Title: Investigation of brain cortical development in moderate-late preterm infants

Authors: *X. GENG, P. H. CHAN, C. LAI, W. C. W. CHU, H. S. LAM, P. C. M. WONG; Chinese Univ. of Hong Kong, Shatin NT, Hong Kong, Hong Kong

Abstract: Preterm birth is among the risk factors for children's developmental delay and language impairment. The majority of preterm babies (up to 84%) are moderate to late preterm (MLPT) infants, and relatively less attention has been paid to their potential neurodevelopmental issues. One recent study have reported abnormal total CSF volume in MLPT infants. Another study showed that rain volumes were associated with cognitive and language development in MLPT children at 2 years of age. However, it is not clear whether MLPT infants show differences in cortical measures. Cortical measures have been shown to relate to later behavioral outcomes in full term infants.

A total of 31 newborn infants were included in the study: 17 MLPT (32-36 weeks' gestational age (GA)) vs 14 term babies (>37 weeks' GA) with an age range of 6-89 days (corrected chronological age) at MRI scan. Age and sex between the two groups were matched (MLPT: 47.5 days, 9 girls; control: 52.3 days, 8 girls). MRI data were acquired during natural sleep. An MRI-compatible incubator was used for individuals with weight < 5KG. T1-weighted structural images were acquired to extract neural cortical features, with spatial resolution=0.8x0.8x0.8 mm3, TR=1.8s, TE=2.82ms, flip angle=8o. The raw data was sent to infantFS, a FreeSurfer based pipeline that provides infants templates for template-guided segmentation. The major processing steps include: intensity uniformization, skull stripping, spatial normalization, tissue segmentation, surface reconstruction of the outer and inner surfaces of the cortex, calculating cortical thickness and surface area. Whole brain vertex-based statistical analysis was conducted using a general linear model: imaging measures=age+Group (MLPT and control). The effect of Group was examined on cortical thickness and surface area.

Compared with controls, decreased cortical thickness in right fusiform gyrus and right primary occipital cortex were found in the MLPT group. Increased cortical thickness in right supramarginal gyrus, and enlarged surface area in left precentral gyrus were also observed in the MLPT group. The cluster of decreased cortical thickness in right primary occipital cortex, and that of increased surface area in left precentral gyrus remained significant after multiple comparison correction. These findings suggest that moderate to late preterm birth may affect the

development of primary visual and sensori-motor cortices as early as perinatal period of life. These abnormal sensory processing areas may later affect higher-order cognitive processing, which may eventually contribute to neurodevelopmental problems later in life.

Title: Adult-born neurons maintain hippocampal cholinergic inputs and support working memory during aging

Authors: *M. BOMPOLAKI[1,2], G. KIRSHENBAUM[1,2], C.-Y. CHANG[3], R. SHANSKY[4], A. HARRIS[1,2], L. M. SAVAGE, Ph.D.[5], E. D. LEONARDO[1,2], A. DRANOVSKY[1,2];

Abstract: Adult neurogenesis contributes to the maintenance of normal hippocampal functions and its impairment has been implicated in disorders of stress, memory and cognition. However, a systems level understanding of how low levels of ongoing neurogenesis contribute to major brain functions over time is lacking. We have performed a connectivity analysis of inputs into the dentate gyrus in mice living without neurogenesis. Animals that do not have neurogenesis in adulthood developed a slow-emerging deficit in the spontaneous alternation task indicating working memory impairments. This deficit was accompanied by selective reorganization of the cholinergic projection to the dentate gyrus (DG). Somatotopic organization of medial septal cholinergic hippocampal inputs was lost after 5 months without neurogenesis as neurons that normally project to the ventral hippocampus also innervated the dorsal hippocampus. Thus, more cholinergic neurons projected to the dorsal DG overall. Despite increased cholinergic connectivity, the levels of acetylcholine (ACh) in the dorsal DG were significantly lower in

animals without neurogenesis than controls. Behavioral pharmacology studies revealed that functional deficits in acetylcholine signaling precede the delayed changes in cholinergic innervation and ACh levels. We hence used fluorescent acetylcholine sensor fiber photometry to study the dynamics of ACh release in the DG before behavioral, anatomic, and biochemical changes emerged. During these early stages we observed slower and attenuated ACh responses upon task exposure when cognitive demand is highest. This result suggests that adult neurogenesis is important for maintaining normal cholinergic signaling. Hence, slow structural reorganization of cholinergic innervation, decline in baseline ACh, and accompanying working memory deficits are likely a failed compensatory response to functional disruption of cholinergic signaling. Importantly, chemogenetic increase in cholinergic signaling rescued behavioral deficits in animals long after anatomic and biochemical changes took place. Our findings support the notion that ongoing neurogenesis throughout life is necessary to maintain normal septohippocampal circuit function and optimal working memory performance. These results have important implications for understanding age and stress related cognitive decline and for treatment development.

