates theimportant role of Lag3 in the microglia. Targeting of microglia Lag3 could have beneficial effectsand open a new therapeutic avenue for neurodegenerative diseases.

Title: The binding of L-DOPA to the siderophore-binding protein Lipocalin-2

Authors: *S. ALHASSEN[1], A. ALACHKAR[3], M. KHOUDARI[5], M. SENEL[5], O. CIVELLI[4], W. S. ALHASSEN[2];
[2]Pharmacol., [1]Univ. of California, Irvine, West Covina, CA; [3]Pharmacol., [4]Univ. of California Irvine, Irvine, CA; [5]Univ. Of California, Irvine, Irvine, CA

Abstract: Parkinson’s disease (PD) is a neurodegenerative disease that is characterized by the degradation of dopaminergic neurons in the substantia nigra pars compacta causing tremors, rigidity, bradykinesia, and akinesia. Most strategies for treating PD largely depend on the replacement of lost dopamine. The gold standard for treating PD symptomatically is through levodopa (L-DOPA), which is the precursor to dopamine, however, this treatment has many issues, mainly the effectiveness of the treatment over time and the dyskinesia that may develop over chronic L-DOPA treatment. Lipocalin 2 (Lcn2) is a protein that’s function is to bind to siderophores, which are small iron-chelating compounds. By sequestering iron, Lcn2 prevents its use by bacteria and thus limits its growth. L-DOPA has also been shown to bind to iron through its catechol structure. We hypothesize that Lcn2 may play a role in PD and chronic L-DOPA treatment by transporting any excess L-DOPA that has bind to iron into the cell, which may have damaging effects. Using surface plasmon resonance imaging (SPRi), we can monitor interactions in real time, as well as their specificity, kinetics, and affinity. Through SPRi we can monitor if there is an interaction between Lcn2 and the L-DOPA-iron complex. We were able to show that this interaction does occur and is specific to iron and the catechol structure. Compounds with a similar catechol structure to L-DOPA, such as dopamine, also showed interaction, but to a lesser

degree. Compounds similar in structure to L-DOPA with slight modifications to the catechol structure showed very little to no interaction, suggesting that the catechol structure is necessary for the interaction to occur. Through immunohistochemistry, we stained human embryonic kidney (HEK293) cells that have been treated with Lcn2 and the L-DOPA-iron complex. Using select antibodies for both Lcn2 and L-DOPA, we would be able to see if Lcn2 is able to bring the complex into the cell. Chronic L-DOPA treatment causes tolerance and less effectiveness of the drug, leading to higher dosing of the treatment. As the dosing increases, there is an abundance of free L-DOPA that then binds to iron, which is then brought into the cell via Lcn2. Once in the cell, L-DOPA has a number of toxic and deteriorating effects, which may be the cause of some of the negative side effects of chronic L-DOPA treatment.

Title: The effects of locomotion in the sensory cortex of awake APP/PS1 mice

Authors: *B. EYRE, O. SHABIR, L. LEE, J. BERWICK, C. HOWARTH;
Univ. of Sheffield, Sheffield, United Kingdom

Abstract: The brain is an energy-demanding organ, consuming approximately 20% of the body's energy supply[1]. In order to regulate its own energy demands the brain has developed a mechanism, known as neurovascular coupling (NVC). NVC ensures that when neurons are active, there is a rapid increase in cerebral blood flow to that same brain region[2]. Evidence suggests this mechanism is impaired in many neurological disorders, including Alzheimer's disease (AD)[3, 4]. Many studies have relied on anaesthesia to investigate neural activity and the subsequent hemodynamic responses. However, anaesthesia can have profound impacts on NVC - including dampening neural activity and reducing cerebral blood volume (CBV)[5]. Due to this, groups have started to investigate NVC using awake rodents[6, 7]. However, behaviour such as locomotion has the potential to confound sensory-evoked NVC responses. This study aims to examine NVC in an AD mouse model, in addition to examining the effects of short bursts of locomotion on sensory-evoked responses. Adult 9-12m APP/PS1 (B6;C3-

Tg(APPswe,PSEN1dE9)85Dbo/Mmjax) (AD n=8 (7 male, 1 female), WT n= 5 (3 m, 2 f)) and old 16-19m (AD n=4 (2 m, 2 f), WT n=4 (1 m, 3 f)) mice received a thinned window surgery. One-week after surgery animals were habituated to a spherical treadmill where 2-dimensional optical imaging spectroscopy (2D-OIS) was used to measure changes in cerebral hemodynamics, in response to a whisker stimulation and spontaneous trials with no stimulation. The experimenter was blinded from genotype during experiments and analysis. Statistical tests will assess whether there is an effect of the amount and timing (relative to 2s whisker stimulation) of short bursts of locomotion on evoked hemodynamic responses and whether there are any differences in evoked hemodynamic responses when comparing AD and WT mice; both adult and old age mice. Preliminary results suggest that short bursts of locomotion alter the amplitude of sensory-evoked responses, with the timing of locomotion (relative to the whisker stimulation) also altering evoked responses. Additionally, evoked hemodynamic responses appear preserved when comparing AD and WT mice. We suggest that during awake imaging, locomotion should be monitored to ensure results are not confounded by the effects of this behaviour. 1. Zlokovic, BV. (2008) Neuron 57, 178-201. 2. Title: A Circuit Model of the Circle of Willis and its Clinical Applications

Authors: D. ANANDAYUVARAJ[1], *R. BAIG[2], E. PONTE[2], ***B. R. SHETH**[1];
[1]Elec & Comp Engg, [2]Univ. of Houston, Houston, TX

Abstract: Our current goal is to model blood flow in the Circle of Willis (CoW) in humans and leverage the model to pinpoint structural weaknesses in individual arteries of the CoW. The CoW is a circulatory anastomosis of several arteries at the bottom (inferior) side of the brain of reptiles, birds, mammals including humans that supplies oxygenated blood to over 80% of the brain. Computational fluid dynamics models of blood flow have investigated structure of arterial segments and junctions, turbulent flow and resulting stagnation. However, these models are not scalable to arterial networks, in part because of their computational complexity, and are thus limited in their clinical applicability. Sidestepping the above critique, we designed a zeroth-order

electrical circuit model of the CoW. Individual arteries of the CoW were modeled as resistors, with the internal carotid artery (ICA) and basilar artery modeled as inlets to the CoW, and the remaining arteries serving as outlets leaving to the rest of the brain. Difference in blood pressure along individual arteries was modeled using Poiseuille's Law, with experimental measurements of diameter and length of human arteries obtained from sources (Iqbal et al. 2013, Hillen et al. 1986, and five others) informing the circuit model. The range of anatomical dimensions reported in human studies was used to constrain randomly generated 100 million+ models (this further allowed us to model individual variation across the population). The flow (current) solution to each individual model was then computed using theorems from circuit analysis based on Kirchhoff's Current Law (KCL) and Kirchhoff's Voltage Law (KVL), and compared with empirical data on blood flow from the literature (e.g. Zarinkoob et al., 2015). We chose to analyze further only those models whose currents (flow rates) fell within the range of human variation for all CoW arteries. In particular, we modeled three of the most common variations in the CoW for which experimental flow data are available – a complete CoW, which is observed in one-half of the population, and two other variations, which together account for nearly 90% of the total variation. A preliminary regression analysis showed that the ICA, the Middle Cerebral Artery, Posterior Cerebral Arteries 1 & 2 had flow rates higher than expected across the distribution of ~1950 filtered models of the complete CoW, implying higher levels of shear stress in these arteries and likely sites for future aneurysms and stroke. Our work thus far provides a glimpse into clinical insights that can be gleaned from simpler models of blood flow. The modeling is being extended to more complicated networks and non-stationary blood flows.

Title: Spontaneous vasomotion propagates along cortical arterioles in the mouse brain with similar properties as sensory-evoked vascular reactivity

Authors: *L. P. MUNTING[1], M. G. KOZBERG[1], C. A. AUGER[1], O. BONNAR[1], L. HIRSCHLER[1,2], S. S. HOU[1], S. M. GREENBERG[1], B. J. BACSKAI[1], S. J. VAN VELUW[1]; [1]Massachusetts Gen. Hosp., BOSTON, MA; [2]Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: Sensory stimulation, such as visual stimulation, evokes a local, vasodilation-mediated blood flow increase to the activated brain region, a process referred to as neurovascular coupling (NVC). Spontaneous vasomotion is a change in arteriolar diameter that occurs in the absence of sensory stimulation, at low frequency (~0.1 Hz) and has been suggested to be neuronally entrained (Mateo *et al.*, Neuron 2017). These slow fluctuations in vessel diameter are a driving force for paravascular soluble waste clearance (van Veluw *et al.*, Neuron 2020), the failure of which has been implicated in neurodegenerative disease. NVC-mediated vascular reactivity has been shown to propagate from capillaries along penetrating arterioles to surface arterioles, but it is unclear whether spontaneous vasomotion shows a similar propagation pattern. We therefore imaged arterioles in the visual cortex in 7 awake, head-fixed, male, C57Bl/6J mice (4-5 months old) with 2-photon microscopy over 3 imaging sessions per mouse. In each session, 5-minute time-lapses were acquired at rest and during visual stimulation (at frequencies between 0.025 and 0.1 Hz) to capture both spontaneous and visually evoked vessel diameter changes respectively. 15 µm-spaced regions of interest (ROIs) were drawn along the length of arterioles - on average 18 ROIs per vessel - in every dataset to extract local vessel diameter changes over time. After demeaning, detrending and low-pass filtering (<0.2 Hz), time profiles in each ROI were cross-correlated to the time profile in a reference ROI to determine if the local diameter change was leading or lagging that of the reference ROI. Linear regression was performed through the retrieved leads/lags to determine if there was a significant diameter change propagation (i.e., a wave) along the arteriole. Both at rest and during sensory stimulation, approximately half of the arterioles showed significant propagation of vessel diameter changes (46 % of the vessels during resting state, 59 % during visual stimulation). Evoked changes in vessel diameter were 29 % higher in amplitude than spontaneous changes ($p < 0.001$, Mann Whitney U), but wave detection did not correlate with the magnitude of the diameter change. The mean (± standard deviation) wave speed was 221 (± 102) µm/sec at rest and 253 (± 131) µm/sec during visual stimulation, and in both conditions, ~75 % of the waves travelled upstream. In summary, these results indicate that spontaneous vasomotion, like sensory-evoked vascular reactivity, propagates along cortical arterioles. This likely plays a role in paravascular brain clearance and supports the hypothesis that vasomotion is neuronally entrained.

Title: Optogenetic control of single-arteriole diameter in three dimensions in vivo

Authors: *P. O'HERRON[1], D. A. HARTMANN[2], K. XIE[1], P. KARA[3], A. Y. SHIH[4]; [1]Physiol., Augusta Univ., Augusta, GA; [2]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA; [3]Univ. of Minnesota, Minneapolis, MN; [4]Ctr. for Developmental Biol. and Regenerative Med., Seattle Children's Res. Inst., Seattle, WA

Abstract: Arteries in the brain dynamically modulate their diameter as part of several crucial vascular functions. Arteries dilate and constrict in response to changes in blood pressure to maintain constant flow levels and to protect the microvasculature from pressure-induced damage. Also, arteries rapidly dilate in a spatially localized fashion when there is an increase in local neural activity - a process called functional hyperemia - which is the basis of hemodynamic imaging techniques like fMRI. Altered vascular function, including impaired functional hyperemia and reduced blood flow, is now seen as a contributing factor in many neurological disorders. Thus, there is a critical need for an accurate understanding of vascular dynamics and of how neural activity interacts with and shapes hemodynamic responses. Typically, studies of vascular function either indirectly activate vessels by driving neural activity (e.g. with sensory stimulation), or use pharmacological agents which can have wide-ranging effects and have poor spatial and temporal resolution. This has limited our ability to separate vascular properties from the actions of the rest of the neurovascular unit in hemodynamic studies. Here we present an experimental paradigm to optically probe the contractile function of arterioles in vivo with high spatiotemporal precision. This was done by expressing the excitatory opsin ReaChR in vascular smooth muscle cells and pericytes. Using a 594 nm light-emitting diode we were able to evoke widespread vasoconstriction across the cranial window. With a 1040 nm focused, pulsed laser for two-photon stimulation, we were able to evoke highly localized constrictions targeted to individual pial artery branches or penetrating arterioles. Our dual light-path imaging system allowed the optogenetic stimulation to be performed with simultaneous two-photon imaging to monitor vessel activity. Using a spatial light modulator, we were also able to constrict vessels both above and below the imaging plane. This is a powerful tool to assay vasoconstrictive function of single arterioles across 3-dimensional vascular networks in vivo. We demonstrate its usefulness for studying the conductance of vascular signals and modulating the dynamics of functional hyperemia.

Title: Intranasal treatment with tissue plasminogen activators rescues neuromuscular and cognitive dysfunction triggered by amyloid-ß

Authors: K. UEKAWA, A. ANFRAY, J. SEO, N. CASEY, P. ZHOU, C. IADECOLA, *L. PARK;
Feil Family Brain & Mind Reseach Inst., Weill Cornell Med., New York, NY

Abstract: Amyloid-β (Aβ) is a key pathogenic factor in Alzheimer's disease and suppress the increase in cerebral blood flow (CBF) evoked by neural activity (functional hyperemia). The protease tissue plasminogen activator (tPA) contributes to the NMDA receptor-dependent component of functional hyperemia (PNAS., 105:1073, 2008), and tPA deficiency is involved in the neurovascular and cognitive dysfunction triggered by Aβ (J Neurosci., 40:8160, 2020). Therefore, we investigated whether intranasal administration of recombinant tPA (rtPA) prevents the detrimental neurovascular and cognitive effects of Aβ in mice overexpressing the amyloid precursor protein with the Swedish mutation (tg2576). Male tg2576 mice and wild-type (WT) littermates (10 mice/group) were instilled intranasally with rtPA [20 µg/day (10µl/nostril at 1 mg/ml concentration); 5 days/week] or vehicle (veh; 10µl dH_2O/nostril) starting at 12 months of age and were examined after 3 months of treatment. In veh-treated tg2576 mice, resting neocortical CBF, measured by ASL-MRI, was attenuated (-25%) compared to veh-treated WT littermates (130±3 vs. 98±6 ml/100g/min; $p<0.05$). To test the effect of rtPA on neurovascular coupling, CBF was recorded by laser-Doppler flowmetry in the somatosensory cortex of urethane-chloralose anesthetized mice. In veh-treated tg2576 mice, the increase in somatosensory cortex CBF produced by neural activity evoked by whisker stimulation was attenuated (-40%) compared to veh-treated WT littermates (19±2% vs. 11±1; $p<0.05$). Similarly, the CBF increase elicited by neocortical application of NMDA (40 µM) was reduced in tg2576 mice (-23%) compared with WT littermates ($p<0.05$). Intranasal rtPA in tg2576 mice rescued the attenuation in resting CBF and functional hyperemia ($p<0.05$ from veh-treated tg2576). Next, we assessed nesting behavior, a sensitive test of executive function in mice. In veh-treated tg2576 mice, the nesting score was reduced compared to veh-treated WT mice (-40%; $p<0.05$). Intranasal rtPA rescued nesting behavior in tg2576 mice ($p>0.05$ from veh-treated WT), effects associated with improved resting CBF and functional hyperemia. The findings indicate that tPA supplementation prevents neurovascular and cognitive dysfunction in aged tg2576 mice and, as such, may be a therapeutic strategy to counteract the detrimental effects of Aβ on neurovascular and cognitive function.

Title: A novel approach to detect and eradicate HIV brain viral reservoirs

Authors: *S. VALDEBENITO, E. EUGENIN;
Neuroscience, Cell Biol. and Anat., Univ. of Texas Med. Br., Galveston, TX

Abstract: The human immunodeficiency virus (HIV-1) compromises the central nervous system (CNS) in the infected population (37 million worldwide), resulting in neurological dysfunction that ranges from minor cognitive impartment to dementia in at least half of the individuals. The major obstacle to eradicate HIV infection is viral reservoirs (VR). The VR is defined as anatomical compartments where the virus is quiescent, and upon the disruption of the antiretroviral therapy (ART), HIV replication is reactivated. It has been demonstrated that a small population of human primary microglia/macrophages and astrocytes in vivo and in vitro survives the infection, silent the virus, and generates bystander damage/inflammation. We identified a unique metabolic profile of these cells to produce ATP from glutamate/glutamine. This is significant because glutamate is already dysregulated in the HIV CNS and the more abundant neurotransmitter in the brain. Thus, VR has an unlimited source of energy to survive for an extended time. First, we used a novel multi-component method (HIV-integrated DNA, mRNA, and viral proteins in the same assay) to identify, quantify and characterize VR in brain tissues, from patients with ART, and primary astrocytes and microglia. Later, we isolate the VR from primary astrocytes and microglia using laser capture microdissection and perform a metabolomics analysis, Seahorse, western blot, and mitochondrial sequence. We correlate our results using imaging mass spectrometry for human HIV-infected brain tissues. Our results show that a small population of astrocytes and microglia are VR in the brain, and they use glutamine as a source of energy. Furthermore, our results from imaging mass spectrometry showed a lipid dysfunction in the HIV-infected brain compare with the healthy controls. In conclusion, we propose that these metabolic changes help the VR survive infection and reveal a novel metabolic target to kill and eradicate HIV brain viral reservoirs.

Title: Cortical Spreading Depression (CSD) in Mouse Models of Alzheimer's Disease and Atherosclerosis

Authors: *O. SHABIR[1], L. M. T. LEE[2], B. EYRE[2], C. HOWARTH[2], S. B. WHARTON[3], S. E. FRANCIS[1], J. BERWICK[2];
[1]Dept. of Infection, Immunity & Cardiovasc. Dis. (Faculty of Medicine), [2]Dept. of Psychology, [3]Sheffield Inst. for Translational Neurosci., Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Background: Cortical spreading depression (CSD) is physiological process that causes a wave of depolarisation and subsequent vasoconstriction of arterioles in the brain and is associated with migraine with aura, epilepsy and TBI. The aim of this study was to investigate CSD and neurovascular coupling in mouse models of Alzheimer's disease and atherosclerosis.
Methods: 9-12m old male C57BL/6J mice (WT; n=8), J20-hAPP(Sw,Ind) (AD; n=8), rAAV8-mPCSK9-D377Y + Western Diet (ATH; n=6) & J20-hAPP(Sw,Ind) + rAAV8-mPCSK9-D377Y + Western Diet (MIX; n=5) were used. Cerebral haemodynamics were imaged using optical imaging spectroscopy 3-weeks after a chronically recovered thinned window surgery. A terminal acute imaging session was performed with a multichannel electrode was inserted into the brain causing a mild 'pin-prick' of the brain resulting in CSD. Mice were perfused at the end and brains dissected for immunohistochemistry and qPCR studies.
Results: Electrode insertion into the brain resulted in a wave of haemodynamic changes that occurred in all mice. In WT mice, electrode insertion led to a small decrease in HbT followed by a robust HbT bounce back, immediately followed by a small, sustained vasoconstriction (reduced HbT) that persisted for a short duration. In J20-AD mice, electrode insertion caused a large vasoconstriction to occur which spread across the cortex in a strong wave of vasoconstriction that was followed by a very small, attempted recovery. This was masked by a large sustained and prolonged vasoconstriction of contiguous vessels that persisted for some time. The largest vasoconstriction post-CSD occurred in J20-AD mice, followed by PCSK9-ATH mice. A prolonged and sustained constriction below baseline persisted in all mice post-CSD, however, this effect was recovered to baseline in WT mice during the first stimulation experiment 35 minutes after the CSD occurred. In all disease mouse models, the constriction below baseline was more severe and persisted for a much longer time with a slower haemodynamic recovery.
Conclusions: CSD could be an important biomarker of baseline brain health (potentially relating

to levels of neuroinflammation), and insults such as TBI or systemic disease could worsen NVC causing metabolic deficits that could initiate or progress neurological disease. In addition, acute imaging preparations (i.e., electrode insertion or imaging immediately after surgery) have profound consequences on cerebral haemodynamics and this should be considered performing experiments during this phase.

Title: Progression of Post-traumatic Neurodegeneration Relative to Genetic Modulation of Human Mutant Tau Expression in Mice

Authors: *F. YU[1], D. IACONO[2,3], D. P. PERL[3,4], C. LAI[5], J. GILL[5,4], T. Q. LE[1], G. SUKUMAR[1], P. LEE[3], C. DEVOTO[5], R. C. ARMSTRONG[1,4];

Abstract: Improving diagnosis and treatment of mild-moderate traumatic brain injury (TBI) requires understanding how relatively subtle injury progresses to post-traumatic neurodegeneration with chronic stage atrophy. Tau is mainly localized in myelinated axons in healthy adult brain. The interaction of the tau phenotype with the progression of injury-induced pathology is poorly understood. We used concussive TBI models in male and female mice with 0 (*wt*), 1 (*hemi*), or 2 (*hom*) alleles of the P301S human tau mutation to modulate gene dose-dependent levels of tau expression, hyperphosphorylation, and aggregation. As tau pathology has been associated with repeated concussions, we first examined a repetitive mild TBI (r-mTBI) model of closed head injury, with impacts once per day on five consecutive days. Mice survived for 1 day, 6 weeks or 4 months after r-mTBI or sham procedures. Immunohistochemistry and Simple Western™ protein quantification of the injured brain region confirmed soluble total tau and phosphorylated tau levels were highest in *hom* mice. Simoa™ Neuro-4 multiplex assay analysis of blood samples showed increased serum neurofilament light chain (Nf-L), a marker of

axon damage, at 1 day after r-mTBI as compared to shams. By 4 months after either r-mTBI or sham procedure, *hom* mice had further elevated Nf-L along with increases of total tau. P301S *hemi* mice did not show elevated serum biomarkers in any conditions. Effects from both the injury and tau genotype increased astrogliosis and microglial activation in the corpus callosum. We next examined a single impact moderate TBI (s-TBI) model that produces more extensive axon damage and progressive atrophy of the corpus callosum, which is common in TBI patients with chronic symptoms. Neuropathology demonstrated similar corpus callosum atrophy induced by s-TBI in *wt*, *hemi*, and *hom* P301S genotypes. Neuro-4 multiplex assay analysis showed increased serum Tau and Nf-L at 1 day after s-TBI. By 4 months after either s-TBI or sham procedure, *hom* mice had further elevated serum Nf-L. Quantification of soluble proteins in the injured brain region confirmed increased total tau and phosphorylated tau in *hom* mice, which was not altered in sham vs s-TBI conditions. The combined results from r-mTBI and s-TBI models suggest that both the extent of mutant tau expression and the severity of injury can influence the extent of axon damage and neuroinflammation, but robust tau pathology does not necessarily accelerate TBI induced progression of white matter atrophy.

Title: Morphine attenuates pain-induced hemorrhage following traumatic brain injury (TBI)

Authors: *G. A. GIDDINGS, P. A. BEAN, M. M. TARBET, D. T. JOHNSTON, J. A. DAVIS, E. T. LOUT, M. K. HENWOOD, J. W. GRAU;
Texas A&M Univ., College Station, TX

Abstract: Traumatic brain injury (TBI) from car accidents, combat violence, and falls, is often accompanied by additional injuries (polytrauma) that serve as a source of pain (nociceptive input). Previous work in our laboratory has shown that nociception is detrimental to recovery after spinal cord injury (SCI) or traumatic brain injury (TBI) and leads to increased lesion site hemorrhage (Turtle, 2019, Exp Neurol, 311, 115). The current study explored the circumstances under which pain input promotes hemorrhage after TBI. Male Sprague-Dawley rats received a moderate unilateral injury in the right frontal region using the Leica One device. In Exp. 1, rats

received an intradermal injection of the irritant capsaicin, or vehicle, to either the contralateral or ipsilateral hindpaw. Because sensory fibers in the spinal cord decussate, if afferent drive (rather than a systemic process) is critical, only contralateral pain should promote hemorrhage. Rats were sacrificed 3 hours after injection and perfused with saline. The extent of hemorrhage across the cortical surface was documented and hemoglobin content was assessed using the Drabkin's assay and immunoblotting. Only animals who received pain input on the contralateral hindpaw showed an increase in hemorrhage ($p < 0.01$). Prior work has shown that noxious electrical stimulation (shock) can foster hemorrhage after SCI and that this effect is not blocked by morphine. Exp. 2 examined whether the same is true after TBI. Rats received a systemic injection of morphine (20 mg/kg, i.p.) or its vehicle a day after the frontal region was injured. Thirty min later, half the animals in each condition received 6 min of shock applied to the tail. Blood pressure was measured. Tissue was collected 3 hr after shock treatment. Morphine produced an acute reduction in blood pressure. Shock did not have a lasting effect on blood pressure. Greater hemorrhage was evident on the cortical surface in vehicle treated shocked rats. Pretreatment with morphine attenuated this effect. Ongoing work is examining the circumstances under which pain input fuels hemorrhage after TBI, how it affects behavioral function, and the neurobiological processes involved.

Biol., Temple Univ., Philadelphia, PA; [5]Children's Hosp. of Philadelphia, Philadelphia, PA; [6]Neurobio. and Anat., Drexel Univ. Col. of Med. Neurosci. Program, Philadelphia, PA

Abstract: Children younger than 4 years old are at high risk for sustaining a traumatic brain injury (TBI) and are more likely to suffer psychosocial and behavioral deficits, which may become more prominent as they age into adolescence. We previously reported that TBI in 11-day-old rats resulted in an increase in open arm exploration in the elevated plus maze (EPM) at 4-weeks post-injury. The disruption of glucocorticoid receptor (GR) expression in the hippocampus similarly causes an increase in open arm activity, suggesting that these post-traumatic deficits may be a consequence of altered reactivity to acute stress. In this study, the role of glucocorticoid receptor (GR) function in the dorsal (DH) and ventral hippocampus (VH) in behavioral outcomes in the EPM was assessed at 4-weeks following injury to the 11-day-old rat. Brain injury resulted in a significant increase in open arm exploration in the elevated plus maze in male and female rats, in the absence of overt changes in locomotor activity. Although exposure to the EPM increased corticosterone levels in both sham and brain-injured animals, an increase in the hippocampal expression of the glucocorticoid-inducible gene, serum-and-glucocorticoid inducible kinase 1 (sgk1) mRNA following EPM exposure was only observed in sham-injured animals, suggesting that pediatric TBI may impair GR transcriptional activity. Viral transfection of the human GR (hGR) specifically within the VH reversed the increase in open arm exploration in the elevated plus maze following TBI. In addition, hGR transfection in the VH led to a significant increase in corticotropin releasing hormone (CRH) mRNA expression following exposure to the EPM in brain-injured animals. Together, these findings support an important role of GR function within the VH in the regulation of emotional responses during stress and suggest that impairments in GR function may contribute to the development of altered stress reactivity following pediatric brain trauma.

Title: Astrocyte-derived ApoE is required for the maturation of injury-induced hippocampal neurons and regulates cognitive recovery after traumatic brain injury.

Authors: *T.-S. YU[1], S. G. KERNIE[2];
[1]Columbia Univ. Med. Ctr., New York, NY; [2]Columbia Univ. Col. of Physicians and Surgeons, New York, NY

Abstract: Polymorphisms in the apolipoprotein E (ApoE) gene confer a major genetic risk for the development of late-onset Alzheimer's disease (AD) and are predictive of outcome following traumatic brain injury (TBI). Alterations in adult hippocampal neurogenesis have long been associated with both the development of AD and recovery following TBI and ApoE is known to play a role in this process. In order to determine how ApoE might influence hippocampal injury-induced neurogenesis, we developed a novel conditional system whereby functional ApoE from astrocytes was ablated just prior to injury. While successfully ablating 90% of astrocytic ApoE just prior to a closed cortical impact injury in mice, we observed an attenuation in the development of newly born neurons using a GFP-expressing retrovirus but not in existing hippocampal neurons visualized with a Golgi stain. Intriguingly, animals with a "double-hit", i.e. injury and ApoE conditionally inactivated in astrocytes, demonstrated the most pronounced impairments in the hippocampal-dependent Morris water maze test, failing to exhibit spatial memory after both acquisition and reversal training trials. In comparison, conditional knockout mice without injury displayed impairments but only in the reversal phase of the test, suggesting accumulative effects of astrocytic ApoE deficiency and traumatic brain injury on AD-like phenotypes. Together, these findings demonstrate that astrocytic ApoE is required for functional injury-induced neurogenesis following traumatic brain injury.

Title: Characterization of melanopsin ganglion cell morphology in a mouse model of traumatic brain injury

Authors: *S. DEWAN, S. COOK, M. FUSILLO, M. A. SMITH;
Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Traumatic brain injuries (TBIs) are a significant source of morbidity worldwide that can dramatically affect individuals at any point throughout their lifespan. TBIs can manifest in several different ways, but one of the most common is its impact on the visual system. Sleep-wake disturbances are increasingly recognized as a serious and often prolonged consequence in TBI and other chronic neurodegenerations, suggesting involvement of the non-image forming eye-brain pathways. A potential linkage between the occurrence of post-TBI image and non-

image forming visual impairments may reside within a unique subset of retinal neurons: melanopsin-expressing retinal ganglion cells (mRGCs). These retinal neurons link to brain sites responsible for the regulation of the circadian sleep-wake cycle, but also connect to a variety of other subcortical targets. While mRGC structure and function have been reported in other neurodegenerative conditions such as Parkinson's, Alzheimer's, and glaucoma, there is a continued lack of clear understanding regarding if and how mRGCs are affected following brain injury.
Previously, our lab has reported early neuronal signaling deficits accompanied by morphological changes in glaucoma and Alzheimer's mouse models. These deficits occur in RGCs that remain connected to their postsynaptic targets in the brain and may drive later axon and cell body loss. In this study we sought to determine if similar pre-degenerative morphological changes in mRGCs could be observed following traumatic brain injury. To accomplish this task, we used a combination of immunohistochemistry and high-resolution florescent microscopy to isolate mRGCs in the retina and the brain following a controlled cortical impact. Using Neurolucida 360 image analysis software, we measured dendritic field area, dendritic complexity (# of branch points and branches), soma area, and cell density to assess their general morphology and the integrity of mRGCs following injury. Our results indicated significant reduction in dendritic field complexity and area, despite an unaltered cell density in the retina of injured subjects 1-week after injury. These results suggest mRGC morphology is altered as a result of injury, which may impact their function. This could help explain non-image forming sequelae following brain trauma.

Title: Role of glucocorticoid receptor dysfunction in the dorsal hippocampus in spatial learning deficits following pediatric traumatic brain injury

Authors: *D. LENGEL[1], Z. ROMM[1], N. SNYDER[2], J. W. HUH[4], G. M. SMITH[3], R. RAGHUPATHI[1];
[1]Drexel Univ., Philadelphia, PA; [3]Dept of Neurosci., [2]Temple Univ., Philadelphia, PA; [4]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) in children younger than 4 years old leads to long-term deficits in cognitive function and learning ability that can persist or even worsen as children age into adolescence. In this study, the role of glucocorticoid receptor (GR) function in the dorsal hippocampus (DH) in chronic hippocampal-dependent cognitive function and synaptic plasticity were assessed following injury to the 11-day-old rat. Brain injury produced significant impairments in spatial learning and memory in the Morris water maze in male and female rats. These deficits were not associated with overt histopathology within the DHC. Brain injury also impaired Long Term Potentiation (LTP) in the CA1 region of the DH in both male and female rats. An assessment of the expression of GRs and glucocorticoid-associated genes in the DH immediately following the first day of water maze training revealed a significant decrease in the expression of the glucocorticoid-inducible gene, serum- and glucocorticoid-kinase 1 (sgk1) in brain-injured animals relative to sham-injured animals, suggestive of an impairment in GR transcriptional activity. Lentiviral transfection of the human GR (hGR) in the DH improved spatial learning and memory in the Morris water maze and also attenuated LTP deficits following TBI. Finally, GR overexpression in the DH resulted in a significant increase in the mRNA expression levels of sgk1, and the glutamate receptor subunits GluA1 and GluN1 following water maze training. Overall, these findings support an important role of dorsal hippocampal GR function in learning and memory deficits following pediatric TBI, and suggest that these effects may be related to the regulation of glutamate receptor subunit expression in the DH.

Title: The nicotinic acetylcholine receptor modulator AVL-3288 attenuates hippocampal-based cognitive deficits following repeated mild traumatic brain injury in adolescent rats

Authors: *T. MCCORKLE, R. RAGHUPATHI;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Sports-related concussions (SRC, a subset of mild Traumatic Brain Injury) in adolescents is a leading cause of long-term cognitive deficits. We have developed an age-appropriate and clinically relevant model of SRC in adolescent (35-day old) male and female Sprague Dawley rats by subjecting them to 3 separate episodes of an impact to the intact skull

(2.0mm depth at 5.5m/s velocity) over 7 days. Rats were tested for hippocampal-dependent spatial working memory at 1-and-4 weeks post-injury in the Morris water maze (MWM; female n=7/group 1 week and 4/group 4 weeks; male n=7/group 1 week and 8/group 4 weeks) and at 4 weeks in the novel object location (NOL) tasks (female n=8 uninjured (sham), 11 injured; male n=8/group). At 1 week, only male brain-injured animals exhibited significant deficits in locating the hidden platform in the MWM over the 5-day testing period compared to the male sham rats (sex*injury p=0.0007). However, both male and female brain-injured animals exhibited this deficit at 4 weeks (injury p=0.000002). Similarly at 4 weeks, both male and female brain-injured rats had significant difficulty recognizing the new location of an object they had been familiarized with in an earlier trial (injury p=0.000003). We hypothesized that impaired cholinergic transmission may be a mechanistic basis for these cognitive deficits. Positive allosteric modulation of nicotinic acetylcholine receptors (nAChR) via AVL-3288 was reported to diminish spatial learning deficits in moderately brain-injured adult male rats. Therefore, male and female rats underwent repeated mild injury or sham surgery in adolescence and then were injected with AVL-3288 at 30 minutes prior to testing the animals in either the MWM or NOL tasks at 4 weeks post-injury (female n=6/drug group, n=5/vehicle group; male n=6/group). Treatment with AVL-3288 attenuated injury-induced cognitive deficits in both tasks (treatment p=0.004 MWM, p=0.001 NOL) suggesting that reduced activity of the nAChR may underlie post-traumatic cognitive deficits.

Title: Alterations in neuronal calcium activity after traumatic brain injury.

Authors: *P. SAWANT-POKAM[1], J. GAYNES[2], I. ANTHONY[1], K. BRENNAN[1];
[1]Dept. of Neurol., Univ. of Utah, Salt lake city, UT; [2]Univ. of Colorado, Denver, CO

Abstract: Traumatic brain injury (TBI) is increasingly recognized as a source of long-term neurological dysfunction that affects both military and civilian populations, with spreading depolarizations (SD) as known agents of clinical worsening after TBI. SD may also be involved in network plasticity after TBI. Using *in vivo* two-photon microscopy, we compared spontaneous and SD-associated calcium activity in layer 2/3 excitatory neurons after controlled cortical

impact (CCI) TBI in the hindpaw cortex (1-1.5 mm from the edge of a CCI lesion centered on barrel cortex) of Thy1-GCaMP6s mice. 48 hours after injury, neurons demonstrated a significant increase in cell volume, as expected given known edema at this time point, and prolonged but less frequent spontaneous intracellular calcium transients compared to sham animals. When we induced SD 48 hours after CCI, SD-associated calcium transients had a significantly greater area under the curve in TBI compared to sham animals. In contrast to changes in SD calcium transients, fluorescent imaging of extracellular glutamate signaling revealed no difference during SD between CCI and sham, suggesting that glutamate is not implicated in the larger SD calcium load. However, we also observed spontaneous 'plumes' of glutamate signaling in layer 2/3 somatosensory cortex of CCI mice. These events, which are suggestive of basal glutamate dysregulation, were absent in sham mice. Plume events also occurred in sham and CCI mice during SD propagation. The contrast between glutamate and calcium dynamics during SD after TBI suggests calcium-specific dysregulation that may be separable from glutamatergic activity. Yet glutamate plumes at baseline reveal that glutamatergic function is not normal either after TBI. Both phenotypes suggest a network under strain, with apparently separate mechanisms involved in two cardinal pathways of excitability and plasticity. Ongoing work seeks to understand these mechanisms.

Title: Thyroid hormone reverses cell-type specific pathways and circuits perturbed by traumatic brain injury

Authors: *G. ZHANG[1], N. PHI[1], I. AHN[1], Z. YING[1], G. DIAMANTE[1], N. WANG[1], I. CELY[1], R. LITTMAN[1], F. GOMEZ-PINILLA[1,2], X. YANG[1,3];

Abstract: Traumatic brain injury (TBI) is a tremendous burden around the world affecting civilian, military, and athletes. The etiology of mild traumatic brain injury (mTBI) is complex

due to the tissue and cellular heterogeneity and the disrupted circuits within and between cell populations across the affected brain regions. that underlie cognitive impairments and subsequent neurological disorders. We previously employed single cell RNA sequencing (scRNAseq) to investigate the vulnerable cell types and cell-type specific changes in genes and pathways following mTBI in the hippocampus and frontal cortex, which revealed Ttr, a transporter of thyroid hormone thyroxine (T4), as a potential therapeutic target. Administration of T4 significantly reversed the cognitive impairment caused by mTBI. To understand the molecular targets of T4 treatment, we conducted scRNAseq of hippocampus and frontal cortex at the acute (24hr) and chronic (7days) phases of mTBI with or without T4 treatment at single cell resolution. We found that T4 treatment reversed the genes, pathways, and cell-cell interactions disrupted by mTBI at different timescales with distinct regional patterns. Our results provide a spatiotemporal dynamics of the molecular pathways and circuits underlying the therapeutic potential of T4 to mitigate mTBI induced cognitive and neurological disorders.

Title: Traumatic brain injury to primary visual cortex produces long-lasting circuit dysfunction

Authors: *A. TIERNO[1], J. C. FRANKOWSKI[1], A. T. FOIK[1,2], J. R. MACHHOR[1], D. C. LYON[1], R. F. HUNT[1];
[1]Anat. and Neurobio., Univ. of California Irvine, Irvine, CA; [2]Ophthalamic Biol. Group, Intl. Ctr. for Translational Eye Res., Polish Acad. of Sci., Warsaw, Poland

Abstract: Primary sensory areas of the mammalian neocortex have a remarkable degree of plasticity, allowing neural circuits to adapt to dynamic environments. However, little is known about the effects of traumatic brain injury on visual circuit function. Here we used anatomy and *in vivo* electrophysiological recordings in adult mice to quantify neuron responses to visual stimuli two weeks and three months after mild controlled cortical impact injury to primary visual cortex (V1). We found that, although V1 was largely intact in brain-injured mice, there was

~35% reduction in the number of neurons that affected inhibitory cells more broadly than excitatory neurons. This reduction was layer-specific, with inhibitory neurons reduced in more superficial layers of the injured cortex and excitatory neuron loss throughout all cortical layers. V1 neurons showed dramatically impaired responses to visual stimuli and weaker orientation selectivity and tuning *in vivo*, consistent with loss of cortical inhibition. This deficit was present two weeks after injury and persisted long-term. As the first demonstration of cortical circuit dysfunction following central visual system neurotrauma, our results show a single, mild contusion injury produces profound and long-lasting impairments in the way V1 neurons encode visual input.

Title: Predicting recovery of consciousness in intensive care units

Authors: *S. BLAIN-MORAES, A. FRANTZ, C. MASCHKE, C. DUCLOS;
McGill Univ., Montreal, QC, Canada

Abstract: Background: Individuals who have suffered a severe brain injury typically require extensive hospitalization in intensive care units (ICUs), where critical treatment decisions are made to maximize their likelihood of recovering consciousness and cognitive function. These treatment decisions can be difficult when the neurological assessment of the patient is limited by unreliable behavioral responses. Reliable objective and quantifiable markers are lacking and there is both (1) a poor understanding of the mechanisms underlying the brain's ability to reconstitute consciousness and cognition after an injury and (2) the absence of a reliable and clinically feasible method of tracking cognitive recovery in ICU survivors. Our goal is to develop and validate a clinically relevant EEG paradigm that can inform the prognosis of unresponsive, brain-injured patients in the ICU.
Methods: We will recruit 200 continuously-sedated brain-injured patients across five ICUs. Between 24 h and 7 days post-ICU admission, high-density EEG will be recorded from behaviorally unresponsive patients before, during and after a brief cessation of pharmacological sedation. Once patients have reached the waking stage, they will be asked to complete an

abridged Cambridge Brain Sciences (CBS) battery, a web-based series of neurocognitive tests. The test series will be repeated every day during acute admission (ICU, ward), or as often as possible given the constraints of ICU and ward care. Following discharge, patients will continue to complete the same test series on weekly, and then monthly basis, for up to 12 months following injury.
Results: To date, we have recruited 20 patients to this study. We have recorded EEG from 15 patients with injuries ranging from stroke to severe traumatic brain injury. Further, we have begun cognitive testing in 10 patients and have CBS data for some patients up 6 months post-coma. Recruitment is ongoing at multiple sites across Canada. Preliminary results suggest that EEG may have predictive potential for both functional and cognitive outcomes following pharmacologically-induced coma.
Anticipated findings: We anticipate our findings will lead to an increased ability to identify patients, as soon as possible after their brain injury, who are most likely to survive, and to make accurate predictions about their long-term cognitive and functional outcome. In addition to providing critically needed support for clinical decision-making, this study has the potential to transform our understanding of key functional EEG networks associated with consciousness and cognition.