Title: Ultrastructure of the teleost optic tectum : electron microscopic analysis

Authors: J.-M. HERMEL[1], ***K. YAMAMOTO**[1], J.-S. JOLY[2];
[1]Univ. Paris-Saclay, CNRS UMR9197, Gif-sur-Yvette, France; [2]TEFOR Paris-Saclay, CNRS UMS2010, INRA UMS1451, Gif-sur-Yvette, France

Abstract: Unlike the mammalian brain, the optic tectum (OT) is particularly well-developed in the teleost brain. It has been known that the teleost OT contains stem cell niche that contributes post-embryonic growth of the structure, nevertheless, very little is known about the ultrastructure of this area. Here, we acquired, stitched and combined images of low to meso resolution (500X-10000X) in order to get both a wide (200µmx200µm) portion of the structure with a good picture of the ultrastructure of the cells present in the OT stem cell niche. Based on this technique we observed several genuine anatomical data. We observed the presence of a basal lamina with several branch in the area of stem cell niche. The cells of the same putative age i.e. being at the

same distance from the cell niche dividing area have an inter-digitized membrane but not with their older or younger neighbor. In the ventricle between some ventricle contacting cells, there is a network of extracellular space that might play a role in the cell movement thus in the physical growth of the OT. The OT ventricle contains many closed membrane structure that appear to be actively produced by cells bordering the ventricle. Contrary to the adult, at 7 dpf, there is no blood capillaries in the posterior part of the OT. At 43hpf, there are many small bundles of axon in the process of being ensheeted. Most often, a single oligocyte is enwrapping up to 15 axons at the same time. At early stages, very few cells are ciliated with only one cilium but there is also few multiciliated cells. We observed also few peculiar cases of nuclear mitochondria. Finally, we describe the presence of stretched cells organized in bundles. These cells, most probably tanycytes have often a single cilia in the ventricle and their long process extend most of the time toward blood capillaries where it is possible to observe fenestration. Altogether, we believe that the technic of stitching images obtained at several resolution and these anatomical observations will contribute to a better understanding of the brain stem cell niches.

Title: Singing-related activation of darpp-32+ adult-born neurons in zebra finch hvc

Authors: *J. V. ARONOWITZ[1], B. FILIO, III[1], Y. ZHAO[1], K. NELSON-MAROIS[1], C. L. PYTTE[2], G. B. AARON[1];
[1]Wesleyan Univ., Middletown, CT; [2]Psychology, Queens Col., Flushing, NY

Abstract: In many songbirds including zebra finches (*T. guttata*), new neurons are continually incorporated into brain regions that subserve song learning, perception, and production. HVC (proper name), a brain region necessary for song production, receives and integrates new neurons (HVC NNs) throughout the life of the animal. Approximately half of these HVC NNs can be retrogradely labeled from the robust nucleus of the arcopallium, the first synaptic relay in the vocal motor pathway underlying learned song production. Interestingly, both backfilled and non-backfilled HVC NNs express the activity-dependent immediate early genes ZENK and c-Fos during song production, suggesting that they are active during song production once they are integrated into existing HVC circuitry (Tokarev, et al., 2016). Our lab has recently shown that approximately 50% of HVC NNs express DARPP-32 during their first month post-mitosis.

DARPP-32 is a phosphoprotein related to the expression of dopamine receptors, although its activity is modulated by many different neurotransmitter systems including glutamate and norepinephrine. Furthermore, these DARPP-32+ HVC NNs receive putative tyrosine hydroxylase synaptic contacts, have transiently larger nuclei than DARPP-32-neg HVC NNs, and cannot be retrogradely labeled from RA at 28 days post mitosis, suggesting that they may be represent a unique subtype of adult-born neuron in HVC. Here, we show that DARPP-32+ HVC NNs express immediate early genes following song production, and that singing-related immediate early gene expression is related to neuronal age and may be related to the social context in which the song is sung.

Title: Age-dependent electroencephalographic spectral patterns during midazolam-induced general anesthesia for congenital heart surgery in children

Authors: I.-K. SONG[1], Y.-S. KIM[2], B. A. LEE[1], W.-J. SHIN[1], *S.-E. KIM[2];
[1]Asan Med. Center, Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of; [2]Seoul Natl. Univ. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Background: Age-dependent electroencephalographic (EEG) characteristics may guide brain monitoring during general anesthesia (GA) in children, considering the neurodevelopmental state of the brain [1,2]. However, the dynamics of EEG in children receiving GA for congenital heart surgery (CHS), which can be affected by hypothermia, fluctuations in cerebral metabolism, and anesthetics [3], has not been elucidated. This study investigated the changes in EEG spectral patterns according to age and to body temperature variation during CHS under midazolam-induced GA in children. **Methods:** Four-channel frontal EEG was recorded continuously from 55 children (aged 0-48 months) undergoing CHS with midazolam-induced GA. The effect of midazolam-induced GA on brain was compared across four age-groups in EEG spectral power: 0-2 months (n=6), 3-4 months (n=18), 5-7 months (n=6), and 8-42 months (n=25). In addition, EEG oscillatory patterns were analyzed according to the five stages of CHS determined by the core body temperature: pre-hypothermia, cooling,

hypothermia, rewarming, and recovery. We computed group-median spectrograms by taking the median power across all subjects at each time and frequency of each stage. Peak frequencies within the alpha (8-13 Hz) and beta (20-30 Hz) range were assessed by a peak detection algorithm and manually adjusted according to the stages. **Results:** During maintenance of midazolam-induced GA, the frontal spectrogram demonstrated distinct distributions of slow-delta, alpha, and beta oscillations according to age group. Alpha oscillations were prominent in subjects aged 3-4 months, whereas beta oscillations were prominent in subjects aged five months and older. In the cooling period, the peak frequency of beta oscillations slowed down, shifting significantly toward the alpha band boundaries. The rewarming period showed a gradual acceleration of a slowed beta band that returns to physiological levels as core body temperature rises. **Conclusions:** A significant age-dependent EEG spectral patterns were observed during midazolam-induced GA. Anesthesia-induced age-dependent EEG characteristics changed in different ways following body temperature alterations during CHS, likely due to differences in brain development. These results indicate that EEG monitoring is essential during GA and can provide useful information on the appropriate depth of anesthesia in relation to the neurodevelopmental status of children.

Title: Prolonged Integration of Adult-born Axin2 Cell Lineage into Granule Neurons of the Dentate Gyrus

Authors: *K. SHARIFI[1], F. FARZAD[1], S. SOLDOZY[1], M. KALANI[2], P. TVRDIK[1];

Abstract: The Wnt pathway plays multiple roles during adult neurogenesis. The expression of Axin2 is induced by Wnt/β-catenin signaling, lending this gene a sensitive indicator of canonical Wnt activity. We have employed pulse-chase genetic lineage tracing with the Axin2-CreER allele to follow the fate of Axin2-positive cells in the hippocampus. Simultaneously with tamoxifen induction of Axin2 fate mapping, the dividing cells were marked with 5-ethynyl-2´-deoxyuridine (EdU). Tamoxifen induction resulted in significant increase of dentate gyrus

granule cells three months later; however, none of these neurons contained EdU signal. Conversely, six months after the tamoxifen/EdU pulse-chase labeling, EdU-positive granule neurons were identified in each animal. Our data implies that Axin2 is expressed in several different stages of adult granule neuron differentiation, including the dividing neural stem cells. However, our data also indicates that the process of integration of the adult-born neurons from certain cell lineages may take longer than previously thought.

Abstract: Most mammals generate new neurons during adulthood that are incorporated into a pre-existing olfactory circuit, presumably to keep their functionality intact. This process is known as adult neurogenesis, and involve different types of cells: stem cells, amplifying cells and migrating cells. This migrating neuroblasts, depart from the walls of the lateral ventricles (SVZ), and travel through the olfactory peduncle (OP) conforming the rostral migratory stream (RMS), until they reach the olfactory bulbs (BO) where they differentiate into interneurons. This migratory process has been widely described in rodents but not as well in primates. The potential of this process as a model for developing neuronal replacement strategies for brain repair in humans, requires better characterization in animal models more similar to own. In this work we present 6 cases of young adult primates (*Macaca fascicularis*) in which the olfactory tract was longitudinally dissected into the main olfactory bulb, and an anterior and a posterior region of OP. Immunofluorescence (IF) and Electron microscopy (EM) techniques were performed to identify the cytoarchitecture and cell populations, such as glia (GFAP-positive cells) and

migrating neuroblasts (DCX-positive cells) along the OP. In addition, stereological estimation of the number and occupied area of DCX-positive cells present in the OP were performed.Our findings show that, unlike rodents, where there is an internal, single, and continuous RMS, macaques show a different organization with neuroblasts conforming several chains at level of the caudal regions (closer to the SVZ), which tend to converge reaching the OB, and even groups of migrating cells over the periphery of the OP. Furthermore, all these migrating cells travel in waves forming clusters, not in a continuous way. We also observed some examples of morphologies compatible with radial migrations along the OP. These cells seem to be capable to leave the glial scaffold that guides the RMS and join into the surrounding tissue, reaching even the outermost layers for unknown reason. Further studies in humans and close phylogenetically species are necessary to elucidate the underlying process of adult human neurogenesis and its clinical applications. **KEYWORDS: Adult neurogenesis, doublecortin, macaque, migration, olfactory peduncle**