Title: Short-term cognitive profile of patients with Traumatic Subarachnoid Hemorrhage (tSAH) during the acute phase of the injury

Authors: *E. MORENO[1], M. RAMIREZ FLORES[2], J. CONTRERAS VACA[3];
[1]Psychology Fac., Univ. Nacional Autónoma De México, Ciudad De México, Mexico;
[2]Psychology Fac., Univ. Nacional Autonoma de México, Mexico City, Mexico; [3]Inst. Mexicano del Seguro Social, Mexico City, Mexico

Abstract: Traumatic Subarachnoid Hemorrhage (tSAH), a secondary event to Traumatic Brain Injury, with high morbidity and mortality, causing a high rate of disability, such as cognitive sequelae, hindering their social and occupational reintegration. Objective: This project sought to explore and identify the short term cognitive profile during the acute stage of injury in adult patients in order to identify the first cognitive domain deficits. Method: At the Regional General Hospital #2 "Doctor Guillermo Fajardo Ortiz" from "Instituto Mexicano del Seguro Social".

There were 15 patients with tSAH (age: 30; Schooling: 13.4 (3.83); M: 11; F: 4; Fisher scale: Grade II: 40%; Grade III: 40%; Grade IV: 20%), paired with a control group with Musculoskeletal Trauma (MT) by age and schooling; 15 patients (age: 30.8; Schooling: 13.2 (2.95); H: 10; M: 5). The Revised Integrated Neuropsychological Exploration Program "BARCELONA TEST" Mexican version was applied. Results: The tSAH group shows cognitive deficit in; Spatial Orientation, Fluency and Grammar, Language Processing Speed, Short and long-term verbal memory; Selective Attention, Perceptual Reasoning and Abstraction. Conclusion: The presence of the tSAH shows lower cognitive performance compared to the MT group, posing a higher response latency in areas associated with the evocation of information by semantic field and lexical comprehension; executive functions, main planning, supply and perceptual reasoning.

Title: Hormone levels impact concussion recovery assessment metrics in female varsity athletes - A preliminary study

Authors: *A. E. PIERIAS, D. J. GORBET, H. EDGELL, L. E. SERGIO;
York Univ., North York, ON, Canada

Abstract: Sports-related concussion is one of the most difficult injuries to diagnose and track. Research has provided evidence for the continued need of updating tools and metrics in hopes of increasing objectivity, specificity, and sensitivity. Research surrounding concussion has uncovered differences in the nature of injury, and recovery trajectory related to sex, previous history of concussion, age, and experience in sport. As such, it has become evident that research in the area of concussion should included males and females as separate groups, and account for as many other covariates as possible. Previous research from our lab noted sex-specific differences in performance on a complex visuomotor integration task and the reporting of emotionality symptoms in those with and without a history of concussion. This study seeks to expand on previous data by investigating the relationship between levels of estradiol, testosterone, and progesterone, and aspects of the sport concussion assessment tool (SCAT) along with a complex visuomotor transformation task in female varsity athletes. Participants included 30 female varsity athletes (16 with a history of concussion). All participants were asymptomatic by current standards at the time of testing. Participants were tested on two visuomotor skill tasks, one of which was a standard slide-finger-to-target on a touchscreen and the other was a complex transformation with a decoupled gaze/hand location and reversed visual feedback (requiring cognitive-motor integration). They also completed the SCAT3/5 assessment, and a saliva sample was collected. No significant group differences were found on any of the metrics - with and without the controlling for levels of estradiol, testosterone, or progesterone. When collapsed into a single group, progesterone was moderately positively correlated with overall performance on a visuomotor transformation task, and testosterone was moderately positively correlated with the cognitive-motor integration trials (two levels of dissociation) of the visuomotor transformation task. We suggest that these hormones may therefore have an impact on the sensitivity of current metrics and clinicians should take into account these impacts when making return to play decisions.

Title: Customizing rTMS treatment targeting for co-occurring alcohol use disorder and mild traumatic brain injury using multi-modal neuroimaging data as neurobiological markers.

Authors: *A. HERROLD;
Edward Hines Junior VA Hosp., Hines, IL

Abstract: Alcohol use and mild traumatic brain injury co-occur, as well as, increase the risk, exacerbate symptoms, and worsen outcomes for each condition. While rTMS is an active area of investigation for the treatment of alcohol use disorder (AUD) and mild traumatic brain injury (mTBI) each in isolation, there is no consensus on the optimal rTMS site of stimulation for each of these conditions, let alone when they co-occur. Our objective was to customize rTMS targeting to improve alcohol craving among Veterans with co-occurring alcohol use disorder and mTBI (AUD+mTBI). We integrated data from a group-level fMRI analysis from a cross-sectional study to inform a subsequent pilot, ongoing, rTMS RCT recruiting from the same participants. To determine the target network, we first conducted a group-level analyses of alcohol cue reactivity fMRI task data collected from Veterans with AUD+mTBI (n=10), AUD only (n=6) and controls (n=5). Second, Neurosynth.org was used to determine areas of the brain most highly correlated with the left caudate locus of fMRI task activation. We used this aggregated functional connectivity database to select the cinguloopercular (CON) resting state network for rTMS targeting. Third, we customized the stimulation target by determining the site within the left DLPFC most correlated with the CON using individual-level rs-fMRI data utilizing published methods for a single AUD+mTBI Veteran. At the group level, Veterans with AUD+mTBI had significantly greater cue-induced activation ($p < 0.01$) in reward-related brain regions than healthy controls. Further, activity in the caudate hotspot was functionally connected to the CON. We identified the customized left DLPFC TMS target with strongest correlation to the CON at the individual level for a Veteran with AUD+mTBI. This target was anatomically distinct from that determined by more standard clinical methods. There were no AEs and the rTMS paradigm in the pilot RCT is safe and tolerable, thus far. We will examine how connectivity to the rTMS site of stimulation changed between pre- and post-rTMS and the relationship to symptom data to inform treatment responsiveness. Individualized rs-fMRI data can be used to customize TMS targets for AUD+mTBI with relevance to alcohol cue-induced

activation. Ongoing work will examine whether this customization improves alcohol-related outcomes after TMS.

Abstract: Chronic traumatic encephalopathy (CTE) is a neurodegenerative disease linked to exposure to repetitive head impacts (RHI). The diagnostic lesion for CTE is hyperphosphorylated tau protein (p-tau) in perivascular neurons with or without astrocytes at cortical sulcal depths. Simulations of impact forces experienced by athletes suggest that shear stress and deformation of the brain is greatest at sulcal depths. The shearing forces lead to inflammation within the depth of the sulcus. Neuroinflammation is associated with dysregulated neoangiognesis. We hypothesize that this type of injury stimulates neoangiogenesis through neuroinflammation and regional hypoxia. To investigate vascular proliferation in the context of RHI and CTE, we examined optically cleared sections of postmortem human dorsolateral frontal cortex from the VA-BU-CLF (UNITE) Brain Bank. Study participants included those with neuropathologically diagnosed CTE (n=10 severe, n=10 mild), RHI exposure without CTE (n=8), and RHI-naïve controls (n=7). The tissue was post-fixed using the SHIELD protocol and optically cleared using a modified version of passive CLARITY. Vasculature was stained with fluorescently labeled tomato lectin allowing high-resolution observation of three-dimensional vessel morphology. We quantitated variables including branch density and fractional volume to evaluate features associated with angiogenesis. In the grey matter at sulcal depths, branch density and fraction volume were significantly increased in CTE cases compared to RHI-exposed cases

without CTE. Furthermore, in the grey matter sulcus of non-CTE cases with a history of RHI exposure, blood vessel branch density was increased, and fraction volume was decreased compared to RHI-naïve controls. Blood vessel fraction volume in the grey matter sulcus correlated positively with the area of p-tau staining determined histologically. These findings demonstrate that vascular remodeling occurs at both the sulcus and gyral crest in those with a history of RHI compared to naive controls. In those with CTE, the magnitude of the vascular remodeling in the sulcal depth is greater than in RHI. Previous work has demonstrated that the depth of sulcus in CTE is also a focus of neuroinflammation. Together, these findings suggest RHI is associated with global gray matter neoangiogenesis, and in CTE lesions, chronic neuroinflammation further increases vascular changes.

Title: A proteomics study of CSF protein biomarkers of Niemann-Pick Disease, Type C1

Authors: *W. LI[1], A. GRAYSON[2], Z. GOLDBERG[2], N. YANJANIN[3], E. BERRY-KRAVIS[2], F. PORTER[3], S. COLOGNA[1];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]Rush Univ., Chicago, IL; [3]NIH, Bethesda, MD

Abstract: Nieman-Pick Disease, Type C1 (NPC1) is an autosomal recessive, fatal neurodegenerative disorder that is caused by mutations in *NPC1*, which encode a cholesterol transporter located on the membrane of the lysosome. As a result, unesterified cholesterol and sphingolipids accumulate in the lysosome, leading to many clinical phenotypes including hepatosplenomegaly, vertical gaze palsy, and progressive cerebellar and cortical degeneration. To date, there is no FDA-approved therapy for NPC1 patients, however, intrathecal treatment with VTS-270 (2-hydroxypropyl-beta-cyclodextrin, adrabetadex) and an oral drug, arimoclomol are being evaluated clinically. In order to identify biomarkers that can provide insight into disease pathophysiology, VTS-270 treatment status, and treatment response, our group is

investigating proteomic changes in cerebrospinal fluid (CSF) obtained from NPC1 patients who were treated with VTS-270 and healthy controls. In total, 17 NPC1 patient samples and 10 healthy controls have been analyzed. Briefly, CSF samples were depleted with a human serum albumin/IgG column to remove the most abundant proteins in the CSF. Proteins were then reduced, alkylated, and digested followed by isobaric labeling with a TMT10 multiplexing kit. Data were acquired on a Q-Exactive nanoLC-MS system and analyzed using the SEQUEST algorithm via the Thermo Proteome Discoverer software. Several differential proteins were found among the groups including Cytochrome c, Parvalbumin alpha, and Cathepsin D, implying that these proteins could be the potential biomarkers for VTS-270 treatment status and treatment response. Additional patient specimens are currently being evaluated as well as correlation analysis to establish the protein of responders and non-responders to VTS-270.

Title: Apoe4 polymorphism and reduced olfactory neural activation in aging

Authors: M. S. HIPOLITO[1], N. RAI[1], R. SETH[5], J. W. VANMETER[6], M. SHELBY[2], ***M. M. MISIAK-CHRISTIAN**[3], C. NWAOKOBIA[5], K. F. MANAYE[3], T. OBISESAN[4], E. NWULIA[1];
[1]Psychiatry and Behavioral Sci., [2]Genetics, Grad. Sch., [3]Physiol. and Biophysics, [4]Med., Howard Univ., Washington, DC; [5]Evon Medics LLC, Elkridge, MD; [6]Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Objective: Olfactory dysfunction is associated with Alzheimer's Disease development. Our previous study revealed that odor identification tasks activated several olfactory brain regions more than odor memory tasks. In this study, we examined if apolipoprotein E ε4 (ApoE ε4) positivity contributed to reduced brain activations in the primary olfactory cortex regions were Alzheimer's neuropathology begins. **Method:** African American adults (N=11), who completed comprehensive battery of cognitive tests, odor psychophysical tasks, magnetic resonance imaging (MRI) under 3-Tesla scanner while performing episodic odor

memory tasks 55 - 75 years old, were genotyped for APOE polymorphisms. ApoE ε3 homozygote subjects were compared to carriers of ε4 allele on their performances in psychophysical tasks and cognitive score, and in the degree of neural activations in olfactory regions of interest. Areas of difference between the two groups were identified using an uncorrected t-statistic of 1.5, and FDR cluster-level correction of $p<0.05$ was used for multiplicity of tests (the cluster defining threshold was set at $p<0.01$). **Results:** There were 6 non-ApoE ε4 carriers (i.e., ε2/ε3 and ε3/ε3) and 5 ε4 carriers (i.e.ε3/ε4). Both groups were comparable educational, ethnic and other demographic characteristics. Though no significant differences in episodic odor memory tasks between groups, non- ε4 carriers had greater activation than ε4 carriers in several of the classical olfactory brain regions. No olfactory regions exhibited greater activation in ε4 carriers over the ε3 homozygotes. **Conclusion:** fMRI-based odor memory studies may be more potent than odor memory tasks alone in differentiating older non-ApoE ε4 carriers from ε4 carriers. Given the strong association between ε4 and AD development, if replicated this approach may contribute towards improved early detection of Alzheimer's disease.

Title: Associations between catecholamine synthesis, locus coeruleus-entorhinal functional connectivity, and Alzheimer's pathology

Authors: *C. J. CIAMPA[1], J. H. PARENT[1], T. M. HARRISON[2], J. N. ADAMS[2], A. MAASS[3], W. J. JAGUST[2], A. S. BERRY[1];
[1]Brandeis Univ., Waltham, MA; [2]UC Berkeley, Berkeley, CA; [3]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany

Abstract: The locus coeruleus (LC) is the brain's major source of the neuromodulator norepinephrine and is among the first brain regions to accumulate Alzheimer's disease (AD)-related tau pathology. Prominent models of AD pathophysiology posit that tau spreads trans-synaptically, first from LC to temporal regions, and is driven by neuronal activity. We probed relationships between LC catecholamine (norepinephrine/dopamine) synthesis capacity measured with [^{18}F]Fluoro-l-m-tyrosine (FMT) PET, temporal tau pathology measured with [^{18}F]Flortaucipir PET, and functional connectivity measured with 3T resting state fMRI. Participants were cognitively normal older adults (n = 50, mean age = 77) whose β-amyloid status was characterized with [^{11}C]Pittsburgh compound B (PiB) PET (16 [^{11}C]PiB+). LC functional connectivity analyses focused on correlating fMRI activity with entorhinal cortex (EC), which is structurally connected with LC and shows measurable tau pathology in normal aging. All regression models included age, sex, and years of education as covariates. Analyses testing relationships between LC catecholamine synthesis capacity and functional connectivity found lower LC [^{18}F]FMT net tracer influx (Ki) was related to higher functional connectivity between LC and anterolateral/transentorhinal cortex (t(44)=-2.09, p=.04), the first EC subregion to accumulate tau. We found no relationship between EC [^{18}F]Flortaucipir standardized uptake value ratio (SUVR) and LC-EC functional connectivity or LC [^{18}F]FMT Ki (both p > .44). However, higher LC-EC functional connectivity was associated with higher [^{18}F]Flortaucipir SUVR in a temporal tau meta-region of interest (EC, amygdala, hippocampus, fusiform, parahippocampal, middle temporal and inferior temporal gyri; t(39)=2.24, p=.03). A model including [^{11}C]PiB status revealed a significant [^{11}C]PiB by LC-EC functional connectivity interaction (t(37)=3.78, p=.001). Higher functional connectivity was associated with higher [^{18}F]Flortaucipir SUVR for Aβ+ but not Aβ- participants. Together, these findings link higher LC functional connectivity with greater temporal tau burden and lower LC catecholamine synthesis. These results are consistent with models proposing activity-mediated tau spread, and implicate lower LC catecholamine synthesis as a factor increasing one's susceptibility to tau spread. Future studies should investigate longitudinal relationships between catecholamine synthesis, functional connectivity, and AD pathology to better understand the influence of the LC-catecholamine system on aging trajectories.

Title: Intracellular Rather Than Extracellular Diffusion MRI Measures Predict Working Memory Performance in Healthy Older Adults

Authors: *C. BAUER[1], V. ZACHARIOU[2], P. MAILLARD[4], A. CAPRIHAN[5], B. T. GOLD[3]; [2]Cognitive Neurosci. of Aging Lab., [3]Neurosci., [1]Univ. of Kentucky, Lexington, KY; [4]Univ. of California Davis, David, CA; [5]The Mind Res. Network, Albuquerque, NM

Abstract: Diffusion tensor imaging (DTI) is widely used in MRI research to estimate white matter health in the aging human brain, but little is known about which specific DTI indices are most predictive of cognitive function. While fractional anisotropy (FA) reflects diffusion associated with both intracellular (tissue) and extracellular (Free Water [FW]) compartments, recent multi-compartment models (FW-correction [includes FW-corrected FA and FW] and NODDI [includes intracellular volume fraction {ICVF} and orientation dispersion index {ODI}]) provide more specific intracellular or extracellular compartments. Here, we compared the strength of association between these different DTI metrics to both age and cognition (working memory [WM] performance). Ninety-nine healthy older adults (ages 60-85; 61 women) were recruited from the Lexington community and scanned at the University of Kentucky using a 3 Tesla MRI Siemens Magnetom Prisma with a 64-channel head coil. A 126-direction main DTI sequence using 4 b-values (0, 500, 1000, and 2000 s/mm^2), a reverse phase-encoding direction DTI sequence, and an fMRI sequence were acquired. Participants performed an in-scanner visual WM task (N-back; control, 1-back, and 2-back conditions) during fMRI acquisition with WM performance calculated using D-prime. A network of brain regions showing functional activation during the WM task was defined across participants using a group-level functional contrast (2-Back > [1-Back/2 + Compare/2]/2). White matter tracts connecting the functionally-activated working memory network was reconstructed using probabilistic tractography. Each participant's diffusion measures were extracted from skeletonized white matter tracts connecting WM regions using FSL's tract-based spatial statistics. Linear regression models with diffusion measures as the predictors and age or D-prime (with age as a covariate) as the dependent variables were conducted in SPSS controlling for gender. All diffusion measures except ODI significantly predicted age. However, only ICVF (p = 0.035) and FW-corrected FA (p = 0.061; marginal significance) specifically predicted D-prime. Our results suggest that intracellular-associated (axonal loss and demyelination) rather than extracellular-associated (neurodegeneration, vascular dysfunction, or neuroinflammation) diffusion may be more sensitive to WM performance.

Ctr., Calgary, AB, Canada; [9]Cerebrovascular Concussion Lab., Calgary, AB, Canada

Abstract: Self-reported neuropsychological assessments in post-concussive cohorts have highlighted an increased risk of developing anxiety, depression, and/or stress disorders. The majority of these assessments are made using a single time point. However, repeated self-reported assessments of anxiety have demonstrated clinical potential. Minimal research has been conducted on the potential of repeated stress measures to increase the classification of individuals with a concussion history. This study consisted of 45 participants (67% female), 24 participants had concussion history (54% female, 23.91 ± 3.25 years old) and 21 participants had no concussion history (81% female, 23.31 ± 6.55 years old). Participants completed two separate questionnaires assessing self-reported stress. The Perceived Stress Scale (PSS) was administered once (day one of seven; Model 1) and the Daily Stress Questionnaire (DSQ; Model 2) was administered at the same time every day for seven consecutive days. We fitted two separate logistic models estimated using maximum likelihood to classify concussion history using stress, sex, handedness, and age as predictors. The models used stress measures obtained from the total PSS score and the daily total DSQ scores. Classification accuracy of concussion history was compared between both models. The first model correctly classified 62.5% of cases and no significant association between stress and concussion history was observed (beta = -0.04, 95% CI [-0.20, 0.11], p = 0.602; Std. beta = -0.20, 95% CI [-1.03, 0.55]). The second model correctly classified 82.2% of cases and identified statistically significant associations between stress and concussion history (beta = 1.95, 95% CI [1.22, 2.81], p < .001; Std. beta = -0.23, 95% CI [-0.76, 0.21). Daily measures of stress predicted concussed cohorts with 20% greater accuracy than singular measures. Our findings indicate that repeated self-reported stress measures better classify concussed cohorts and offer additional interaction between stress and concussion history

that weekly measures lack. Moreover, repeated measures of stress could prove useful in informing treatment and rehabilitation.

Title: A developmental model for the emergence of orientation preference map in the mouse superior colliculus

Authors: *K. TEH[1], J. SIBILLE[2], J. KREMKOW[3];
[1]Neurosci. Res. Ctr., Charite-Universtätsmedizin Berlin, Berlin, Germany; [2]Neurosci. Res. Ctr., Charité – Universitätsmedizin Berlin, Berlin, Germany; [3]Neurosci. Res. Ctr., Charité-Universitätsmedizin Berlin, Berlin, Germany

Abstract: The mouse superior colliculus (SC) has been shown to have an orientation preference map (OPM; Ahmadlou and Heimel, 2015; Feinberg and Meister, 2015; but see Chen et al., 2020). However, the OPM in the mouse SC does not represent all orientations equally as in the primary visual cortex. More specifically, different regions of the SC visual layers tend to overrepresent specific orientations, and a retinotopy-based concentric OPM pattern has been observed (Ahmadlou and Heimel, 2015). The underlying developmental mechanisms that give rise to the observed OPM in the mouse SC are still unclear. During development of the visual system, there are spontaneous activities spreading across the retina in wave-like patterns, where the stage III retinal (S3) waves are known to play an important role in circuit development, such as fine-scale retinotopic refinement. In the mouse SC, the S3 waves exhibit non-uniform propagating directions with net biases towards the caudal direction (Gribizis et al., 2019). In addition, the OFF retinal ganglion cells (RGCs) are recruited with a delay compared to ON RGCs during S3 waves (Kerschensteiner and Wong, 2008). Here, we hypothesize that these biases in the S3 wave propagating directions, together with the OFF-ON delay, could play a role in establishing the OPM in the mouse SC during development. To test this hypothesis, we studied a computational model of visual system development that incorporates the above-mentioned S3 wave features for examining the properties of the established OPM. By using the Hebbian learning mechanism to refine the RGC-SC connections, we show that the OFF delayed responses can segregate the ON- and OFF-RGC inputs to individual SC neurons, which locally

give rise to the orientation preference (Kremkow et al., 2016). Furthermore, we demonstrate that the biases in S3 wave propagating directions can mediate the formation of an OPM with a concentric pattern. In our model, the orientation preferences are represented based on their retinotopy, with each retinotopic location having biases in representing specific orientations, as observed in vivo (Ahmadlou and Heimel, 2015; Feinberg and Meister, 2015). In summary, our model suggests that OFF delayed responses of S3 waves can mediate local microscopic segregation of the ON-OFF receptive subfields of the postsynaptic SC neurons, whereas the biases in the wave propagating direction determine the overall macroscopic organization of the OPM. Taken together, these findings suggest that the S3 waves could instruct the formation of the OPM in the mouse SC by fine-tuning the receptive field of postsynaptic SC neurons.

Title: A simpler model can unify a broad range of phenomena in retinotectal map development

Authors: *S. S. JAMES, S. P. WILSON;
Psychology, The Univ. of Sheffield, Sheffield, United Kingdom

Abstract: In the Chemoaffinity Theory, the retinotectal axon projection uses pairs of orthogonal signalling gradients in the retina to specify the eventual location of synapses formed on the tectum. Similar tectal gradients provide a coordinate system which allows each axon to approach a pre-specified destination. Although the ephrins have been shown to guide axons toward their destination, a complete account of the local interactions which recreate the topography of the retinal cells is lacking. In line with the assumptions of the Chemoaffinity Theory, a model developed by Simpson & Goodhill (2011) provides an account of the basic topographic arrangement of axons on the tectum, and reproduces the effects observed in a range of surgical and genetic manipulation experiments. However, this model does not represent chemotactic guidance as a local mechanism, and instead continuously provides each simulated axon with explicit information about the direction in which to grow to reach a pre-specified target. In addition to the inclusion of a global chemoaffinity term, this model includes a competitive interaction for space between growth cone agents and a receptor-ligand axon-axon interaction in order to account for the full set of experimental manipulations. Here, we replace the chemoaffinity term with a gradient-following model consisting of axonal growth cone agents that

carry receptor molecule expression at a level determined by the location of the soma on the retina. According to this entirely local model, growth cones moving on a simulated tectum are guided by two pairs of opposing orthogonal signalling molecules representing the ephrin ligands. We show that with *only* the chemoaffinity term and a receptor-ligand axon-axon interaction term (meaning that *all* growth cone interactions are by receptor-ligand signalling), a full range of experimental manipulations to the retinotectal system can be reproduced. Furthermore, we show that the observation that competition is *not* an essential requirement for axons to find their way (Gosse et al., 2008) can also be accounted for by this simpler model, due to the opposing influences of signalling gradient pairs. Finally, under the assumption of exponentially varying receptor expression in the retina, we demonstrate that ligand expression should either be exponential, if the receptor-ligand signal induces repulsion (i.e. gradient descent), or logarithmic, if the signal induces attraction (gradient ascent). Thus, we show that a model analogous to that which can explain thalamocortical patterning in the barrel cortex (James et al., 2020), can also account for the self-organization of topographic maps in the retinotectal system.

Title: Brain-derived neurotrophic factor modulates retinal ganglion cell output synapses in the dorsolateral geniculate nucleus

Authors: *M. VAN HOOK;
Univ. of Nebraska Med. Ctr..

Abstract: Brain-derived neurotrophic factor (BDNF) is important in development and also plays roles in synaptic and neuronal plasticity. In the dorsal lateral geniculate nucleus (dLGN) of the thalamus - the primary projection target for retinal ganglion cells (RGCs) responsible for conscious vision, BDNF is present in RGC axons and the BDNF receptor TrkB is present on RGC axon terminals and post-synaptic thalamocortical (TC) relay neurons. The goal of this study was to determine how BDNF influences synaptic transmission and neuronal function within the adult dLGN. This was assessed with whole-cell patch clamp recordings from dLGN TC neurons in brain slices from adult mice (6-12 weeks old) of both sexes. RGC synapses (retinogeniculate/RG synapses) were activated in the presence of 60 μM picrotoxin either in parasagittal slices with an electrode positioned in the optic tract or in coronal slices via photic

activation of channelrhodopsin expressed in RGC axons (Chx10-Cre;Ai32 mice). Cortical feedback synapses were activated with an electrode positioned in the corticothalamic tract in parasagittal slices. Bath application of BDNF (20 ng/mL) led to an enhancement of RG synaptic transmission, as evidenced by an increase in excitatory post-synaptic current (EPSC) amplitude (27+/-6% increase, n = 18 TC neurons, p=0.016, paired t-test) and this was prevented by pre-treatment of the TrkB blocker cyclotraxin-B (p=0.74, n = 4 TC neurons). This was accompanied by a reduction in the frequency (p=0.006) and amplitude (p=0.008, n = 11 TC neurons) of miniature EPSCs and a small decrease in the AMPA/NMDA ratio (p=0.027, n = 8 TC neurons). In the presence of cyclothiazide (200 μM) and gamma-DGG (100 μM), BDNF had no effect on RG release probability, as assessed using paired pulse (50-1000 ms intervals) and 10 Hz train stimulation (3 s duration). However, BDNF did increase synaptic vesicle pool size, as indicated by an increase in Y-intercept of a line fit to the plot of cumulative EPSC amplitude. There was no statistically significant effect of BDNF on corticothalamic feedback synaptic strength; neither EPSC amplitude (p=0.3, n = 5 TC neurons) nor the paired pulse ratio (p=0.86) were altered following BDNF application. Finally, BDNF led to a slight TC neuron depolarization (3.6+/-0.9 mV, p = 0.0014, n = 14 TC neurons), but no statistically significant change in spiking (p=0.88, paired t-test, n = 7 TC neurons). These results indicate that acutely-applied BDNF enhances RG synaptic transmission by an increase in presynaptic vesicle pool size, although it also appears to influence post-synaptic receptors and membrane properties of TC neurons in the dLGN.

Title: The role of retinal BDNF on the development of the dorsolateral geniculate nucleus

Authors: *E. BIERLEIN[1], A. BHANDARI[1], M. J. VAN HOOK[2];
[1]Ophthalmology and Visual Sciences, Pharmacol. and Exptl. Neurosci., [2]Ophthalmology & Visual Sci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Brain-derived neurotrophic factor (BDNF) is a regulator of nervous system plasticity that plays important roles in the development and maintenance of synapses and neurons. BDNF is transported to the dorsolateral geniculate nucleus (dLGN), the visual relay center of the thalamus, and released by retinal ganglion cell axons, making this system an interesting model

for studying the role of BDNF in circuit development. However, the role of retinal BDNF in development has not been characterized in the dLGN. Thus, our goal was to determine how retinal BDNF influences the development of the dLGN by selectively deleting retinal BDNF using Cre-lox technology. We used a mouse line with Cre expression specific to the retina (Chx10-Cre) crossed with BDNFfl/fl mice to selectively delete BDNF from the retina to analyze the resulting changes in the structure and function of the dLGN in adult mice (9 to 14 weeks) of both sexes. To test for visual system function differences between Chx10-Cre;BDNFfl/fl (cKO) and control (C57Bl/6J or BDNFfl/fl mice), we analyzed eye tracking abilities in an optomotor (OMR) task using stimuli of varying spatial frequency and found that cKO mice spent less time tracking than controls (ctr) ($p=0.03$; cKO n = 16, ctr n = 10 mice, unpaired t-test). There were no differences in outer retinal light responses as seen in dark-adapted electroretinogram (ERG) ($p=0.7$ A wave, $p=0.9$ B wave; cKO n = 10 eyes, ctr n = 16 eyes, unpaired t-test), suggesting that OMR differences arose from changes in retinal ganglion cells or their projection targets in the brain. In whole-cell patch clamp recordings of miniature excitatory post-synaptic currents (mEPSCs) conducted on dLGN thalamocortical (TC) neurons, cKO mice had a lower area in cKO mEPSCs ($p=0.006$) likely due to differences in decay kinetics (cKO n = 17 cells, 8 mice; ctr n = 9 cells, 4 mice, nested t-test). To analyze TC neuron structural differences between cKO and ctr mice, we performed Sholl analyses on neurobiotin-filled TC neurons and found that cKO TC neurons were significantly less complex than ctr TC neurons ($p=0.03$, -7.183 ± 3.066 SEM; cKO n = 11 cells, 6 mice; ctr n = 10 cells, 4 mice). Analysis of binocular segregation using intravitreally injected cholera toxin b (CTb) tracers in prepubescent mice indicated no significant differences ($p=0.9$; cKO n = 7 mice, 13 sections; ctr n = 7 mice, 14 sections, unpaired t-test). Thus, retinal BDNF influences visual behavior as well as the structure and function of dLGN TC neurons. These results further our understanding of both developmental and neurodegenerative processes in the visual system.

Title: Direct ipRGC input to the Substantia Innominata

Authors: *J. D. BHOI[1,2], G. W. SCHWARTZ[3], M. ARANDA[1], T. M. SCHMIDT[1];
[1]Neurobio., [2]Nuin, Northwestern Univ., Evanston, IL; [3]Ophthalmology, Northwestern Univ., Chicago, IL

Abstract: The Substantia Innominata (SI) is a region of the basal forebrain which contains a population of cholinergic neurons that project diffusely throughout the cortex to modulate neural activity. This cholinergic neuromodulatory system is hypothesized to be involved in attention and arousal. The SI receives retinal input, but little is known about the retinal ganglion cell (RGC) types which project to this region or the circuits to which they contribute. To first characterize the extent of retinal projections to the SI, we intravitreally injected Cholera Toxin Subunit-B conjugated with a fluorescent protein, allowing us to visualize RGC terminals in the brain. We used an object-based colocalization analysis to count the number of RGC terminals in the SI within 1 μm of cholinergic neurons, identified based on the expression of choline acetyltransferase (ChAT). We observed RGC terminals closely apposed to cholinergic neurons, potentially making functional synapses. The number of RGC terminals near ChAT-positive neurons was significantly reduced when the one channel was rotated prior to the colocalization analysis. To identify the RGC types which project to the SI, we injected AAV-CAG-GFP into the SI to retrogradely label SI-projecting RGCs with GFP. Using cell-attached electrophysiology we recorded from retrogradely labeled RGCs in whole-mount retinas and classified the ganglion cells based on their light response. Many of these RGCs were the intrinsically photosensitive (ip)RGCs. In support of this, fluorescent labeling of ipRGC axons revealed substantial innervation of the SI by ipRGCs. Finally, we exposed mice to a 15-minute light pulse at 1000 lux and immunolabeled the SI for the immediate early gene c-fos to determine whether the SI receives light input from RGCs. Excitingly, we noted increased c-fos labeling in the SI of animals exposed to light in comparison to those exposed to dark only, suggesting that the SI receives functional light input from RGCs. Together, these data suggest that ipRGCs signal to neurons in the SI, suggesting a potential role for ipRGCs in regulating neuromodulatory networks of the brain based on environmental light conditions.

Title: Probing the role of retinorecipient target cells in visual circuit regeneration

Authors: *S. G. VARADARAJAN[1], O. S. DHANDE[1], P. LE[1], A. D. HUBERMAN[1,2,3,4]; [1]Neurobio., [2]Ophthalmology, Stanford Univ., Stanford, CA; [3]Bio-X, Stanford Univ. Sch. of Med., Stanford, CA; [4]Wu Tsai Neurosciences Inst., Stanford, CA

Abstract: Vision is the most important sense for humans to navigate the world and survive. Retinal ganglion cells (RGC) transmit light information in the environment to the brain and therefore represent a key bottleneck for vision. RGCs are vulnerable to damage in neurodegenerative diseases and injuries that cause blindness and impact millions of people, such as glaucoma and traumatic injury. *As RGCs and their axons are part of the central nervous system, they cannot repair themselves after injury*. One promising approach is to reapply fundamental mechanisms that drive the formation of visual circuits during development, to promote re-growth and connectivity of RGC axons with retinorecipient targets. During development, both RGCs and their targets play a key role in forming the retinofugal (eye-to-brain) pathway to allow functional vision. While many studies have focused on the cellular and molecular events occurring in the RGCs to promote regeneration, *far less is known about the role of target cells in RGC axon regeneration*. Here we are testing a novel idea that post-synaptic target cells in the retinofugal pathway can be leveraged to promote regeneration of visual circuits. During development, target-derived cues and neural activity are required in both, the RGCs and the target cells, to connect and refine RGC axons with their synaptic partners in the brain. Using a chemogenetic approach in a distal injury model, our data shows that *increasing electrical activity of neurons in the distal optic pathway can promote regeneration of RGC axons*. To investigate the specific contribution of retinorecipient target cells in this model, we identified a new mouse line to precisely activate cells that reside in the nucleus of the optic tract (NOT), a subcortical retinorecipient target in the accessory optic system that is responsible for image stabilization. Our preliminary data shows that specific activation of retinorecipient targets is sufficient to promote RGC axon regeneration, suggesting that target-derived cues are important to promote robust, accurate rewiring of injured visual circuits. These experiments will address the role of post-synaptic cells in CNS repair and will have widespread relevance for treating blinding diseases, stroke and traumatic brain injury.

Title: Pathological and compensatory background mechanisms of hypoxia-induced long-term potentiation of NMDA neurotransmission in the visual retinocollicular pathway

Authors: *H. DUMANSKA, N. VESELOVSKY;
Dept. of Neuronal Network Physiol., Bogomoletz Insitute of Physiol. NASU, Kyiv, Ukraine

Abstract: Hypoxia is the main accompanying factor of numerous diseases. Identification of the processes and mechanisms underlying the early stage of hypoxic injury of the visual retinocollicular pathway will benefit the future treatment of navigation, orientation, and visual attention impairments.We developed the unique in vitro model of the retinocollicular pathway – the coculture of dissociated retinal cells and superficial superior colliculus (SSC) neurons. In such a model, each synaptically connected pair of retinal ganglion cell (RGC) − SSC neuron reflects a single retinocollicular projection. Using paired patch-clamp and local superfusion technique, we recorded pharmacologically isolated NMDA−mediated postsynaptic currents in SSC neurons by generation action potentials in presynaptic RGCs under normal and hypoxic conditions. The decay time constant of postsynaptic currents was fit using a single exponential function.Hypoxia up to 5 min induces long-term potentiation of NMDA neurotransmission. Moreover, we observed a significant reduction of voltage-dependent magnesium blockade of evoked NMDA response during oxygen deprivation. Also, we analyzed the dynamics of the decay time constant of all NMDA−mediated currents under normal and hypoxic conditions. This analysis revealed that hypoxia initiates a rapid and irreversible decrease of the decay time (from 38.3 ± 5.6ms to 19.2 ± 6.8ms).Pathological hypoxia-induced potentiation of NMDA neurotransmission leads to an increase of calcium influx and, as result, to apoptotic cell death. We detected two bidirectional effects that accompanied such LTP with opposite effects. First, hypoxia reduces voltage-dependent magnesium blockade of NMDA receptor – one of the well-known protective mechanisms. This enhances the pathological effect of LTP of the NMDA transmission and causes an additional injury. Contrarily, the decrease of the decay time of NMDA currents during oxygen deprivation leads to the decrease of the calcium influx. Since kinetic and functional properties are determined by NMDA receptor subunit composition, such a decrease indicates an increase in NR2A-to-NR2B subunit ratio at the retinocollicular synapses. We assumed that rapid changes in subunit composition are associated with lateral receptor mobilization from adjacent locations, rather than with a new subunit expression.
The results obtained reflect that hypoxia-induced LTP of NMDA transmission is accompanied by bidirectional pathological and compensatory mechanisms that might be targeted to prevent hypoxia-involved lesions of the retinocollicular pathway.

Title: Visual stimulus features are represented throughout the basal ganglia

Authors: *J. FABRE, A. J. PETERS, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: [Introduction] The basal ganglia are key structures in sensorimotor associations, receiving sensory input from the cortex which is thought to then influence downstream motor areas. For instance, neurons in the striatum have been shown to be selective for visual stimuli. However, it is not known whether selectivity is present in downstream structures and whether stimulus representations become increasingly more general. [Methods] To address this question, we used Neuropixels probes to record from the striatum, globus pallidus external (GPe), and substantia nigra reticulata (SNr) in head-fixed naive mice passively viewing a variety of visual stimuli: gratings of different orientation, spatial frequency, location, and an array of natural images. [Results] In the striatum, GPe and SNr, few neurons were visually-responsive. In all these structures, we found neurons responsive to visual images, and selective for orientation, spatial frequency, location and specific natural images. These neurons were generally selective for multiple features at once. We could also reliably decode natural images from striatal cell activity above chance level. [Conclusions] We conclude that neurons across the entire basal ganglia -- not just in striatum -- encode the properties of visual stimuli. We are currently comparing the visual responses between the striatum, GPe and SNr to understand the transformation that takes place between these nuclei. Given the role of basal ganglia in learning sensorimotor transformations, we are currently also recording activity in the striatum, GPe and SNr while mice perform a visual sensorimotor go/ no go task.

Title: The functional role of inhibitory neurons in the brainstem circuit mediating the optokinetic reflex

Authors: *A. LAVOIE, Y. HE, J. LIU, B. LIU;
Cell and Systems Biology; Biol., Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Reflexes are critical to sustain life. For instance, the optokinetic reflex (OKR) is an involuntary eye movement that stabilizes retinal images. The OKR is mediated by neural circuits in the brainstem accessory optic system (AOS). Interestingly, there are various types of AOS neurons, defined by their anatomy, molecular markers, and functional properties, such as glutamatergic excitatory neurons and GABAergic inhibitory neurons. It is well known that AOS nuclei consist of rich population of inhibitory neurons. However, it remains unknown whether this genetically-defined population encodes different visual information compared to its counterpart, the excitatory population. Nor have the functional role of inhibitory neurons in the OKR been completely understood. To address these questions, I paired in vivo electrophysiology, optogenetics and chemogenetics. I found that inhibitory neurons differed in their functional properties and played an important role in modulating the functional properties of AOS neurons. These findings provide insights on how visual information is processed by brainstem circuits to insure appropriate reflexive behavior.

Title: Input from torus longitudinalis drives binocularity and spatial summation in the larval zebrafish tectum

Authors: A. L. TESMER, N. P. FIELDS, ***E. ROBLES**;
Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: A common feature of vertebrate visual systems is that lower-order and higher-order visual areas are reciprocally connected. Feedforward projections confer visual responsiveness to higher-order visual neurons while feedback projections likely serve to modulate the responses of

lower-order visual neurons in a context-dependent manner. Optic tectum is the largest first-order visual brain area in zebrafish and is reciprocally connected with the torus longitudinalis (TL), a second-order visual brain area that does not receive retinal input. The functional role for feedback projections from TL to tectum has not been previously demonstrated. We demonstrate that TL feedback projections to tectum drive binocular integration and spatial summation in a specific tectal circuit. We performed genetically targeted, cell type-specific functional imaging in tectal pyramidal neurons (PyrNs) and their two input neuron populations: retinal ganglion cells (RGCs) and neurons in TL. PyrNs encode gradual changes in scene luminance using a complement of three distinct response classes that encode different light intensity ranges. Functional imaging of RGC inputs to tectum suggest that these response classes originate in the retina, supporting a model in which RGC input specifies PyrN functional class. In contrast, our data suggest that TL input serves to endow PyrNs with large, compound receptive fields that span both retinal hemifields. These findings reveal a novel role for the zebrafish TL in binocular integration and spatial summation.

Title: Non-linear frequency-dependence of neurovascular coupling in the cerebellar cortex: the vasodilation-vasoconstriction competition hypothesis

Authors: G. GAGLIANO[1], A. MONTEVERDI[1,3], S. CASALI[1], U. LAFORENZA[2], C. GANDINI WHEELER-KINGSHOTT[1,4], L. MAPELLI[1], ***E. D'ANGELO**[1,3];
[1]Brain and Behavioral Sci., [2]Mol. Med., Univ. of Pavia, Pavia, Italy; [3]Brain Connectivity Ctr., IRCCS Mondino Fndn., Pavia, Italy; [4]Ion, UCL, London, United Kingdom

Abstract: Neurovascular coupling (NVC) is the process adjusting local cerebral blood flow according to neuronal activity (NA). Although NVC provides the basis for the blood-oxygen-level-dependent (BOLD) effect used in functional MRI (fMRI), the relationship between NVC and NA is still to be elucidated in detail. Recent studies in humans reported non-linear BOLD signals in the cerebellum during the execution of motor tasks with intensity-graded grip force application, with differences in vermis and hemisphere regions. This observation led to the

investigation of the NVC/NA relationship using a range of input frequencies in acute mouse cerebellar slices of vermis and hemisphere. Time-lapse imaging in bright-field conditions was used to detect capillary diameter changes following mossy fibers activation at different frequencies. Our results showed that capillary diameters increased in response to mossy fiber activation in the 6-300 Hz range, with a marked inflection around 50 Hz (vermis) and 100 Hz (hemisphere). The corresponding NA was recorded using high-density multi-electrode arrays and was correlated to capillary dynamics through a computational model, thus allowing us to dissect the main components of cerebellar granular layer responses recorded as local field potentials. In a previous work, we reported that in the cerebellar granular layer, NVC involves a balance between the NMDAR-NO pathway driving vasodilation and the mGluRs-20HETE pathway driving vasoconstriction. Simulations showed that the NMDAR-mediated component of the granular layer response was sufficient to explain the time-course of the capillary dilation but not its non-linear frequency-dependence, suggesting that the mGluRs-20HETE pathway could play a role at intermediate frequencies range. These parallel control pathways imply a *vasodilation-vasoconstriction competition hypothesis* that could adapt local hemodynamics at the microscale bearing implications for the interpretation of fMRI signals.

Title: Phyllum: a phy plugin for automatic cell classification of high-density neural recordings in the cerebellum

Authors: *F. NAVEROS[1,2], A. SÁNCHEZ LÓPEZ[1], J. F. MEDINA[1];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Computer Architecture and Technol., Univ. of Granada, Granada, Spain

Abstract: New high-density neural probes like Neuropixels offer unprecedented access to the brain because they allow us to record the activity of thousands of neurons simultaneously. To decipher the code embedded within the spike activity of the recorded neural populations, it is

critical to develop classification tools that can be used to assign these spikes to specific cell types. Here, we introduce *Phyllum*, a software package for automatic layer identification and cell classification of high-density electrophysiological recordings in the cerebellar cortex. *Phyllum* is designed to work with spike data that has been sorted with Kilosort and loaded into Phy - a widely-used graphical user interface optimized for curating data collected with high-density multielectrode arrays. We analyzed a series of Neuropixels recordings from different regions of the mouse cerebellar cortex in which the location of the probe was marked with a fluorescent dye and could be confirmed histologically. Neurons were classified with *Phyllum* using an automatic two-step algorithm that involved pre-assigning each individual spike cluster to one of the three layers within the cerebellar cortex (granular, Purkinje or molecular), followed by cell identification based on firing statistics and waveform properties. We found that this two-step process allowed *Phyllum* to outperform previous cell classification algorithms designed for analysis of single neuron recordings. To facilitate distribution and implementation of our software package, we are making *Phyllum* available as an open-source plugin for Phy.

Title: Neuropixels in the mouse cerebellar cortex

Authors: *A. SÁNCHEZ-LÓPEZ[1], S. OHMAE[1], F. NAVEROS[1,2], M. HEMELT[3], C. HULL[3], J. MEDINA[1];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Computer architecture and technology, Univ. of Granada, Granada, Spain; [3]Neurobio., Duke Univ. Sch. of Med., Durham, NC

Abstract: Much of what we know about the function of the cerebellar cortex comes from recordings of Purkinje cells in awake and behaving animals, which are typically made one cell at a time. In contrast, there is less information available about the activity of other cell types in the cerebellar cortex, or how these different cell types interact with each other. To fill this gap, we are currently using high-density Neuropixels probes to record the activity of neuron ensembles in two different regions of the mouse cerebellar cortex known to play a role in motor learning.

Here, we show that: (1) Neuropixels probes provide excellent stability and signal-to-noise during recordings in head-fixed mice, allowing us to measure the spontaneous, sensory and motor-related activity of 50-100 neurons simultaneously for long periods of time often lasting >3 hours, (2) Automatic spike sorting with Kilosort can achieve performance on par with that of manual sorting by expert users (<2% false positives and negatives), as long as the data is curated taking into account the known and idiosyncratic properties of cerebellar neurons, (3) Cell-type identity, which we are validating with opto-tagging experiments in some cases, can be ascertained by inspecting the waveform and the firing-pattern statistics (autocorrelogram, inter-spike-interval distribution, etc,) of each individual neuron, as well as its layer location within the cerebellar cortex, (4) Local interactions between neighboring neurons belonging to either the same or to different cell-specific groups, are common and easily detectable in crosscorrelograms. Altogether, our results provide the foundation necessary to analyze in vivo interactions between different cell types in the mouse cerebellum, providing a first glimpse at how the population activity is orchestrated during behavior.

Title: Signal transformations along the cerebellar output pathway in behaving mice

Authors: *M. BEAU[1], R. RATTO[1], M. VARADI[1], D. COHEN[2], D. KOSTADINOV[1], M. HAUSSER[1];
[1]Univ. Col. London, London, United Kingdom; [2]Bar Ilan Univ., Ramat Gan, Israel

Abstract: To understand cerebellar function, it is crucial to understand how cerebellar output is generated. This remains an open question: the interplay between the Purkinje cells (PCs) -- the output neurons of the cerebellar cortex -- and the cerebellar nuclear cells (NCs) -- the ultimate output neurons of the cerebellum -- remains poorly understood. PCs are GABAergic, and they could influence NC output either by directly inhibiting them, or by entraining them via rebound spiking. Which of these two modes prevails in vivo in a physiological setting, and how this depends on PC synchrony, remains controversial.
We are addressing this problem by recording simultaneously from PCs and NCs using Neuropixels silicon probes inserted at an angle that allows us to reach monosynaptically

connected PCs and NCs. Using a combination of cell-type specific optogenetic tagging, prior knowledge about the firing properties of cerebellar cell types, and post-hoc 3D atlas registration of our recording sites, we identified PC (simple and complex spikes) and NC units in lobule simplex and interpositus nucleus respectively. We executed these recordings in mice performing a variety of behaviours: a motor task involving forelimbs coordination (wheel steering), locomotion, and reward prediction. We used cross-correlations to infer putative monosynaptic inhibition between PCs and NCs separated by up to a millimeter of tissue. We devised novel analysis strategies to account for sub-millisecond synchrony among local populations of PCs in order to disentangle direct inhibitory connections from confounding correlations caused by the synchrony of neighbouring PCs. Observing the relative firing of putatively connected PCs and NCs during behaviour, we found different signal transmission regimes in various behavioural contexts: anticorrelation during movement (wheel steering, locomotion), suggesting that PC inhibition predominates; and a positive correlation during reward prediction, suggesting that mossy fibres excitation predominates. We were also able to characterize the impact of complex spikes on nuclear firing: unexpectedly, nuclear cells were not inhibited but rather excited concomitantly with complex spikes, suggesting a domination of direct climbing fibre input over PC inhibition. These recordings constitute the first instance of direct readout of the impact of Purkinje simple and complex spikes on their target nuclear neurons, and shed light on the long debated signal transformations taking place along the cerebellar output pathway during behaviour.

Title: Structured connectivity of the cerebellar cortex enables noise-resilient preprocessing for pattern association

Authors: *T. NGUYEN[1], L. THOMAS[1], J. RHOADES[1], I. RICCHI[1], C. YUAN[1], A. SHERIDAN[2], D. HILDEBRAND[1], J. FUNKE[2], W. REGEHR[1], W.-C. A. LEE[3];
[1]Harvard Med. Sch., Boston, MA; [2]HHMI Janelia, Ashburn, VA; [3]BCH / Harvard Med. Sch., Boston, MA

Abstract: The cerebellum is critical for coordinated motor control and is implicated in complex behaviors, such as cognition and emotion. For motor coordination, the network is thought to detect and correct errors between expected and executed motor commands according to the forward model. How the network performs this task in the face of environmental and neural noise is unclear. The main feedforward circuit is relatively simple. Mossy fibers (MFs) carrying information from across the central nervous system provide input to large numbers of granule cells (GrCs) in the first layer of the network. The massive number of GrCs then converge by way of their parallel fibers in the second layer of the network to provide input to Purkinje Cells (PCs), the sole output of the cerebellar cortex. Influential theories on how information is processed that were established decades ago largely assumed random connectivity across the network; information theoretical models show that random connectivity can increase the encoding capacity of the first layer of the network. However, maximizing encoding capacity makes networks less resilient to noise. To understand how the circuit may address the tradeoff between encoding capacity and resilience, we used automated large-scale transmission electron microscopy and an automatic image segmentation pipeline using convolutional neural networks to map connectivity in the cerebellar cortex. In contrast to standard random connectivity models, we find that GrCs selectively sample MF boutons. Specifically, GrCs redundantly sample MF boutons, potentially increasing the resilience of the network to noise. GrCs also oversample specific MF boutons, potentially enhancing the transmission of specific information. Furthermore, adjacent PCs receive synapses from largely different populations of GrCs. However, PCs sample selectively from GrCs sharing MF bouton inputs. Taken together, we find redundant and selective connectivity across multiple network layers in the cerebellum that may enhance circuit resilience and help amplify and distinguish small differences in input patterns for a pattern association network.

Title: The role of distinct cerebellar circuit neurons in locomotion and locomotor learning

Authors: *J. R. JACOBS[1], M. R. CAREY[2];
[1]Neurosci., Champalimaud Ctr. for the Unknown, Lisboa, Portugal; [2]Neurosci., Champalimaud Ctr. For the Unknown, Lisboa, Portugal

Abstract: The cerebellum is a brain structure involved in various sensorimotor and cognitive functions. For locomotor behaviors, the cerebellum is critical for keeping movements calibrated and coordinated across the body. Further, within the cerebellar circuit, various cell types have been mapped to distinct functions required for proper execution of movement. Here, we sought to ascertain how various cerebellar circuit neurons contribute to overground locomotion and locomotor learning on a split-belt treadmill in adult mice. We targeted Purkinje cells, granule cells, and a combination of granule cells and mossy fiber inputs for ablation via cell-type specific, cre-recombinase mediated expression of the diphtheria toxin receptor (DTR) and subsequent intraperitoneal administration of diphtheria toxin (DT). We found that ablations across all cell types caused an ataxic phenotype and impairments in locomotor learning, both of which scaled with the degree of cell death. Generally, the observed phenotypes in the two behaviours were similar to those previously reported for ataxic mutant mice, as forward motion of individual limbs was largely spared, while other 3D limb movements and interlimb coordination were impaired. Surprisingly, we also found that incomplete granule cell ablation led to outcomes commensurate with near/complete loss of Purkinje cells in both learning and overground locomotion. Overall, our results suggest that cell-specific manipulations within the cerebellar circuit yield overlapping phenotypes but gradations in outcome are observed in a cell-type dependent manner.

Title: Chronic, mesoscale Ca2+ imaging of cerebellar Purkinje cells in awake behaving mice using single photon microscopy

Authors: *M. L. STRENG[1], R. E. CARTER[2], K. TOGNERI[1], V. RAJENDRAN[1], S. B. KODANDARAMAIAH[1], E. I. KROOK-MAGNUSON[3], T. J. EBNER[4];
[2]Neurosci., [1]Univ. of Minnesota, Minneapolis, MN; [3]Univ. of Minnesota Syst., Minneapolis, MN; [4]Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN

Abstract: A major challenge in cerebellar physiology is determining how the highly conserved cytoarchitecture of the cerebellar cortex underlies its contributions to ongoing behavior. Clusters of cerebellar Purkinje cells can be characterized by their parasagittal organization, expression of molecular markers, or by sources of common inputs: climbing fibers or parallel fibers. While a wealth of information is known about this cytoarchitectural organization, it is unclear how the functional information conveyed by Purkinje cells is organized throughout the cerebellar cortex, as most observations of Purkinje cell activity have been limited to individual cells or local populations. We recently developed a method for mesoscale recording of Purkinje cell Ca^{2+} activity in head fixed, behaving mice using transparent polymer windows of ~ $7mm^2$. This technique allows for the chronic recording of individual Purkinje cells across multiple folia, both vermis and simplex regions, bilaterally. Single photon Ca^{2+} imaging in PcP2-GCaMP6s mice, which exhibit sparse expression of GCaMP6s in Purkinje cells, enabled us to separately identify Ca^{2+} modulation that could be attributed to somatic activity (presumably partially reflective of parallel fiber modulation of simple spike activity) and dendritic activity (presumably reflective of climbing fiber driven complex spike activity) within the same recordings (consisting of ~100s of Purkinje cells). The chronicity of the approach allowed for recordings to be obtained in n = 6 mice over a period of ~3 months, with a minimum of ten recording sessions per mouse.To characterize Purkinje cell dendritic and somatic information, we performed blind source separation using the spatial Independent Component Analysis (sICA) algorithm JADER. At higher magnification, sICA identified independent components (ICs) corresponding to individual Purkinje cell dendrites or somata. The time courses of dendritic and somatic ICs appeared consistent with complex spike events and changes in simple spike activity, respectively. At the mesoscale level, sICA identified local populations of Purkinje cells, in which dendritic ICs were organized in the parasagittal domain, whereas somatic ICs were organized across a folium in the medial-lateral domain. Both dendritic and somatic ICs were highly modulated during behavior. Together, these results highlight an exciting new technique to characterize the functional properties of Purkinje cell populations across the cerebellar cortex. They also shed new light on the functional and spatial organization(s) of climbing fiber and parallel fibers systems and their ultimate influence on Purkinje cell output.

Title: Identifying Purkinje neuron state from calcium imaging data using machine learning

Authors: *A. VARMA[1], S. UDUPA[2], M. SENGUPTA[3], P. GHOSH[2], V. THIRUMALAI[1]; [1]Natl. Ctr. for Biol Sci., Bangalore, India; [2]Indian Inst. of Sci., Bangalore, India; [3]Washington Univ. Sch. of Med. in St Louis, St Louis, MO

Abstract: Purkinje neurons (PNs), the GABA-ergic principal neurons of the cerebellum, exhibit membrane potential bistability, firing either tonically or in bursts. Several studies have implicated the role of a population code in cerebellar function, with bistability adding an extra layer of complexity to the code. Calcium imaging is the method of choice to interrogate the activity of neuronal populations, however it does poorly at reporting the membrane potential state or the spiking patterns. Nevertheless, we hypothesised that the calcium signal might potentially contain information about the state of the PN.To bridge the gap between electrophysiology and imaging, we performed simultaneous patch-clamp electrophysiology and calcium imaging on larval zebrafish PNs. We used this ground truth dataset to develop a method of reconstructing the calcium signal given an electrophysiological trace. The calcium signal can be taken to be the convolution of spike timings with a GCaMP kernel. However, PNs have two sources of calcium - simple spikes (SS) and climbing fiber (CF) input. We treated each source as having its independent kernel and linearly summed their convolutions with corresponding event timings to produce a calcium signal reconstruction. The optimal combination of SS and CF kernels was found by minimizing the error between the reconstruction and the ground truth. We find that this method generalizes well across cells, and is independent of the state of the neuron.We then compiled electrophysiological recordings from PNs, grouped them by state, and applied this method on them to generate a large dataset of state-labelled calcium signal reconstructions (N=957 traces, from n=138 recordings). This data was used to train a 1-D convolutional neural network (1-D CNN) model to classify the state of a Purkinje neuron based on its calcium signal alone. A model with a single convolutional layer with 12 kernels, 5 samples long, and a stride length of 1 sample, performed best, with >85% accuracy on both training data as well as previously unseen data. Moreover, this network, which was trained only on reconstructions, identified PN state accurately even when presented with traces obtained from experiments. This tool opens up new avenues of research into understanding the role of Purkinje neuron bistability in cerebellar circuit function.

Title: Acquisition of a complex locomotor task: activity of cerebellar molecular layer interneurons and gait dynamics

Authors: *A. ANDRY[1], H. STEIN[2], J. GABILLET[1], C. BATIFOL[1], N. CAYCO GAJIC[2], M. GRAUPNER[1];
[1]Saints-Pères Paris Inst. for the Neurosciences, Univ. de Paris, Paris, France; [2]Dept. d'Études Cognitives, École Normale Supérieure, Univ. Paris Sci. et Lettres, Paris, France

Abstract: The cerebellum is one of the key brain regions involved in motor coordination and learning. It is known that the cerebellum processes sensorimotor information to learn and refine the timing of movement patterns. However, the cellular underpinnings of such sensorimotor input integration and processing remain largely unknown. By combining calcium imaging with behavioral analysis, we study the role of a fundamental microcircuit for sensorimotor integration: the molecular layer interneuron (MLI) network, which provides a strong control over the output cells of the cerebellar cortex - the Purkinje cells. For this purpose, we implemented a complex locomotor task which allows us to perform calcium imaging while mice learn to walk on a runged treadmill over several sessions stretching over multiple days. To record longitudinally the activity in a large population of MLIs in lobulus simplex, GCaMP7f is expressed by stereotaxic injections of floxed AAV viral vectors of parvalbumin Cre mice. The runged treadmill is motorized which requires the animal to make steps of discrete lengths from rung to rung, involving a high level of sensorimotor integration. The high-speed behavioral video recordings are subsequently analyzed using DeepLabCut to extract paw locations. Individual paw trajectories are segregated into swing and stance phases based on relative speed and distance to the rungs.
Molecular layer interneurons in the cerebellar simplex exhibit pronounced locomotion-related activity: fluorescence increases globally in the MLI population upon locomotion onset and shows rich dynamics during walking. We first asked whether MLI calcium dynamics are related to the stepping pattern of the animal. To check for this, we aligned and averaged cell-specific transients to the beginning of swings. We found that a large proportion of recorded MLIs show swing-related transients consisting in fluorescence increases or decreases or combinations of both, depending on the cell. Swing-related transients of individual cells are paw-specific, as one would expect from the forelimb motor region. Our behavioral analysis of paw movements on the runged treadmill revealed that steps get longer and faster over the course of learning across days, consistent with results reported from the Erasmus ladder. While both novice and expert mice showed antiphasic paw movements of the forelimbs, fixed phase relations between hind- and forelimbs developed over days, resulting in a more regular, stability-centered gait. Our results shed light on the involvement of the cerebellar interneurons in generating coordinated movement in mammals.

Title: Cerebellar associative learning underlies reach adaptation

Authors: *D. J. CALAME, A. L. PERSON;
Physiol. and Biophysics, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: A leading hypothesis of cerebellar function is that the cerebellum shapes a feedforward control policy to calibrate motor actions to meet a goal. Such a control policy is thought to be generated by Purkinje cells (PCs) which act as associative learners, shaping their simple-spike firing in response to cerebellar inputs based on complex spike-mediated plasticity. A critical component of this hypothesis is that PCs learn to use descending neocortical commands and sensory afferents to form an anticipatory control policy, and if these inputs unexpectedly change, PCs adapt to reestablish control. Here, we test this hypothesis by optogenetically stimulating cerebellar mossy fiber afferents originating in the basal pontine nucleus during a skilled reaching movement in mice (ChR2, 50-ms train). When stimulating in closed-loop during every trial, reach kinematics were perturbed time locked to the stimulus, but after several trials, reaches adapted to resemble baseline trials. During washout, when perturbation was removed, reaches displayed aftereffects in the direction opposing the initial deviation well timed to the position of stimulation, consistent with other paradigms of sensorimotor adaptation. Single-electrode and high-density cerebellar extracellular single-unit recordings targeted to the primary fissure, between Lob 4/5 and Simplex, showed that PCs encode reach kinematics, especially position of the paw, both at the population level and in individual cells. We hypothesized that time-locked adaptation could be explained by parallel fibers conferring continuous kinematic information to PCs throughout the reach, weighted by error-based plasticity. Using LASSO regression, we found that PC firing rates continuously represented upcoming kinematics across the reach epoch. To test whether motor context accounts for timed motor adaption, we modified the perturbation design by randomizing stimulus position during the stimulation block. Supporting the idea that sensorimotor context accounts for aftereffects, no aftereffects were observed following randomized-position perturbations. A cerebellar model recapitulated behavioral findings in both fixed and randomized-position

stimulation experiments and showed that reweighting inputs temporally associated with error occurred regardless of the position of a perturbation; however, aftereffects were accounted for by accumulated learning in temporally correlated inputs, absent in randomized-stimulation blocks. Together the data suggest that the cerebellum learns a control policy by ascribing cause and effect based on the reliability of temporal association of active inputs to errors.

Title: Cerebellar Abnormalities Associated with Loss of the Synaptic Scaffold CASK Follow a Degenerative Trajectory and Manifest Differentially Based on Sex

Authors: *P. PATEL[1], J. HEGERT[3], I. CRISTIAN[3], A. KERR[4], L. LACONTE[1], S. SRIVASTAVA[1], M. A. FOX[4], D. F. ENGLISH[2], K. MUKHERJEE[1];
[1]Virginia Tech., Roanoke, VA; [2]Neurosci., Virginia Tech., Blacksburg, VA; [3]Orlando Hlth., Orlando, FL; [4]Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: A major open question in biomedical neuroscience is how singular genetic insults may affect different regions of the nervous system with varying specificity and severity. *CASK* is one such gene which associates with microcephaly and intellectual disability globally, but with a disproportionately severe hypoplasia of the cerebellum and hindbrain structures relative to forebrain structures. The CASK protein has been implicated in axon guidance, cell polarity, ion channel localization, active zone maintenance, and brain lamination. However, conflicting evidence exists on the nature of CASK's involvement in these functions and none explains the disproportionate effects on hindbrain structures. Here, we first demonstrate in human that complete absence of CASK produces no defect in brain lamination or neuronal migration but does manifest with severe cerebellar volume diminishment; this decrease in cerebellar volume is likely degenerative due to observed regression in motor skills and upregulation of glial fibrillary acid protein expression in the cerebellar cortex. Next, using a murine model where CASK is deleted from cerebellar cells post-developmentally, we mechanistically demonstrate that cerebellar hypoplasia is indeed due to late degeneration rather than developmental deficits. In the murine model, cerebellar development completes normally and gross motor skills are properly acquired by post-natal day 30 (p30), however by p100, cerebellar volume has decreased by approximately 60-70% with collapsing of the molecular layer and profound depletion of

cerebellar granule neurons (GCs) with no Purkinje cell (PC) death observed. Alterations in cerebellar morphology are accompanied by severe ataxia. In order to investigate the physiological mechanism of ataxia resultant from this degeneration, we will utilize single-unit recording from individual PCs to measure the simple spike to complex spike ratio observed in these projecting GABAergic cells – the only output of the cerebellar cortex. Recording from PCs in the context of GC loss, we will interrogate (1) the *in vivo* physiology of PCs in the absence of parallel fiber glutamatergic input and (2) the role of the complex/simple spike ratio on ataxia. Overall, the disproportionate cerebellar hypoplasia observed in human *CASK* mutations and murine models of CASK loss is degenerative in nature beginning at early ages. The X-linked nature of the *CASK* gene leads to expressivity patterns which result in plateau of degeneration in mosaic heterozygous mutations but devolving into full degeneration and epileptic encephalopathy in cases of hemizygous mutations in males having only one copy.

Title: Pharmacological intervention reverses impaired learning in a mouse model of Fragile X syndrome, consistent with a saturation model

Authors: *A. SHAKHAWAT[1], J. BHATEJA[3], J. FOLTZ[2], J. L. RAYMOND[4];
[2]Neurobio., [1]Stanford Univ., Stanford, CA; [3]Dept. of Biol. Structure, Univ. of Washington, Seattle, WA; [4]Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Experience-driven synaptic plasticity is thought to play a pivotal role in learning and memory. The enhancement of synaptic plasticity would seem to have the potential to enhance learning, however, it is often accompanied by the opposite—impaired learning. In the *Fmr1* knockout mouse model of Fragile X syndrome (FXS), there is enhanced associative long-term depression at the cerebellar parallel fiber-Purkinje cells synapses (PF-Purkinje cell LTD), but impaired cerebellum-dependent eye blink conditioning (Koekkoek et al. 2005). Here, we characterized oculomotor learning in Purkinje cell-specific *Fmr1* knockouts (L7- *Fmr1* mutant)

and used behavioral and pharmacological manipulations to test a saturation model of the detrimental effect of enhanced associative plasticity on learning. L7- *Fmr1* mutant mice exhibited the same, highly specific pattern of vestibular ocular reflex (VOR) learning deficits that we have found previously in other lines of mice with enhanced *or* impaired PF-Purkinje cell LTD. In particular, the L7- *Fmr1* mutant mice were impaired on learning to increase the VOR gain, whereas learning to decrease the VOR gain was spared. Moreover, the impairment of VOR-increase learning was more severe for high frequency (1 Hz) visual-vestibular training than low frequency (0.5Hz) training. Our previous experimental and theoretical work (Nguyen-Vu et al, 2016) suggested that the enhancement of PF-Purkinje cell LTD might impair learning by allowing spontaneous activity in the cerebellum to saturate LTD prior to training, making this mechanism unavailable to be recruited at the appropriate parallel-Purkinje cell synapses to support learning. This saturation model makes two predictions about interventions to reverse the learning deficits caused by enhanced synaptic plasticity, which were confirmed in our experiments. First, behavioral pre-training designed to reverse LTD at the PF-Purkinje cell synapses eliminated the oculomotor learning deficit in the L7- *Fmr1* mutant mice. Second, a pharmacological manipulation designed to suppress neural activity and thereby limit the induction of associative LTD during the pre-training period also reversed the learning deficit in the L7- *Fmr1* mutant mice. These results could have implications for the development of novel clinical approaches for patients with autism and other disorders caused by enhanced synaptic plasticity.

Title: Comparison of the calcium responses of Purkinje cells in the cerebellar flocculus to retinal slip and non-visual input

Authors: *A. S. FANNING, A. M. SHAKHAWAT, J. L. RAYMOND;
Neurobio., Stanford Univ., Stanford, CA

Abstract: Climbing fiber input to the cerebellum carries instructive signals that guide plasticity and learning by eliciting complex spikes accompanied by large calcium transients in Purkinje cells. In the flocculus of the cerebellum, climbing fibers have been viewed as encoding oculomotor errors in sensory coordinates, because the complex spikes in Purkinje cells convey retinal slip information. However, in the same neurons, complex spikes also can be driven by non-visual input. To assess their role in contributing to plasticity, we compared the calcium responses driven by the visual and non-visual input to these Purkinje cells. Although both drive complex spiking, multiple mechanisms can modify or shunt the calcium response that accompanies a complex spike. Therefore we recorded the calcium responses of a population of GCaMP6f-expressing Purkinje cells in awake behaving mice during optokinetic and/or vestibular stimulation to compare the calcium responses to these visual and non-visual inputs. During visual (optokinetic) stimuli and pairing of vestibular and visual stimuli, the calcium level increased during contraversive retinal image motion. During performance of the vestibulo-ocular reflex in the dark, calcium increased during contraversive head rotation and the associated ipsiverse eye movements. The amplitude of the non-visual calcium response was comparable to that during conditions with retinal image motion present that are known to induce oculomotor learning. Thus, the population calcium responses of Purkinje cells in the cerebellar flocculus to visual and non-visual input are similar to what has been reported previously for complex spikes, suggesting that multimodal instructive signals control the synaptic plasticity supporting oculomotor learning.

Title: In vivo two-photon imaging of Purkinje cell activity during adaptation to sensorimotor mismatch

Authors: V. NGUYEN, *B. M. STELL;
UMR8003, CNRS, Paris, France

Abstract: To probe the internal models used by the cerebellar cortex during movement, we imaged Purkinje cells during adaptation to sensorimotor mismatches introduced into a simple reaching paradigm. A lick port was positioned in front of head-fixed mice and its lateral position was controlled in a 1:1 ratio via an electromechanically coupled joystick (gain = 1). Water

rewards were delivered from the lick port when it was positioned approximately 13 mm lateral to the center of the mouth, and could be retrieved when mice used the joystick to recenter the lick port in front of its mouth. This paradigm has several advantages: i) mice learn it very quickly (412 ± 110 trials on the 5th day on the setup; n = 8 mice), ii) sensorimotor mismatches can be repeatedly introduced within sessions by alternating different gains between the joystick and the lick port, iii) it engages cerebellar cortex on the surface of lobules IV/V of the vermis and simplex, which are easily accessible to *in vivo* electrophysiology and 2-photon imaging. When the gain between the joystick and the lick port was changed from 1 to 2 (i.e. the lick port moved twice as fast as the joystick) all mice overshot their mouths when attempting to retrieve water rewards but quickly adapted to the new gain within 5 - 10 trials by decreasing limb velocity and position, (n = 9 mice). Upon returning to control conditions mice increased limb velocity and position within 5 - 10 trials to adapt back to the control gain of 1. We used 2-photon imaging of GCaMP7 and GCaMP8 to monitor complex spikes in Purkinje cell dendrites during adaptation to changes in gain. Under control conditions we did not observe complex spikes linked to any component of the movement, but when the gain was increased, and sensorimotor mismatch occurred, we recorded movement related complex spikes from large regions of lobules IV/V in the vermis and simplex until the mouse adapted its limb kinematics to the new gain. These findings support classical models of supervised learning in which climbing fibers signal erroneous motor output to Purkinje cells via complex spikes.

Title: Circuit dissection of neural instructive signals for associative cerebellar learning

Authors: *N. SILVA[1], J. RAMIREZ[1], D. PRITCHETT[1,2], M. CAREY[1];
[1]CHAMPALIMAUD CENTRE FOR THE UNKNOWN, Lisboa, Portugal; [2]Biol. Dept., Howard Univ., Washington D.C., WA

Abstract: Here we investigate the cellular basis of neural instructive signals for delay eyeblink conditioning, a cerebellum-dependent form of classical conditioning. In this paradigm, animals learn to blink to an initially neutral conditioned stimulus. Learning is driven by repeatedly pairing the conditioned stimulus with an air puff unconditioned stimulus (US) directed at the eye which drives an unconditioned response. Signals related to the air puff are conveyed to the cerebellum by climbing fibers, which provide strong synaptic inputs that elicit complex spikes in Purkinje cells. Complex spikes are thought to provide cellular instructive signals for plasticity that is hypothesized to underlie many forms of motor learning. However, the instructive stimuli that drive learning are often tightly associated with a reflexive movement - in this case, a blink in response to the air puff - that could be conveyed to the cerebellum via alternate pathways. It has therefore been difficult to dissociate climbing fiber activation from sensorimotor signals relating to these reflexive behavioral responses when identifying instructive signals for learning on the cellular level. Here we used cell-type specific perturbations of climbing fiber activity to test their necessity and sufficiency for learning. By combining behavioral, optogenetic and electrophysiological approaches, we further dissociate complex spike activity from reflexive movements. We find that optogenetically-evoked complex spikes can substitute for an air puff US to induce learning, even in the absence of an evoked blink. Further, evoked blinks that do not drive complex spikes do not drive learning. Finally, we found that in cases where expression of ChR2 in climbing fibers led to decreased probability of sensory-evoked complex spike responses, mice were unable to learn to an air puff US. However, under the same conditions, animals learned well to an optogenetically-evoked climbing fiber US. Together, these results support a necessary and sufficient role for climbing fibers as instructive signals for associative cerebellar learning.

Title: Quantification of endogenous parvalbumin expression across Purkinje cell subtypes through CRISPR knockin of Cas9 fusions and the consequences for intrinsic firing properties

Authors: *C. BRANDENBURG[1], B. ALTAS[2], A. POULOPOULOS[3];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, AL; [3]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Although long used as a general PC marker, the calcium binding protein parvalbumin labels a subpopulation of PCs based on high and low/no expression, with a conserved distribution pattern across animals examined. The parvalbumin subtypes show differences in spontaneous firing that can be modified by altering calcium buffer content. These subtypes also show differential responses to potassium and calcium channel blockade, suggesting a mechanistic role for variability in PC intrinsic firing through differences in ion channel composition. Since antibody titrations for immunohistochemistry had varying results in quantifying parvalbumin expression, we use Cas9 fusions delivered to Purkinje cells via *in utero* electroporation to insert a fluorescent marker in the endogenous parvalbumin locus and quantify parvalbumin expression across cerebellar modules.

Title: Fast and slow learning signals mediated by climbing fiber inputs to cerebellar Purkinje cells

Authors: *D. KOSTADINOV, M. BEAU, M. HAUSSER;
Univ. Col. London, London, United Kingdom

Abstract: Learning to execute goal-directed behaviors often consists of multiple phases - an early acquisition stage and later refinement stage. In the cerebellum, climbing fiber inputs to Purkinje cells are a key source of instructive signals for learning. These inputs are traditionally thought to drive learning by conveying sensorimotor errors, but there is increasing evidence that they can also implement other modes of learning, including reward-based reinforcement. It remains unclear, however, how these instructive signals emerge in climbing fibers, how they are used by the cerebellum during the acquisition and refinement phases of learning, and whether the same Purkinje cells mediate these different forms of learning. To address these questions, we have used two-photon calcium imaging to longitudinally record from the same populations of climbing fiber inputs to Purkinje cells over several weeks as head-fixed mice learned to execute

a virtual reality-based visuomotor integration task to obtain a delayed reward. Throughout training, we interleaved cued and unpredictable rewards between task trials. Once mice became proficient at the task, we introduced sensorimotor perturbations by altering the gain between object translation and wheel movement in single sessions. To quantify how sensory, motor, and reward-related activity were represented in climbing fiber inputs over learning, we built statistical models that use these task parameters to predict neural activity and compared how well models trained on sessions from expert mice were able to predict activity in naive mice and vice versa. We inferred several principles of how climbing fiber population dynamics change across learning on multiple time scales. In naïve mice, inputs already exhibited modulation by specific sensory and motor parameters, and these representations were generally maintained. In expert mice, responses to salient cues such as rewards became more reliable and could emerge in inputs that did not exhibit responses to these signals at the start of training. Moreover, responses to predictable stimuli were progressively suppressed. During gain change manipulations, the responses to operant rewards increased dynamically as animals adapted their behavior, supporting an active role in these signals for rapid learning. These data demonstrate that the same climbing fiber populations convey multimodal signals to Purkinje cells that are well-suited to drive learning of all variables that may assist animals in executing goal-directed behaviors, and that climbing fiber inputs, which are thought to be the main drivers of learning in the cerebellum, are themselves subject to instruction.

Title: Dendritic processing implements spike-timing dependent plasticity (STDP) in cerebellar Golgi cells

Authors: *T. SORBO, E. D'ANGELO;
Dept. of Brain and Behavioral Sciences, Unit of Neurophysiol., Univ. di Pavia, Pavia, Italy

Abstract: The existence of a precisely organized neuronal circuitry in the cerebellum is crucial for information processing and long-term synaptic plasticity induction. This latter, in various specific forms, determines persistent modifications in neuronal activity and synaptic

transmission providing the basis for learning and memory. In the cerebellum, it is through to be responsible for timing and adaption and, ultimately, for cerebellar control of movement and brain processing. Timing in the cerebellar circuit is tightly controlled by inhibitory interneurons. Among these, Golgi cells located in the granular layer play a primary role in modulating the input to Purkinje cells. Golgi cell receive inputs on apical and basal dendrites by parallel and mossy fibers, respectively. However, the mechanisms through which these neurons integrate input patterns is still unclear. In fact, little is known about how Golgi cells process the input signals, generate plasticity and modulate the gain and timing of signals conveyed to Purkinje cells. Recently, theoretical models predicted that spike-timing dependent plasticity (STDP) at mossy fiber-Golgi cells synapse would be a pivotal mechanism of Golgi cells inhibition at the cerebellar input stage. Furthermore, a computational model suggested the mechanisms through which Golgi cells dendrites might integrate and process the inputs transmitted by parallel and mossy fibers, implying that dendritic processing and plasticity in Golgi cells would depend on the spike time intervals between these two inputs. This project investigated, for the first time, Golgi cells STDP using whole-cell patch-clamp recordings in acute mice cerebellar slices. Mossy fibers spikes either anticipated or followed those on parallel fibers with a phase difference of ±75 ms. Indeed, STDP emerged, with peaks at ±20 ms, precisely matching computational predictions. Mechanistically, NMDA channel unblock at mossy fiber synapses on basal dendrites are the potential coincidence detectors of mossy and parallel fiber activity. This hypothesis is now under experimental testing. In summary, this work shows that dendritic processing is instrumental to STDP and opens new perspectives on the role of Golgi cells in determining learning and plasticity in the cerebellar circuit.

Title: Excitatory and inhibitory synaptic currents in Olig2(+) eurydendroid neurons in larval zebrafish cerebellum during associative motor learning

Authors: *M. NAJAC, D. L. MCLEAN, I. M. RAMAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: The larval zebrafish cerebellum is required for associative motor learning, such as learning to swim in response to a neutral visual stimulus that predicts a tactile stimulus to the tail.

During training, Purkinje cells alter their firing patterns, and the disruption of their activity prevents learning. Here, we studied excitatory and inhibitory synaptic currents (EPSCs and IPSCs) during learning in *Olig2(+)* eurydendroid neurons (ENs), a subset of Purkinje target cells, which are glutamatergic output neurons of the zebrafish cerebellum. We recorded EPSCs (at -60 mV) which result from direct input from parallel fibers and IPSCs (at 0 mV) from Purkinje cells, while monitoring fictive swimming from ventral root activity in immobilized larvae (dpf 6-8). The unconditioned stimulus was a mild electric tail shock triggering fictive swimming (unconditioned response, UR) and the conditioned stimulus was a low-intensity 2-s blue light. With repeated pairing of the shock to light offset, ~50% fish (n=22/41) acquired conditioned responses (CRs) after ~25 trials (range: 3-65). During fictive swimming (both CRs and URs), all *Olig2*(+) ENs (20/20) showed robust increases in EPSCs and IPSCs, with inhibition always far exceeding excitation, but only a few *Olig2*(+) ENs also showed light-associated synaptic activity without a motor response (6/20). Thus, synaptic activity was purely motor-associated in 70% of cells and mixed sensory-motor in 30%, with no obvious topographical distribution. The timing of swimming-associated PSCs differed for CRs and URs. For URs, PSCs in *Olig2*(+) ENs and the ventral root signal began simultaneously, but for CRs, PSCs preceded the ventral root signal by ~100 ms (n=21). The charge transfer during EPSCs as well as IPSCs was similar during CRs and URs that were not preceded by a CR. However, charge transfer was reduced during URs that followed CRs (IPSCs: n=18, p=0.01; EPSCs: n=20, p=0.002), consistent with previous observations in mice of reduced spiking to the US after learned responses in cerebellar output neurons. The US preceded by the CS evoked larger IPSCs than the US alone, even at the very first CS+US pairing. Over the course of learning, however, no gradual modification of synaptic currents was observed; the amount and timing of synaptic responses were simply toggled by the presence or absence of CRs. These results suggest that the synaptic plasticity leading to the emergence of CRs must occur upstream of parallel fiber synaptic signals, at the level of granule cells, consistent with imaging studies in mice, but that these modified synaptic inputs drive *Olig2*(+) ENs to contribute to the production of learned motor responses.

Title: Chemoarchitecture of the human inferior olive

Authors: *G. SENGUL[1], U. TURE[2];
[1]Anat., Ege University, Sch. of Med., Izmir, Turkey; [2]Anat., Yeditepe University, Sch. of Med., Istanbul, Turkey

Abstract: The inferior olive is the most prominent feature of the hindbrain, located in the ventrolateral part of the brainstem. It plays a major role in motor learning and motor coordination by providing the climbing fibers - one of the two major excitatory inputs to the cerebellar cortex. In this study, we have used numerous immunohistochemical markers to analyze the chemoarchitecture of the inferior olive of the human. A human brainstem was sectioned serially using a cryostat at a thickness of 60 µm, stained and observed under light microscopy. As in other animals, the inferior olive of the human consists of the principal, medial, and dorsal nuclei. We have analyzed transverse sections from Obex +7 and Obex +12, and observed substance P, tyrosine hydroxylase, neuropeptide Y, calbindin, calretinin, parvalbumin, calcitonin-gene-related peptide, choline acetyl transferase, cocaine-and amphetamine-related peptide (CART), GABA, glutamate, glycine, galanin, nitric oxide synthase, enkephalin, and vasoactive intestinal peptide immunoreactivities in all subnuclei - the principal, medial, and dorsal nuclei - of the inferior olive.