Title: Activity-based anorexia in mice downregulates oligodendrocyte lineage cells

Authors: *Z. WANG[1], C. V. MELENDEZ-VASQUEZ[2], N. S. BURGHARDT[3], A. ALMAKTAR[1];
[1]Hunter Col. CUNY, New York, NY; [2]Hunter Col., New York, NY; [3]Dept. of Psychology, Hunter College, CUNY, New York, NY

Abstract: Anorexia nervosa (AN) is a life-threatening eating disorder that occurs predominately in women, usually begins during adolescence, and frequently involves excessive exercise, which is thought contribute importantly to the development and maintenance of the disorder. Previous studies indicate that AN is associated with deficits in white matter, but the effects of AN on central nervous system myelination are poorly understood. We used the activity-based anorexia model (ABA) in mice to study how the combination of food restriction and exercise affects oligodendrocytes, the glial cells responsible for forming myelin. Adolescent (postnatal day 42)

female C57Bl/6N mice were distributed into 4 groups: ABA (restricted food access; unlimited wheel access), wheel control (WH; unlimited food and wheel access), food-restricted control (FR; restricted food access, unlimited access to a locked wheel), and homecage control (HC; unlimited access to food and a locked wheel). For the ABA and FR groups, access to food was limited to the first 2 hours of the dark cycle, during which time mice were free to eat as much as they wanted. Mice that lost 25% of their baseline weight were immediately removed from the experiment while the remaining mice were tested for 11 days. Tissue was collected after one day of recovery and immunocytochemistry was used to stain coronal brain slices (n=4 mice/group) for CC1, a marker of mature oligodendrocytes, and NG2, a marker of immature oligodendrocyte progenitor cells. Fiji was used to quantify stained cells in the corpus callosum and cortex. As expected, ABA and FR groups lost substantial weight compared to the non-food restricted groups, with the FR group surviving in the model longer than the ABA group ($p<0.001$). Weight loss in the ABA group correlated with levels of wheel running ($r=0.38$), which were significantly higher during the light cycle than the WH control group ($p<0.001$). In the corpus callosum, mice in the ABA condition had 74-81% fewer cells stained for CC1 (10.25±1.1 vs 38.75 ±8.9) and NG2 (16.25±3.3 vs. 88±31.7) than the HC control group. Although the FR group had 30-38% fewer oligodendrocyte lineage cells than the HC controls, this change was not statistically significant. Of note, exercise alone did not affect cell counts in the WH controls. Interestingly, no group differences in CC1+ or NG2+ cells were detected in the cortex. Together, these findings indicate that ABA drives downregulation of oligodendrocyte lineage cells in the corpus callosum. We continue to study the underlying cause of these changes, consequent effects on myelination, and implications for patients with AN.

Radiology, Univ. of Hong Kong, Hong Kong, Hong Kong; [5]Russell H. Morgan Dept. of Radiology and Radiological Science, Sch. of Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Apolipoprotein E *(APOE)* ε4 allele is not only the strongest genetic risk factor for sporadic Alzheimer's disease (AD) but is also associated with poor white matter (WM) integrity in the healthy population. We previously reported a significant reduction of oligodendrocyte (OL) population in the frontal cortex of AD subjects carrying *APOE4* alleles, but the cellular mechanism remains unknown. Here, we aim to test if *APOE4* disrupts OL plasticity and alters WM integrity. To investigate, the relationship between neuroimaging and OL lineage was examined in *Apoe*-knockout (*Apoe*$^{-/-}$), humanized APOE3 and APOE4 (*hAPOE*)-knockin mice at 1, 3, 6, & 12 months ($n \geq 4$/group) using preclinical 3T MRI, histology analysis, Y-maze behavioral test as well as gene and protein expression assays. In the neocortex and corpus callosum, unexpectedly, minimal differences in myelin expression (MBP, PLP, MAG, MOG) were found between all mouse strains across all age groups by immunohistochemistry, immunoblotting and real-time PCR. Despite the constant myelin level, diffusion kurtosis imaging consistently identified significant alterations of WM integrity in the anterior cingulate among the transgenic mice, where abnormally increased radial diffusivity ($P = 0.0275$) and mean diffusivity ($P = 0.044$) were found in *Apoe*$^{-/-}$ and hAPOE4 genotype mice reflecting disrupted myelination vs control. Intriguingly, stereotactic radiological-histological analysis of gray matter (*Anterior cingulate, motor, somatosensory cortex*) and WM (*Genu, external capsule, cingulum and anterior commissure*) at 10 months (Bregma 0.8) revealed significant and region-specific disruption of OL lineage by APOE4 genotype. In the anterior cingulate of hAPOE4 mouse, altered WM integrity was accompanied by 23% reduction in the overall Olig2^{+} OL population and 60% loss of CC1^{+} mature OLs, despite a 3.2 fold increase of the committed Nkx2.2^{+} OL precursor cells (OPC, relative to wildtype). Such accumulation of OPCs was also found in the genu, body and splenium of the corpus callosum along the midline of hAPOE4, but not hAPOE3 mice. No cognitive impairment nor neuronal loss was identified. These in vivo findings were further validated by primary OL cultures where we found that postnatal OL derived from *Apoe*$^{-/-}$, hAPOE3 and hAPOE4 animals developed normally. However, lipidated recombinant human ApoE4, but not ApoE3 protein, suppressed the differentiation and halved the formation of MBP^{+} myelin sheet formation in *Apoe*$^{-/-}$ OPCs (-52.3%, $P = 0.026$). Together, *APOE4* is likely to hamper OPC differentiation and their myelination is sustained only by a disproportionally reduced mature OLs that may ultimately jeopardize WM integrity.