Title: Laminar origin of corticostriate projections from prefrontal and rostral cingulate areas in the macaque

Authors: E. BORRA, M. RIZZO, M. LEO, *G. LUPPINO;
Med. and Surgery, Univ. of Parma, Parma, Italy

Abstract: We have recently found that in the macaque frontal motor areas and frontal operculum corticostriatal (CSt) neurons projecting to the motor putamen are almost equally distributed in layers III, V, and VI, thus challenging the commonly assumed notion that CSt neurons in the macaque brain are primarily located in layer V (Borra et al. 2021, J Neurosci, 41:1455). In the

present study we examined whether this connectional feature applies also to prefrontal and rostral cingulate areas. To this aim, in 3 macaque monkeys we analyzed the laminar distribution of the CSt projections from the ipsilateral hemisphere after retrograde tracer injections in the caudate head (2 injections) and in the precommissural putamen (1 injection). After the tracer injections in the caudate head, cortical labeling was densest in prefrontal areas 9 and 8B and in cingulate areas rostral 24 and 32. Less dense labeling involved other lateral prefrontal areas (46, 45, and 8), area 14, and orbitofrontal areas 11, 13, and 12o. In areas rostral 24, 8B and in most of area 9, CSt labeled neurons involved in almost similar proportion mostly layers III and V. This laminar pattern was independent from variations in the local density of the labeled cells. A similar laminar pattern was observed also in area 45 and in orbitofrontal areas. However, in orbitofrontal areas there was a relatively high proportion of CSt labeled neurons also in layer VI (20% ca.). Furthermore, in a sector of area 8 there was labeling by far predominant in layer III. Finally, in areas 32, 14, and 46 and in the rostral part of area 9, labeled CSt cells were located predominantly in layer V. After the precommisural putamen tracer injection, in the prefrontal and rostral cingulate cortex the labeling was denser in areas 24 (mostly cingulate motor areas 24c and 24d), medial 9/8B, 46, 12r, and 12l. In all these areas labeled CSt cells mostly involved layer V. The present data suggest that, as for frontal motor areas, the laminar distribution pattern of CSt neurons largely varies independently from their density and from the projecting area/sector, but likely according to the target striatal zone. Thus, cortical areas appear to project in different ways to different zones of the striatum, so that different striatal zones are targets of characteristically weighted laminar projections from the various input areas.

Title: Altered spontaneous motor behavior and striatal circuit function in conditional mGluR5 knockout mice

Authors: *J. J. MARSHALL, J. XU, N.-H. YEH, T. NOMURA, J. N. ARMSTRONG, J. G. PARKER, A. CONTRACTOR;
Physiol. Dept., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Metabotropic glutamate receptor 5 (mGluR5) plays a crucial role in regulating plasticity at synaptic terminals formed by cortical pyramidal cells onto spiny projection neurons

(SPNs) in the striatum. Specifically, activation of mGluR5 is required for endocannabinoid dependent long-term depression (LTD) at these synapses. SPNs play key roles in regulating voluntary movement and reinforcement learning. Imbalanced activity between SPNs of the direct and indirect pathways (dSPNs and iSPNs) leads to abnormal motor function and is a feature of diseases affecting the basal ganglia, such as Parkinson's and Huntington's disease. However, the role of mGluR5 dependent plasticity in generating balanced spatiotemporal patterns of activity in these two pathways is unclear. To address this, we've generated mice that lack mGluR5 selectively in either direct or indirect pathway SPNs (dSPN and iSPN mGluR5 KO mice). Our characterization of these mice has revealed increased spontaneous locomotor activity in the open field in iSPN mGluR5 KO mice. Conversely, dSPN mGluR5 KO mice show decreased locomotor activity in the open field and when exposed to running wheels in the home cage. Additionally, dSPN knockout mice show reduced spontaneous expression of simple motor behaviors such as digging and nest building. While a variety of electrophysiological properties of dSPNs from these mice are normal when measured in an *in vitro* slice prep, *in vivo* microendoscopy shows that dSPN KO mice have changes in the spatiotemporal patterns of dSPN activation in the dorsal lateral striatum during spontaneous exploration of the open field. This demonstrates, therefore, that mGluR5 activation in dSPNs is required for the normal functioning of striatal circuits. Ongoing work is examining the role of mGluR5 dependent plasticity in mediating alterations in activity of the dorsal lateral striatum during motor learning.

Title: Collective dynamics of a sparse population of striatal neurons in freely moving mice

Authors: L. TIROSHI, Y. ATAMNA, *J. A. GOLDBERG;
Med. Neurobio., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Spiny projection neurons (SPNs) - the main population of striatal neurons - play a central role in movement initiation. Recent studies have shown that SPNs form spatially compact neural clusters of co-active neurons that code for the same types of movement. These clusters were extracted from groups of hundreds of SPNs that were imaged simultaneously with

microendoscopes. When endoscopically imaging densely packed neurons, an extensive background signal arising from neuropil activity is observed in addition to the somatic signals. Recent studies have characterized these neuropil signals and concluded that they are spatially highly-correlated and represent collective neural activity that is distinct from that of the somata. These results raise the question - could the spatially correlated neuropil signal be introducing spurious correlations among SPNs thereby creating an illusion of compact cell clusters operating together? To address this issue, we performed microendoscopic calcium imaging in a sparse population of putative SPNs (pSPNs, identified by immunoreactivity to either GAD or DARPP32). This approach allowed us to explore the collective pSPN activity while maintaining a good separation between the neuropil and somatic signals, as well as, between the signals from different somata. As a first step, we studied the relationship between pSPN activity and the self-initiated movements of freely moving mice. Next, mice underwent an operant conditioning paradigm, and we examined pSPN responses as they learned to associate an auditory cue with a reward. As previously reported, we found that pSPN activity is modulated around the onset of self-initiated movement, as well as following the presentation of task-related cues in the conditioning paradigm. Interestingly, we detected two types of responses around the various behavioral events - while the majority of responsive cells increased their activity following the relevant event, some pSPNs became significantly less active. By focusing on a sparse neuronal population we were able to track individual cells across imaging sessions. While the percentage of significantly responsive pSPNs remained stable, the identity of cells responding around the same type of behavioral event changed considerably from session to session. Finally, we found that the correlation between the activity of pSPN pairs does not depend on the distance between them, in contrast to previous reports of spatially compact clusters. Thus, by focusing on a sparse population of cells, we were able to uncover properties of the collective dynamics of striatal pSPNs that were not previously appreciated.

Title: Membrane potential dynamics during cholinergic transmission onto dopaminergic axons

Authors: *P. KRAMER, S. BRILL-WEIL, Z. KHALIQ;
NIH/NINDS, Bethesda, MD

Abstract: Axons of dopamine neurons are locally modulated by striatal cholinergic interneurons through presynaptic nicotinic receptors (nAChRs). However, the nature of cholinergic transmission is unknown. The prevailing view based on electron microscopy is that cholinergic neurons signal largely through non-specific, slow volume transmission. Functional studies examining the regulation of striatal dopamine release show that synchronous activation of cholinergic interneurons can trigger dopamine release through activation of axonal nAChRs alone. Yet, the indirect nature of the methods used so far have been insufficient to allow precise examination of this axo-axonal transmission. To test this, therefore, we obtained patch-clamp recordings of the axonal membrane potential to precisely examine spontaneous and evoked cholinergic transmission onto striatal dopaminergic terminals. Our axonal recordings reveal the presence of clear phasic depolarizations that occur spontaneously at rates of 1-2 events per second, and which were abolished by nicotinic receptor antagonists. The cholinergic-evoked depolarizations had average rise times slightly less than 20 ms indicating the likely presence of a non-classical synapse. Tetrodotoxin-block of spike evoked transmission resulted in a 10-fold reduction in the frequency of spontaneous EPSPs but had no effect on amplitude, confirming that these events represent true miniature events resulting from quantal release. Paired-pulse stimulation of cholinergic interneurons with light-evoked opsins or electrical stimulation showed the marked synaptic depression. Importantly, we also show that the kinetics of nicotinic EPSPs are shaped by acetylcholinesterase, which limits the activation of nicotinic receptors distal to the site of ACh release. Thus, we provide the first comprehensive examination of membrane dynamics during axo-axonic synaptic transmission onto the dopaminergic axons. Although the large and extensively branching axonal arbors of dopamine neurons have led to the idea of global signaling, our data showing synaptic-like depolarizations suggests instead that local signaling within the arbor may also contribute to striatal subregion circuit dynamics.

Title: Anatomical and functional characterization of a direct input from basolateral amygdala to dorsolateral striatum

Authors: *Z. B. HOBEL[1], J. L. PLOTKIN[1,2];
[1]Neurobio. & Behavior, Stony Brook Univ., Stony Brook, NY; [2]Stony Brook Sch. of Med., Stony Brook, NY

Abstract: The dorsal striatum is crucial for motor learning and balance of action strategies, in part through dense inputs from sensory- and motor- related cortical areas. Limbic-associated brain regions, including the amygdala, also innervate the dorsal striatum, providing a mechanism for limbic-associated information to influence striatal action selection. Input to the striatum from the amygdala comes predominately from the basolateral nucleus (BLA) and densely innervates the dorsomedial (DMS) and ventral subdivisions of the striatum. If and how the BLA also innervates the functionally distinct neighboring dorsolateral striatum (DLS) is unclear. Here, we use a combination of anatomical circuit tracing, optogenetics, 2-photon imaging and slice electrophysiology to characterize the connectivity between the BLA and DLS in the mouse brain. We identified a population of DLS-projecting BLA neurons that is topographically distinct from the more numerous DMS-projecting population. These DLS-projecting BLA neurons form functional axo-spinous synapses on approximately 20-25% of DLS striatal spiny projection neurons. We further show that DLS- and DMS-projecting BLA neurons are integrated differently into prefrontal cortex circuits, with DMS-projecting BLA neurons sending axonal collaterals to the medial prefrontal cortex and DLS-projecting neurons sending axonal collaterals to more lateral prefrontal areas. Experiments aimed at understanding the role of this novel projection in modulating behavior are ongoing.

Title: Corticospinal populations broadcast complex motor signals to coordinated spinal and basal ganglia circuits.

Authors: *A. NELSON, B. ABDELMESIH, R. COSTA;
Columbia Univ., New York, NY

Abstract: How the brain and spinal cord transform neuronal activity into coordinated movement is a central question in neuroscience. Many models of motor control emphasize the role of sensorimotor cortex in directing movement, principally through the direct axonal projections corticospinal neurons (CSNs) make to the spinal cord. In addition to their intimate access to

motor output, CSNs also possess strikingly expansive supraspinal axon collaterals, the functional organization of which is largely unknown. Experimentally characterizing this architecture been limited by an inability to map, measure, and manipulate interconnected circuits defined by their synaptic targets. Using anatomical and electrophysiological circuit mapping techniques, we reveal dorsolateral striatum (DLS) as the preeminent target of CSN collateral innervation. Moreover, we show that CSNs are the only population of neurons that project directly to both spinal cord and DLS. CSNs evoke larger postsynaptic responses in D1- over D2-expressing striatal spiny projection neurons (SPNs), a bias that is mediated through more, rather than larger, synapses made on D1 SPNs. This supraspinal bias is reflected in the spinal cord: CSN populations that target D1 or D2 SPNs show preferential targeting of distinct spinal cord circuits, revealing coordinated spinal and forebrain connectivity. We combined multiphoton imaging of CSNs, transsynaptic rabies tracing from D1 or D2 SPNs, and a sequential lever press task to characterize the information encoded in the activity of CSNs and their collaterals in DLS. Contrary to more conventional perspectives, CSN populations encode not only individual movements and muscle output, but also higher-order information related to the onset and offset of motor sequences. Furthermore, similar patterns of complex activity are broadcast by CSN populations targeting different downstream striatal circuits. Our results reveal a logic of coordinated connectivity between forebrain and spinal cord circuits, where separate CSN modules broadcast similar muscle- and non-muscle-related information to downstream circuits, suggesting that differences in postsynaptic connectivity ultimately dictate motor specificity.

Title: An alternative cortico-subcortical loop for motor coordination

Authors: *E. BOSZ[1,2], V. M. PLATTNER[3], M. A. DIANA[4], L. ACSADY[1];
[1]Inst. of Exptl. Med. HAS, Budapest, Hungary; [2]Semmelweis Univ., Budapest, Hungary;
[3]Sainsbury Wellcome Ctr., London, United Kingdom; [4]Pierre et Marie Curie Univ., Paris, France

Abstract: Basal ganglia process frontal cortical signals which is then conveyed to thalamus via giant multisynaptic inhibitory terminals before they return to the cortex via the thalamocortical pathway, closing the loop. Unilateral interference with basal ganglia activity induces characteristic, unilateral rotation. The brainstem also contains several locomotor centers. Similar

to the basal ganglia the pontine reticular formation (PRF) also sends large multisynaptic terminals to the intralaminar thalamus (IL). Futhermore the PRF innervated by the basal ganglia. Activation of PRF fibers in the IL results in a strong motor phenotype, a complete behavioral arrest. In this study, we examined the cortical inputs of the PRF inhibitory cells (GlyT2+) and their function in order to assess whether frontal cortex is able to inhibit and/or pattern IL activity via a PRF inhibitory interface. We also tested the effect of optogenetic activation of inhibitory PRF cells on locomotor behavior. Injections of AAV-ChR2 into the frontal cortex (M2 and cingulate - Cg) of RBP4-Cre/Glyt2-eGFP double transgenic mice revealed that GlyT2+ neurons of the PRF receives L5 inputs. Cortical terminals contacted mostly mid caliber dendrites and spines of the GlyT2+ cells. In *in vitro* preparation photoactivation of frontal cortical fibers faithfully produced purely glutamatergic synaptic responses on PRF-GlyT2 cells. Juxtacellular recording and labelling in the PRF showed that photoactivation of frontal L5 cells evoked short latency APs with high probability in the PRF GlyT2+ cells at high stimulation frequency (10-20 Hz). Spontaneous rhythmic activity of Glyt2+ cells was tightly linked to the slow cortical oscillation. Pharmacological inactivation of the cortex led to decreased, irregular firing of the GlyT2+ neurons. Photoactivation of PRF Glyt2+ cells resulted in unilateral rotation. Photoactivation of PRF-IL GlyT2+ fibers led to significant decrease in the firing rate of IL cells *in vivo*, suggesting that frontal cortical activity may lead to decreased IL output in a selected IL cell population. Our results suggest that synchronous frontal cortical activity conveying a behavioral signal computed by frontal cortical regions can reliably activate inhibitory neurons of the PRF. PRF GlyT2 cells in turn transfer this to the IL as an inhibitory signal strongly affecting thalamocortical and thalamostriatal activity akin to the basal ganglia circuits.

Title: Strengthening of cortico-striatal synapses from task-relevant motor cortex neurons during learning

Authors: F.-J. HWANG[1], R. H. ROTH[1], Y.-W. WU[2], Y. SUN[1], Y. LIU[1], J. B. DING[1]; [1]Stanford Univ., Stanford, CA; [2]Academia Sinica, Taipei, Taiwan

Abstract: The execution of skilled movements requires the coordinated activity of multiple brain regions and learning new motor skills involves adaptations of the connectivity between brain regions. The motor cortex and striatum are two key motor regions of the brain and play crucial roles in generating and organizing voluntary movement. Yet, how the synaptic connectivity between these regions is modulated during motor learning has not been defined. To assess this, we train mice on a single pellet reaching motor learning task and use the genetic fos-TRAP system to identify task-relevant neurons in the primary motor cortex (M1). We found that the degree of reactivation of this labeled neuronal population highly correlates with the level of mouse performance on the reaching task. By expressing channelrhodopsin (ChR2) in task-relevant neurons, we further probed the functional connectivity of cortico-striatal projection neurons onto spiny projection neurons (SPNs) in the dorsolateral striatum (DLS). Combining optogenetic stimulation and two-photon Ca2+ imaging in brain slices, we were able to identify the individual dendritic spines receiving inputs from task-relevant M1 neurons. We found that motor learning led to an increase in the number and strength of cortico-striatal inputs onto SPNs and that these inputs form local clusters along SPN dendrites. Together, our results indicate that a population of task-relevant neurons emerges in M1 during motor learning and that the projections of these neurons to the striatum are strengthened. This form of synaptic plasticity can functionally impact dendritic integration on dendrites of SPNs in the striatum and may play a role in the formation of precise motor sequences during learning.

Title: An undergraduate team project to reconstruct neural circuits controlling Drosophila grooming behavior using an Electron Microscopy dataset for the fly's ventral nerve cord

Authors: N. HILL[1], P. LAWTON[1], K. ROSS[1], ***P. TANG**[1], M. TEITZ[1], D. WRIGHT[1], D. SYED[1], S. YOSHIKAWA[1], J. S. PHELPS[2], W.-C. A. LEE[3], J. H. SIMPSON[1];
[1]Univ. of California Santa Barbara, Santa Barbara, CA; [2]Harvard Univ., Cambridge, MA; [3]BCH / Harvard Med. Sch., Boston, MA

Abstract: Fruit flies perform sequential grooming behaviors, yet the neural pathways that coordinate these actions remain largely unknown. Recent, large-scale connectome efforts led to the collection of electron microscopy (EM) datasets for the fly nervous system, which allows for the investigation of neural circuits at synaptic resolution.
Since January 2021, a team of ~50 UCSB undergraduate students learned to trace neurons in the EM dataset of the adult female ventral nerve cord collected by the Lee and Tuthill labs (Phelps, et al 2021) using CATMAID, a collaborative tracing platform (Saalfeld et al 2009). This project provided remote research opportunities during COVID restrictions. Peer training is in development to incorporate new tracers and has expanded to include the Neuroglancer software/web interface (Dorkenwald et al 2020) as auto-segmentation data becomes available. Tracers were divided into three groups, led by student team leads and senior lab members. Each team reconstructed different neurons identified as critical for grooming in previous optogenetic activation screens:
I. wPN1 neurons are a pair of cholinergic interneurons that have dendrites in the wing neuropil and synaptic arbors in T3 on each side. These neurons were identified to affect coordinated wing grooming. GRASP data suggests that wPN1 receives synaptic input from wing campaniform sensilla, mechanosensory neurons embedded in the cuticle. A bundle of ~150 sensory neuron candidates has been partially reconstructed in the EM, and synaptic connections onto wPN1 have been identified by tracing.
II. 13A/13B inhibitory lineages: Neurons in the 13A/B lineage contain several distinct morphological types that project ipsilaterally in the T1 neuromere. Partial EM reconstructions have shown synaptic connections between some 13A neurons and subsets of leg motor neurons; some 13B neurons are indirectly connected to motor neurons through 13As. The catalog of projection types may illuminate how these inhibitory neurons contribute to leg coordination during grooming.
III. Mago-no-te (MGT): Activation of MGT promotes thoracic grooming. Light level and EM reconstruction of the pair of MGT neurons show two distinct branches. The ventral medial branch contains the post-synaptic sites between the T1 and T2 neuromeres, while the dorsal lateral branch contains a majority of the presynaptic sites in the T3 neuromere. Its pre-synaptic partners may include sensory neurons, a hypothesis that is being tested by EM neuron tracing. Complete tracing of these target neurons and mapping their synaptic connections will reveal new neural circuits that contribute to the regulation of fly grooming behavior.

Title: Roundup® And glyphosate exposure elicits proconvulsant behavior in caenorhabditis elegans

Authors: *A. S. NARAINE[1,2], I. SWEENEY[2], R. AKER[2], M. KALVEY[3], A. SURTEL[2], V. SHANBHAG[4], K. DAWSON-SCULLY[5,1];

Abstract: As 3 billion pounds of herbicides are sprayed over farmlands every year, it is essential to advance our understanding of the influence that pesticides may have on neurological health and physiology of both humans and other animals. Herbicidal investigations, specifically those involving glyphosate-based herbicides, are often one-dimensional as the majority of studies examine glyphosate by itself, while farmers and the general public use commercial products which contain a myriad of chemicals in addition to glyphosate. Previous works have demonstrated neurotoxicity in *C. elegans*, but it has also been shown that humans suffer significant physiological effects at subtoxic thresholds. It was our contention that physiological effects could be exacerbated by dilutions far lower than those required to degrade neuronal tracts, and a rescue of those effects would demonstrate a significant dysregulation rather than outright neurodegeneration. We compared how glyphosate and Roundup® affect convulsant behavior in *C. elegans* and found that glyphosate (n=100) and Roundup® (n=104) both increase seizure-like behavior ($p<0.01$). Key to our initial hypothesis, we found that treatment with an antiepileptic drug (AED) rescued the prolonged convulsions ($p<0.001$). Notably, these effects were found at concentrations that are 1,000-fold dilutions of previous findings of neurotoxicity. In addition to prolonged convulsion, we discovered a significant percentage of nematodes exposed to Roundup® (33.5%) did not recover from their convulsions at all even compared to glyphosate (12.9%), however AED treatment completely alleviated the non-recovery status.

Title: Neural circuitry underlying sensorimotor decisions

Authors: *M. LEHMAN[1,2], S. AUTRAN[1], T. JOVANIC[1];
[1]Paris-Saclay Inst. of Neuroscience, CNRS UMR9197, Paris-Saclay Univ., Gif-sur-Yvette, France; [2]Doctoral Sch. N°568, Paris Saclay Univ., Le Kremlin Bicetre, France

Abstract: From finding nearby food to escaping a predator, animals must respond to sensory cues with appropriate motor actions in order to survive. The neural circuit mechanisms underlying the transformation of sensory information into appropriate motor output remain incompletely understood. It is for instance unclear how one action is selected among several possible responses to a single stimulus. In addition, how the selected action is specified by motor circuits depending on stimulus characteristics is not known either at the cellular and synaptic levels. To understand these mechanisms better, it would be important to map the entire neural circuitry from the sensory to the motor side in a model organism allowing functional testing of such circuits. Thanks to recent progress in connectomics, allowing the mapping of entire neural circuits in electron microscopy (EM) with synaptic resolution and to the genetic toolbox for cell-specific neuronal manipulations and monitoring, Drosophila larva presents itself as such a model. We will here present our progress on the investigation of the neural circuitry underlying larval responses to an aversive mechanosensory stimulus, the air puff. Drosophila larvae typically respond to the air-puff with either startle or escape behaviours (Jovanic et al, 2016). The selection of one action implies the inhibition of other, mutually exclusive, actions. Competitive interactions between the neural modules underlying startle and escape behaviors could thus exist in order to enable the selection between the two. Using inactivation and optogenetic activation of single neurons in behaving larvae combined with video tracking and automated behavioral detection (Masson et al., 2020), we determined the role of interneurons at different sensorimotor stages and found they are differentially involved in startle and escape behaviors. Some of these neurons promote one response and repress another suggesting they are involved in competitive interactions. Using EM-based connectomics, we are now mapping the startle and escape sensorimotor pathways and investigating where and how both pathways could interact. The connectivity motifs underlying these interactions should allow the execution of one behaviour at the expense of another. One possible connectivity pattern could be that of reciprocal inhibition of inhibition (Jovanic et al. 2016, Koyama and Pujala, 2016). Determining the neural circuit mechanisms underlying sensorimotor decisions in a model system where we can trace all connections and manipulate single neurons may bring insights into the neural circuit mechanisms of competitive interactions in general.

Title: Differential Corpus Callosum Connections Across Mammalian Orders

Authors: A. GUZMAN, P. PATEL, N. A. SCHOTTLER, *W. GRISHAM;
Psychology, UCLA, Los Angeles, CA

Abstract: Prior work in this lab showed primates possessing proportionately larger neocortices than rodents & ungulates (but not carnivores). Here we analyzed long cortico-cortical connections, the corpus callosum (CC), in mammals with larger brains (primates, carnivores, and ungulates) as well as smaller (rodents). Images from the Comparative Mammalian Brain Collection and The Human Brain Atlas at Michigan State U. were used. Measures of CC thickness were taken from 3 ant-post levels (anterior-most section of CC, section where hippocampus appears, and posterior-most section of CC) in 42 species from the 4 orders. CC measures were made off the midline to avoid the hippocampal commissure. Measures of the neocortex (NC) thickness were made at the same level. For the raw data, the mean thickness of the corpus callosum scaled with the mean thickness of the cortex (slopes ~1.00) except in primates where the CC thickness outstripped the cortex and the slope exceeded 2.6. After correcting for phylogeny, the pattern of residuals was quite different--the slopes were all well below 1.0, and primates had a negative slope. ANOVAs--4 between (order) x 3 within (slice level) and covarying log10 brain size--were done on both raw and phylogeny corrected data. In both raw and corrected CC thickness, the CC was thinnest in ungulates. Similarly, raw and corrected neocortex analyses showed NC to be relatively thin in both ungulates and carnivores. Complex but similar interactions were revealed by analyses of both raw data ratios and corrected ratios of CC/NC: carnivore and rodent ratios did not change much across sections whereas primates' ratios were higher in the posterior section and ungulates' higher in the anterior. Our data are predicated on several assumptions: uniform size and density of CC axons, uniform size and density of cortical neurons, and thicker NC correlated with more CC projections. Nonetheless, our data showed that big-brained animals do not necessarily have thick NC & CC and that there is no straightforward relationship between CC and NC across orders.

Abstract: The medicinal and recreational use of cannabis has become more prevalent around the world. As cannabis compounds interact primarily with the endocannabinoid system (eCS), it is highly important to understand the fundamental roles played by the eCS during early development because perturbations of the eCS in the early stages of life are known to have detrimental impacts on neural development. In this study we aimed to explore how overstimulation of endocannabinoid (eCB) signalling during early embryogenesis affects the development of functional locomotor behaviors. In order to upregulate eCB signalling, zebrafish (*Danio rerio)* embryos were exposed to pharmacological inhibitors of the enzymes responsible for the degradation of the 2 endocannabinoids: anandamide (AEA) and 2-arachidonoylglycerol (2-AG), during the first 24 hours of development. We found that overactivation of eCB signalling resulted in hypolocomotion, as demonstrated through decreased contractile activity within the chorion of embryos at 1 day post fertilization (dpf), while 2 dpf embryos experienced a reduction in the distance and velocity of burst swimming. To ascertain whether sensorimotor development was altered, we examined the reflex response known as the short latency C-start escape at 2 dpf in response to a mechanical stimulus. Embryos treated with eCB degradation inhibitors displayed a significant increase in the response latency of initiating short latency C-start escape responses. Additionally, we sought to determine whether alterations in escape behaviors were also displayed through the sensation of alternative sensory modalities; therefore, we also examined C-start escapes in response to auditory/vibrational (AV) stimuli. Interestingly, we found that eCS overstimulation impairs the responsiveness to AV inputs, as animals treated with eCB degradation inhibitors demonstrated reduced rates of escape in response to sound at 5 dpf. These impairments were still present at 6 dpf as well, suggesting that there is a delay in the maturation of this response. Taken together, these findings indicate that tight regulation of the normal levels of eCB activity during early embryonic stages is critical for locomotor development and that the endocannabinoid system is essential for the maturation of sensorimotor circuits.

Title: State-dependent modulation of sensorimotor decisions

Authors: E. DE TREDERN, D. MANCEAU, V. SUS, ***T. JOVANIC**;
Paris-Saclay Inst. of Neurosci., Gif-sur-Yvette, France

Abstract: In face of aversive stimuli animals first need to decide whether to respond and then how to respond. In addition, they constantly need to balance their decisions to avoid dangers and threats with pursuing food search. These decisions are modulated by animal's internal state. Food-deprived animals were shown to be more likely to ignore aversive stimuli and to be more responsive to appetitive food-related stimuli. However, whether and how nutritional states affect non-feeding related decisions is not well understood. In order to address this question and investigate the neural circuit mechanisms underlying the state-dependent modulation of behavior, we combine automated behavioral detection, neuronal manipulation, functional imaging and electron microscopy in Drosophila larva. We have previously described a circuit that controls the decision between startle and escape-like behavior following a mechanical stimulus. We hypothesized that integration of other information, such as the feeding state, might occur through long-range projections that connect to this circuit. To investigate this, we first characterize how diet affect behavioral responses following a mechanical stimulus. Then, we describe how the activity of the already known neuronal substrates of decision making are differentially modulated by animal's nutritional status using 2-photon calcium imaging in intact larvae. Finally, we map additional substrates of decisions between startle and escape behaviors. Understanding the neural circuit mechanisms underlying simple decisions of whether and how to avoid aversive stimuli and how these decisions can be modulated by the internal state in the Drosophila larva where we can study neural circuit mechanisms with single cell and synaptic resolution across the nervous system, might shed light on the principles underlying theses processes across species.

Sci., The Univ. of Texas Rio Grande Valley, Brownsville, TX; [5]Inst. for Neurosci., Harlingen, TX

Abstract: Environmental exposures and environmental influences play a vital role in brain development and may permanently impact the brain. In this study, we examined the effects of environmental enrichment (EE) in a non-traditional animal model, *Monodelphis domestica* (n = 40: $n_{NonSocialNonEnrichment(control)} = 6$, $n_{NonSocialEnrichment} = 14$, $n_{SocialNonEnrichment} = 19$, $n_{SocialEnrichment} = 7$), using the combination of behavioral indicators and immunohistochemical markers (i.e., postsynaptic density-95 (PSD-95) and brain-derived neurotrophic factor (BDNF)), particularly in the frontal cortex and hippocampus. *Monodelphis* has recently gained popularity as an alternative animal model for neurodevelopmental research, allowing researchers to examine the impact of environmental influences at early development stages.In Experiment 1 (i.e., the object-place recognition test), there was a statistically significant interaction effect of the number of times the animals interacted with old and new objects ($F(3,35) = 120.66$, $p < .001$), despite the sex and housing conditions. Females, in particular, interacted more with new objects compared to males, which may indicate sex differences in cognitive ability ($M_{FemaleOldObject} = 16.62$, $M_{FemaleNewObject} = 47.14$, $M_{MaleOldObject} = 19.06$, $M_{MaleNewObject} = 39.78$, $F(1,37) = 5.98$, $p < .01$). There were no differences between each enrichment condition. Based on the open field test (Experiment 2), latency to immobility of animals in the non-social enrichment condition was marginally significantly higher compared to the social enrichment condition ($U = 234.5$, $p = .09$). There were marginal significant differences in latency distribution to immobility according to the types of housing conditions ($\chi^2 = 7.143$, $p = .067$). The difference regarding the mobility duration between sex was also statistically significant ($F(1, 32) = 4.922$, $p < .05$). However, there were no significant differences between the conditions in the rotarod test (Experiment 3). The insignificant results may have been due to the fact that we exposed the animals to only one inanimate object in the EE condition.We also did a pilot test to examine PSD-95 and BDNF, particularly in the frontal cortex and hippocampus, and found the expression of the markers in these areas. We are currently conducting immunohistochemistry to examine the effects of social and EE on neuroplasticity. We expect that the PSD-95 and BDNF in the EE condition will be significantly increased compared to the control and social enrichment conditions. Together, this research may offer researchers an alternative animal model and opportunity to examine the impact of EE on neuroplasticity.

Title: Uncovering developmental changes in the neural circuits that regulate the production of mouse ultrasonic vocalizations

Authors: *N. PRANIC, C. KORNBREK, Z. HE, C. CHAE, K. A. TSCHIDA;
Psychology, Cornell Univ., Ithaca, NY

Abstract: Vocalizations are an essential means of communication in social animals, both human and non-human. Animals vocalize throughout their lifetimes, and vocalizations produced at different developmental stages serve distinct roles in behavior and are in turn elicited by distinct cues and contexts. Mouse (*Mus musculus*) pups produce ultrasonic vocalizations (USVs) in response to isolation and cold exposure, eliciting retrieval behavior from the mother, whereas adult mice produce USVs in response to social partners**.** However, the neural circuits that underlie the production of USVs in mouse pups remain poorly described. In addition, whether and how these circuits change over development as mice shift from producing isolation-induced USVs to producing social USVs remains unknown. To address these questions, we're applying a dual labeling strategy to examine developmental changes in the populations of neurons that are active during USV production at different ages. First, we will use an activity-dependent labeling strategy (TRAP2 transgenic mice crossed with Ai14 mice) to fluorescently label neurons throughout the brain that are active when mouse pups (PND 8) produce isolation-induced USVs. At a later point in development, USVs will be elicited from these same mice (either isolation-induced USVs at a later point in early development or social USVs in adolescence or adulthood), and Fos immunolabeling will be performed to compare neuronal populations that are active during USV production at different developmental stages. These experiments will reveal neuronal populations that regulate USV production across development, as well as shed light on the neural circuit changes that enable the emergence of social USV production in adolescent mice.

Title: Midbrain circuits for context-dependent vocalization in the mouse

Authors: *P. ZIOBRO, Z. HE, A. SADANGI, K. A. TSCHIDA;
Cornell Univ., Ithaca, NY

Abstract: Vocalizations are an essential means of communication in humans and more broadly in mammals. To communicate effectively, animals must vocalize in the right way at the right time, and accordingly, animals produce different acoustic categories of vocalizations in different behavioral contexts that serve different communicative functions. Despite the importance of vocalization to mammalian social behavior, the neural circuits that allow animals to produce different acoustic types of vocalizations according to social context remain undescribed. To address this question, we study the neural circuits that underlie vocalization in mice, which produce ultrasonic vocalizations (USVs) during same-sex and opposite-sex social interactions and lower frequency squeaks in painful or aversive contexts. The midbrain periaqueductal gray (PAG) contains neurons essential for vocalization in mammals, and a recent study identified a specialized population of neurons in the PAG of the mouse whose activity is both necessary and sufficient for the production of USVs (referred to as PAG-USV neurons; Tschida et al., 2019). In the current study, we ask whether PAG-USV neurons are active during the production of squeaks, to begin to understand whether these neurons are uniquely important for USV production, or alternatively, contribute to the production of multiple acoustic types of vocalization.

To test whether PAG-USV neurons are active during the production of squeaks, we employ an activity-dependent labeling strategy (TRAP2 transgenic mice crossed with Ai14 mice) which permits the expression of fluorescent protein in neurons throughout the brain that were recently active during behavior. PAG-USV neurons are fluorescently labeled following social encounters marked by USV production in male and female mice. Ten days later, these same mice are either presented again with a social partner to elicit USV production a second time or are subjected to a mild footshock paradigm to elicit the production of squeaks. Fos immunostaining is then performed to label neurons that were active during the second behavior session, and the overlap of neurons within the PAG labeled during the first and second behavior sessions will be examined. These experiments will shed light on the functional organization of the midbrain circuits that allows animals to select and to produce the appropriate type of vocalization for a given behavioral context.

Title: Adaptive control of vocal suppression in the mouse brain

Authors: *V. MICHAEL[1], S. XIAO[2], R. D. MOONEY[3];
[1]Duke, Durham, NC; [2]Neurobio., Duke Univ., Durham, NC; [3]Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: Vocal communication is a key social behavior by which humans and other mammals form and maintain social bonds, convey information about social status and mating fitness, and engage in cooperative behavior. The decision to vocalize is regulated by the ongoing environmental context, including the presence of external sensory and social cues, as well as the animal's own internal state and past experience. Though vocalizations are an important medium for sexual and social signaling between conspecifics, in many respects, the decision *not* to vocalize is equally important, as vocalizing in the wrong context may increase the risk of unnecessary energy expenditure, of retaliation by a dominant conspecific, or of attracting the attention of eavesdropping predators or parasites. Despite extensive research on circuits necessary for vocal production, little is known about forebrain networks that *suppress* vocalizations in response to appropriate environmental cues.
Mice produce complex ultrasonic vocalizations (USVs) in a variety of social contexts, allowing researchers to study the circuits underlying vocal control using advanced genetic tools. The midbrain periaqueductal gray (PAG) is a critical node in the vocal motor circuit whose activity is obligatory for vocalizations. Previously, we identified a subpopulation of PAG-projecting amygdala neurons on the border of the central and medial amygdala ($Amg_{C/M\text{-}PAG}$ neurons) whose activity is sufficient to suppress ongoing vocalizations via direct inhibition of a subpopulation of PAG neurons that are active during USV production. In the current study we sought to further characterize the identity and function of these neurons. We showed that $Amg_{C/M\text{-}PAG}$ neurons suppress vocalizations in both male and female mice across social contexts and that $Amg_{C/M\text{-}PAG}$ neurons express estrogen receptor alpha (Esr1). We then imaged the activity of $Amg_{C/M\text{-}PAG}$ neurons during social and non-social interactions. Finally, we traced the direct monosynaptic inputs to $Amg_{C/M\text{-}PAG}$ neurons and interrogated the function of inputs to this region from the medial preoptic area. Together these experiments improve our understanding of how $Amg_{C/M\text{-}PAG}$ neurons regulate adaptive vocal control.

Title: A novel reticular oscillator in the brainstem synchronizes neonatal crying with breathing

Authors: *P. WEI[1], M. COLLIE[1], B. DEMPSEY[2], G. FORTIN[2], K. YACKLE[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Inst. de Biologie de l'Ecole Normale Supérieure, Paris, France

Abstract: Human speech can be divided into short, rhythmically-timed elements, similar to syllables within words. Even our cries and laughs, as well as the vocalizations of other species, are periodic. However, the cellular and molecular mechanisms underlying the tempo of mammalian vocalizations remain unknown. Here we describe rhythmically-timed neonatal mouse vocalizations that occur within single breaths, and identify a brainstem node that structures these cries, which we name the intermediate reticular oscillator (iRO). We show that the iRO acts autonomously and sends direct inputs to key muscles in order to coordinate neonatal vocalizations with breathing, as well as paces and patterns these cries. Furthermore, we identify a set of molecular markers that labels the iRO neurons. These results reveal that a novel mammalian brainstem oscillator embedded within the conserved breathing circuitry plays a central role in the production of neonatal vocalizations.

Title: Calling from the heartbeat: cardiovascular gating of vocal behavior in freely moving macaque monkeys

Authors: *C. RISUENO SEGOVIA[1], O. KOC[1], P. CHAMPEROUX[2], S. R. HAGE[3];
[1]Ctr. For Integrative Neurosci., Tubingen, Germany; [2]European Res. Biol. Ctr., Baugy, France; [3]CIN, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Communication is a keystone of animal behavior. However, the physiological states underlying and gating natural vocal signaling are still largely unknown. In this study, we investigated the correlation of affective vocal utterances with concomitant cardiorespiratory mechanisms. We telemetrically recorded electrocardiography, blood pressure, and physical activity in six freely moving and interacting cynomolgus monkeys (Macaca fascicularis). Our results demonstrate that vocal onsets are strengthened during states of sympathetic activation, and are phase locked to a slower Mayer wave and a faster heart rate signal at ~2.5 Hz. Vocalizations are coupled with a distinct peri-vocal physiological signature based on which we were able to predict the onset of vocal output with high precision using three machine learning classification models. These findings emphasize the role of cardiorespiratory mechanisms in gating vocal onsets to optimize arousal levels and minimize energy expenditure during natural vocal production.

Title: Two functions for one tract: the tradeoff of vocalizations and breathing in male rats

Authors: C. P. SCHAEFER, IV, ***T. RIEDE**;
Midwestern Univ., Glendale, AZ

Abstract: Breathing movements are governed by metabolic demands. They can be modulated by locomotion or emotional responses. Vocal production requires adaptations of breath control since the airflow through the respiratory tract is the source for vocal sounds like laughing, crying, human speech or calling in nonhuman mammals. Previous work from our lab suggests that vocal patterns in male rats are entrained to prevalent breathing movements. The use of a particular breathing pattern (e.g., eupneas or sighs) is reflected in vocal characteristics. In order to test this hypothesis further, the objective of this work was to determine whether increased breathing rates due to an increased metabolic demand, would affect vocal production. We investigated this in

awake and spontaneously behaving rats. Rats produce 22-kHz vocalizations during forced treadmill running. Those calls do not differ in fundamental frequency during a noxious context in which animals freeze. After 3 weeks of training, we recorded breathing movements and vocalizations in 8 male SD rats, ages 4 to 6 months, at rest and during running. If laryngeal vocal movements are entrained to prevailing breathing movements, we expected that vocal characteristics would change during increased breathing rates. As predicted, some vocal characteristics changed during running. Call duration shortened with decreased eupnea duration and increased breathing rates. Fundamental frequency, although overall not different to a non-running context, demonstrated a positive correlation with running speed. Unexpected was the observation of numerous spectral features not observed in a non-running context, such as frequency jumps, call interruptions, mid-call transitions to audible screams and absence of sound during a vocal exhalation. Those spectral features suggest that operation of the laryngeal valve is challenged during running since ultrasonic whistle production requires precise motor control of the laryngeal valve and subglottal pressure. Finally, we investigated how non-vocal eupneas and sighs were affected by the presence of vocalizations. Both breath types became longer and the inhale-exhale ratio of eupneas became smaller in the vicinity of vocal breaths. Sighs were produced less frequently during episodes of high vocal rates as if the two patterns were mutually exclusive. In sum, data support the hypothesis that vocal patterns are entrained to prevailing breathing patterns. Results suggest also that there is a reciprocal relationship. The non-vocal breathing movements are affected by the presence of vocal breathing. The study highlights the integrative complexity of breath control and vocal production.