Title: Divergent effects of ATM mutations on oligodendrocytes - the cellular basis of myelin pathology in Ataxia Telangiectasia

Authors: *S. H. S. YEUNG[1], A. CHENG[2], G. W. Y. CHENG[1], K. K. S. MOK[1], K. HERRUP[3], K.-H. TSE[1];
[1]Dept. of Hlth. Technol. and Informatics, Hong Kong Polytechnic Univ., Hong Kong, Hong Kong; [2]Dept. of Ocean Sci., Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [3]Dept. of Neurobiology, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Ataxia Telangiectasia (A-T) Mutated protein (ATM) is a major kinase that responds to DNA double strand breaks. A spectrum of pathogenic mutations of *ATM* is known to cause the rare genetic disease, A-T with cerebellar symptoms of different severity. Myelin pathology emerges as one of the neurological deficits in young A-T patients, but the mechanism is unknown. We proposed that oligodendrocytes (OL) are lost in the A-T cerebellum and here, we aim to delineate the divergent effects on OL lineage mediated by different *ATM* mutations. To test, we characterized the OL population in post-mortem cerebella of ten A-T cases where the ATM mutations were profiled by Illumina-based targeted genomic sequencing. First, 13 distinct pathogenic mutations were identified among A-T cases with four cases were compound heterozygous. In A-T cases with frameshift mutations, the overall cerebellar $Olig2^+$ OL population and mature OLs (mOL, $CC1^+$) were reduced by 53.6 and 87.8% (vs controls), respectively. Importantly, the demise of OL was not correlated with the neuronal atrophy. These histological results were validated by *Atm*-deficient mice, $Atm^{-/-}$ (B6;129S4-Atm^{tm1Bal}/J), where the *Atm* exons was disrupted with no residual ATM activity. In $Atm^{-/-}$ cerebellum, the overall OL, mOL, and their progenitor (OPC) density and myelin proteins were reduced, but OL reduction in the neocortex was accompanied by $NG2^+$ OPC accumulation. We hypothesize that ATM is required for OL differentiation and investigated the putative interactions between ATM and myelin-related proteins in silico. ATM showed strong putative interactions with Myelin regulatory factor (MyRF, $E_{balanced}$ = -1225 KJ mol^{-1}, 113 contacts) and Myelin basic protein (MBP, $E_{balanced}$ = -1123.6 KJ mol^{-1}, 206 contacts). Intriguingly, the ATM-MBP interaction was validated by in co-immunoprecipitation (IP) and IP-based liquid chromatography-mass spectrometry analysis, and the site (MBP^{Ser99}) is a known phosphorylation site for myelin compaction. Importantly, the strength of the putative ATM-MBP was significantly reduced among the A-T cases carrying mutations terminating ATM at the spiral/pincer region (≤1238 a.a, $p < 0.003$), and the cases carrying early ATM disruption showed a significantly reduced density

of Olig2^{+} and CC1^{+} OLs without affecting neurons. The impact of partial ATM mutation is being validated in a model harbouring truncated but active ATM residue (*Atm*^{Awb};B6.129S6-Atm^{tm1Awb}/J). Together, ATM is intrinsically required for OL differentiation. The diverse effects of mutation variants to hinder interactions between ATM and myelin-related proteins may be the molecular mechanisms of the diverse myelin pathology in A-T.

Title: The HIV-1 antiretroviral cocktail Triumeq disrupts oligodendrocyte maturation through dolutegravir-induced integrated stress response dysfunction.

Authors: *R. PUTATUNDA[1], L. M. ROTH[1], B. DI SANZA[1], M. A. ROMER[1], K. L. JORDAN-SCIUTTO[2], J. B. GRINSPAN[3];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Dept Pathology, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Neurol., Children's Hosp Philadelphia, Philadelphia, PA

Abstract: Despite the development of antiretroviral therapies (ART), approximately half of all HIV-1 infected individuals develop a spectrum of cognitive and psychiatric sequelae, collectively known as HIV-1 associated neurocognitive disorders (HAND). While ART decreased the clinical severity of HAND, notable histopathological features, such as white matter abnormalities and myelin loss, have persisted, lending credence to the possibility that ART drugs themselves may be modulating CNS dysregulation. Our laboratory has implicated five front-line ART drugs in hampering oligodendrocyte maturation and myelin protein production, raising concern about the use of ART drugs during CNS development. Therefore, we proposed to examine the front-line ART drug combination given to HIV-1 positive pregnant women: Dolutegravir, Abacavir, and Lamivudine (also known as Triumeq). We hypothesized that this combination would inhibit oligodendrocyte maturation. Treating primary rat oligodendrocyte precursor cells (OPCs) with the Triumeq drug combination for 24 hours, followed by co-treatment with this combination of drugs after induction of differentiation decreased the number of mature oligodendrocytes and myelin protein production after 3 days in a concentration-

dependent manner. As the number of OPCs and apoptotic cells remained similar to controls, these data suggest that this drug combination attenuates OPC differentiation. Subsequent analyses demonstrated that Dolutegravir was primarily responsible for this differentiation deficit. Finally, treatment of OPCs with trans-ISRIB, a drug that inhibits the integrated stress response (ISR) after Dolutegravir treatment prevented low, but not mid-dose differentiation deficits. Together, these data demonstrate a potential role for the ISR in Dolutegravir-induced oligodendrocyte differentiation deficits.

Title: Loss of very long chain sphingolipid synthesis in oligodendrocytes causes rapid microglial activation, followed by myelin degeneration and early lethality.

Authors: *J. D. TEO[1,2], O. C. MARIAN[1,2], H. P. MCEWEN[1], H. SONG[1,2], J. C. BRÜNING[3], A. S. DON[2,1];

Abstract: Myelin is comprised 70-80% of lipids. The sphingolipids galactosylceramide (GalCer), sulfatide (ST), and sphingomyelin (SM) are essential for myelin stability and function. Whether the specific acyl chain composition of these lipids affects myelin stability is less clear. GalCer and ST are synthesized from C22-C24 ceramides (very long chain ceramides) by ceramide synthase 2 (CerS2), which is very highly expressed in oligodendrocytes. Prior studies have shown than myelin is destabilised and deteriorates in mice with universal CerS2 deletion, which was attributed to a reduction in total GalCer content. To clarify the requirement for very long chain sphingolipids in myelin biosynthesis and stability, we generated C57BL6 mice lacking CerS2 specifically in myelinating cells ($CerS2^{\Delta O}$), by crossing mice homozygous for a floxed CerS2 allele to those expressing cre recombinase from the CNP gene locus (CNP-cre). Littermates not expressing CNP-cre were used as controls. Motor function was assessed by rotarod, balance beam and grip strength tests. Mice (n=5/6 per group) were culled at 6, 10 and 16 weeks of age (6W, 10W, 16W). Myelin content was assessed by lipidomic mass spectrometry, luxol fast blue (LFB) staining, and western blotting for myelin proteins. Immunofluoresent

staining for mature oligodendrocytes, astrocytes, and microglia was quantified blinded to the experimental groups. This project was approved by the University of Sydney animal ethics committee. At 6W, total levels of GalCer, ST, and SM were not reduced in CerS2$^{\Delta O}$ mice, as loss of C22-C24 sphingolipids was compensated by increased levels of shorter-chain C18 lipids. Myelin content and glial response were unaffected at 6W. At 10W, reactive astrocytes and microglia accumulated in white matter of CerS2$^{\Delta O}$ mice, even though myelin content, mature oligodendrocyte density, and motor function remained comparable to controls. Pronounced myelin atrophy, motor deficits and severe gliosis were observed in 16W CerS2$^{\Delta O}$ mice. 50% of CerS2$^{\Delta O}$ mice died by 5 months of age. In conclusion, synthesis of very long chain sphingolipids by CerS2 is not essential for myelin formation during development. However, the loss of CerS2 in oligodendrocytes results in myelin degeneration, motor deficits and lethality prior to 6 months of age. Astrogliosis and morphological transformation of microglia precedes loss of oligodendrocytes and myelin, suggesting that the shorter acyl chain composition in CerS2$^{\Delta O}$ myelin lipids destabilises myelin and elicits phagocytic microglia. Understanding the mechanisms by which these events occur could lead to the development of new therapeutics for demyelinating diseases.