Title: Social cues interact with intrinsic circuit dynamics to drive the choice between two communication signals in Drosophila

Authors: E. STEINFATH, A. KHALILI, *J. CLEMENS;
European Neurosci. Inst., Göttingen, Germany

Abstract: Communication is multi-modal - when we interact, we speak, gesticulate, and touch. However, how the different acoustic, visual, and tactile cues are selected and coordinated to

support communication is unclear. We address this issue in the vinegar fly which thanks to its complex social behavior and genetic toolbox is ideal for dissecting the neural basis underlying communication behaviors. During courtship, male flies produce two types of communication signals to woo the female: air-borne “courtship song” is produced by moving the wing, while substrate-borne “vibrations” are transmitted via the legs. The sensory cues and the neural circuits that drive the courtship song are well studied. However, little is known about the sensory and neural basis underlying the production of vibrations, and the cues and circuits that select between song and vibrations. Here we identify the context cues that drive the choice between the two communication signals and provide first insight into the circuit underlying that choice. To address this issue, we developed an experimental setup to record the interactions of flies during courtship alongside the male song and vibrations. Statistical modeling based on pose tracking suggests that the switch from song to vibration is induced by female stationarity, which we causally tested by optogenetically controlling female walking during courtship. We then identified two clusters of neurons - called pC2 and P1 - which control the switch between song and vibrations in an opposing fashion: Optogenetic activation of pC2 neurons in solitary males induced song during and persistent vibrations after activation. By contrast, activation of P1 neurons induced vibrations during and after activation, while song only occurs sparsely after activation. Sensory cues provided by the presence of a female overwrite these intrinsic dynamics resulting in more song production after the activation. Our results suggest that the choice between two communication signals in Drosophila is likely driven by inhibitory cross-talk between the pC2 and P1 neurons or their downstream targets. Social cues, which could differentially activate pC2 or P1, interact with the complex circuit dynamics arising from this cross-talk to choose the context-appropriate signal. Overall, this provides first insight into the logic underlying the choice between different communication signals via mutual inhibition modulated by social cues.

Title: Nucleus ambiguus cell loss and inflammation pair with vocal changes in an adult rat model of Parkinson disease

Authors: E. H. DAO, S. A. LECHNER, J. M. WELSCH, ***C. A. KELM-NELSON**;
Dept. of Surgery | Div. of Otolaryngology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: The pathology underlying cranial motor dysfunction, including vocalization, is poorly understood for progressive degenerative disorders including Parkinson disease (PD). Complete loss of function of the *Pink1* gene in a rat model causes an early and progressive form of the disease, analogous to the inherited familial type. In both humans and rats, the brainstem and larynx are mechanistically responsible for vocal motor functions. Male *Pink1*-/- rats show vocal communication differences compared to wildtype controls including changes in ultrasonic vocalization acoustics that affect functional communication, as well as alterations within vocal motor brainstem regions (*e.g.*, nucleus ambiguus, increased α-synuclein) and larynx muscle biology (*e.g.*, thyroarytenoid muscle, increased centralized nuclei and decreased intrinsic force). However, it is unknown whether (A) nucleus ambiguus motoneuron cell density is related to ultrasonic vocalization acoustics in this PD model or (B) if alterations in nucleus ambiguus gene expression contributes to behavioral changes in this model. In this study, male *Pink1*-/- rats were tested for vocalization acoustics during a recording session and then injected with Fluorogold, a retrograde tracer, unilaterally into the vocal fold. After 7 days, immunohistochemistry and unbiased stereology were used to count Fluorogold-positive motoneuron cell bodies. Relationships between cell numbers and vocal acoustics were assessed; there was a significant positive correlation between number of cells and duration of the calls; suggesting that reduced motoneuron density may compromise vocal duration. On a separate group of rats, RNA sequencing was used to examine nucleus ambiguus differential gene expression in male *Pink1*-/- rats compared to age-matched wildtype controls (n=513 up-regulated; n=327 down-regulated genes). Using the ENRICHR tool, the top up-regulated biological pathways (*genes*) included several inflammatory pathways: interleukin (IL) activation of NF-kappa β (*Sqstm1;Prkcz*), IL-1 (*Pik3r2;Irak4;Sqstm1;Prkcz*), IL-5 (*Gsk3a;Rps6kb2;Pik3r2*), IL-6 (*Gab1;Pik3r2;Agt*) signaling pathways as well as cell death (*Aph1b;Ubb;Sqstm1;Uba52*). These data are the first to suggest that vocalization dysfunction in *Pink1*-/- rats may be linked to nucleus ambiguus motoneuron inflammation.

Title: Rescue of vocal deficits with exercise in a Pink1-/- rat model of Parkinson Disease

Authors: *J. D. HOFFMEISTER[1,2], C. K. BROADFOOT[4], N. SCHAEN-HEACOCK[2], S. A. LECHNER[3], M. KRASKO[2], A. NISBET[2], J. RUSSEL[2], J. SZOT[2], T. J. GLASS[6], N. P. CONNOR[7], C. A. KELM-NELSON[8], M. R. CIUCCI[5];
[1]Univ. of Minnesota, Minneapolis, MN; [3]Dept. of Surgery | Div. of Otolaryngology, [2]Univ. of Wisconsin-Madison, Madison, WI; [5]Surgery-Otolaryngolgy, [4]Univ. of Wisconsin Madison, Madison, WI; [6]Surgery, [7]361 Goodnight Hall Scott H, Univ. of Wisconsin, Madison, WI; [8]Dept. of Surgery, Div. of Otolaryngology, Univ. of Wisconsin Madison Dept. of Surgery, Madison, WI

Abstract: Vocal deficits are common in Parkinson Disease (PD) and because they do not respond to drugs, targeted vocal exercise is the primary treatment. While exercise improves symptoms for some individuals, many do not respond. To optimize treatment, it is essential to understand the mechanisms by which vocal exercise modifies behavioral and neural function. Previously, we have shown vocal exercises rescue vocal deficits at an early/prodromal timepoint (4 months) in the *Pink1-/-* rat model of PD, and that vocal exercise was associated with increased 5HT immunoreactivity in the hypoglossal nucleus. Here, we extend that work to later timepoints (6 and 10 months of age--midstage) as most patients with PD do not begin vocal exercises until later in the disease. We hypothesized vocal exercise would rescue ultrasonic vocalization intensity at both time points. (Note: as part of a larger study, these rats also underwent tongue training, not discussed here). For both the 6- and 10-month cohorts, *Pink1* -/- rats were randomly assigned to vocal exercise or non-exercise control conditions, and wild type (WT) rats were all assigned to non-exercise control condition. All rats were tested at baseline, and after 8 weeks of exercise or non-exercise training. Vocal exercise used food to reward increased USV intensity, frequency modulation, and complexity. Primary outcomes were USV intensity, average peak frequency, and call complexity. Average peak frequency of frequency-modulated calls was greater for the WT group than for *Pink1-/-* exercise (6-month $p<0.0001$, 10-month $p< 0.05$) and *Pink1*-/- non-exercise (6-month $p<0.0001$, 10-month $p<0.05$) groups. The 6-month *Pink1-/-* exercise group had a greater percentage of complex calls than the 6-month WT group ($p<0.05$). While vocal exercise resulted in greater vocalization complexity at 6-months, this was not observed at 10-months, and intensity was not rescued at 6 or 10 months, contrary to earlier timepoints in this model. Tissue analyses of monoaminergic immunoreactivity in brainstem nuclei are ongoing. These behavioral findings suggest benefits of vocal exercise in PD may be more-beneficial earlier in the disease, and will be considered relative to neural tissue analyses.

Title: Parallel evolution of neuroepigenomic specializations in vocal learning mammals

Authors: M. E. WIRTHLIN[1], I. KAPLOW[1], S. ZHANG[1], T. A. SCHMID[2], M. M. YARTSEV[3], A. R. PFENNING[1];
[1]Computat. Biol., Carnegie Mellon Univ., Pittsburgh, PA; [2]Helen Wills Neurosci. Inst., [3]Bioengineering, Univ. of California Berkeley, Berkeley, CA

Abstract: Vocal behavior is a highly variable behavioral phenotype, ranging from simple grunts and hisses to the complex vocal learning exemplified by human speech. Although the neuroanatomical, electrophysiological, and molecular bases for this behavior are being explored in a handful of species, an overall picture of how genomic differences subserve this trait remain elusive. Here, we assessed the transcriptomic and epigenomic profile of several brain regions

involved in vocal control in a bat species with extensive vocal plasticity (Rousettus aegyptiacus) and compared them to datasets collected from comparable brain regions in rodents, rhesus macaque, and human. Despite the extensive nucleotide sequence turnover resulting from 150 million years of mammalian evolution, we were able to identify conserved sets of regulatory sequences associated with brain region-specific transcriptional specializations, as well as uniquely shared specializations in the vocal control circuits of humans and bats. These findings suggest that there may exist fundamental genetic mechanisms for the evolution of complex vocal behavior, as well as implicating genomic changes in gene regulatory sequences, rather than changes in genes themselves, as a hotbed for the evolution of mammalian vocal-motor behavior.

Sch., Boston, MA; [4]RAND Corp., Santa Monica, CA; [5]Sch. of Publ. Hlth., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Exposure to discrimination has been linked to disruptions in stress reactivity and emotion regulation processes. Chronic stress is a risk factor for emotional dysfunction, including depression, anxiety, and posttraumatic stress (Cano et al., 2016; Brooks Holliday et al., 2018). However, the neural mechanisms by which discrimination ultimately affects mental health remain unclear. Thus, it is important to determine the inter-relationships among discrimination, neural reactivity to stress, and mental health. The acute stress response is mediated by a neural network that consists of the prefrontal cortex (PFC), inferior parietal lobule (IPL), hippocampus, and amygdala. We hypothesized that stress-induced activity within these brain regions would vary with prior exposure to discrimination. Furthermore, changes in the activity of these regions may alter reactivity to future stressors, which may harm mental health. In the present study, adolescent exposure to discrimination was measured at four-time points between the ages of 11

and 19 years. Psychological distress (i.e., depression, anxiety, and posttraumatic stress symptoms) and neural reactivity to acute psychosocial stress were measured when participants were young adults (Mean Age: 20.03). Neural reactivity to stress was assessed in 301 participants using a variant of the Montreal Imaging Stress Task (MIST) during functional magnetic resonance imaging (fMRI). A linear mixed-effects model (LME) compared stress-evoked brain activity to discrimination as a dichotomous variable (i.e., Discrimination versus No Discrimination). Greater neural reactivity was observed within the dorsolateral PFC, inferior and superior parietal lobes, lingual gyrus, and middle temporal gyrus in participants who reported discrimination versus those who reported no discrimination. A secondary LME analysis compared stress-evoked brain activity to discrimination as a continuous variable. Hippocampal reactivity to stress varied negatively with the amount of discrimination experienced. In addition, participants that reported discrimination also reported higher levels of depression, anxiety, and posttraumatic stress. The present results suggest that exposure to discrimination may alter the stress reactivity of brain regions that support emotion regulation processes (e.g., PFC, hippocampus, and IPL). Taken together, the present findings suggest that discrimination may alter neural reactivity to stress, which may in turn have long-term implications for the psychological well-being of those exposed to discrimination.

Title: The relationship between threat sensitivity and anxiety symptoms in community violence exposed urban adolescents

Authors: *A. HEETER, N. LIPANSKI, B. BORG, H. MARUSAK;
Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: Community violence (CV) exposure, defined as witnessing or experiencing acts of violence, is a chief public health concern. Prior research by our group and others demonstrates that adolescents living in urban environments are disproportionately exposed to CV than their non-urban peers, and CV exposure is associated with greater anxiety symptoms in urban youth. Given prior research demonstrating that threat sensitivity may mediate anxiety symptoms in adult and adolescent populations, threat sensitivity may serve as a psychobiological mechanism linking CV to the elevated risk of anxiety in urban youth. Our ongoing survey study examines the impact of CV on anxiety symptoms in urban adolescents exposed to high CV rates to test this

hypothesis. Here, we present a preliminary analysis from this ongoing study on 24 adolescents (*M*±*SD*=15.3±1.3 years; 58% female; 58% Black American) residing in Detroit, Michigan. Youth completed validated measures of CV exposure (Things I Have Seen and Heard scale) and anxiety symptoms (Screen for Child Anxiety Related Disorders; scores >25 indicate a clinically significant anxiety disorder). Threat sensitivity was measured using a novel questionnaire that captures sensitivity to ambiguous (i.e., potential) and unambiguous (i.e., acute) threats via CV-related vignettes. Correlation analyses were conducted on continuous variables. Twenty-three adolescents (96%) reported exposure to some type of CV during their lifetime and had on average six different exposure types. The most endorsed CV items were witnessing adults yelling (92%), an arrest (83%), a beating (75%), and hearing gunshots (75%). Our sample also reported high average anxiety symptoms (M=32±17), with most youth (58%) reporting scores indicative of an anxiety disorder. There was a relationship between reported symptoms of anxiety and threat sensitivity, such that more anxiety symptoms were associated with greater sensitivity to unambiguous but not ambiguous threat. Overall, our results suggest a relationship between sensitivity to acute (i.e., predictable, unambiguous) threat, particularly anxiety in urban adolescents who experience high rates of CV. Heightened sensitivity to unambiguous threats may be adaptive in the short term by allowing potential victims of CV to be on alert and avoid potential danger. However, long-term heightened threat sensitivity may be detrimental. Given that anxiety frequently begins during adolescence understanding the underlying psychobiological mechanisms may lead to better interventions that target threat sensitivity (e.g., cognitive bias modification) to prevent anxiety in at-risk adolescents.

Title: Examination of sex specific behavioral and metabolic effects incurred by acute stress and adult dietary exposure

Authors: *K. SALHANY, Jr., J. GAULIN, J. MELO, Z. DJABAKATIE, A. TOORIE;
Biol., Rhode Island Col., Providence, RI

Abstract: Stress experienced throughout discrete phases of development (i.e., adolescent vs adult period) can confer long lasting effects on neuroendocrine physiology, psychological

function, and metabolism in a sex-specific manner. While the hypothalamus-pituitary-adrenal (HPA) axis mediates basal homeostatic aspects of metabolism, acute stress increases HPA axis activity, which leads to enhanced sympathetic nervous activity and elevated circulating glucocorticoids. Sustained elevations in circulating glucocorticoids are associated with an increased risk of developing metabolic syndrome (MetS) and its associated symptoms (i.e., glucose dyshomeostasis, dyslipidemia, and systemic insulin resistance). MetS can arise independently due to genetic makeup, social constraints, and/or environmental exposures. However, multifactorial interactions, such as gene by environmental interactions or stress by diet interactions, can result in diverse cellular and systemic outcomes serving to protect or predispose against pathologies, including MetS. A Sprague Dawley model of acute restraint stress was utilized to evaluate the sex-specific neuroendocrine, behavioral, and hepatic glucoregulatory metabolic effects occurring as a result of prior stress experience (adolescent vs adult) and adult diet interaction following long-term maintenance on a control or obesogenic (45% fat, 17% sucrose; fat-sucrose diet (FSD)) diet. Preliminary findings suggest that prior stress experience alters diet-induced metabolic and neurobehavioral effects in a sex-specific context.

Title: Early micronutrient supplementation modulates the early-life stress induced alteration in emotional behaviour and hypothalamic DNA methylation in adolescent male mice

Authors: *V. BEGNI[1], K. REEMST[2], J. KOTAH[2], D. CHEISHVILI[3,5], M. SZYF[4], M. RIVA[1], A. KOROSI[2];

Abstract: Exposure to early life stress (ELS) is a well-known risk factor for psychiatric disorders. Emerging evidence suggests a possible role of nutrition in stress-induced enduring alterations in cognitive and emotional functions. In this regard, we have recently shown that ELS reduces the level of the amino acid methionine, a micronutrient essential for methylation. We showed that a short early nutritional supplementation with methyl donor micronutrients (including methionine) can rescue the ELS-induced cognitive impairments and hypothalamic-pituitary-adrenal (HPA) axis hyperactivity (Naninck et al., 2017). We thus set out to study how

such early micronutrient supplementation, with and without a previous ELS exposure, modulates the response to an acute restraint stress (AS) during adolescence. To this end we exposed C57BL/6J male mice to a ELS model consisting of limited bedding and nesting materials from postnatal day 2 to 9. Control (CT) animals were left undisturbed in their home cages (n=45 CT and 45 ELS). During the same period both groups were fed with either standard or supplemented diet. Half of both CT and ELS adolescent animals were then exposed to AS and next tested for anxiety and depressive-like behaviors. The hypothalamus was dissected and processed for genome wide methylation analyses using the Illumina Mouse Methylation BeadChip. At the neuroendocrine level, we observed that neither ELS nor the supplemented diet affects the dynamic of corticosterone release in response to AS. Concerning the behavioral aspect, while only few changes were observed at basal condition (i.e. impaired self-care behavior), following AS a more clear anxiogenic profile was present in ELS-exposed mice (i.e. reduced time spent in the open arms of elevated plus maze and in the light chamber of dark/light box) and the supplemented diet partly prevented these ELS-induced impairments. Finally, at the level of hypothalamic DNA methylation, we observed that AS exposure induced a differential response in DNA methylation profile depending on ELS background. Interestingly, several of the differentially methylated genes belong to the Y chromosome, and the supplemented diet modulated these effects, rescuing the ELS-induced alterations in this response. Altogether, the supplemented diet appears to (at least partially) prevent the observed behavioral alterations. Remarkably it also induces long-lasting effects on hypothalamic methylation levels, which is dependent on ELS history and AS exposure during adolescence. In conclusion, we observed that an early nutritional intervention might modulate the impact of ELS-exposure on coping with stressors later in life.

Title: Lifelong enhancement of body mass from adolescent stress

Authors: *K. M. MORAN, L. F. GONZÁLEZ-MARTÍNEZ, Y. DELVILLE;
Psychology, Univ. of Texas, Austin, Austin, TX

Abstract: In hamsters, exposure to stress in adulthood causes increased body weight. We addressed how social stress during puberty would impact food intake and body weight. Stressed hamsters started gaining significantly more weight than controls after only two days of stress exposure. Over a two-week period, stressed subjects gained 10% more weight and consumed more food than controls. At the end of the stress period, stressed hamsters collected nearly twice as many palatable sugar pellets from an arena than controls. Stressed subjects presented 15-20% more body fat in mesenteric, inguinal, and retroperitoneal fat pads. In order to assess the duration of these effects, we analyzed data from previous studies keeping hamsters for over two months past the stress period in puberty. Our analysis shows that stressed hamsters stopped gaining more weight after the stress period, but their body weights remained elevated for over two months, consistently weighing 10% more than their non-stressed counterparts. We also analyzed conditioning training data collected after the period of stress in late puberty and early adulthood (P56 to P70) that was part of the original studies. Training consisted of lever pressing for palatable food rewards. At these times, previously stressed hamsters retrieved similar numbers of food pellets from the conditioning chambers, suggesting no difference in appetite after the stress period. These data showing a long-lasting effect of stress on body weight may be relevant to studies on the ontogeny of lifelong obesity.

Title: Corticosterone administration in adolescence enhances habit learning in adulthood: Blockade by mifepristone

Authors: *T. M. GADBERRY, M. G. PACKARD;
Psychological and Brain Sci., Texas A&M Univ., College Station, TX

Abstract: Extensive evidence indicates a link between early life stress (ELS) in humans and a subsequent predisposition to psychopathologies that are characterized in part by maladaptive habitual behaviors. Stress and anxiety are factors that can influence the relative use of mammalian memory systems implicated in such disorders. Specifically, cognitive memory functions of the hippocampus are typically impaired by stress/anxiety, whereas habit memory functions of the dorsolateral striatum (DLS) are enhanced. However, these effects have been primarily observed in adult animals, and the effects of stress on these memory systems have not

been extensively investigated in the context of ELS. We have previously observed that administration of the stress hormone corticosterone (CORT) during adolescence enhances subsequent DLS-dependent habit formation in adulthood. The present study was designed to further elucidate the role of CORT in this phenomenon by examining the effects of concurrent administration of the broad steroidal antagonist Mifepristone (MIFP). Four groups of Long-Evans male adolescent rats (PND 37±4) received two peripheral injections daily over five days: first, either MIFP (30mg/kg) or its vehicle, followed by a 15-min interval, then either CORT (5mg/kg) or its vehicle. Subjects then matured into adulthood undisturbed (~3 weeks) before training in a DLS-dependent water plus maze task. In this task, rats were released from different starting positions (i.e. north or south) and were required to make a consistently reinforced body turn response (i.e. always turn right) at the maze choice point to mount a hidden escape platform. Consistent with our previous findings, administration of CORT during adolescence facilitated task acquisition in adulthood relative to controls. However, MIFP given prior to CORT in adolescence blocked subsequent enhancement of habit formation. Finally, rats given MIFP alone did not significantly differ from controls. Taken together, these findings provide further evidence that chronic administration of corticosterone during adolescence can facilitate subsequent DLS-dependent habit formation and highlights glucocorticoid function as a potential underlying mechanism by which ELS may influence habit learning in adulthood.

Title: Adolescent social isolation differentially perturbs adult value-based decision making in female and male mice

Authors: *E. N. HOLLY[1], P. PAREEK[2], M. V. FUCCILLO[1];
[1]Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Drexel Univ., Philadelphia, PA

Abstract: Adolescence is a critical period in social and cognitive development, characterized by rapid increases in exploration, social interaction, and neural connectivity. While social isolation at any developmental stage can have long-term consequences on physical and mental health, mounting evidence demonstrates a profound impact of adolescent social isolation (ASI) on a wide range of behavioral and physiological endpoints in adulthood. Goal-directed behaviors and

value-based decision making are integral in daily function, but the impacts of ASI on these behaviors remain largely unexplored. To model ASI, female and male C57bl6/J mice were bred in house and weaned at P21 into either single or group housing. After P60, mice were trained in a self-initiated operant task consisting of three phases: (1) initiation: entry in a central port initiated the trial, and two retractable levers were extended, (2) choice: mice must respond on one of the levers within 10s, (3) outcome valuation: levers retracted and the outcome was delivered. Responding on the active lever resulted in chocolate or vanilla liquid reward, while responding on the inactive lever resulted in 4s darkness. After 1s intertrial interval, a new trial began. To test initial learning, mice were first trained to respond on one lever. After acquisition, mice were run in a serial reversal task, where the active lever reversed after 8/10 correct responses for 10d. We then probed how mice use information about reward value and temporal costs to guide decision making. To test how ASI affected how mice valued rewards, mice were presented with rewards of varying contrasting volumes (15µl vs 0, 5, or 10µl). Next, to test how costs were integrated into decision making, varying temporal delays (1.5, 3, or 4.5s) were applied to the larger 15µl reward. Preliminary data suggest ASI differentially impacted how female and male mice learned and made decisions about values and costs in adulthood. Compared to socially housed females, ASI female mice acquired the operant task significantly faster, were more explorative in choice behavior throughout the serial reversal task. In contrast, compared to the socially housed males, ASI males took significantly more time to acquire the operant task, but showed increased sensitivity to reward value, more consistently choosing the larger reward even when the reward difference was small and when the temporal cost was high. Together, these data demonstrate long-lasting impacts of adolescent social isolation on adult value-based decision making in both males and females. Ongoing work is building neuroeconomic models to further dissect the impacts of isolation stress on choice behavior.

Title: Acute and persistent sex-dependent effects of social instability stress on anxiety-like and social behaviour in Wistar rats.

Authors: *A. SURAKKA[1], A. ELTAHIR[2], S. MURRAY[2], S. PATEL[2], A. C. HANSSON[1], R. SPANAGEL[1], C. M. MCCORMICK[2];

[1]Central Inst. of Mental Hlth. Mannheim, Mannheim, Germany; [2]Brock Univ., St:Catharine's, ON, Canada

Abstract: In adolescence, the quantity and quality of social interactions shape adult social function. To better understand effects of adolescent social instability stress (SS: 1-hr daily isolation and change in cage mate between postnatal day [P] 30-45) in rats, female and male Wistar rats were tested in adolescence or in adulthood. In the elevated plus-maze (on P46 or P71), SS rats showed reduced anxiety compared to control (CTL) rats, as did females relative to males and adults relative to adolescents. When tested on P47 or P48, SS rats spent less time in social interaction than did CTL rats, and females spent less time in social interaction than did males. Females made more entries into arms (locomotion measure) than males. In the social novelty test (on P48 or P72), SS male rats spent more time in social approach toward a novel peer than toward their cagemate, but only when tested in adolescence. There was no effect of SS in females, although they spent more time near the cagemate than the novel peer. SS rats also made more rears in the test arena and explored the corners more than did CTL rats, In the social memory test (P50 or P74), the three-way interaction was significant, with lower memory performance in SS than CTL males in adulthood. Thus, social instability stress in adolescence in Wistar rats alters the behavioural repertoire, with enduring decrements in social behaviour, enhanced exploratory behaviour, and reduced anxiety-like behaviour.

Title: Adolescent environmental enrichment and social stress modulate expression of the same gene families within both nucleus accumbens and hippocampus in a genetic rodent model of stress vulnerability

Authors: *A. M. O'CONNOR, M. H. HAGENAUER, L. C. T. FORRESTER, E. R. RICHARDSON, F. I. ROB, E. K. HEBDA-BAUER, S. J. WATSON, Jr., H. AKIL; Univ. of Michigan, Ann Arbor, MI

Abstract: Background: Adolescence is a critical period for the development of emotional circuitry and a time of increased vulnerability to environmental influences and stressors. This study examined the impact of adolescent environmental enrichment (EE) and social defeat (SD) stress on gene expression within two emotional brain regions (nucleus accumbens (NACC) and hippocampus (HC)) using RNA-sequencing. These interventions were studied in selectively bred Low Responder (bLR) rats that exhibit elevated anxiety-like behavior and stress vulnerability. **Methods:** From postnatal day 35 (P35) to P60, male bLR rats (generations F49-F56) were placed in a complex social and physical environment for 1 hr/day for 5 days/week (EE group) or kept in standard housing (NIL group). From P61-64, the rats experienced either social defeat within the resident-intruder paradigm (SD group) or were placed in a novel cage (NIL group) for 15 min/day. From P65-67, the rats underwent behavioral testing (P65: open field, P66: social interaction, P67: elevated plus maze), and were sacrificed on P68. Brains were flash-frozen and dissected at -20°C (NACC: hole punch, HC: whole dorsal HC). For each sample, a cDNA library was constructed and sequenced (Illumina NovaSeq S2), producing 50bp paired-end reads. Reads were aligned to genome assembly Rnor6 (STAR) and summarized into counts per transcript (featureCounts: Ensembl 96 annotation). Following quality control and normalization, the final datasets contained ~17,000 transcripts/region, with sample sizes of NACC: n=46 (n=10-14/subgroup) and HC: n=25 (n=5-8/subgroup). Differential expression was calculated using the limma/voom method and a model including technical co-variates (RNA concentration, batch). Results were compared to gene sets related to functional ontology (MSigDB:C5), cell type/anatomy (DropViz, BrainInABlender, HippoSeq), and manipulations in brain tissue (GeneWeaver, Gemma, literature) using a custom .GMT file and fast Gene Set Enrichment Analysis. **Results:** Within both brain regions there was a convergence of differential expression in association with both manipulations (EE & SD) on a set of genes dominated by the protocadherin family and major histocompatibility complex (RT1), as well as an enrichment of effects within gene sets previously linked to stress, social behavior, and cell type. **Conclusion:** Although often treated as opposing interventions, EE and SD share many common features, including social interaction, stress, and a novel environment. Our results indicate that these two interventions can produce both opposing and converging changes in gene expression in emotional circuitry during adolescence.

Title: Molecular and behavioral consequences of social defeat stress in adolescent female mice

Authors: *A. PANTOJA URBAN[1,4], S. RICHER[1,4], A. MITTERMAIER[2], M. GIROUX[4], C. FLORES[3,4];
[1]Integrated Program in Neurosci., [2]Fac. of Sci., [3]Dept of Psych, McGill Univ., Montreal, QC, Canada; [4]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Social stress in adolescence increases risk to psychiatric disorders, including depression, anxiety, and substance abuse. During adolescence, the prefrontal cortex (PFC) is still maturing remaining sensitive to environmental influences. The Netrin-1/DCC guidance cue pathway controls dopamine (DA) axon growth to the PFC across adolescence, by promoting mesolimbic DA axon targeting in the nucleus accumbens (NAc). Using a modified version of the adult mouse accelerated social defeat stress paradigm (AcSD), we demonstrated that AcSD in adolescence dysregulates the Netrin-1/DCC system in mesolimbic DA regions, altering PFC DA development and inducing deficits in inhibitory control in adulthood (Vassilev, Pantoja-Urban, et al., 2021). Given that men and women show differential vulnerability to stress and to psychopathologies of adolescent onset, we adapted our adolescent AcSD model in males to adolescent female mice and assessed whether it (i) induces social avoidance 24 h later, (ii) regulates Netrin-1/DCC expression in pre- and postsynaptic components of mesolimbic DA circuitry one week later, and/or (iii) alters behavioral inhibition in adulthood. Adolescent C57BL/6J female mice were introduced, twice a day, to aggressive CD-1 mice for 4 days. A social interaction test was used to measure social avoidance behavior and to categorize them as "resilient" or "susceptible". Sample size for each experiment: control (n=10) and social defeat stress (n=15). Levels of *Dcc* mRNA were quantified in the ventral tegmental area (VTA) using qPCR. Behavioral inhibition was measured using the Go/No-Go task. As we found in adolescent male mice, the majority of adolescent females exposed to AcSD do not show social avoidance. This proportion was not determined by the CD-1 aggression, since the number of attacks did not differ between female resilient and susceptible groups across all stress sessions. In adulthood, female mice that showed a social avoidance resilient phenotype in adolescence, display deficits in cognitive inhibition compared to control groups. Instead, female mice that showed social avoidance in adolescence seem to be protected against cognitive dysfunction. Adult female mice exposed to AcSD in adolescence do not differ in their locomotor activity or motivation to work for a food reward. The expression of *Dcc* mRNA in the VTA, contrary to males, does not differ across female groups. We are currently examining Netrin-1 expression in the NAc and assessing DA connectivity in the PFC. These results suggest that the effects of social stress in adolescence

on cognitive and metabolic function may be sexually dimorphic and involve different molecular processes.

Title: Chronic social defeat during adolescence increases depression-like behaviors and induces long-lasting learning and memory impairments in male Swiss Webster mice participation of adrenal and gonadal axes

Authors: *H. MANCHA-GUTIÉRREZ[1], E. M. ESTRADA-CAMARENA[2], L. MAYAGOITIA-NOVALES[2], E. LOPEZ-PACHECO[1], C. LOPEZ-RUBALCAVA[1]; [1]CINVESTAV-IPN, Mexico City, Mexico; [2]Inst. Nacional de Psiquiatría, Mexico City, Mexico

Abstract: Chronic stress exposure during adolescence is a significant risk factor for the development of depression. Chronic social defeat (CSD) is an animal model of depression with excellent ethological, predictive, discriminative and face validity. Because the CSD model has not been thoroughly examined as a model of stress-induced depression within the adolescence stage, we evaluated the short and long-term behavioral and neuroendocrine effects of the CSD during early adolescence. To do this, male Swiss Webster (SW) mice at postnatal day (PND) 28 were exposed to ten consecutive days of CSD (PND28-37), control mice were handled daily. Twenty-four hours (mid-adolescence) or four weeks (early adulthood) after the CSD, independent groups of mice (n=7) were tested in the social interaction test (SIT), the forced swimming test (FST), or in the Barnes maze. After that, their brains (n=4) were obtained for serotonin transporter autoradiography. Independent groups of mice (n=3) were euthanized (at five days intervals) before, during, and after the CSD to obtain trunk blood for serum hormones (corticosterone and testosterone) immunoassays. The CSD during early adolescence induced 1) enduring depression-like behaviors as inferred from reduced social interaction ratio (social avoidance) in the SIT and increased immobility behavior (behavioral despair) in the FST, moreover, the CSD-induced depression-like behaviors correlated in an age-dependent manner with the SERT binding in the hippocampus, 2) long-lasting learning and memory impairments as deduced from increased primary latencies to find the escape box in the Barnes maze, and 3)

higher levels of serum corticosterone in both mid-adolescence and early adulthood and lower levels of serum testosterone from mid to late adolescence. Overall, our results 1) show that CSD during early adolescence induced long-lasting depression-like behaviors and reveal the critical and age-dependent role of SERT in the normal brain development, as well as in the development of pathological behaviors, 2) show that CSD during early adolescence induced enduring cognitive deficits, and 3) highlight the vulnerability of the interaction between adrenal and gonadal axes, evidencing the importance of adequate interaction between these axes during adolescence for the normal brain and behavioral development.

Title: Alteration of the α5 GABA receptor and 5HTT lead to cognitive deficits associated with major depressive-like behaviors in a 14-day combined stress rat model

Authors: *G. NGOUPAYE[1,2], M. MOKGOKONG, Jr[2], T. MADLALA, Jr[2], M. V. MABANDLA[2];
[1]Univ. of Dschang, Dschang, Cameroon; [2]Univ. of Kwazulu Natal, Wesville, South Africa

Abstract: Introduction: Current models used to study the pathophysiology of major depressive disorder (MDD) are laborious and time consuming. This study examined the effect of a 14-day combined stress model (CS; corticosterone injection (40mg/kg, s.c.) and chronic immobilization stress for 14 days) versus a 28-day corticosterone only model (daily injection of 40mg/kg corticosterone for 28 days) on 1) depressive-like behaviour and cognitive deficits, 2) serotonergic and GABAergic systems of the hippocampus and prefrontal cortex (PFC), regions implicated in the pathophysiology of MDD in adult male Sprague Dawley rats. **Materials and methods:** Depressive-like behaviors and cognitive deficits were assessed in the forced swim test (FST), sucrose preference (SPT), Morris water maze (MWM) and novel object recognition (NORT) tests. Effects of the stress model on the GABAergic and serotonergic systems were measured using real-time PCR and ELISA respectively to detect expression of , α5 $GABA_A$ receptor, the serotonin transporter (5-HTT), the serotonin 1A receptor ($5\text{-}HT_{1A}$), and the concentrations of corticosterone (plasma), GABA and acetylcholinesterase (AChE) in the hippocampus and Prefrontal cortex (PFC). **Results:** Findings revealed that the CS group showed

increased immobility time in the forced swim test, time to reach the Morris water maze (MWM) platform, higher corticosterone level, and increased expressions of hippocampal and PFC 5-HT_{1A} and α5 $GABA_A$ receptors, and AChE compared to their control groups. In contrast, reductions in sucrose preference ratio, discrimination index in NORT, time in MWM target quadrant, and expression of hippocampal 5-HTT was noted relative to their control group. Compared to the 28-day corticosterone only group, PFC 5-$HT_{1A,}$ Hippocampal 5-HTT were reduced, while PFC 5-HTT, Hippocampal α5 $GABA_A$ receptors, and Hippocampal α5 $GABA_A$ receptors, and AChE concentrations were higher in the CS group. **Conclusion:** Our CS model induced depressive-like behavior with early cognitive deficits in rats affecting both hippocampus and PFC. The CS model may be useful in investigating new and comprehensive treatment strategies for MDD. **Key word:** Combined stress, Depression, Cognitive deficit, , α5 GABA receptors, GABA, 5-HT_{1A}, 5-HTT.

Title: Early Life Stress Inoculation Effects on Adult Anxiety-Related Behaviors

Authors: *O. AKINBO[1], L. MATUSZEWICH[2], A. J. GRIPPO[3];
[2]Dept. of Psychology, [1]Northern Illinois Univ., Dekalb, IL; [3]Dept of Psychology, Northern Illinois Univ. Dept. of Psychology, Dekalb, IL

Abstract: Stress is frequently discussed in the context of its harmful psychological and physiological effects. However, mild stressors may also build resiliency when encountering intense stressors later. This stress inoculation creates a buffering effect to reduce the negative outcomes associated with later stress. Rodent models have been used to investigate the resilience-promoting effects of early life inoculation protocols, such as brief handling by an experimenter. Further, environmental enrichment (EE) that involves exposure to small toys and access to physical exercise, may promote stress resilience by decreasing anxiety and depressive-like behaviors. The socially monogamous prairie vole is an ideal model to investigate whether stress inoculation protects against social stress given their social structure of pair bonding, living in family groups, and demonstrating negative behavioral and physiological responses to social stressors. The current study investigated if anxiety-like behaviors would be reduced during adulthood after early life exposure to either (EE) or brief handling. Male (n=24) and female (n=24) prairie voles were randomly assigned to either EE continuously (n =8/sex) or 10 seconds

of cup handling daily (n=8/sex) for 7 days, or left unmanipulated (n=8/sex) during the early life period [postnatal (PND) day 29-35]. On PND36, animals underwent a 4-week social isolation period and subsequently a 5-minute open field test. Preliminary data analyses indicate that EE animals spent significantly more time grooming in the open field compared to both unmanipulated and handling groups, with no sex effect. This observation may support prior research that EE reduces anxiety-like behaviors in socially isolated prairie vole adults. However, center section exploration was slightly reduced in EE and handling groups vs. the unmanipulated group, which may indicate slightly increased anxiety. It is possible that the lengths of the early life manipulations may need to be increased to achieve stress-resilience effects on anxiety-related behaviors, as seen in 21-day manipulations (Pryce et al., 2001, 2003), or that the manipulations may be more harmful than helpful when presented at an early age. This study provides a foundation for investigating potential early life manipulations to promote stress inoculation against social stressors in the prairie vole model. Further, the clinical implications may provide deeper insight into the effectiveness of early life resiliency strategies as forms of protection against adulthood social stress.

Title: The effect of early life trauma on amygdalar corticotropin releasing factor (CRF) expression and later life pain sensitivity

Authors: J. ZUKE, *M. BURMAN;
Univ. of New England, Biddeford, ME

Abstract: Increases in neonatal intensive care unit (NICU) admissions over the past several decades are likely responsible for the concomitant drop in infant mortality. However, the experiences these infants endure in the NICU leave them vulnerable to later life psychological disorders such as anxiety and depression. Utilizing a rodent model, our lab explores how a common NICU procedure (maternal separation, handling, and needle pricks to the paw) 4 times daily for the first 7 days of life, alters behavior and CRF receptor expression in juvenile rats. We've previously demonstrated that neonatal pain increases amygdala CRF expression during our neonatal manipulations. Additionally, we've observed that neonatally manipulated rats

display reduced amygdala CRF expression as juveniles. Moreover, rats that receive neonatal pain demonstrate reduced anxiety or fear during the early juvenile period, but demonstrate a stress-induced tactile hypersensitivity following a foot-shock stessor. We consider this a two-hit process, in which the neonatal pain creates a vulnerability to a pain-like state that is activated by the occurrence of later-life stress.The current studies further this work in two regards. First, we examine whether neonatal pain alters amygdala CRF receptor expression, in addition to altering the expression of CRF itself. Second, we also investigated whether a physiological stressor (Hind paw incision) is sufficient to produce the juvenile hypersensitivity. In Experiment 1: juvenile rats that experienced neonatal pain (or not) were subject to a secondary psychological stressor (using electric shock stress) or left undisturbed (basal) during the juvenile stage. Brain tissue was collected to examine amygdalar CRF receptor (receptors 1 and 2) expression using RNAscope® in situ hybridization (ISH). These results were quantified (number of cells, luminance of expression and area expressing) and compared to our previous ISH work quantifying CRF expression in the basolateral and central nucleus of the amygdala. In Experiment 2: juvenile rats that experienced neonatal pain (or not) were subject to a secondary physiological stressor (hind-paw incision) or left undisturbed (basal) during the juvenile stage. Subjects were tested in both a 2-day thermal conditioning place preference assay and single day hind paw weight bearing assay during the juvenile period. Only rats that received neonatal pain and the hind paw incision demonstrated a significant avoidance of the previously hot side, consistent with enhanced sensitivity. Together, these studies add to the growing that amygdalar CRF mediates the effects of neonatal trauma on subsequent pain sensitivity.

Title: Sex differences in cholinergic regulation of dopamine release mediate sexually dimorphic behavior

Authors: *L. J. BRADY[1,2], J. TAT[3], K. C. THIBEAULT[4,2], S. O. NOLAN[1,2], C. A. SICILIANO[1,4,2], E. S. CALIPARI[1,2,4];

Abstract: The mesolimbic dopamine system is involved in the expression of sex-specific behaviors and is a critical mediator of many psychiatric disease states. While work has focused on sex differences in the anatomy of dopamine neurons and relative dopamine levels, an important characteristic of dopamine release from axon terminals in the nucleus accumbens (NAc) is that it is rapidly modulated by local regulatory mechanisms independent of somatic activity. One of the most potent regulators of dopamine terminal function is through nicotinic acetylcholine receptors (nAChRs). In the NAc dopamine is released in tonic (slow and regular) and phasic (short, burst/spikes) patterns that are subject to heavy modulation by cholinergic (ChAT) systems through α4β2* containing nAChRs located directly on dopamine terminals. However, our understanding of the interaction between the ChAT and dopamine systems has been completed almost entirely in male subjects and our preliminary data show that this interaction is fundamentally different in females. Using ex-vivo fast-scan cyclic voltammetry combined with pharmacological antagonism of α4β2*-nAChRs with DhβE in NAc slices from males, naturally cycling (intact) and ovariectomized females, we find that ChAT regulation of dopamine release through nAChRs is not present in intact female mice. Deficits in nAChR modulation of dopamine release in intact females are not affected by the estrous cycle but can be rescued by ovariectomy – indicating that ovarian hormones play a role in this process. Previous work has shown that estradiol (E2) has affinity for nAChRs; however, these studies have shown that E2 is capable of inducing nAChR-mediated currents in cell culture and the consequences of these effects on dopamine release remain to be explicitly defined. We find that E2 increases dopamine release acutely, an effect that is blocked by antagonism of α4β2-nAChRs. Finally, we observed sex-specific effects of ChAT interneuron activity on reward-seeking behavior using Gq-DREADDs injected into the NAc of ChAT-cre$^{+/-}$ mice to selectively activate ChAT interneurons during positive reinforcement operant conditioning with sucrose. Overall, we show that circulating ovarian hormones alter the ability of α4β2*-nAChRs on dopamine terminals to modulate dopamine release in the NAc suggesting that sex differences in ChAT regulation of dopamine neurotransmission underlies sex-dependent differentiation in reward learning. Moving forward it will be critical to directly link these sex-differences to reward processing and reinforcement learning for the development of sex-specific pharmacotherapies to treat a variety of psychiatric disorders.