Title: DYT6 dystonia mutation causes hypomyelination and the loss of YY1 binding

Authors: *A. E. ROGERS[1], A. J. KIM[3], S. KIM[2], S. S. PAPPAS[3,4], W. T. DAUER[3,4,5], D. YELLAJOSHYULA[6];

Ctr., Dallas, TX; [6]Dept. of Neurol., Univ. Of Michigan, Ann Arbor, MI

Abstract: Dystonia is a disabling neurological disorder that manifests as prolonged involuntary twisting movements. DYT6 is an inherited form of isolated dystonia caused by mutations in *THAP1* encoding the transcription factor THAP1. In previous studies, we demonstrated that THAP1 is essential for CNS myelination due to its cell-autonomous role in the oligodendrocyte

lineage using mouse models with conditional deletion of *Thap1*. However, it is not known if the many DYT6 disease mutations reported have any effect on CNS myelination. The phe81leu (F81L) missense mutation is representative of a category of poorly understood mutations that do not occur on residues critical for DNA binding. Using a knock-in mouse line that we generated containing the *Thap1*^{F81L} allele, we demonstrate that the F81L mutation (THAP1^{F81L}) impairs THAP1 transcriptional activity and results in CNS hypomyelination. Strikingly, THAP1^{F81L} showed normal DNA binding at target loci, but disrupted the binding of YY1 - a cofactor of THAP1 with a role in the development of oligodendrocyte lineage. Our studies suggest a model of molecular pathogenesis in which THAP1^{F81L} normally binds DNA but cannot form a functional transcription complex.

Title: Does demyelination accelerate the neuropathology progression of Alzheimer's disease? - a radio-pathological investigation

Authors: *K.-H. TSE[1], G. W. Y. CHENG[1], J. HUANG[2], K. K. S. MOK[1], S. H. S. YEUNG[1], Z. CHEN[2], H. K. F. MAK[3], K. W. Y. CHAN[2,4], K. HERRUP[5];

Abstract: Myelin abnormalities such as white matter (WM) volume reduction, microstructural changes and WM hyperintensity are common in the aging brain. Such neuroimaging detections are often found in cognitive decline and early in late-onset Alzheimer's disease (AD). We recently reported the loss of oligodendrocytes (OLs), the only myelinating glia, in human brain before amyloid plaques formation in dementia. Here, we hypothesize that such early demise of

myelin and OL population may exacerbate AD pathogenesis. To test, we asked if induced myelin loss can accelerate classic AD pathology in common transgenic mouse models. The APP/PS1 (*B6.Cg-Tg(APPswe,PSEN1dE9)85Dbo/Mmjax*) carrying human *APP*$^{K595N/M596L}$ plus Presenilin 1(PS1^{dE9}) and the R1.40 (*B6.129-Tg(APPSw)40Btla/Mmjax*) harboring just human *APP*$^{K670N/M671L}$ normally exhibit amyloid deposition by 6 and 14 months, respectively. To induce demyelination, both strains and wildtype controls between 9-12 weeks (male, n = 4-6 / group) were subjected control or cuprizone diet (0.2% w/w) for four weeks before behavioral tests and stereotactic radiological-histological analysis using 3T preclinical MRI and immunohistochemistry. While no behavioral changes were observed, diffusion kurtosis imaging revealed the region-specific WM microstructural alternations (fractional anisotropy, radial diffusivity, and mean diffusivity) after demyelination in all animals. In the anterior cingulate and the genu of the corpus callosum, the overall Olig2^{+} OL population and ASPA^{+} and CC1^{+} mature OLs were reduced by more than 50%, as expected. To investigate the classic AD pathology, we examined if the demyelination accelerated the formation of amyloid plaque (6E10) and the DNA double strand breaks (DSBs) the brain. In APP/PS1, but not R1.40, demyelination increased 6E10 signals within cortical neurons and across neuropil at four months old. In both AD strains and the wildtype control, demyelination increased the number of neurons exhibiting 53BP1^{+} DSB nuclei, suggestive of the loss of neuronal genomic integrity. This observation is consistent with our previous report of human multiple sclerosis and AD where myelin and OL degeneration in frontal cortex were associated with neuronal DSBs and ectopic cell cycle re-entry. These DNA damage inductions were also found in the OL in the genu and is likely correlated with the demise of their population amid myelin loss. Together, our data suggested that myelin loss may drive AD pathology in a premature stage. We are currently examining the radiological-histological analysis between neuronal cell cycle re-entry, OL pathology, and the magnetization transfer signals upon demyelination.