Title: The effects of homeostatic-related peptides in the nucleus accumbens shell on palatable feeding in the rat, with and without concurrent μ-opioid receptor stimulation

Authors: *W. E. PRATT, A. E. CARNEY, C. DO, A. M. GROOME, A. J. SMITH, C. J. CALAFIORE;
Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: Amongst its many important motivational functions, the nucleus accumbens (NAc) is central for regulating consumption of food based upon palatability, promoting intake on sweet and fatty foodstuffs high in caloric density that are hedonically pleasing. Nonetheless, the medial NAc shell receives inputs from the hypothalamus that indicate current energy state via release of the homeostatic-related peptides NPY, AGRP, CART, αMSH, orexin/hypocretin, and MCH, although the function of these signals on palatable feeding is not well-studied. This project examined if these homeostatic-related peptides affect feeding through direct actions on the medial NAc, and if they may interact with regional μ-opioid receptor signaling (known to enhance both hedonic responses to sugar solutions and increase food intake). 23 gauge stainless steel guide cannulas were surgically implanted bilaterally above the anterior medial NAc shell of male Sprague-Dawley rats. After recovery, non-restricted animals were given access to a high fat/sucrose diet for daily 2-hr feeding sessions. Food intake, water intake, and locomotion were monitored. Once each group of animals (N= 8/group) was acclimated to the feeding chamber and injection procedures, rats received bilateral NAc injections of vehicle (0.5 μl/side) or one homeostatic-related peptide, counterbalanced across days. On separate treatment days (all separated by at least 48 hrs), each group also received peptide injections with or without co-administration of the μ-opioid receptor agonist DAMGO (0.025 μg/side). NAc injections of the orexigenic peptide NPY (0, 0.67, and 1.0 μg/side) increased intake of the sweetened fat diet during the 2-hr session, both alone and when co-administered with DAMGO. AGRP (up to .94 μg/side) had no effect on palatable feeding within the session, though AGRP treatments led to weight gain over the next 24 hrs. Orexin A injections (at 3.56 μg/side) increased sweetened fat diet intake, but did not enhance the pro-feeding effect of μ-opioid receptor stimulation of the region. MCH did not significantly increase feeding on its own, but caused a biphasic effect on DAMGO-elicited intake, significantly decreasing consumption at 0.5 μg/side and enhancing it at 1.0 μg/side. The anorectic peptide CART (at 1.0 μg/side) inhibited feeding with and without DAMGO coinfusion, and reduced body weight in the next 24 hrs. αMSH had no significant effects on consumption of the sweetened fat diet. These findings suggest that homeostatic-related signals from the hypothalamus to the NAc have various and distinct effects on the consumption of palatable diets, in some cases modulating μ-opioid receptor stimulation of feeding.

Title: Role of rD4 receptors on the consumption of a sucrose solution and the appetite process

Authors: S. HERNÁNDEZ-CORREA, V. E. LÓPEZ-ALONSO, F. CORTÉS-SALAZAR, *R. E. ESCARTÍN-PÉREZ, J. M. MANCILLA-DÍAZ, ***D. DÍAZ-URBINA**;
Lab. of Neurobio. of Eating, UNAM-FES Iztacala, Tlalnepantla de Baz, Mexico

Abstract: Ingestion of sugar solutions induces binge-eating behavior (BEB). Moreover, the dopamine D4 receptor (rD4) is implicated in the preference for palatable diets. However, whether the central rD4 modulate the consumption of a palatable solution, altering the behavioral process controlling feeding has not been explored yet. Here we explored the preference for a sucrose solution (5%, 10% and 20% sucrose) in rats and then we evaluate the effect of the central blocking of rD4 on the microstructure of drinking behavior in satiated rats with access to a sucrose solution. In the first experiment, Wistar male rats had 7 days of access to the 3 sucrose solutions at onset of the light phase for one hour. We measured the consumption (1h) and the microstructure of drinking behavior of each solution, and a clear preference for the 20% solution was observed. The microstructure of drinking analysis indicated the increase of frequency and duration of bouts, and increase of meals and time-inter meals, which suggest the affectation of the appetite process, delaying the satiety development. In the second experiment, Wistar male rats had one hour of access only to the 20 % sucrose solution. After 10 days, animals received an intracerebroventricular injection of vehicle or the rD4 selective antagonist L745870 (1µg/5µl or 2 µg/5µl). We observed that L745870 (1 and 2 µg) decreased the sucrose consumption (g/1h). L745870-2µg increased bouts frequency but decreased the duration of bouts, time-inter bouts, and meal size, suggesting the decrease of the appetite for the solution. Togheter this findings suggest that rD4 are involved in the regulation of palatable solutions, suggesting a potential use of the rD4 for the treatment of BEB or obesity

Title: The mGluR2 agonist LY379268 reduces sucrose taking, seeking, and motivation in male and female rats

Authors: *J. W. GRIMM, F. SAUTER, D. MACDOUGALL, E. SPAULDING, K. STENSGAARD, M. HARDY, K. R. GRIFFIN, B. MARX;
Psychology and Program in Behavioral Neurosci., Western Washington Univ., Bellingham, WA

Abstract: There are sex differences in the prevalence and severity of substance use disorders and in disordered eating and obesity rates. However, preclinical assessment of pharmacotherapies for the addiction behaviors underlying drug and food addiction, such as craving, have been conducted primarily with male rodents. For example, Bossert et al. (PMID 16834996) found that the mGluR2 autoreceptor agonist LY379268 reduced sucrose-seeking, but not sucrose-taking, in male rats. The aim of the present study was to explore the generality of the anti-craving ("anti-seeking") effect of LY379268 across sexes. In addition, the effect of the drug on motivation to receive sucrose was assessed using a progressive ratio (PR) schedule of reinforcement. Different groups of adult male and female Long-Evans rats (N = 91) were challenged with LY379268 in three experiments: 1.) fixed ratio (FR) schedule of reinforcement (taking), 2.) extinction of responding previously reinforced on the FR (seeking), or 3.) responding reinforced on a progressive ratio (PR) schedule of reinforcement (motivation). For each experiment, rats first responded for 10% liquid sucrose on a FR in 10 daily 2-h sessions. For the PR study, this was followed with training on a PR for 7 daily 3-h sessions. Rats were then challenged in a counterbalanced order with LY379268 (0, 1.5, 3, 6 mg/kg; IP; 30 minute pretreatment) on test days followed by either three reacquisition days of FR (experiments 1 and 2) or PR (experiment 3) responding. Female rats responded at a higher rate for sucrose on both the FR and PR. LY379268 reduced responding in a dose-related manner in all three experiments. There were no clear sex-specific effects of the drug on responding. These findings replicate previous findings of sex differences in sucrose taking, seeking, and motivation. The generality of the anti-taking, -seeking, and -motivation effects of LY379268 across male and female rats support further evaluation of this and other compounds that modulate synaptic glutamate as potential anti-addiction pharmacotherapies.

Title: Exercise tendencies modulate changes to opioid or exercise-induced reward

Authors: *A. R. TITUS;
Univ. of Missouri St. Louis, St. Louis, MO

Abstract: Reward changes were observed in rodents with different exercise tendencies by utilizing the conditioned place preference (CPP) paradigm. Colleagues at the University of Missouri - Columbia established three distinct genotypes with reliable phenotypes among Wistar rats: low volume runners (LVR), high volume runners (HVR), and wild-types (WT). Adult male Wistar rats from each of these groups were given a rewarding stimulus of either access to a running wheel or an injection of morphine. Results indicated that there was no difference in the strength of CPP between the rewarding stimuli. Extinction was significantly more effective in LVR than HVR and WT animals, as LVR animals spent a lower percentage of time in their assigned conditioning chambers after eight days of exposure to the CPP paradigm without a rewarding stimulus. It was confirmed that running wheel access and opioid administration were comparably rewarding in all groups. The conclusion is that, compared to HVR and WT, LVR animals with their different genotypes and phenotype also have a unique pattern of behavioral responses to an opioid and to running.

Title: Impact of prenatal escitalopram on probabilistic reversal learning and social approach in male and female offspring

Authors: *J. BEZENAH[1], A. TEJADA[1], G. KELLY[1], M. ESPINOSA[1], L. R. AMODEO[2]; [1]Psychology, California State University, San Bernardino, San Bernardino, CA; [2]Psychology, California State Univ. San Bernardino, San Bernardino, CA

Abstract: Selective serotonin reuptake inhibitors (SSRIs) are frequently used during pregnancy and while SSRIs are considered safe during pregnancy, there is limited knowledge of the long-term consequences of perinatal SSRI exposure on cognitive and behavioral development. SSRIs increase extracellular serotonin (5-HT), which contributes to their clinical effectiveness in major depressive and anxiety-related disorders. However, this hyper-serotonergic state during pregnancy can be transferred from the mother to the fetus through the placenta, causing potential alterations in neurotransmission and neural functioning. Further, recent human studies have demonstrated prenatal exposure to SSRIs in humans may increase susceptibility to autism spectrum disorder (ASD) and developmental delays. In a recent systematic review and network meta-analysis comparing the efficacy and acceptability of antidepressant drugs, escitalopram was shown to be one of the most effective antidepressants. However, as one of the newer SSRIs on the market introduced in 2002, there is still a lack of information on its safety profile during pregnancy. This study focused on behavioral flexibility, repetitive behaviors, and social behavioral deficits seen in ASD individuals. To this end, we administered escitalopram (0 or 10 mg/kg, s.c.) to nulliparous female Long-Evans rats for the first (E0-10) or last half (E11-20) of the embryonic period. Young adult male and female offspring were subsequently tested on a battery of behavioral tasks including probabilistic reversal learning task, open field conflict, marble burying and socialapproach task. Preliminary results demonstrate that prenatal escitalopram sex-dependently alters open field conflict, marble burying, and reversal learning but has noimpact on social behaviors

Title: Serotonin 1B receptor mediated impulsivity is associated with increased subjective reward valuation

Authors: *S. S. DESROCHERS, K. M. NAUTIYAL;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Dysregulation of impulsive behavior is an important characteristic of many different psychiatric disorders, including ADHD and conduct, gambling, and substance use disorders. However, disordered impulsivity may be caused by the dysregulation of several different behavioral and cognitive substrates. Our prior preclinical studies have demonstrated that adult mice lacking serotonin 1B receptor expression (5-HT_{1B}R; tetO1B model) have increased impulsive action (e.g. inability to withhold responding) in tests such as the Go/No-go, as well as enhanced preference for larger rewards, but no difference in impulsive choice (e.g. intolerance to delays), making it an ideal model for studying the underlying causes of one kind of impulsivity. In the present results, we first confirm prior impulsive action findings using a different paradigm: the 5-choice serial reaction time test (5CSRTT). Mice lacking the 5-HT_{1B}R have increased premature responding (a measure of impulsive action), but show no differences in measures of attention. We hypothesize that this impulsive action phenotype is the result of changes in reward processing, specifically causing increased valuation of palatable substances and a subsequent inability to withhold responding for reward. Therefore, to directly examine reward valuation, we next studied hedonic responding for different concentrations of a palatable reward in a brief access lickometer protocol. Mice lacking the 5-HT_{1B}R reach maximum licking at relatively lower concentrations of reward than controls, indicating increased 'liking'. Finally, we examined how reward-associated stimuli influence behavior with a modified Pavlovian-to-instrumental transfer (PIT) test, where classically conditioned reward paired cues were subsequently used as an instrumental outcome. There are no genotype differences in acquisition of Pavlovian responding, but interestingly 5-HT_{1B}R knockout mice show enhanced instrumental responding for reward paired cues, which could be due to a subjectively increased reward value associated with the cue. Future work using variable reward amounts in wild type mice will more generally address how reward value impacts behavior this modified PIT test. Together these data suggest that an absence of 5-HT_{1B}R expression not only increases impulsivity, but also causes more general changes in subjective reward valuation. To determine whether these behavioral results are due to developmental or on-line adult mechanisms, data from an adult rescue of 5-HT_{1B}R expression are forthcoming.

Title: The role of lateral hypothalamic orexin-glucose inhibited neurons in reward-based feeding

Authors: *S. TEEGALA[1], K. D. BECK[2], V. H. ROUTH[3];
[1]Pharmacology, Physiol. & Neurosciences, Rutgers, Sch. of Grad. Studies, Newark, NJ; [2]Neurosci., East Orange VAMC/NJ Med. Sch., East Orange, NJ; [3]Pharmacology, Physiol. & Neurosciences, Rutgers, Newjersey Med. Sch., Newark, NJ

Abstract: Weight loss maintenance rarely succeeds suggesting that lasting changes occur in brain circuitry controlling food intake. Lateral hypothalamic area (LHA) orexin neurons drive "reward-based" feeding by activating the ventral tegmental area (VTA) dopamine (DA) neurons. LHA orexin neurons are inhibited by glucose (GI neurons). Weight loss decreases levels of the satiety hormone leptin and increases the orexigenic hormone ghrelin. Ghrelin directly enhances, while leptin suppresses the activation of orexin-GI neurons in low glucose. Increasing LHA glucose after weight loss blunts motivation for food reward. Based on these data, we hypothesize that *preventing changes in the glucose sensitivity of LHA orexin-GI neurons following weight loss blunts reward-based feeding and aids in weight loss maintenance.* We will first determine if glucose and ghrelin converge on the same signaling pathway in orexin-GI neurons. We found that pertussis toxin (PTX; 100 ng/ml), a G-protein coupled receptor (GCPR) inhibitor, blocked the effect of low glucose ($p<0.001$) in mice. PTX predominantly blocks Gαi/o which is negatively coupled to adenylate cyclase (AC) and it's downstream effector, protein kinase A (PKA). In support of this, the PKA inhibitor, Rp-cAMP (10μM) blocked the effect of low glucose (N=5 mice, $p<0.05$) on orexin-GI neurons while inhibition of protein kinase C (PKC; coupled to Gαq) did not. These data suggest that the inhibitory effect of glucose is due to a Gαi/o-mediated reduction in AC activity and that reducing glucose relieves this inhibition, allowing AC to activate PKA. We found previously that a 24-hr fast (high ghrelin/low leptin) increased activation of LHA orexin-GI neurons in low glucose and induced glutamate plasticity on VTA DA neurons. Here, we determined if weight loss also enhances glutamate transmission on VTA DA neurons. Compared to control adlib fed mice, mice weight restricted to 85% of their original body weight increased the amplitude of glutamatergic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) currents (N = 6 mice, $P<0.05$), and the AMPA/N-methyl-D-aspartate (NMDA) receptor current ratio ($p<0.010$) on VTA DA neurons. Dialyzing glucose into the LHA of weight restricted rats during a progressive ratio test significantly reduced the number of active lever presses (N=6 rats, $p<0.01$) and breakpoint ($p<0.001$) for sucrose. These data suggest that weight restriction leads to persistent changes on VTA DA neurons by decreasing the glucose sensitivity of orexin-GI neurons and inhibiting these neurons could prove beneficial in long-term weight loss maintenance.

Title: Glucagon-like Peptide-1 (GLP-1) Signaling in the Ventral Tegmental Area (VTA) Mediates Neuropeptide-Y (NPY) and Ghrelin Stimulated Operant Responding for Food and Alcohol Reward

Authors: *K. J. COLVIN, A. M. BRIGANDE, O. DAO, J. G. DARWICH, P. J. CURRIE; Psychology, Reed Col., Portland, OR

Abstract: Glucagon-like peptide-1 (GLP-1) is a gastric and brain derived neuropeptide recently implicated in natural reward and drug-induced euphoria. GLP-1 receptors are expressed throughout the brain, including mesolimbic neurons of the reward circuit. Here, it is hypothesized that GLP-1 interacts with additional brain peptides to alter reward salience. In the present study, we investigated the impact of the GLP-1 agonist, exendin-4 (Ex-4), on the stimulatory effect of neuropeptide Y (NPY) and ghrelin in relation to food and alcohol reward. In order to probe the interaction effects of GLP-1, NPY, and ghrelin within the ventral tegmental area (VTA), we measured alcohol intake or operant responding for sucrose pellets after the administration of GLP-1 and NPY, GLP-1 and ghrelin, or GLP-1 with combined NPY-ghrelin treatment in male Spraque-Dawley rats. Rodents were stereotactically implanted with guide cannulae to permit direct VTA administration. After training on a progressive ratio 3 (PR3) schedule, animals were first injected with Ex-4 into the VTA at doses 0-0.1 µg. Rats were then immediately injected with NPY (0-300 pmol) and/or ghrelin (0-200 pmol). Separate rats were administered similar treatment and then tested in an alcohol two-bottle choice paradigm. Our findings indicated that while NPY and ghrelin stimulated operant responding for sucrose pellets and increased alcohol intake, Ex-4 suppressed intake, and more importantly, significantly reduced the NPY and ghrelin-stimulated sucrose pellet and alcohol consumption. Overall, our findings suggest that VTA NPY and ghrelin administration increase operant responding for food and alcohol reward and that these effects are attenuated by VTA Ex-4 pretreatment. These data provide compelling evidence that central GLP-1, NPY, and ghrelin systems interact within the brain to modulate reward salience.

Title: Effects of CB2 receptor activation in the anterior cingulate cortex on motivation for a sucrose solution

Authors: E. M. HERNANDEZ-MORALES[1], J. C. RODRIGUEZ-AGUILAR[2], N. F. ROMERO-OCHOA[1], F. CORTÉS SALAZAR[1], V. E. LOPEZ-ALONSO[1], ***R. E. ESCARTIN-PEREZ**[1];

Abstract: Researchers in the area of Neurobiology of obesity have focused on the brain mechanisms that regulate eating behavior to understand the neuronal processes, which contribute to abnormal weight gain. The areas of the reward circuit and those related to emotional regulation are fundamental, and one of the anatomic sites where the activity of such circuits converges is the anterior cingulate cortex (ACC), where cannabinoid neurotransmission has important neuromodulatory activity. Although it is well established that CB1 receptors (CB1r) consistently stimulate the consumption of hypercaloric and palatable food, contributions of CB2 receptors (CB2r) in this phenomenon are not yet completely clarified. To our knowledge, there are only a few reports that CB2r activation produces opposite effects to those produced by CB1r activation and that these effects are observed several hours after CB2r activation. Consequently, to evaluate the contribution of the CB2r of the rat ACC on the motivation for palatable food, we propose the hypothesis that the activation of CB2r would decrease the motivation for a sucrose solution (10%). Male Wistar rats (190-230 g, n= 12) were trained with a sequence of operant conditioning programs, starting with a fixed ratio 1 (FR1, 30 min), then with a fixed ratio 5 (FR5, 30 min), and finally with a progressive ratio program (RP, response ratio= $[5e^{(0.2 \times \text{trial number})}] - 5$) to measure motivation for the sucrose solution. PR sessions finished when the subject failed to obtain at least one reward in 60 min or in absence of responses in a 4-min period. Microinjection cannulas were stereotaxically implanted unilaterally in the ACC, and subjects received intra-ACC injections of vehicle (0.9% saline, 5% DMSO) or the CB2r agonist (GW405833, 0.25 µg). The effects of CB2r activation were evaluated in independent subjects at two different periods, 15 minutes and 8 hours after intra-CCA injections. We measured the response rate (lever presses/min), the total number of responses, and the breakpoints (number of lever presses to obtain the last reward) under the PR program. Our results showed that activation of CB2r did not produce significant effects on the breakpoints, and we only observed a tendency to decrease the motivation for the sucrose solution. However, when we analyzed the lever presses rate, we found that 8 hours after intra-ACC administration of GW405833, the percentage of responses per minute significantly decreased. Our results are consistent with the hypothesis that the activation of cB2r in the ACC may affect the reinforcing value of the sucrose solution. However, these effects are not detectable in the hour after the administration of the agonist.

Title: Morphine accumulates in the mouse retina following systemic injection

Authors: *N. BERGUM[1], M. LAMCZYK[2], J. VIGH[2];
[2]Biomed. Sci., [1]Colorado State Univ., Fort Collins, CO

Abstract: Melanopsin-expressing intrinsically photosensitive retinal ganglion cells (ipRGCs) mediate the entrainment of mammalian sleep-wake rhythms to environmental light. Interestingly, recent mouse studies from our lab revealed that ipRGCs express functional μ-opioid receptors (MORs), the primary molecular target for opioid analgesics. Furthermore, MOR agonists can directly inhibit ipRGC firing, which could prevent ipRGCs from regulating sleep-wake rhythms in response to light. In humans, opioid metabolites can be detected within eye following opioid use. However, it remains unclear whether opioids accumulate in the mouse retina following systemic exposure. To confirm the fidelity of a mouse model for studying how opioids might affect sleep-wake behavior via ipRGCs *in vivo*, we set out to investigate whether morphine reaches the mouse retina following systemic delivery. We collected tissue (retina and serum) from the adult male mice (2-4 months) at 8 different time points over a 12-hour period (n=8/time point) following a single 20 mg/kg intraperitoneal morphine injection. Morphine levels in serum and retina were measured using liquid chromatography-tandem mass spectrometry. Thus, we were able to establish a pharmacokinetic profile of morphine in the retina relative to serum. While morphine levels were high in both tissues initially, morphine persisted in the retina whereas serum morphine levels decreased to near undetectable levels after three hours. Interestingly, results from this study not only show that systemically administered morphine is deposited in the retina, but also that morphine remains there long after the drug has been metabolized in the blood. This supports the idea that opioids could persistently activate MOR on ipRGCs, altering the ability of ipRGCs to transmit light information to the brain's sleep-wake circuitry.

Title: Glucagon-like peptide-1 analog reduces heroin seeking and taking in rats

Authors: J. DOUTON, N. HORVATH, A. HAJNAL, ***P. S. GRIGSON**;
Neural and Behavioral Sci., Penn State Univ. Col. of Med., Hershey, PA

Abstract: Drug addiction is a chronic brain disease characterized by the uncontrolled use of a substance. Due to its relapsing nature, addiction is difficult to treat, as individuals can relapse following even long periods of abstinence and, it is during this time, that individuals are most vulnerable to overdose. In 2020, America reported the highest number of overdose deaths ever recorded. Opioid overdoses, in particular, have been increasing for decades, making it imperative that we find new treatments for opioid use disorder. We hypothesize that drugs of abuse generate a state of 'need' in the individuals that can only by corrected by more drug. This state is akin a state of physiological need such as thirst or hunger. Indeed, hormones that modulate hunger and satiety, like glucagon-like peptide-1 (GLP-1) and its analogs, have shown promise in reducing motivated behaviors for cocaine, amphetamines, nicotine, alcohol, and recently opioids. In this study, we test the effectiveness of the GLP-1 analog, liraglutide (LIR), in reducing heroin addiction-like behavior, and the potential side effects associated with the treatment. We show that daily treatment with LIR (0.1 mg/kg sc) increased the latency to take heroin, reduced heroin self-administration, prevented escalation of heroin self-administration, and reduced drug-induced reinstatement of heroin seeking behavior in rats tested 6 h later. A one-hour pretreatment time, however, was not effective in reducing cue-induced seeking. Moreover, we showed that, while LIR (0.1, 0.3, 0.6 and 1.0 mg/kg sc) supported conditioned taste avoidance of a LIR-paired saccharin cue, it did not elicit intake of the antiemetic kaolin. Further, while repeated administration of LIR did not reduce water intake, it did reduce food intake and body weight gain at all doses, except 0.1mg/kg. Overall, the data show that LIR is effective in reducing heroin taking and heroin seeking at doses that do not cause malaise and have a modest effect on food intake and body weight gain.

Title: Regional and evolutionary conservation of opioid-mediated suppression of parvalbumin cell inhibition

Authors: *A. P. CACCAVANO, K. A. PELKEY, C. J. MCBAIN;
Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Develop. (NICHD), Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: The opioid system in the central nervous system plays a crucial role in pain sensation, stress response and mood, and is a key target for drugs of abuse. With a high risk of dependency, mortality from respiratory depression, and epidemic levels of abuse, opiates pose significant public health challenges. Although there have been significant advances in understanding the neural substrates of endogenous and exogenous opiates, critical gaps remain in our understanding of how opiates modulate different neuronal subtypes and their activity within microcircuits. Within the hippocampus, opiates suppress the activity of inhibitory parvalbumin-expressing (PV) cells, and thus disinhibit excitatory pyramidal cells (PCs). This effect is primarily mediated through mu opioid receptors (MORs), which are associated with the reward-processing of both natural stimuli and drugs of abuse. While these insights from the rodent hippocampus have been critical for understanding the effect of opiates in the brain, it is unknown if opioid-mediated suppression of inhibition is conserved in other cortical regions, or in higher species. This study utilized an optogenetic approach, employing Cre-recombinase mice to selectively express a light-sensitive opsin in inhibitory PV cells. Light-evoked inhibitory synaptic currents were recorded in excitatory PCs via whole cell patch clamp, and the opioid sensitivity assessed with a MOR-specific agonist (DAMGO) and antagonist (CTAP). Excitatory PCs were recorded within hippocampal subregions, as well as visual, motor and prefrontal neocortex. Consistent with prior studies, light-evoked responses consistently exhibited robust DAMGO sensitivity in the CA1 region of hippocampus. However, across neocortical regions this DAMGO sensitivity was highly variable, indicating a potential specialization of hippocampal PV cells. To assess if opioid-mediated suppression of PV-cell activity is evolutionarily conserved, similar experiments will be conducted in non-human primates utilizing a viral strategy targeting the evolutionally-conserved and PV-specific E2 enhancer of the voltage-gated sodium channel gene Scn1a.

Title: Dual agonism at mu-opioid and adrenergic-alpha$_2$ receptors are necessary to produce the discriminative-stimulus effects of the primary kratom alkaloid mitragynine in rats

Authors: *M. L. CROWLEY[1], A. PATEL[2], S. OBENG[2], L. F. RESTREPO[2], L. R. GAMEZ-JIMENEZ[2], N. P. HO[2], F. LEON[1], M. M. MOTTINELLI[1], C. R. MCCURDY[1], L. R. MCMAHON[2], T. HIRANITA[2];
[1]Dept. of Medicinal Chem., [2]Dept. of Pharmacodynamics, Univ. of Florida Col. of Pharm., Gainesville, FL

Abstract: The kratom alkaloid mitragynine may combine two critical pharmacological mechanisms in a single molecule, mu-opioid and adrenergic-alpha$_2$ agonism, that currently is achieved clinically with separate drugs (e.g., methadone and lofexidine, respectively, for opioid use disorder/withdrawal syndrome). We have demonstrated that the mu-opioid receptor agonist morphine (15 min prior to sessions) partially mimics the discriminative stimulus effects of the primary kratom alkaloid mitragynine (32 mg/kg, i.p.) in Sprague-Dawley rats. Moreover, our group has shown that the antiallodynic effects of mitragynine in rats are blocked by the adrenergic-α_2 receptor (Aα_2R) antagonist yohimbine. Using rats discriminating i.p. 32 mg/kg of mitragynine from its vehicle, here we compared time-effect functions (5, 15, 30, 60, 90, 120, 180, 240, 360, and 240 prior to sessions) of substitution of morphine, the Aα_2R agonists (clonidine and lofexidine) and antagonist (yohimbine). Greater than 80% drug-lever responding was produced by morphine at 3.2 mg/kg 60 min post-injection, clonidine at 0.1 mg/kg 60 min post-injection, and lofexidine at 0.56 mg/kg 180 min post-injection. At the dose producing full substitution, morphine did not significantly modify rates of lever-pressing, thermal antinociception in the hotplate assay at 52°C, or thermomodulation, i.e., rectal temperature. However, clonidine and lofexidine decreased rates of responding to 25% and 50% of control and rectal temperature by 3.8°C and 3.9°C, neither clonidine nor lofexidine significantly modified hotplate response latency. The dose-effect function of mitragynine discrimination was shifted rightward and downward by the opioid receptor antagonists naltrexone (0.032 mg/kg) and naloxone (0.1 mg/kg), as well as by the Aα_2R antagonists yohimbine and atipamezole (both at 3.2 mg/kg). These results suggest that mitragynine exerts its in vivo effects via dual agonism at μ-opioid and adrenergic-α_2 receptor.

Title: Acute glucagon-like peptide-1 receptor agonist liraglutide prevents cue-, stress-, and drug-induced heroin seeking in rats

Authors: *J. E. NYLAND[1], J. E. DOUTON[2], S. L. MILLS-HUFFNAGLE[1], N. K. ACHARYA[1], D. SUN[1], P. S. GRIGSON[1];
[1]Penn State Col. of Med., Hershey, PA; [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: In the last decade, opioid use disorder (OUD) has been a threat to public health, being declared an epidemic by the Centers for Disease Control (CDC). The recent COVID-19 pandemic has intensified the crisis, with a national 29% increase in overdose deaths from October 2019 to September 2020, and preliminary data from the CDC suggesting overdose deaths in 2020 surpassed those during the peak of the opioid epidemic. For those who decide to seek medication for addiction treatment (MAT), initiating buprenorphine among patients who are not yet experiencing withdrawal may paradoxically precipitate withdrawal. For this reason, many MAT pathways recommend initiating treatment only among patients already experiencing symptoms of withdrawal and subsequently titrating the dose during an observation period. During this period, patients are particularly vulnerable for relapse. Recent research has shown that hormones that modulate hunger and satiety can also modulate reward behavior associated with drugs of abuse. For example, the short-acting analog of glucagon-like peptide-1 (GLP-1), an incretin hormone that regulates homeostatic feeding, has been shown to reduce responding for normally rewarding stimuli such as food, cocaine, heroin and nicotine in animal models. In this study, we tested the effects of a single, acute exposure to the long-acting GLP-1 analog, liraglutide, on a rat model of heroin reinstatement. We found that, in rats with heroin self-administration experience, an acute dose of 0.3 mg/kg liraglutide (sc) was effective in preventing relapse after exposure to the three major precipitators of relapse: drug-associated cues, stress, and the drug itself. Finally, we confirmed that the effects observed in drug seeking are not due to a locomotor depression or impairment, as liraglutide did not significantly alter performance in a rotarod test. These results provide an avenue to explore non-opioid treatments for OUD in

humans that can bridge the gap between cessation of opioid use and initiation of MAT to prevent relapse.

Title: Reduced Dopamine Terminal Function in the Nucleus Accumbens following Heroin Self-Administration

Authors: *B. GEORGE, M. H. DAWES, E. G. PECK, S. R. JONES;
Physiol. and Pharmacol., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Recent evidence has illustrated that heroin produces its rewarding and addictive effects, at least partially, through activation of the mesolimbic dopamine system. Notably, it has been shown that heroin seeking can be attenuated by systemic administration of antagonists of negative regulators of the dopamine system, such as kappa opioid receptors (KOR) or presynaptic D3 receptors (D3R), thus increasing dopamine levels. Therefore, it is likely that withdrawal from chronic heroin exposure drives a state of hypodopaminergia in the nucleus accumbens (NAc), as previously observed following withdrawal from chronic stimulant and alcohol use. To this end, this study aimed to (1) investigate alterations in the dopamine terminal function following heroin self-administration in male and female rats and (2) identify a mechanism for hypodopaminergia following chronic heroin self-administration. Adult male and female Long Evans rats were trained to self-administer heroin (0.05 mg/kg/inf) and then placed on long access (LgA; FR1, 6-hr session, unlimited infusions, 0.05 mg/kg/inf) heroin self-administration paradigm to induce escalation of heroin intake. Following LgA, rats were utilized for neurochemical analyses - *in vivo* microdialysis and *ex vivo* fast-scan cyclic voltammetry (FSCV) in the NAc. The results support previous literature in that following LgA, male and female rats had decreased basal extracellular levels of dopamine as well as a reduced dopaminergic response to a heroin challenge (0.1 mg/kg/inf, IV) in the NAc during withdrawal from heroin self-administration. FSCV results revealed that heroin exposed rats have reduced dopamine release during single-pulse stimulations but increased phasic-like dopamine release during stimulation trains (5 pulses, 5-100Hz) when compared to their heroin naïve counterparts. In addition, we found that presynaptic D3R and KOR activity in the NAc was increased

following LgA in male and female rats. These results reveal a marked reduction in dopamine system function following heroin exposure and identify a potential mechanism in the NAc that may drive the hypodopaminergic state observed during heroin withdrawal.

Title: Unexpected role of endogenous opioid receptors in adversity-induced addiction in females

Authors: *S. C. LEVIS, M. T. BIRNIE, N. KAMEI, J. L. BOLTON, J. S. MONTESINOS, C. R. PERRONE, T. Z. BARAM, S. V. MAHLER;
UC Irvine, Irvine, CA

Abstract: Background: Early life adversity (ELA) is associated with vulnerabilities to reward-related problems, such as addiction to pro-hedonic opioid drugs. Women may be particularly vulnerable, suggesting a sex-specific derangement of reward circuit maturation by ELA. However, the mechanisms by which this occurs are poorly understood. We employed a naturalistic model of ELA in rats to examine the impacts of ELA on functional maturation of the reward circuit, focusing on disruption of opioid drug seeking behaviors. **Methods:** Adult female ELA-experienced rats were tested for aspects of opioid addiction-like behaviors including free consumption and economic demand elasticity to measure motivation for opioid drugs. ELA-induced changes in reward circuitry were examined using c-Fos expression as a marker of neurons activated by heroin. To gain insight into ELA-induced molecular changes in reward-related regions, we employed RT-qPCR for a suite of molecular candidates. Finally, following on our intriguing molecular findings, we pharmacologically manipulated endogenous opioid signaling during opioid self-administration to test the mechanisms of ELA-enhanced opioid seeking. **Results:** ELA led to enhanced motivation for opioid drugs in female rats, in accord with our prior findings. Reward circuit activation by heroin distinguished ELA from control females, with differential activation in nucleus accumbens. Preliminary data suggest that these ELA-induced vulnerabilities and opioid-induced activity may involve altered opioid receptor expression and signaling in specific nodes of the in the reward circuit. **Conclusions:** ELA

produces a sex-specific pro-addiction phenotype in female rats, which may be caused by disrupted functional maturation of reward circuits, leading to aberrant neural activity and opioid signaling upon opioid exposure.

Title: Bac-mediated overexpression of striatopallidal neuron specific gene gpr6 heightened aversive effects of opiate withdrawal

Authors: *J. LINDEN, C. S. PARK, H. LAM, N. T. MAIDMENT, X. W. YANG; Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: The G protein-coupled receptor GPR6 is highly selectively expressed in the striatopallidal or D2 medium spiny neurons (MSNs) in the striatum. Our prior study mice deficient in *Gpr6* showed elevated reward-driven instrumental conditioning behavior. Here, we hypothesize that *Gpr6* function, in part through its constitutive signaling to increase cAMP production in D2-MSNs, could also modulate aversive behaviors such as learned avoidance tasks. Importantly, the D2-MSNs in the nucleus accumbens has been shown to be critical for aversive learning and, in the context of drug addiction, avoidance behavior associated with opiate withdrawal.

Here, we genetically test the in vivo function of GPR6 in modulating the aversive effects of opiate withdrawal. We developed a new conditional BAC transgenic mouse model (BAC-*Gpr6*) overexpressing murine *Gpr6* under its own genomic regulation. We evaluated these animals using a conditioned place aversion (CPA) assay using the μ opioid receptor antagonist naloxone, either alone or after chronic morphine exposure. We showed that in BAC-*Gpr6* mice, aversion to the drug-paired compartment was induced for a low dose of naloxone that failed to produce any avoidance in wildtype controls. Similarly, in naloxone-induced morphine withdrawal CPA, we found that low dose naloxone potentiates withdrawal avoidance in BAC-*Gpr6* but not in wildtype animals. To decipher the possible transcriptomic mechanism through which Gpr6 modulates withdrawal aversion, we subjected BAC-Gpr6 mice and wildtype controls to low-dose naloxone and performed RNA sequencing in tissue from dorsolateral and ventral striatum, two regions enriched in μ opioid receptor. We will present our findings on genes that are

differentially expressed based on Gpr6 gene dosage increase and hence could play a role in modifying aversive behaviors in opiate withdrawal.

Title: Modulation and Visualization of Hippocampus-driven Defensive Networks

Authors: *K. E. DORST[1], R. A. SENNE[2], S. RAMIREZ[2];
[1]Grad. Program For Neurosci., [2]Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: This research aims to provide a framework for the network interactions that govern differential defensive responses to aversive mnemonic stimuli. Specifically, both the brainwide and behavioral effects of artificially reactivating a particular fearful memory in a given region are largely unknown. Defensive behaviors, which are aberrantly expressed in PTSD and anxiety, include both active avoidance and passive freezing but manifest depending on the brain-state and the environment of the animal. Here, we alter environmental contingencies to test for the capacity of a defined set of hippocampal cells to differentially drive defensive behaviors when optogenetically activated. Our preliminary results show that artificial reactivation of the same set of cells processing fear manifests as anxiogenic responses, or freezing behavior, depending on whether these cells are stimulated in a large open field, or in a small chamber. These results suggest that a subset of cells, upon activation, recruit different neural substrates to generate diverging behavioral outputs. Our current work utilizes immunohistochemical and graph theory analyses to identify candidate regions mediating state-dependent defensive behavioral switches. Together, our work provides insight into the capacity of discrete sets of cells to produce various behavioral responses.

Title: Erasable hippocampal neural signatures predict memory discrimination

Authors: N. KINSKY[1], D. ORLIN[2], ***E. RUESCH**[3], S. RAMIREZ[3];

Abstract: Despite the ubiquitous use of contextual fear conditioning (CFC) to study episodic memory, there is a knowledge gap pertaining to how neural code evolves during the consolidation of short-term memory into long-term memory. Previous studies have demonstrated that CFC causes a reorganization, or remapping, of hippocampal place fields. This phenomenon suggests that the hippocampal neural code may provide a substrate for the retention and recall of CFC memories. Here, we leveraged the spatial and temporal resolution of single-photon calcium imaging in conjunction with CFC to further characterize the heterogeneity of hippocampal remapping over long-time scales in freely moving mice. We exposed mice to two different arenas throughout the experiment so we could test the specificity of the CFC memory. Moreover, we tracked behavior in the days before, during, and after shock to examine the long-term stability of the CFC memory. A cohort of mice received anisomycin, a protein synthesis inhibitor that disrupts long-lasting synaptic plasticity, immediately after shock to block consolidation. We hypothesized that anisomycin would temporarily arrest learning-related changes in the event rate of neurons and turnover of active neurons between sessions, and would prevent remapping of their place field locations. We found that freezing returned to pre-shock levels in the days following CFC for anisomycin mice but not for control mice corroborating previous findings. Surprisingly, we also observed that anisomycin temporarily accelerated the turnover of active neurons. This increased cell turnover was concomitant with a general shutdown of neural activity up to two days later. Thereby, we posit the amnestic effects of anisomycin could stem from the disruption of constitutive processes in conjunction with blocking learning-related plasticity. Additionally, the degree to which mice discriminated between arenas correlated with the amount of cell turnover between the arenas. This finding supports the idea that the hippocampal neural code provides a substrate for differentiating between arenas. Future analyses will investigate whether cell turnover between arenas relates to cell turnover across days and how freezing-related neural responses evolve through the course of consolidation and amnesia. Finally, we are

currently working to utilize single-photon calcium imaging to investigate the heterogeneity of CFC induced remapping in the dentate gyrus sub-region of the hippocampus. Together, our data provide physiological insight on how hippocampal cell populations are differentially contributing to the processes underlying memory consolidation and recall.

Title: Dorsal versus Ventral Lateral Septum in the Regulation of Fear

Authors: *C. A. RIZZI-WISE, D. V. WANG;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Appropriate behavioral instincts such as fear or avoidance behaviors in response to threat are critical for survival. However, excessive or misplaced fear is maladaptive and can have a negative impact on daily living for people who suffer from fear-associated disorders such as PTSD. With this clinical implication, there are still many avenues regarding the neural circuitry underlying the regulation of fear that have yet to be comprehensively studied. Recently gaining interest, the Lateral Septum (LS) is positioned to have an important role in the regulation of affect, including fear, given its critical position in relaying spatial and contextual information from the hippocampus to downstream hypothalamic regions. Using optogenetics and a contextual fear conditioning procedure, our data reveals the presence of two functionally different yet parallel pathways that originate in the hippocampus and project to the LS: the dorsal (d) CA1-to-dLS pathway likely increases the expression of fear whereas the ventral (v) CA1-to-vLS pathway decreases the expression of fear. To further explore these differences, our use of in vivo electrophysiology has uncovered firing property differences between the dLS and vLS relating to how this region is able to regulate different affects, with a focus on fear. In line with our findings that the dLS versus vLS has opposing behavioral controls, this appears to manifest from opposing firing changes as well. In response to different affective or neutral environments, the dLS has a pattern of increasing its firing rate whereas the vLS has more neurons that decrease their firing rate.This in-depth research will provide a novel understanding of LS circuitry which is helpful for the development of advanced treatment options for those with dysregulated behaviors relating to negative emotions.

Title: Two populations of retrosplenial cortical neurons in memory consolidation

Authors: *A. N. OPALKA, D. V. WANG;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: About one third of life is spent asleep, indicating that this offline state serves an important physiological relevance. During sleep, a process called memory consolidation occurs where newly acquired information is transformed into long-lasting memories. It is well-established that this process consists of hippocampal-cortical communication, where hippocampal ripple oscillations (150-250 Hz) coordinate with cortical slow-wave delta oscillations (1-4 Hz). These cortical delta oscillations have a cyclic pattern: the Up state of each cycle consists of increased neuronal activity, whereas the Down state of each cycle consists of almost complete neuronal silence. We recently have shown an interaction between the retrosplenial cortex (RSC) and hippocampus, such that clusters of RSC neurons fire at distinct time points in relation to the hippocampal ripple oscillation during sleep: RSC Up states precede the hippocampal ripple, while RSC Down states follow the hippocampal ripple. This suggests that RSC population activity may orchestrate memory consolidation. Here, we employed *in vivo* electrophysiology and advanced data analyses, including cell assembly analysis, to study RSC neuronal activity in freely behaving mice during consolidation. Interesting, our results revealed that ~25% of the RSC population started to fire at the Down state and reached maximal firing at the Down-to-Up transition. Therefore, we termed these RSC neurons the Down state assembly (DSA), and the remaining RSC neurons as non-DSA. We found that DSA activity preceded non-DSA activity, leading us to hypothesize that the DSA may initiate and maintain subsequent non-DSA network activity crucial to memory consolidation. In support of this, DSA activity increases during consolidation of a contextual fear experience. Although preliminary cross-correlation analyses reveal a low probability of DSA neurons directly interacting with non-DSA neurons, DSA neurons may project to another region for the initiation and maintenance of non-DSA network activity. Ongoing analyses will further investigate patterns within non-DSA activity, along with the interaction between these two RSC subpopulations. Results from this study may reveal that DSA activity coordinates activity of select non-DSA populations, and whether this activity drives the communication with other relevant brain regions to enable the

processing of distinct memories. Altogether, these findings will provide insight on the mechanisms of memory, which could shed light on how detailed information is integrated and organized into brain networks.

Title: Emerging neural ensemble codes in the hippocampal-amygdala circuitry underlie memory formation

Authors: *J. LIU, D. V. WANG;
Drexel Univ., Philadelphia, PA

Abstract: Memory formation requires communication between the hippocampus and its functionally connected brain regions. Although it is well-established that the hippocampal-amygdala circuitry is essential for contextual fear memory, it remains unknown how the neural ensembles between these two brain regions cooperate to form a stable fear memory. We focused on studying memory acquisition and subsequent consolidation by employing a contextual fear conditioning procedure. First, we applied an independent component analysis for cell assembly detection of data recorded in the basolateral amygdala (BLA) during the post-training slow-wave sleep (SWS), a stage critical for memory consolidation. We found that only one BLA cell assembly (consisted of ~5% of the neurons) was strongly regulated by hippocampal CA1 ripples, indicating a specificity of hippocampal-BLA communication for memory consolidation. Moreover, all neurons from this assembly started to fire robustly after the mouse received footshocks during training, and were reactivated during a subsequent recall test. Our further analyses showed that this cell assembly was modulated by ripples only during the post-, but not pre-training sleep. A rapid hippocampal-BLA information flow around the times of sharp wave ripples was confirmed by generalized linear models (GLMs). Importantly, unlike the BLA, the vast majority of CA1 neurons were recruited in the memory acquisition and subsequent consolidation and retrieval processes, indicating two distinct strategies for information coding between the hippocampal-BLA dialogue. These results suggest that a BLA fear memory cell assembly is rapidly generated during training, subsequently consolidated with hippocampal CA1 during post-training sleep, and maintained for fear memory retrieval, whereas most of the CA1

neurons participate in the same processes. Our data provide new insights into the understanding of the mechanism of memory formation in the hippocampal-BLA network.

Abstract: The hippocampus (HPC) is the seat of learning and memory where theta and sharp wave ripples organize place cells to tile experience. Downstream regions must be able to read out this information for memory consolidation to occur. Recently, the gRSC has been identified to exhibit similar activity to CA1 (i.e. theta, sharp wave ripples, and place cells). However, how this activity is produced in gRSC and its role in learning and memory is far less understood than in HPC CA1.
By densely sampling (20um resolution) the LFP across all layers of the gRSC in awake head-fixed mice using linear 64 channel silicon electrodes we aim to understand how the gRSC circuitry supports oscillatory activity for learning and memory. We identify high frequency oscillations (HFOs) in the 150-250 Hz frequency band, sharp waves, theta oscillations, and theta-nested gamma oscillations occurring in different layers across the gRSC. Specifically, sharp waves and HFOs are predominantly found on layer (L) 1 and L2/3 respectively. Theta and gamma oscillations are distributed across the layers. We also show differences in putative pyramidal cell and interneuron (Cell Explorer) responses to these distributed LFP activities. Pyramidal cells and interneurons increase firing rate at times of sharp waves in L1 and HFOs in L2/3. As well as distributed phase and frequency locking to the different LFP oscillations found across the layers. These findings show important network dynamic differences between the layers of the gRSC. Functionally, this implies each layer has different responsibilities in information processing and provides the neuroscience community with a more detailed understanding of the layer specific differences in the gRSC.

Abstract
The amygdala and hippocampus are bidirectionally interconnected and support complementary functions. In particular, the hippocampus is essential for remembering associations between objects and spatial contexts, and the amygdala can in turn modulate those hippocampus-dependent memories. For example, optogenetic stimulation of the basolateral complex of the amygdala (BLA) in a previous study accelerated acquisition of hippocampus-dependent object-context associations. Under naturalistic conditions, the BLA is engaged by stimuli with affective or social salience. For instance, pharmacological inactivation of the BLA in a previous study altered female rats' spontaneous preferences for conspecific urine odorants relative to plant-based non-social odorants. The present study addressed how affective odorants influenced oscillations in the BLA and hippocampus as rats performed a hippocampus-dependent object-context association task. Female rats learned to associate objects, which were small pots filled with scented digging media, with spatial contexts, which were visually-distinct boxes. Specifically, two objects (A and B) were differentially rewarded in two boxes by burying a food reward in only one object in each context (i.e., Box 1: A+B-; Box 2: A-B+). Local field potentials were recorded from the BLA and ventral hippocampus as rats performed the task under four different conditions. All four conditions included one object scented with a plant-based odorant. The second object was scented with one of the following: conspecific male urine, conspecific female urine, fox urine, or a second plant-based odorant. The overall question of interest was whether oscillatory activity in the BLA and hippocampus would differ between

conditions. Preliminary results suggested that oscillatory dynamics in the BLA and hippocampus correlated with task performance. The results have implications for understanding bidirectional interactions between the amygdala and hippocampus.

Title: Hippocampal-amygdala memory circuits govern experience-dependent observational fear

Authors: *J. I. TERRANOVA[1], J. YOKOSE[1], H. OSANAI[1], W. D. MARKS[1], J. YAMAMOTO[1], S. OGAWA-KITAMURA[1], T. KITAMURA[1,2];
[1]Dept. of Psychiatry, [2]Dept. of Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The empathic ability to vicariously experience the other's fearful situation, called observational fear (OF), is critical for survival. In OF, an observer witnesses a demonstrator in an aversive situation and responds with fear. Rodent studies have established behavioral models of OF and identified several brain regions and molecules important for OF. In particular, neural processes in the anterior cingulate cortex (ACC) and basolateral amygdala (BLA) networks are considered to be the center for OF. It is well known that both prior similar fear experience in the observer and social familiarity with the demonstrator can facilitate OF. Such a unique feature allows individuals to increase their empathic ability. For example, if the demonstrator's reaction to aversive stimuli is robust, the observer expresses OF without prior experiences (we refer to as Naive OF), which has been generally used as a rodent OF model. However, in nature and our lives, the demonstrator's reaction is often ambiguous and difficult to understand. To fully understand the other's situation, the observer uses both prior similar fear experience and social familiarity with the demonstrator, which facilitates OF. Some studies suggest that ACC activity

might be modulated by prior similar fear experience in the observer and social familiarity with the demonstrator. However, the neural circuit mechanisms of experience-dependent OF (Exp OF) have not yet been systematically investigated, and it remains unknown whether ACC and BLA are essential for Exp OF. Moreover, the hippocampus (HPC), particularly dorsal HPC (dHPC), is crucial for formation of own contextual fear experience, whereas ventral HPC (vHPC) is crucial for the formation and recall of social recognition memory. Thus, pre-requisite understanding of others' aversive situations may recruit dorsoventral HPC function to integrate memory information about prior similar fear experience in the observer and social familiarity with the demonstrator to elicit Exp OF. Here, we demonstrate that dorsoventral HPC to BLA pathways, without involving ACC, are crucial for Exp OF, while the ACC to BLA pathway is essential for Naive OF. Second, we found that fear memory engram cells in BLA are encoded during prior similar own fear experience, are reactivated during Exp OF, and are necessary for Exp OF. dHPC neurons generate fear memory engram cells in BLA during prior fear experience, while vHPC neurons respond to the familiar demonstrator's fearful situation, which reactivates the engram cells in BLA to elicit Exp OF. Our study provides new insight for memory engram-dependent perception-action coupling that underlies empathic behaviors like Exp OF.

Abstract: The hippocampus is involved in processing a variety of mnemonic computations including the spatiotemporal components, as well as the corresponding emotional dimensions, of contextual memory. Recent studies have demonstrated vast structural and functional heterogeneity along the dorsal-ventral axis of the hippocampus, and while much is known about how the dorsal hippocampus processes spatial-temporal content, much less is known about whether or not the ventral hippocampus (vHPC) partitions positive and negative experiences into distinct sets of cells. Here, we combine transgenic and all-virus based activity-dependent tagging strategies to visualize multiple valence-specific engrams in the vHPC and demonstrate two partially segregated, albeit physiologically similar, populations that respond to positive and negative experiences. We then optogenetically manipulated the terminals of these engrams to drive preference or aversion and asses their capacity to switch. Next, using an RNA Sequencing approach, we find that vHPC positive and negative engram cells display distinct transcriptional programs in which -neuroprotective and neurodegenerative -related gene sets are enriched, respectively. Ongoing studies are investigating the role of negative engrams in the induction and cascade of Alzheimer's disease. Together, our findings provide a novel means by which to visualize multiple engrams within the same brain, point to their unique genetic signatures as putative avenues for future therapeutic interventions, and investigate their role in neurodegenerative disease.

Title: Engram transition from recent to remote memory recall is accompanied with connectivity-related changes

Authors: *R. REFAELI[1], T. KREIZEL[2], I. GOSHEN[2];
[1]hebrew university of jerusalem, jerusalem, Israel; [2]Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: When memory is acquired, a group of neurons with high activity levels during learning are allocated to support it. Some of these neurons will later participate in the recall of this memory. Their activity during the *acquisition* of memory is necessary for recall of recent (days post-acquisition) and even remote (a month and more post-acquisition) memories. Recent memory involves relatively fast processes that take place during the first hours to days following learning. Remote memories, however, are consolidated over much longer time scales, in yet not

well-defined processes termed together 'systems consolidation'. This process involves changes in multiple brain regions that enable the persistence of the memory. In this research we targeted the transition of memory from recent to remote recall, in order to find missing links between these memory stages. For that purpose, we tagged a first cFos+ cells using genetic manipulation, and a second group of cFos+ cells using IHC, within the same mouse. Thus allowing comparison of the two populations in each animal. First, we show that neuronal activation throughout different stages in memory consolidation is consistent in the hippocampus, but not in other memory-related brain areas, compared to the acquisition. Secondly, during the transition from recent to remote recall, several brain areas maintain fixed ensembles, not necessarily similar to the acquisition. Furthermore, hyperactivation of hippocampal astrocytes during acquisition, known to enhance recent memory, increases the percentage of CA1 reactivated cells between recent and remote, strengthening the hypothesis that the strength of recall is bound to the engram reactivation. In order to define whether the ensembles supporting remote memory are selected based on their connectivity and if they differ from the ensembles supporting recent memory, CA1 cells were marked based on their projection target. We found that the transition from recent to remote does include recruitment of projection-based sub-population; CA1 to ACC projecting cells are more likely to be activated during remote than during recent recall or acquisition. Additionally, hyperactivation of CA1 astrocytes during acquisition of memory also increases the activation of the CA1 to ACC-pc during recent but not remote. Lastly, analyzing projections of active cells from the CA1 during different stages of memory, using full brain reconstruction, revealed that as time progresses, the CA1 to ACC projections ratio increases, compared to other areas monosynaptic connected to the CA1, such as the Supra Mammillary Bodies or Nucleus Accumbens.

Title: Ensemble activity patterns underlying spatial navigation and reversal learning in aged and young adult mice

Authors: *W. MAU[1], L. CHEN[2], Z. DONG[2], T. SHUMAN[3], D. J. CAI[4];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [4]Neurosci., [3]Mount Sinai, New York, NY

Abstract: Normal aging is often accompanied by cognitive decline. The hippocampus is particularly afflicted during aging, resulting in impaired memory in rodents, non-human primates, and humans. Age-related deficits have been observed in spatial reversal learning, yet we do not know how hippocampal activity patterns might contribute to this deficit. To answer this question, we used calcium imaging with head-mounted Miniscopes to study the stability and transience of hippocampal activity patterns in aged and young adult mice performing a spatial reversal task. We trained mice to navigate to goal locations on a circular track for rewards. Then after multiple days of this training, mice are forced to ignore the old goal locations and navigate to new ones for reward (spatial reversal learning). Young adult mice (~7 months old) consistently learn the initial goals, then during spatial reversal learning, they also learn the new goal locations within 30 minutes. Aged mice (~17 months old) learn the initial goals just as quickly as young mice, but perform worse during spatial reversal learning, suggesting that they are more inflexible in learning new goal locations. To examine the neural correlates of this age-related reversal learning deficit, we turned to the calcium imaging data. Using independent component analysis (ICA), we identified neuronal ensembles comprised of co-activated neurons (Lopes-dos-Santos et al., 2013, *J. Neurosci Methods*). In young mice, these ensembles weaken during spatial reversal learning, suggesting that CA1 ensembles undergo reorganization in order to learn new goal locations. This reorganization is less prevalent in aged mice, which could explain their impairments in spatial reversal learning. We also observed specific deficits in learning-induced excitability in CA1 of aged mice. These excitability deficits could underlie differences in CA1 ensemble patterns that could ultimately contribute to spatial reversal learning deficits seen in aging.

Title: Network dynamics of dorsal hippocampal CA1 and CA3 during fear memory encoding and recall

Authors: *C. DONG[1], S. KRISHNAN[2], M. SHEFFIELD[3];
[1]Univ. of Chicago Committee On Neurobio., Chicago, IL; [2]Biol. Sci. Div., [3]Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Episodic memories—memories of experiences placed in time and space— form through associations made in the hippocampus between distinct stimuli within specific contexts. Recent studies have shown that in a contextual fear conditioning (CFC) paradigm, which causes the formation of an episodic-like memory, optogenetic activation of neurons in hippocampal CA1, CA3 or Dentate Gyrus that are "tagged" during induction of CFC can sufficiently trigger retrieval of the fear-memory. The existence of "engram-cells" in different hippocampal subnetworks suggests that the intact hippocampus is critical for episodic memory formation and recall. However, how the anatomically connected but functional distinct subnetworks in the hippocampus, such as CA3 and CA1, coordinate the information to support memory formation and recall remains unknown. This question can only be solved by studying the cross-network interactions during memory formation and recall. Here, we implement a novel behavioral paradigm for CFC where functional two-photon imaging of the hippocampal CA1 and CA3 will be performed in head-fixed mice navigating virtual contexts undergoing fear conditioning and during fear memory recall across multiple days. We observed CFC behaviors in head-fixed mice similar to freely moving animals. More importantly, we have now connected behavior with the dynamics and interactions of hippocampal subnetworks in CA1 and CA3 to help better understand the role of cross-network dynamics in episodic memory formation and recall.

Title: Do engram cells discharge like memory cells during optogenetic activation?

Authors: *C. GARCIA JOU[1], E. PARK[2], D. DVORAK[3], E. R. LEVY[3], A. A. FENTON[3];
[1]City Univ. of New York, New York, NY; [3]Ctr. for Neural Sci., [2]New York Univ., New York, NY

Abstract: Engram cell (EC) experiments genetically tag neurons that are active during learning so that they can be optogenetically manipulated to test whether their reactivation is necessary and sufficient for the expression of a memory. Hippocampal ECs have been identified in mice using threat-conditioning paradigms, but the results challenge established notions of how the hippocampus encodes and processes information. Consider for example, that hippocampal ECs are place cells that discharge at specific locations of a conditioning environment to represent that environment. During conditioning, a pair of cells with coincident firing fields in the north of the environment may discharge together, but never when cells with firing fields in the south discharge. However, these three place/engram cells would be activated synchronously during optogenetic activation, making it difficult to imagine how the optogenetic activation could result in replaying or reactivating the representations that were stored during conditioning. We have begun to investigate this contradiction. We first established that optogenetic tagging and activation of CA1 was sufficient to express a conditioned-place avoidance known to require place cells and their dynamic temporal discharge. 5-Hz optogenetic activation of memory-tagged cells was sufficient to express the conditioned avoidance in both neutral familiar and entirely novel environments without either the CS or US. We recorded ensembles of CA1 cells in a subset of mice under anesthesia after the optogenetic test and behavioral demonstration of sufficiency. Firing rates increased ~77% during 7 mW, 473 nm, theta-frequency optogenetic activation, and increased their likelihood of discharging to 1% in response to each 15 ms light pulse. Remarkably, CA1 cell pairs maintained their pre-established co-firing relationships such that pairs of cells that cofired before stimulation continued to cofire during stimulation, and cell pairs that did not cofire continued not to cofire (7mW: $r = 0.36$, compared to control: $r = 0.51$). Ensemble CA1 recordings in awake, head-fixed mice also confirmed that 5 and 10 Hz optogenetic stimulation produces an evoked discharge pattern in single cells that can be distinguished from control discharge. These initial observations indicate the importance of monitoring patterns of neural discharge during EC experiments in order to assess whether or not memory-related temporal discharge patterns are maintained during optogenetic stimulation in EC experiments that elicit conditioned responses.

Title: Exploring the early properties of CA3 engram neurons with a novel viral tool

Authors: D. CUPOLLILO[1], C. MARNEFFE[1], C. REYNAUD[1], S. DEFORGES[1], N. GROSJEAN[1], ***C. MULLE**[2];

Abstract: Forming new memories after a one-time experience requires initial encoding then consolidation over time. The hippocampal CA3 region is a key structure involved in multimodal information integration and initial memory storage. In this work, we describe the development and validation of a novel tool for fast-labeling of engram neurons (FLEN). FLEN is based on c-Fos activity-dependent transient expression of a destabilized fluorescent marker ZsGreen1 rapidly after one-trial learning (few hours). With FLEN, we explored the electrophysiological properties of c-Fos activated CA3 neurons following one-trial learning. In parallel, we have employed the Robust Activity Marker (RAM) system to label CA3 engram neurons 24 hours following a novel experience. Comparing FLEN positive and RAM positive neurons allows to show that both intrinsic excitability and synaptic properties of CA3 pyramidal neurons undergo progressive plastic changes over the first day following a one-trial memory task.

Title: Etomidate blocks the formation of stable hippocampal engrams in WT but not interneuronα5-GABA$_A$R-KO mice

Authors: *M. ZHU[1], M. PERKINS[2], R. LENNERTZ[2], R. A. PEARCE[2];
[2]Anesthesiol., [1]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Studies of place cells have shown that the hippocampus encodes a cognitive map, and that stable place-specific firing patterns (engrams) represent memory traces. Here, we examined what an amnestic dose of etomidate does to engram formation and stability in WT mice and in mice lacking α5-GABA$_A$Rs in interneurons (α5-i-KO), which serve as its target (A Abdulzahir,

SfN 2021). We measured cellular activity in freely exploring mice using GCaMP6f and a mini-endoscope (Inscopix), and we captured the mouse's position using Noldus EthoVision. Mice underwent two 10-min recording sessions per day, separated by four hours (AM and PM), with unique sets of sensory cues used each day to create new contexts. Image processing and statistical analysis were performed using IDPS software (Inscopix) and custom-written MATLAB routines.
Under control conditions (saline IP), place-specific firing patterns, as determined by mutual information between spatial position and cellular activity, were observed in 10-20% of imaged cells (up to 1200 per field) in both WT and α5-i-KO mice. 50-60% of place cells observed during AM sessions exhibited similar firing patterns in PM sessions, demonstrating that mice had formed and recalled stable engrams. This similarity was quantified by Population Vector (PV) correlation between position-specific firing rate maps (WT-sal 0.52±0.12, α5-i-KO-sal 0.43±0.14, $p<0.0001$ vs. shuffle for both groups). In WT mice, etomidate (2-8mg/kg IP 30 minutes prior to the AM session) produced dose-dependent reductions in both place cell formation and stability, with significant loss of PV correlation at 7 mg/kg (WT-etom 0.23±0.16, $p<0.001$ vs. WT-sal). By contrast, the PV correlation was unchanged in α5-i-KO mice injected with 7 mg/kg etomidate (α5-i-KO-etom 0.42±0.12, $p=0.83$ vs. α5-i-KO-sal), indicating that mice had successfully formed stable engrams. To demonstrate that mice formed context-specific engrams, in a separate group of experiments with WT mice we altered the context between AM and PM sessions. This change resulted in significantly reduced PV correlations (WT-alt-context 0.35±0.11, $p<0.001$ vs. WT-sal). Additionally, 7mg/kg etomidate did not cause any changes in overall cellular activity (events per second) for either genotype (WT-sal 0.08±0.02, etom 0.07±0.02, $p=0.14$; α5-i-KO-sal 0.09±0.03, etom 0.09±0.03, $p=0.37$), or alter the probability that the any given cell would be active during both AM and PM sessions (WT-sal 0.57±0.11, etom 0.53±0.18, $p=0.39$; α5-i-KO-sal 0.66±0.08, etom 0.70±0.07, $p=0.56$). These findings provide additional evidence that etomidate targets interneuronal α5-$GABA_A$Rs to suppress contextual memory formation.

Title: α5-$GABA_A$ receptors located on inhibitory interneurons mediate contextual memory suppression by etomidate in mice

Authors: *A. ABDULZAHIR[1], R. NAGARAJAN[2], U. RUDOLPH[3], R. A. PEARCE[4]; [1]Univ. of Wisconsin Madison, Madison, WI; [2]Dept. of Comparative Biosci., Univ. of Illinois at Urbana-Champaign, Urbana, IL; [3]Dept. of Comparative Biosci., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [4]Anesthesiol., Univ. of Wisconsin, Madison, WI

Abstract: Suppression of memory is one of the primary goals of general anesthesia. Previous investigations have shown that etomidate blocks both long term potentiation of excitatory synapses (LTP – a cellular model of memory) and contextual memory (a surrogate for episodic memory) by targeting $GABA_A$Rs that incorporate α5 subunits (α5-$GABA_A$Rs).[1,2] We recently reported that selectively eliminating α5-$GABA_A$Rs from hippocampal pyramidal neurons did not interfere with etomidate's ability to suppress LTP *in vitro*,[3] suggesting that α5-$GABA_A$Rs on non-pyramidal cells might be instrumental in etomidate-induced amnesia. Here, we tested this hypothesis by selectively eliminating α5-$GABA_A$Rs from inhibitory interneurons and measuring etomidate suppression of contextual memory in the Context Pre-exposure Facilitation Effect (CPFE) paradigm.[4] Experiments were performed using α5-$GABA_A$R-interneuron knockout (α5-i-KO) mice, in which the α5-$GABA_A$Rs were selectively eliminated from interneurons by crossing mice carrying a 'floxed' Gabra5 gene with mice expressing Cre-recombinase under the control of the Gad2 promoter. Restriction of Cre expression to interneurons was confirmed by crossing Gad2-Cre mice with a TdTomato reporter mouse. Western blot analysis showed that α5 subunit expression was not measurably reduced in α5-i-KO mice compared to WT, consistent with the predominant expression of α5-$GABA_A$Rs in pyramidal neurons. Both WT and α5-i-KO mice injected with saline before pre-exposure (sal) displayed significantly higher freezing scores than no-pre-exposure (npe) controls (WT-npe 25 ± 5 %, α5-i-KO-npe 17 ± 5 %, n=5 each; WT-sal 41 ± 3 %, α5-i-KO-sal 41 ± 4 %, n=12 each; $p<0.01$ sal vs. npe), at levels not different from each other ($p=0.5$), demonstrating that the pre-exposure resulted in contextual memory formation, and that eliminating α5-$GABA_A$Rs from interneurons did not itself interfere with memory. Administration of etomidate significantly reduced freezing scores in WT mice (α5-i-KO-sal 17±2%, n=12, $p=0.01$ vs. WT-sal) but not in α5-i-KO mice (α5-i-KO-sal 37±4 %, n=12, $p=0.47$ vs. WT-sal). These findings support the hypothesis that α5-$GABA_A$Rs on interneurons mediate contextual memory suppression by etomidate.

Title: Is the rat prefrontal cortex crucial for cognitive control during spatial cognition?

Authors: *E. PARK[1], G. GRUBS[1], D. TABORGA[1], K. NICHOLAS[1], A. S. AHMED[1], K. O'REILLY[2], A. A. FENTON[1];

Abstract: Cognitive control tasks require using relevant information while ignoring competing irrelevant information. Prior work inactivating hippocampus during an active place avoidance task suggested hippocampus is crucial for cognitive control of spatial information. The task requires rodents on a rotating arena to avoid a stationary shock zone by using stationary cues while ignoring information from the rotating arena. During this task, the discharge of hippocampal neurons alternates judiciously between representing stationary and rotating locations according to the animal's proximity to shock and ability to avoid the shock zone, demonstrating cognitive control in hippocampal discharge. The central role of the medial prefrontal cortex (mPFC) in cognitive control is well established; mPFC damage causes deficits in cognitive control tasks. Here we evaluated whether rat mPFC lesion impairs active place avoidance to test a "central-computation" hypothesis that mPFC is essential for the computations required for cognitive control. An alternative "local-computation" hypothesis asserts that cognitive control can be accomplished via local computations by neural circuits, independent of mPFC. We compared active place avoidance after ibotenic acid lesion of mPFC (n = 10) and sham (n = 8) rats. After testing behavior, in a subset of the rats (lesion n = 8, sham n = 8), we evaluated the lesion and its consequences by measuring cytochrome oxidase (CO) activity in 14 functionally-related brain regions. CO activity correlations between the dorsal and ventral hippocampi, amygdala, retrosplenial cortex and nucleus reunions were weaker after mPFC lesion indicative of reduced functional coupling between related brain areas. Behaviorally, post-surgery, both groups learned to enter the shock zone less (Group: $F_{1,16} = 0.002$, $p = 0.9$; Day: $F_{1,16} = 26.3$, $p = 10^{-4}$; Trials: $F_{3.22,\ 51.50} = 36.8$, $p = 10^{-13}$), and increased the latency to first enter the shock zone across trials (Group: $F_{1,16} = 0.1$, $p = 0.8$; Day: $F_{1,16} = 69.6$, $p = 10^{-7}$; Trials: $F_{5.33,\ 85.33} = 12.2$, $p = 10^{-9}$). Memory retention at 24-h did not distinguish the groups (entrances: $t_{16} = 1.0$, $p = 0.4$; time to first enter: $t_{16} = 1.0$, $p = 0.3$). Both groups learned a new conflicting avoidance when the shock was relocated 180° to further assess cognitive flexibility (Group: $F_{1,16} = 0.21$, $p = 0.7$; Day: $F_{1,16} = 8.9$, $p = 0.01$; $F_{1.89,\ 30.12} = 18.55$). These data demonstrate that computations required for cognitive control can occur locally in brain networks independently of the mPFC, in support of the local-computation rather than the central-computation hypothesis.

Title: Photoactivated proteolysis targeting chimeras (PHOTACs) for light-activated degradation of specific synaptic proteins in hippocampal tissue

Authors: *A. FENTON[1], C. JOU[4], T. KO[2], A. B. GRAU-PERALES[3], M. REYNDERS[5], D. TRAUNER[2];

Abstract: The degradation of proteins with Proteolysis Targeting Chimeras (PROTACs) is currently revolutionizing pharmacology. Our group has introduced photoswitchable versions, so called PHOTACs, that allow for optical degradation of specific proteins. Our initial targets are proteins that are hypothesized to be crucial for maintaining memory. The synaptic plasticity and memory hypothesis, a dogma of neuroscience, asserts that memory is maintained by sustaining neurotransmission across specific synaptic pathways, but definitive identification of the crucial molecular mechanisms requires tools to selectively degrade candidate proteins at specific sites at specific times of the learning/memory process. To test the feasibility of the PHOTACs approach, we developed a CaMK2-PHOTAC for neuronal CaMKIIα because this protein is crucial for maintained synaptic structure and function. Light activation (385 nm) of the CaMK2-PHOTAC ($n = 7$) decreased CaMKIIα immunolabeling 3-fold compared to controls ($p<0.001$), specifically, the non-activated CaMK2-PHOTAC (dark condition, $n = 7$, $p<0.001$), tissue incubated with ACSF with light ($n = 6$, $p<0.03$) or without illumination ($n = 3$, $p<0.01$). No differences were observed in parvalbumin immunolabeling ($p>0.9$), nor in the number of DAPI-stained nuclei ($p<0.9$), demonstrating specificity of the CaMK2-PHOTAC. Because CaMKIIα maintains synaptic structure, we next tested whether CaMK2-PHOTAC depresses synaptic transmission in the medial perforant pathway (MPP) that terminates in the suprapyramidal dentate gyrus of acute mouse hippocampus slices. While 100 ms 385 nm light pulses every 10 s did not change responses in the control slices, the illumination depressed baseline synaptic responses in CaMK2-PHOTAC-incubated slices ($n = 7$), as predicted for loss of CaMKIIα in maintaining baseline synaptic function. The effect required light activation because the synaptic responses persisted in the CaMK2-PHOTAC slices that were not illuminated ($n = 5$). These biochemical

and electrophysiological findings demonstrate that CaMK2-PHOTAC is effective in brain tissue, is cell permeable, and targets CaMKIIα with no evidence of toxicity. Finally, we will discuss the development of PHOTACs that target other proteins hypothesized to be crucial for maintaining long-term potentiation of synaptic function (LTP) and the persistence of long-term memory.

Title: Visualizing remote spatial memory in the hippocampus

Authors: *A. GRAU-PERALES[1], R. M. HARRIS[3], H.-Y. KAO[4], J. M. ALARCON[5], H. A. HOFMANN[6], A. A. FENTON[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY; [3]Integrative Biol., The Univ. of Texas At Austin, Austin, TX; [4]Dept of Neurol., Univ. of Michigan, Ann Arbor, MI; [5]Dept. of Pathology, SUNY Downstate Med. Ctr., Brooklyn, NY; [6]Univ. of Texas at Austin, Austin, TX

Abstract: The input-specific populations of hippocampal synapses can undergo long-term synaptic changes, which are assumed to store memory. However, which specific constellations of hippocampal synaptic populations undergo these experience-dependent modifications is an open question. The atypical protein kinase C isoform, PKMζ is necessary and sufficient for the maintenance of LTP at hippocampal synapses and the persistence of long-term memory in a hippocampus-dependent active place avoidance task. Thus, PKMζ expression can be used to test hypotheses for which input-specific synaptic populations change long-term memory storage and cognitive information processing. To investigate the subcellular distribution of PKMζ in the hippocampus we used ArcCreER^{T2} x ChR2-EYFP mice to label memory-associated cells. Trained (n=4) and untrained (n=4) mice received 30-min trials on a rotating arena, to learn to avoid a stationary shock zone. Before the last training trial, all mice received 4-OH tamoxifen to induce Arc-driven expression of ChR2-EYFP. Trained mice expressed conditioned avoidance 1 month later. Immunohistochemical analysis of EYFP identified an increased number of memory-activated pyramidal cells in CA1 and CA3, and granule cells in the suprapyramidal blade of dentate gyrus (DG) compared to untrained mice. Memory-induced increases in PKMζ also followed this pattern, and identified input-specific patterns of memory-related synaptic populations. Memory training increased PKMζ-EYFP co-expression at CA3-CA1 Schaffer

collateral synapses but not where the TA entorhinal inputs terminate. To discover what other candidate molecules may be implicated in this memory, we used transcriptome profiling of hippocampus subregions after active place avoidance training (n's=17). A day after expressing the avoidance memory, 214 genes were differentially expressed in DG, 16 in CA1, and none in CA3 compared to controls. Most immediate early genes were upregulated. Gene Ontology analysis of the differentially expressed genes showed that memory was associated with activation of transcription and synaptic differentiation in DG but not CA3 or CA1. Hypothesis-driven candidate molecule analyses did not yield significant changes in the transcripts for PKMζ and other LTP-associated molecules, nor did they covary with memory expression, ruling out strong transcriptional regulation but not translational regulation. These observations confirm the importance of PKMζ activity in long-term memory maintenance and identify an input-specific distribution of memory-related hippocampal synaptic populations for long-term active place avoidance memory.

Title: A code for space in hippocampal coactivity dynamics independent of place fields

Authors: *E. R. J. LEVY[1], E. PARK[2], A. A. FENTON[1];
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY

Abstract: The hippocampus is crucial for spatial navigation as well as the acquisition and persistence of memories, especially episodic memories that contain environmental information. The standard cognitive map hypothesis for decoding information from neuronal discharge states that information is encoded in the activity of single neurons called place cells. Place cells are hippocampal principal cells with activity tuned to locations in a particular environment. It is not straightforward how such a code can represent the current environment without extensive spatial exploration and at the ms-to-s timescales of neural computations. Because hippocampal principal cells are governed by intrinsic and behaviorally modulated temporal dynamics, such as oscillations in the local field potential, we considered an alternative hypothesis. This coactivity hypothesis does not rely on single cell place tuning, rather it asserts that spatial information is encoded in the moment-to-moment cofiring relationships amongst an ensemble of neurons.

To compare the importance of these two coding schemes for encoding environments, we recorded CA1 activity across a multi-week experience of two physically distinct environments. Using a bright-field miniature microscope placed above a surgically implanted GRIN lens, we imaged mouse CA1 principal neurons expressing virally-induced GCaMP6f.
In addition to replicating the standard findings of CA1 remapping experiments, we find that at the 1-s time resolution, cell pair coactivity is stable within environments and distinct between environments. We show that this environment-discriminating information in cell pair coactivity is not a result of the cells' place tuning. Decoding environments from cell-pair coactivity is effective and even improves after removing cell-specific place tuning. Similarly, decoding environments directly from ensemble activity in CA1 is accurate and does not rely on place cells, high-rate cells, or low-rate cells. Instead, we find that discrimination relies on cells that have a propensity to anti-cofire with other cells at the 1s timescale.
Evaluating the 1-s low dimensional structure of CA1 activity with a non-linear algorithm, IsoMap, we find that it is organized on a 2D manifold that naturally discriminates the two environments. This non-linear projection discrimination relies on cell-pair coactivity, in particular, anti-coactive cell pairs.
We conclude that ensemble cofiring relationships are a neural code for environmental space, independent of place fields, and is advantageous for moment-to-moment identification of the current environment.

Title: Temporal Order of Increased Signal Coordination Within and Between PFC-Hippocampus After Learning of a Dynamic Spatial Task

Authors: *C. DICKSON[1], J. M. BARRY[2];
[1]Univ. of Vermont, BURLINGTON, VT; [2]Neurolog. Sci., Univ. of Vermont, Burlington, VT

Abstract: The mPFC is responsible for goal planning and decision making while the hippocampus is essential for spatial learning and memory. In a spatial active avoidance task requiring planning and spatial memory, we therefore predicted dynamically coherent neural activity at a theta timescale within (mPFC-mPFC, dHC-dHC, vHC-vHC) and between (mPFC-

dHC, mPFC-vHC) these two regions according to moment by moment cognitive and behavioral task demands. Moreover, we aimed to measure the development of this dynamic signal coordination as a function of task learning. Adult male rats were bilaterally implanted with EEG electrodes and local field potentials recorded in the mPFC, dorsal hippocampus (dHC), and ventral hippocampus (vHC) while subjects learned the active avoidance task. Whole training session mPFC-HC, mPFC-mPFC, and HC-HC theta coherence increased as a function of spatial learning. For mPFC-HC, the greatest coherence change within the theta bandwidth coincided with the unimodal coherence peak at ~7.5Hz. While rats were beginning to learn the task (Early session), the mPFC-dHC was more coherent than the mPFC-vHC, despite significantly lower synaptic connectivity. Prior to avoidance, theta coherence demonstrated a regional temporal sequence in which transitory peaks were observed between the mPFC-mPFC and mPFC-HC and dHC-dHC. Moreover, coherence within the theta bandwidth fluctuated between epochs for mPFC-HC and mPFC-mPFC, showing distinct frequency distributions in coherence. Theta coherence within and between the mPFC and hippocampal poles change as a function of learning and cognitive demand during active avoidance on a rotating arena. These temporally ordered coherence signatures reveal unique field potential coherence properties operating on a second-by-second timescale that coincide with transient cognitive states. Importantly, these results proved the importance of analytical timescale, demonstrating how information is lost when coherence is averaged across time or across the frequency band. It remains unclear what the content of these discrete frequency distributions within the theta bandwidth conveys and if they are functionally important. However, the results support the findings of other experiments indicating a causal role for 8-9 Hz mPFC-HC coherence for spatial avoidance. Future work will use optogenetic interventions to examine whether theta frequency specificity in signal coordination across the mPFC and hippocampal circuit provides qualitatively different types of information.

Abstract: Due to the complex anatomy, cell-type diversity, lack of simple, noninvasive delivery methods, and the challenge to evaluate the outcome, genetic engineering in the central nervous system (CNS) has been largely limited to costly, time-consuming, and laborious germline transgenesis. In order to overcome these hurdles, a neurotropic genome editing approach was developed for noninvasive generation of somatically engineered mice with a wide-scale and dose-dependable genome editing footprint in adult mouse brains. Our strategy facilitates sparse, stochastic, and dosage-dependent genetic labeling to characterize the morphology and neuropathology of single-neurons. To overcome the trade-offs in volume imaging for single-neuron analysis, an unsupervised deep learning network was used to augment the quality of volume imaging. we here describe the use of deep learning-based generative adversarial networks (GANs) to aid in the identification and visualization of subcellular neuronal structures within volume imaging data. Our empirical results demonstrate that CycleGAN can learn an unsupervised image model from high-quality images to identify relevant signals in low-quality images. In particular, we also show that CycleGAN can robustly adjust image noise to identify Purkinje neuron dendrites to enable rapid multi-neuron 3D reconstruction and segmentation using IMARIS. We developed a workflow and proposed the concept of "broad spectrum single-cell pathology analysis" to gain unprecedented temporal and spatial profiling of single-cell neurodegeneration and neuroinflammation after stroke. This approach can be used as a powerful genetic tool to generate loss- or gain- of function genetic modifications in CNS to probe structure, function/dysfunction and causal pathogenesis in Neurodegenerative/neurodevelopmental disorders and to develop disease-modifying therapy.

Title: Intersectional mapping of multi-transmitter neurons in the brain

Authors: J. XU[1], A. JO[2], R. DEVRIES[3], S. DENIZ[2], S. CHERIAN[2], I. SUNMOLA[2], X. SONG[4], J. MARSHALL[2], T. L. DAIGLE[5], A. CONTRACTOR[2], T. N. LERNER[2], H. ZENG[5], ***Y. ZHU**[2];

Abstract: Many neurons can produce, store, and release multiple neurotransmitters. The existence of such multi-transmitter neurons complicates our understanding of the brain and neural circuits. Intersectional strategies based on dual-recombinase system are particularly powerful in mapping brain-wide distributions of these multi-transmitter neurons based on expressions of genes needed to establish neurotransmitter identity. In this study, we performed a brain-wide mapping of neurons that are potentially capable of co-releasing glutamate and GABA. By creating intersections between VGLUT (VGLUT1, VGLUT2, or VGLUT3) and VGAT with Cre/Flp double recombinase system, we identified 30 brain regions that contain co-expression neurons in the adult, including 19 VGLUT2/VGAT regions and 11 VGLUT3/VGAT regions. While some of these regions have been previously identified, more than half of them have not been reported before. We also discovered another 32 brain regions co-expressing VGLUT and VGAT during the development but not in the adults. Using viral tracing with Intersect AAVs, we identified 14 brain regions that innervate the lateral habenula (LHb) with glutamate/GABA co-transmission, which doubles what is known. Furthermore, with co-injection of two AAVs that label VGLUT-expressing and VGAT-expressing neurons with different colors, we identified another 25 LHb-projecting regions exclusive of VGLUT2/VGAT projecting neurons. These regions provide glutamatergic innervations alone (6 regions), GABAergic innervations alone (11 regions), or mixed innervations originated from sole glutamatergic and sole GABAergic neurons (8 regions). These results reveal an unanticipated abundance of glutamate/GABA co-transmission in the brain and add to our understanding of the afferent circuitry to the LHb.

Title: Short promoters for directing AAV protein expression in specific classes of cortical interneurons

Authors: *G. BARANAUSKAS[1], K. RYSEVAITE-KYGUOLIENE[2], I. SABECKIS[2], D. H. PAUZA[2], T. TKATCH[3];
[2]Inst. of Anat., [3]Neurosci. Inst., [1]Lithuanian Univ. of Hlth. Sci., Kaunas, Lithuania

Abstract: BACKGROUND: Gene delivery to neurons by nonpathogenic recombinant adeno-associated virus (AAV) is becoming a method of choice in many fields of neuroscience and is showing increasing promise for treatment of human diseases. However, there is still a limited choice of promoters suitable for neuron-type specific expression of AAV delivered genes. Therefore, we designed two promoters suitable for expression of AAV delivered genes in two types of cortical interneurons, somatostatin (SOM) and parvalbumin (PV) expressing cells.AIM: To identify the specificity of expression of AAV delivered genes controlled by two promoters designed by us.
METHODS: Regulatory sequences for two promoters were selected based on homology of gene surrounding regions of several mammalian species including humans. The specificity of gene expression was established by determining co-localization of the fluorescence of viral YFP and the fluorescence of antibodies to neuronal markers. AAV particles were injected in visual cortex area V1 of adult rats (2 - 4 months old). 10 - 14 days post-injection the rat brains were perfused with 4 % PFA phosphate buffer solution and then sliced to 100 um thickness. The slices were treated with antibodies to GAD65/67, CamKIIa, GABA, SOM, PV, vasoactive intestinal peptide (VIP) and cholecystokinin (CCK). Confocal images of the first 20 um from the slice surface were then taken and used for co-localization analysis.
RESULTS: The first promoter was designed to be specific to PV interneurons. Indeed, the analysis of confocal images taken from 3 rats showed that approximately 2/3 of viral YFP labelled neurons were also labelled by PV antibodies (383/605, 63 %). Meanwhile, only 16 % of neurons expressing viral YFP were also labelled by antibodies to SOM (37/228). In addition, co-localization tests with CamKIIa antibodies showed little overlap: only <7 % of neurons expressing viral YFP were also labelled by CamKIIa antibodies. Currently we are performing experiments to determine the specificity of a putative SOM promoter.
CONCLUSIONS: Our results show that we were able to design a promoter that restricts AAV delivered gene expression to interneurons with a strong preference to PV class of interneurons.

Title: Efficient and Specific Sensor and Actuator Delivery to the Rodent Peripheral Nervous System through Systemic AAVs

Authors: *X. CHEN[1], S. RAVINDRA KUMAR[1], D. YANG[2], C. D. ADAMS[3], T. WANG[1], D. WOLFE[1], J. GRIFFITHS[1], R. NOSEDA[4], J. R. KEAST[3], I. M.-C. CHIU[2], V. GRADINARU[1]; [1]Biol. and Biol. Sch., Boston, MA

Abstract: The peripheral nervous system (PNS) is critical in regulating end-organ function and feedback signal transmission to the central nervous system (CNS). To achieve precise genetic manipulation within the PNS, more efficient and targeted gene delivery vehicles are needed. Adeno-associated viruses (AAVs) have become the vector of choice for gene delivery in vivo but non-invasive administration of natural serotypes targets the PNS with mixed efficiency and specificity. Attempts to circumvent these limitations by direct administration of AAV are often either surgically challenging or have incomplete coverage. To further explore the potential of targeting PNS with engineered-capsid, we utilized the advanced selection platform Multiplexed-CREATE (Kumar et al, Nature Methods, 2020) to perform selection in vivo on PNS areas of interest. Preliminary Next Generation Sequencing (NGS) analysis of the recovered sequences revealed two novel AAV variants: AAV-PHP.PNS1 and AAV-PHP.PNS2. In vivo validation in C57BL/6J adult mice by i.v. delivery of the variants packaging EGFP under a strong ubiquitous CAG promoter showed enhanced EGFP expression in neurons of the nodose ganglia and Dorsal Root Ganglia (DRG). Consistent with NGS enrichment data, AAV-PHP.PNS1 showed greater specificity to the nodose ganglia and DRG by exhibiting lower overall transduction in peripheral organs including liver (an otherwise strong AAV9 target), while AAV-PNS2 showed higher overall efficiency in targeting ENS. Intraperitoneal delivery of the variants in P1 pups also exhibit strong transduction in DRG, labeling ~40% of the Tuj1+ cells. Among the neuron subtypes, ~53% of CGRP+ neurons were transduced. Intravenous delivery into adult Sprague Dawley rats also resulted in robust transduction in main sensory ganglia (DRG, Trigeminal Ganglia), sympathetic and parasympathetic ganglia, and in the ENS. To explore the vector's potential beyond neuron labeling and tracing, we demonstrate that we could record neuronal activity in nodose ganglia following I.V. delivery of GCamp with PNS1 in adult C57BL/6J mice. We next took a step forward to see whether we could achieve functional manipulation with the new PNS capsids, demonstrating that I.P. delivery of a Cre-dependent excitatory DREADD in Trpv1-Cre mice with PNS1 at P1 in adult mice can induce pain phenotypes. With improved efficiency and specificity towards the PNS in rats and mice for effective sensor and actuator

performance, the AAV-PHP.PNS1 and AAV-PHP.PNS2 capsids can help enhance anatomical and functional studies.

Title: Evaluating the use of systemic AAV-PHP.S to transduce peripheral neurons in a rat model

Authors: *O. YANG, G. ROBILOTTO, A. MORRIS, A. D. MICKLE;
Univ. of Florida, Gainesville, FL

Abstract: Viral transduction is a commonly used tool to manipulate gene expression in rodents. Adeno-associated viruses (AAV) are the most widely used due to their relative safety and long-term efficacy without causing immunological complications. Many different serotypes have been discovered and developed to transduce different populations of neurons preferentially. Unfortunately, efficient targeting of peripheral neurons remains a challenge for many researchers. Recently, Chan et al. (2017) generated AAV-PHP.S, a capsid engineered from the AAV9 serotype, which produced higher transduction efficacy in the peripheral nervous system in c57/B6 mice compared to AAV9. This project aimed to evaluate the efficiency of systemic PHP.S to transduce peripheral neurons innervating the bladder and external urethral sphincter, compared to AAV9. We injected (IP) Wistar rat pups (P1) with either AAV9-CAG-tdTomato or AAV-PHP.S-CAG-tdTomato and after 6 weeks, collected bladder, external urethral sphincter, dorsal root ganglia, major pelvic ganglia, and spinal cord tissue. We then evaluated expression patterns in peripheral tissue and quantified expression in the dorsal root ganglion and major pelvic ganglion. Initial results indicate that systemic delivery of AAV-PHP.S-CAG-tdTomato was more efficient in the transduction of peripheral neurons in Wistar rats than AAV9-CAG-tdTomato. Our results indicate that AAV-PHP.S exhibits improved transduction of neurons in the peripheral nervous system in rats compared to the AAV9 serotype. These results suggest that despite the AAV-PHP.S serotype being optimized for targeting the mouse peripheral nervous system, it may also be a valuable tool in targeting the rat peripheral nervous system.

Title: Dual labeling Vesicular Stomatitis Virus Allows Identification of Virus-Host Dynamics in vivo in the CNS

Authors: *T. KRAUSE, X. MA, C. CEPKO;
Harvard, Boston, MA

Abstract: Viral infection is often assayed by markers of ongoing viral gene expression. Such assays do not identify the cells that do not host ongoing viral replication, despite being exposed to virus, or those having a past history of viral gene expression. This leads to an inability to identify cells that are able to reduce or block virus replication. Using a dual labeling Vesicular Stomatitis Virus (VSV), we were able to overcome these limitations. The virus encodes Cre, expressed from a transcriptional unit that is active immediately after infection, which leads to stable marking of any cell with at least a low level of viral gene expression. It also encodes GFP, which marks cells with higher levels of viral gene expression/replication. Assay of the Cre and GFP readouts allows one to better delineate the dynamics of viral infection in tissue or in culture. By performing stereotactic injections of VSV into the murine CNS parenchyma, we found that the majority of productively infected cells (GFP positive) were neurons. In contrast, the cell types that were exposed to virus, but resistant to viral replication, were glia. Using this dual labeling system, we plan to further elucidate the mechanisms behind viral tropism and establishment of infection.

Title: High-throughput testing of sedation and anesthesia in Drosophila by volatiles and aerosols with positional recording (VAAPR) system

Authors: *Z. YUAN, S. HANSEN;
The Scripps Res. Inst., Jupiter, FL

Abstract:

General anesthesia is a drug-induced reversible loss of consciousness (LOC) in animals. Anesthetics have been used clinically for more than 150 years in humans. Systems for accurately measuring anesthesia are complicated by sedation that precedes anesthesia and the very steep hill slopes encountered during dosing of anesthetics (i.e., anesthetics exert their effects over a very narrow concentration range). A high throughput method is in need for testing effects of various kinds and doses of anesthetics and screening potential anesthetic-sensitive genes with high sensitivity and temporal resolution. Previously we built a volatiles and aerosols with positional recording (VAAPR) system for testing anesthetics on Drosophila in 16-well chambers. Here we introduce a new version of VAAPR with 64-well chambers, automated multivalve electric flow meters, and data processing to distinguish sedation and anesthesia. To distinguish between sedation and anesthesia we record and process both activity and vertical position of animals. Flies that stop moving but do not fall, or flies that fall but move and can't regain a vertical position, are identified as sedated. Animals that fall and stop moving are identified as anesthetized. The key event for the latter is the event of falling, which is well-defined and allows for very precise temporal resolution. Furthermore, we introduce the use of survival curves for determining statistically significant anesthetic events in a large number of animals. The use of automated electric flow valves greatly increases the precision that volatile anesthetics can be delivered. Here we use three separate electric flow valves to control O_2 and N_2 separately. This allows us to maintain a constant amount of O_2 while dosing anesthetics in order to avoid potential effects from hypoxemia. We expect this technique to be used for identifying more genes involved in anesthetic sensitivity and other behaviors related to aerosolized drugs.

Title: Trans-synaptic labeling and circuit reconstruction with single neuron resolution by light microscopy in the Drosophila brain

Authors: *Y. LI, K. ATHUKORALA, M. CHEN, L. WALKER, D. CAI;
Univ. of Michigan, Ann Arbor, MI

Abstract: Proper performance of the nervous system relies on the precise function of individual neurons and their intricately-woven network topology. Identifying involved neurons in a circuit, and further resolving the connections between them are critical steps to understand specific brain functions in healthy and disease conditions. Progress in 3D electron microscopy-based circuit reconstruction sheds light on revealing the neural network structure with synapse resolution. However, EM's limitation of data throughput and difficulty of retrieving molecular identity of the reconstructed neurons makes light microscopy a crucial complementary modality.
Recently developed genetic tools, including GRASP, trans-Tango, and TRACT permit identifying anterograde mono-synaptic connections in the Drosophila nervous system. In particular, the latter two can label the full morphology of connected neurons, which promises the potential of revealing the second order neurons' identities and their other connections by the soma locations and projection patterns. That said, it would be ideal to obtain individual neuron's morphology so that the reconstructed network may be mapped to electron microscopy data for detailed connectomic analysis. Furthermore, identity of the second order neurons may be revealed by comparing their morphologies to numerous available light microscopy-based single neuron reconstructions using an informatics tool, e.g. NBLAST. However, current trans-synaptic tools only utilize a single reporter to label the second order neurons, which severely constrains the ability to reconstruct individual neuron's morphology.
To solve this problem, we created a new version of transgenic Bitbow fly to enable multispectral labeling with trans-Tango. Using sample expansion and a custom-built light microscope, we can achieve imaging the whole fly brain with sub-hundred nanometer resolution in a few hours. Combining with computer-aided neuronal tracing, we can now produce brain-scale data with single neuron annotations to build circuit consensus in a high-throughput manner. We envision that these new tools will greatly speed up our progress in brain circuit discovery.

Title: SCAMPR: A pipeline for quantitative analysis and spatial mapping of neuronal mRNA expression

Authors: *R. ALI MARANDI GHODDOUSI[1,2], V. MAGALONG[2], A. KAMITAKAHARA[2,1], P. LEVITT[1,2,3];
[1]USC, Los Angeles, CA; [2]Children's Hosp. Los Angeles, Los Angeles, CA; [3]Keck Sch. of Med., Los Angeles, CA

Abstract: Unraveling the role of neuronal heterogeneity in the production of diverse behaviors requires detailed classification of neurons into related and/or distinct types. Cellular location and gene expression patterns are two of the most used characteristics for identifying neuron types, however, until recently it has been difficult to investigate both of these features in the same tissue. Hiplex RNAScope, a commercially available multiplexed *in situ* hybridization technique, combines high dimensional transcriptomics and topology in the same tissue section by allowing for visualization of over 48 different mRNAs at a single-cell resolution. Existing methods for quantitative analysis of spatial mRNA expression have some challenges, particularly the incomplete and/or inaccurate identification of cell boundaries that impact the correct assignment of transcripts to specific cells. Other factors include a requirement for high computing resources and the generation of exceptionally large datasets during analysis. We developed a dual immunohistochemistry-RNAscope protocol that allows for relatively rapid segmentation of neurons based on their cytosolic and nuclear boundaries. Single-Cell Automated Multiplex Pipeline for RNA (SCAMPR) was developed for semi-automated image processing, quantitative analysis, and data visualization of Hiplex RNAscope. SCAMPR requires modest computing power, generates datasets that are practical in size, and allows for sensitive and specific quantification of mRNA expression in both the nuclear and cytoplasmic compartments of the cells. We demonstrate that SCAMPR is compatible with both peripheral and central neurons. Comparisons between manual segmentation of cellular regions of interest (ROI) and SCAMPR demonstrate a minimum of a 3.5 fold increase in speed during ROI segmentation without a

decrease in accuracy. SCAMPR's utility is shown in pairwise and clustering-based comparisons of single-cell gene expression and the mapping of these relationships back onto the source tissue. Lastly, SCAMPR was applied in two different ways to measure, at cellular resolution, differences in gene expression between experimental groups. We used SCAMPR to compare gene expression in the developing nodose ganglion of mice that were raised under normal rearing conditions (care as usual) to those that were raised in the presence of early life stress. We also compared neurotrophin receptor mRNA expression in the embryonic brainstem of wildtype mice to the expression in mice containing conditional knockouts of the gene encoding the pleiotropic MET receptor tyrosine kinase (*Met)*.

Title: Every Cell Matters: Molecular Cartography™ of the mammalian brain

Authors: B. NILGES, F. REINECKE, A. BOGDOLL, ***N. KASHIKAR**;
Resolve Biosci. GmbH, North Rhine-Westphalia, Germany

Abstract: The brain is a complex organ and understanding its working is one of the holy grails of human scientific pursuits. Quantitative studies of the molecular inventory of the brain stimulate new hypotheses and experiments in basic and translational neuroscience. However, despite the recent advances in sequencing approaches, the spatial architecture of the mRNA expression at single-cell resolution has remained poorly understood. Only the addition of a spatial component to transcriptomic information can provide the context to understand the function of cell types, individual subtypes as well as connectivity within and across anatomically defined regions. Here, using Molecular Cartography (MC) on the mouse brain, we present a novel resource for the neuroscientific community, where we spatially map and quantify the transcript abundance of 100 genes that represent some of the key pathways and markers defining neural cells and CNS signaling. MC enables digital quantification of mRNA molecules, high sensitivity that parallels conventional single-molecule FISH, subcellular resolution in three-dimensions within a 10 µm thick tissue section. The genes were chosen to serve as combinatorial markers for specific cell types and subtypes in the different regions of the brain. We focus on the part of the hemisphere that contains the most relevant neuroanatomical areas such as the cortex, hippocampus, caudoputamen, thalamus, hypothalamus. We demonstrate that: a. MC data matches conventional *in situ* hybridization-based methods demonstrating a high degree of

specificity, b. MC is highly quantitative and correlates with an R^2 of >0.9 with bulk RNAseq data, c. identification and spatial clustering of more than 30 cell types and subtypes, and d. identification of all major cell layers and the heterogeneity of cells within.
Although we focus on the mouse brain as a resource case, MC is equally applicable to other species of neuroscientific interest, e.g., human samples from clinics or brain banks, cell culture models of major neural cell types, and reptilian or fish brains that enable to infer the functions of genes cells and structures based on their conservation throughput evolution. We trust that MC provides a novel and unique opportunity for neuroscience researchers to redefine the mapping of the brain in health, disease, and development.
The mouse brain dataset is available to download for registered users on resolve-biosciences.com.

Abstract: Neuronal cell types are classically defined by their molecular properties, anatomy, and functions. While recent advances in single-cell genomics have led to high-resolution molecular characterization of cell type diversity in the brain, neuronal cell types are often studied out of the context of their anatomical properties. To better understand the relationship between molecular

and anatomical features defining cortical neurons, we combined retrograde labeling with single-nucleus DNA methylation sequencing to link neural epigenomic properties to projections. We examined 11,827 single neocortical neurons from 63 cortico-cortical (CC) and cortico-subcortical long-distance projections. Our results revealed unique epigenetic signatures of projection neurons that correspond to their laminar and regional location and projection patterns. Based on their epigenomes, intra-telencephalic (IT) cells projecting to different cortical targets could be further distinguished, and some layer 5 neurons projecting to extra-telencephalic targets (L5 ET) formed separate clusters that aligned with their axonal projections. Such separation varied between cortical areas, suggesting area-specific differences in L5 ET subtypes, which were further validated by anatomical studies. Interestingly, a population of CC projection neurons clustered with L5 ET rather than IT neurons, suggesting a population of L5 ET cortical neurons projecting to both targets (L5 ET+CC). We verified the existence of these neurons by dual retrograde labeling and by anterograde tracing of CC projection neurons, which revealed axon terminals in ET targets including thalamus, superior colliculus, and pons. These findings highlight the power of single-cell epigenomic approaches to connect the molecular properties of neurons with their anatomical and projection properties.

Abstract: Selective transgene expression is critical to the study of brain cell types including their roles in brain function and disease. However, few tools exist that can selectively target cell populations and can be applied across mammalian species. To enable specific brain cell population labeling across species, we are generating a collection of enhancer-AAV vectors that drive transgene expression in defined cell subclasses. We undertook a systematic screen to find enhancer elements capable of targeting gene expression from AAV vectors to major neocortical cell populations. In previous work, we have described enhancers for several different population of cortical neurons, and we demonstrated the maintenance of specificity in mouse and primate (Mich et al. Cell Reports 2021). Here, we show our progress generating a new collection of enhancer-AAV tools to target glial cell populations. We present a set of astrocyte- and oligodendrocyte-selective enhancers-AAV vectors, and present characterization of their activity across brain regions, and across species. Our growing toolbox of enhancer-AAVs for selective transgene expression will be important to dissect the roles of cell populations in brain function across species.

Title: Spatial annotation of scRNA-seq data by 10x Visium

Authors: *A. C. MITCHELL, M. CHIANG, M. KUNST, K. BROUNER, A. GARY, A. TORKELSON, M. MCGRAW, K. SMITH, C. VAN VELTHOVEN, B. TASIC, H. ZENG; Allen Inst. for Brain Sci., Seattle, WA

Abstract: Over the past decade various single-cell genomics approaches (e.g., RNA-seq) applied to dissociated cells or nuclei have been used to define of cell types at the molecular level. These single-cell molecular profiles can also be used to predict spatial and anatomical location of cell types based on differential marker gene expression. However, to accurately and quantitatively define locations and distributions of cell types highly multiplexed molecular measurements *in situ* are needed. Here we use 10x Genomics Visium spatial gene expression platform (slides with 55 µm spots) to profile transcriptome-wide gene expression from 15 coronal and 8 sagittal sections spanning the mouse brain. The resulting data was integrated with the Allen Institute for Brain Science forebrain scRNA-seq-based taxonomy (https://portal.brain-map.org/atlases-and-data/rnaseq) and Bing Ren's lab BICCN snATAC mouse brain *cis*-element atlas (http://catlas.org/mousebrain). In conclusion, we find that despite lack of single cell resolution, 10x Visium spatial transcriptomics data are valuable for interpretation of scRNA-seq data to define spatial localization/distribution of cell types.

Title: Analyzing blood brain barrier involvement in major depressive disorder using neurovascular cell enrichment and single nucleus RNA sequencing

Authors: *M. LOTSTEIN, J. SAMUELS, M. LEHMANN, M. HERKENHAM; NIH, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Previous work in our laboratory showed that chronic psychosocial stress in mice induces vascular micro-damage in brain, including a decline in blood brain barrier (BBB) function. This damage activates a series of inflammatory pathways in brain-resident immune cells and precipitates depressive-like states. Not only relevant to psychosocial stress, BBB dysfunction underlies a subset of disorders, including Major Depressive Disorder (MDD). We

want to use transcriptomic analysis to examine how barrier cells respond to stress, specifically in MDD. We aim to identify the differences between postmortem samples from MDD and healthy control brains using single-nucleus RNA sequencing (snRNA-Seq). However, snRNA-Seq datasets have a low representation of neurovascular cells, typically limited to small endothelial and microglial clusters. These small sample sizes prevent any rigorous statistical analyses on neurovascular cells, which are frequently overlooked in favor of the more populous neurons and oligodendrocytes. We are using previously published snRNA-Seq datasets to identify signature markers of non-neurovascular nuclei that reside within the nuclear membrane. By staining our isolated nuclei samples with neuronal, oligodendrocyte, and astrocyte markers, we can sort out these dominating cell types. After performing snRNA-Seq experiments on sorted and non-sorted nuclei from frontal cortex of human postmortem brain, our sorted samples have a significant increase in neurovascular populations, including our main cell type of interest—endothelial cells. Further experiments are underway to examine the transcriptomic changes in barrier cells between MDD and healthy control brains after using the signature markers to enrich our samples for neurovascular cells.

Title: Robotag-seq: robot assisted cellular barcoding for transcriptome-wide sequencing of anatomically identified cell populations in intact tissue

Authors: *J. O'BRIEN[1], B. AUCH[2], M. S. RIEDL[3], L. GENGELBACH[2], A. G. J. SKORPUT[3], D. M. GOHL[2,4], L. VULCHANOVA[3], S. B. KODANDARAMAIAH[1];

Abstract: Single cell transcriptomics is a powerful tool for measuring the gene expression patterns within single cells, and it has revealed numerous insights that were previously hidden by the averaging of gene expression patterns across cell populations. The toolkit for single cell transcriptomics currently lacks the ability to integrate spatial and functional information with transcriptomic measurements at scale. Current techniques like Patch-Seq, which combine functional and transcriptomic profiling, are laborious, time consuming, and do not scale easily

for analysis on multiple cells in tissue. In contrast, spatial transcriptomics, which profiles transcriptomes in a spatially resolved manner, lacks the ability to conduct transcriptome-wide measurements at cellular resolution and is depth-limited to only analyzing cells near the tissue surface. Here, we present a robotic microinjector that is programmed to microinject 100's of pre-identified cells in intact neural tissue with unique oligonucleotide barcode-antibody conjugates (hashtags) which target the nuclear pore complex. After injection, nuclei are isolated from the surrounding tissue before transcriptomic profiling using emulsion droplet-based cell partitioning. During transcriptomic profiling, the injected hashtags are recovered and can be used to relate the profiled transcriptomes with the pre-identified cells thereby integrating spatial and transcriptomic information into a single approach. We have demonstrated successful automated microinjection of a fluorescently labeled dextran into neurons in mouse striatum and spinal cord dorsal horn slices with success rates of 96% and 68%, respectively. Additionally, we have demonstrated automated microinjection-mediated tagging of neuronal nuclei in mouse striatum slices with a fluorescently labeled antibody as a precursor step for fluorescence based nuclear enrichment and as a proof of concept for hashtag labelling of nuclei using the same monoclonal antibody. We are capable of performing high-throughput automated microinjections at a rate of approximately 100 neurons per hour which will facilitate transcriptome-wide profiling at scale. We are currently optimizing the processes for nuclear harvesting, enrichment, and subsequent transcriptomic profiling. When fully developed, we anticipate this to be a generalized strategy for barcode tagging specific populations of cells of interest for whole transcriptome analysis in a variety of tissues.

Abstract: Computation within cortical microcircuits is defined by properties of the neurons and the synaptic interaction between them. While heterogeneity among different interneuron types is well established, excitatory pyramidal neurons of the cortex are considered to be largely homogeneous. To identify possible functional differentiations within this pyramidal neuron population and their recurrent synapses, we focused on the human layer 2/3 temporal cortex which is greatly expanded compared to the rodent cortex.
We performed multi-neuron patch-clamp recordings in acute brain slices obtained from patients (22 individuals) undergoing epilepsy resection surgery. In total, we recorded the electrophysiological properties of 1007 pyramidal neurons and 1242 monosynaptic connections. Our high-throughput approach allowed sampling of up to 90 neurons and 170 synaptic connections from single individuals enabling us to assess inter- and intra-individual variability. We observed substantial heterogeneity in cellular parameters with intra-individual variability severalfold larger than inter-individual variability. Hierarchical clustering of the high-dimensional parameter set yielded functionally distinct clusters of pyramidal neurons which were present in each patient. Synaptic properties of recurrent excitatory connections were highly diverse including preliminary evidence for some target-cell specificity.
Taken together, or results show that the human layer 2/3 pyramidal neuron population comprise distinct functional subtypes. This may represent a generic organizational principle that is shared across human individuals and relate to previously reported transcriptomic heterogeneity. The identified diversity in cellular and synaptic function has important implications for the computational capacity of the cortical microcircuit and highlights potential species-specific differences.

Title: Markerless pose estimation programs use on 12 month old infants

Authors: *S. FINKBEINER[1], W. QUACKENBUSH[1], M. REIMERS[1], R. KNICKMEYER[1], C. BEST[2];
[1]Michigan State Univ., Lansing, MI; [2]Michigan State Univ., East Lansing, MI

Abstract: Neural network-based markerless motion tracking programs hold great promise for studying the behavior of both people and animals videotaped in freely moving conditions, by determining the movement of different body parts through space. However, little work has been done using these softwares to evaluate infant motion. The primary objective of the current study was to compare two such systems (DeepLabCut (DLC) and OpenPose (OP)) to each other, as well as to ground truth annotations done by our research team. DeepLabCut is a neural network that was originally trained on mouse models, it requires minimal training from the user before it's implemented; whereas OpenPose is a pre-trained neural network that was trained on humans and required no training before use. We used 22 videos of infants, about 12 months of age, acquired during a behavioral paradigm adapted from the Laboratory Temperament Assessment Battery (Lab-TAB) Mask episode. Videos were provided by researchers at University of North Carolina at Chapel Hill (UNC), who used them to assess infant fear reactivity. We determined that aside from the Neck point, OpenPose1.7.0 is providing more accurate annotations compared with the DeepLabCut2.0.7.2 neural network, which we trained on 2,809 frames. The videos used for annotation were captured from the infant's left side, creating lower confidence values for key points on the right side of the infant (eyes and ears). Aside from the right ear and right eye, the annotation that showed the lowest confidence when using OP was the neck annotation; 81% of infants analyzed showed consistent marginal drops in confidence when compared to other annotated key points. Our team is currently exploring whether we can supplement the OP neural network with data from DLC to attain more accurate neck annotations. Ultimately we will use these pose estimation programs to (1) determine the overall motion of the infants and compare it to parental ratings of infant activity level, (2) assess how infants direct their attention during the mask task and test whether this is associated with expert ratings of infant fear reactivity, and (3) determine if expert ratings of fear reactivity can be predicted from infant motion.

Title: Deep-learning based pose estimation, identification, and end-to-end behavior classification for interacting primates and mice in complex environments

Authors: *M. MARKS[1], J. QIUHAN[1], O. STURMAN[2], L. VON ZIEGLER[2], S. KOLLMORGEN[1], W. VON DER BEHRENS[1], V. MANTE[1], J. BOHACEK[2], M. F. YANIK[1]; [1]ETH Zurich and Univ. of Zurich, Zuerich, Switzerland; [2]ETH Zurich, Zurich, Switzerland

Abstract: The quantification of behaviors of interest from video data is commonly used to study the effects of genetic alterations, pharmacological interventions, and brain functionality. Existing approaches lack the capabilities to analyze the behavior of groups of animals in complex environments. We present a novel deep learning architecture for classifying individual and social animal behavior in complex environments from raw video frames, whilst requiring no intervention after minimal human supervision. Our behavioral classifier is embedded in a pipeline (SIPEC) to perform segmentation, identification, pose-estimation, and classification of complex behavior all automatically with state-of-the-art performance. SIPEC successfully recognizes multiple behaviors of freely moving individual mice as well as socially interacting non-human primates in 3D, using data only from simple mono-vision cameras in home-cage setups. We show how this pipeline can be easily deployed and used by researchers to analyze their behavioral data.

Title: A Unified Model of the Task-evoked Pupil Response

Authors: *S. MIRBAGHERI[1], C. S. BURLINGHAM[2], D. J. HEEGER[2];
[1]Grad. Program in Neurosci., Univ. of Washington, Seattle, WA; [2]Psychology, New York Univ., New York, NY

Abstract: Background: During task performance, pupil size entrains to trial timing, dilating and then constricting sluggishly following trial onsets. This so-called task-evoked pupil response is modulated in amplitude by task demands and behavioral performance. The task-evoked pupil response is commonly used to estimate arousal by assuming pupil size is a linear transformation of task events. We show that estimates of arousal based on this consensus model are not robust to small changes to the task that should not alter arousal level. We propose an alternative model linking the task-evoked pupil response and arousal, which leverages that a common neural input drives pupil size and saccades. **Method:** Human observers performed a forced-choice orientation-discrimination task on a briefly displayed peripheral grating. On easy trials, the grating was tilted far from vertical, and observers achieved ~93% accuracy on average. On hard trials, the grating's tilt was close to vertical, and observers achieved ~70% performance on average. The task difficulty was changed in alternate runs (75 trials/run, 4 s/trial). In a separate version of the task, the wait time between trials was reduced (2 s/trial). We fit a computational model to measurements of pupil size and saccades, generating estimates of arousal level. **Result:** Fitting our model to the data yields: 1) an estimate of the common input that drives both saccades and pupil size and 2) the gain of the input to the pupil, separately for each trial type. Gain scaled with task difficulty and behavioral performance and generalized across tasks with different inter-trial wait times, as expected of a measure of arousal. The estimated arousal from the consensus model, on the other hand, varied considerably with the wait time between trials, indicating that this model over-fits and that pupil size is not a linear transformation of task events. The estimated common input was modulated by the timing of the task and behavioral response, suggesting that it reflects a cognitive representation of task structure. Moreover, the model offers a unified explanation for other phenomena, including modulation of trial-to-trial pupil response variability with task difficulty and a constrictory pupil response time-locked to saccades that scales with task difficulty. **Conclusion:** We propose a novel model that predicts the shape and amplitude of the task-evoked pupil response from saccade timing, estimates arousal robustly, and explains many other phenomena. This model's success suggests strong constraints on the neural circuits that comprise the common driver of saccades and pupil size, as well as the arousal/gain modulator of pupil size.

Title: Nonlinear dimensionality reduction simplifies the control of dexterous prosthetic hands

Authors: *A. PORTNOVA-FAHREEVA[1], F. RIZZOGLIO[2], M. CASADIO[3], F. A. MUSSA-IVALDI[4], E. ROMBOKAS[5];
[1]Northwestern Univ., Evanston, IL; [2]Univ. Degli Studi Di Genova, Genova, Italy; [3]Univ. of Genova, Genova, Italy; [4]Arms And Hands, Shirley Ryan AbilityLab, Chicago, IL; [5]Univ. of Washington, Seattle, WA

Abstract: With the rise of technological advancements, prosthetic hands have seen many improvements in their designs, increasing the number of Degree of Freedoms (DOFs) from simple one-degree hooks to anatomically-correct testbed hand. Nonetheless, the control strategies have been limited, preventing prosthetic users from utilizing the entire plethora of finger dexterity in their devices and limiting them to control only a pre-selected number of grips, either via a simple finite state machine in an on-off pattern or more complex pattern recognition algorithms. In this study, we proposed the use of a nonlinear dimensionality-reduction method, the nonlinear Autoencoder (NAE), to explore the lower-dimensional, *latent*, space of complex human hand kinematics in order to facilitate prosthetic control. The NAE was compared to the more standard Principal Component Analysis (PCA), frequently used to explore the dimensionality of hand kinematics. Performance of the two methods was compared on (a) the ability to accurately reconstruct hand kinematic data from a latent manifold and (b) variance distribution across latent dimensions. The NAE exhibited high performance in its ability to reconstruct hand kinematic data with 94% accuracy from a two-dimensional latent space in comparison to just 78% accuracy in PCA. In addition, the latent dimensions of the NAE exhibited a more equal distribution of variance in comparison to PCA. To test the possibility for the NAE to offer an effective platform to control prosthetic hands, we developed a simple myoelectric controller, in which users were able to control a 15-DOF virtual hand using four forearm muscles. Muscle signals were combined in a vector summation algorithm, allowing the users to operate on a 2D space, which corresponded to the latent space of hand kinematics. As a result, we could decode every point on the control space into its corresponding 15 dimensions of virtual hand kinematics. Through this study, we also explored the complexity of learning a visually high-dimensional task (*i.e.*, controlling a 15D virtual hand) controlled by a low-dimensional space (*i.e.*, 2D latent space) and the effect of the users' training on the visually low-dimensional task (*i.e.*, cursor control) on their learning to perform the task that appeared high-dimensional. Two groups were created, in which one was trained on a 2D cursor-controlling task prior to learning to control the 15D virtual hand, the other one was only exposed to learning to manipulate the virtual hand, without any feedback about the true dimensionality of the control space.

Title: A Simple Device for Real-Time Detection of Head and Body Movements in a Mock Scanner, for Screening and Training Human Subjects and Alert Animals

Authors: *F. AYAD[1], P. HUMANE[2], T. DAVID[3], A. BORTEL[4], A. SHMUEL[3];
[1]Biomed. Engin., McGill Univ., montreal, QC, Canada; [2]McGill Univ., Monteal, QC, Canada; [3]McGill Univ., Montreal, QC, Canada; [4]Montreal Neurolog. Institute, McGill Univ., Montréal, QC, Canada

Abstract: Introduction
With the advent of imaging at ultra-high field, head and body movements are one of the factors that limit our capacity to obtain high resolution/quality data. We have developed a small wearable device with the purpose of acquiring wireless data on head and body movements for real-time analysis while a subject is trained in a mock MRI scanner. This device works in parallel to an in-bore camera used for movement detection, to support subject screening and training to remain still in preparation for MRI.
Methods
Our setup consists of a wireless motion sensor system and an in-bore video camera. The sensor system consists of two highly sensitive, three-axis sensor nodes. The sensor nodes can be placed on the forehead and the hip of the participating human subjects by means of elastic bands, to measure head and body movement, respectively. For alert primates and mice, the sensor is sufficiently sensitive to detect platform vibrations caused by the animal's movement.
The software plots and analyzes the movement data in real-time and alerts the user and the subject when a movement beyond the accepted thresholds occurs.
Results
We have tested the system for training human subjects, alert primates, and alert mice.
Conclusions The proposed system can be used to screen and train human subjects or alert animals to stay still in the MRI. It can also be used for gradually accommodating special subject populations - such as subjects with neurodevelopmental disorders - to staying still in the scanner. The device can contribute to improving imaging quality and reducing the cost of imaging human subjects that are prone to moving and thus producing unusable data. Given the increase in ultra-

high-field (7 Tesla and higher) MRI systems, the implementation of this device is even more important, since movement artifacts are accentuated and especially detrimental in high-field imaging.

Title: Patient-specific diffusion tensor-based thalamic segmentation in deep brain stimulation for essential tremor

Authors: *K. A. MALAGA[1,2], L. HOUSHMAND[2], J. T. COSTELLO[3], J. CHANDRASEKARAN[2], K. L. CHOU[4,5], P. G. PATIL[2,4,5];
[1]Biomed. Engin., Bucknell Univ., Lewisburg, PA; [2]Biomed. Engin., [3]Electrical Engin., [4]Neurol., [5]Neurosurg., Univ. of Michigan, Ann Arbor, MI

Abstract: Thalamic deep brain stimulation (DBS) is an established surgical therapy for essential tremor (ET). Traditional DBS targeting and electric field modeling employ atlas-based approaches, which perform well on average but obscure patient-specific anatomical variability. The objective of this retrospective study was to assess an individualized modeling methodology (N-of-1 approach) for segmenting thalami in ET patients receiving unilateral DBS. The N-of-1 approach uses patient-specific diffusion tensor imaging data to perform thalamic segmentation and volume of tissue activation (VTA) modeling. For each patient (n = 22), the thalamus was segmented into 13 nuclei using k-means clustering. VTAs associated with therapeutic and side effects were computed using finite element analysis and then used to evaluate the segmentation. Segmentation and VTA results from N-of-1 and atlas-based modeling were compared. VTA size and shape varied considerably across patients. Using N-of-1 segmentation, 91% of tremor suppression VTAs overlapped with motor thalamus (100% using atlas-based). Therapeutic VTAs had significantly more motor thalamus overlap than sensory thalamus for both approaches. For sustained paresthesia, 94% of VTAs overlapped with sensory thalamus using N-of-1 segmentation (74% using atlas-based). Sustained paresthesia VTAs had significantly more sensory thalamus overlap than therapeutic VTAs for both approaches. For dysarthria/motor contraction, 68% of VTAs spread outside thalamus (in all directions) using the N-of-1 approach (79% using atlas-based). Dysarthria/motor contraction VTAs had significantly more external

spread than therapeutic VTAs for only the N-of-1 approach. The N-of-1 approach explained DBS side effects better, specifically when patient neuroanatomy differed from the atlas. Although atlas-based results were similarly accurate across patients, the N-of-1 approach may provide greater precision regarding individual outcomes. N-of-1 thalamic segmentation, in particular, enables optimized targeting based on patient-specific anatomical variability.

Title: Logistic regression in machine learning with application to face recognition and unknown rejection

Authors: *H. YUAN[1], M. V. CHAO[2];
[1]Independent Lab., San Marino, CA; [2]Independent Lab., Palos Verdes Peninsula, CA

Abstract: Face recognition in machine learning is generally about recognizing known faces. As science attempts to close the gap between man and machine by building systems capable of learning, we must embrace the importance of the unknown. The ability to differentiate between known and unknown can be considered a critical element of any intelligent self-learning system. (Boult, Cruz, 2019, p. 1). This poster investigates the use of logistic regression in Machine Learning, using an example of how this can be applied to face recognition and unknown face rejection. Machine learning in face recognition, faces of a selected group of people are classified, and all other faces and non-faces are rejected. The classic approach is to estimate the class densities, assigning the face to the class with the highest posterior probability. Performance of the face recognition classifier is counted as good if the known test face is classified correctly. If the known test face is misclassified by the face recognition classifier, then the misclassification is counted as a classification error. If an unknown face is presented to the face recognition classifier, the face recognition classifier could still classify the unknown face erroneously as a known face. Distance thresholds as used in k-nearest neighbor or euclidean based classifiers could classify an unknown face as unknown should the distance threshold not be high enough to declare as a known face, but may not be consistent to reject the unknown. In contrast, logistic regression is a way to use a squashing function or a logistic function to map a real-valued input to the range 0 to 1. Since the logistic or sigmoid output values are between 0 and 1, it would be reasonable to view the output as a probability. Logistic regression predicts positive when the

probability is greater than 0.5 and negative when the probability is less than 0.5. Unknown face rejection is investigated in this poster using the Olivetti face dataset engaging logistic regression with sigmoid output probabilities. A whole approach uses all of the pixels in the Olivetti face image as a feature vector processed in a logistic regression binary classification scheme of one vs all where a face image is either in the Known Class or not in the Known Class (i.e. unknown). Unknown rejection performance is computed and compared using single-look processing with one input unknown face, and multi-look processing with two input unknown faces.

Abstract: Recent advances in machine learning-based markerless pose estimation have dramatically improved the scale and ease with which body landmarks can be tracked in studies of animal behavior. However, pose estimation for animals in a laboratory setting still faces some unique challenges: researchers typically manually generate new labels (~500-1000 labels) for each experimental setup (e.g., for differing behavioral assays, camera angles, lighting conditions, etc.), limiting the generalizability of this approach. Furthermore, each lab trains their own landmark trackers from scratch - the lack of a ‘one-size-fits-all’ kinematic tracker means that different labs track different anatomical landmarks and analyze the resulting kinematic data in idiosyncratic ways. To address these issues, we developed an approach, which we term GlowTrack, for markerless tracking that can generalize across behaviors, experimental setups, and labs. The key innovations are: a) an automated, high-throughput approach for generating

hidden labels free of human error using fluorescent markers at a scale that would not be feasible for human annotation (100's of thousands to millions); b) a multi-camera, multi-light setup for generating large amounts of training data diversity; and c) a technique for massively-parallel tracking of hundreds of landmarks simultaneously, which can provide dense coverage for kinematic analysis. These advances, together with modern approaches for data augmentation, anomaly detection, and temporal smoothing, yield neural network models that generalize across experimental setups, laying the foundation for standardized behavioral pipelines and more complete access to how animals move.