Abstract: Oligodendrocyte (OL) death and white matter loss contribute to functional deficits after spinal cord injury (SCI). OL protection and remyelination by oligodendrocyte precursor cells (OPCs) is critical for functional recovery after contusive SCI. However, SCI-induced, OL-specific changes in gene expression have not yet been reported at the transcriptomic/translatomic level. RiboTag technology allows analysis of mRNAs that are bound to translating ribosomes from specific cell populations marked genetically with a hemagglutinin (HA) tag on a core ribosomal subunit, RPL22. Using *Plp1-Cre^{ERT2}:Rpl22^{HA}* female mice to induce the RiboTag in mature OLs, we isolated OL-specific mRNAs from the injury epicenter following moderate T10 contusion. We initially confirmed reliable isolation of OL-specific mRNAs as evidenced by enrichment of myelin-associated genes only found in OLs when comparing the OL translatome to total RNA samples. Using uninjured cord from naïve mice as a control, extensive changes in OL translatome mRNAs were documented at acute (2 days post injury, dpi), subacute (10 dpi) and chronic (42 dpi) timepoints. These genes included upregulation of the OL injury response markers Klk8 and C4b. Among 77 mRNAs that were highly upregulated selectively in OLs at all timepoints post-SCI, enriched gene ontology (GO) terms included organismal development, cell differentiation, nervous system development and cell-cell signaling. OLs upregulated secreted inhibitors of BMP (*Sostdc1*), WNT (*Sostdc1*, *Sfrp5*) and Notch (*Egfl8*, *Dlk2*) signaling, pathways which are implicated in inhibiting OPC to OL differentiation. Therefore, after SCI, surviving OLs may secrete paracrine factors to enhance OPC/OL differentiation and promote white matter repair. Such a notion is consistent with a documented occurrence of OPC-mediated remyelination in areas where OLs are still present.

Title: Differential effects of the integrated stress response kinases PERK, PKR, GCN2 and HRI on oligodendrocyte survival and locomotor recovery after spinal cord injury

Authors: *S. SARASWAT OHRI[1], Y. LIU[1], K. ANDRES[1], R. HOWARD[1], S. MYERS[1], D. CAVENER[2], M. HETMAN[1], S. WHITTEMORE[1];
[1]Kentucky Spinal Cord Injury Res. Ctr., Louisville, KY; [2]Eberly Col. of Sci., PennState, KY

Abstract: The integrated stress response (ISR) pathway is integral to the proteostasis network that is crucial to maintain cellular homeostasis under physiological and pathological conditions. The mammalian ISR is mediated by 4 independent kinases: protein kinase RNA (PKR)-like kinase (PERK), general control non-de-repressible 2 (GCN2), double-stranded RNA-activated protein kinase (PKR) and heme-regulated inhibitor (HRI). Activation of all ISR kinases phosphorylates eIF2α (eukaryotic initiation factor 2α) which results in general protein synthesis inhibition and in selective translation of stress response mediator proteins such as activating transcription factor 4 (ATF4) and CCAAT/enhancer binding homologous protein (CHOP). However, the spectrum of their upstream activating stimuli differs, albeit with some overlap. Using genetic and pharmacological inhibition of the unfolded protein response (UPR), we previously demonstrated improvements in hindlimb locomotion after thoracic SCI and implicated oligodendrocyte (OL) survival as a potential mechanism. Here, we explore the functional contribution of the individual kinases of the ISR pathway to the pathogenesis of SCI. Thoracic contusive SCI resulted in induction of all ISR kinases 24 hours post-injury. Global deletion of *Pkr* or *Gcn2* failed to improve locomotor recovery after SCI. Targeted loss of *Perk* in OL lineage cells resulted in enhanced pro-apoptotic *Atf4* and *Chop* mRNA levels in mice acutely (72 hours) after thoracic contusive SCI. Consistent with this, post-injury recovery of hindlimb locomotion and white matter sparing were impaired in OL-*Perk*$^{-/-}$ mice and correlated with greater loss of oligodendrocyte precursor cells (OPCs)/OLs at the injury epicenter six weeks post-SCI. In contrast, after SCI, constitutive *Hri*$^{-/-}$ mice showed reduced *Atf4* and *Chop* mRNA levels acutely and demonstrated improvement in hindlimb locomotor recovery at six weeks post-SCI that correlated with enhanced white matter sparing and reduced loss of OPCs/OLs at the injury epicenter. Collectively, data show that the ISR kinases differentially contribute to OPC/OL loss and implicate PERK and HRI as critical pro- and anti-survival mediators after SCI, respectively. The differential effects of *Perk, Pkr, Gcn2* and *Hri* deletion on functional recovery after SCI potentially reflects fundamental differences in outcome of ISR activation in specific signaling and/or cellular contexts.. Abstract: Zinc is an essential micronutrient required for proper function during neuronal development, due to its ability to modulate neuronal function and structure. A fully functional description of zinc on axonal processing in the central nervous system remains elusive. Here we defined the role of intracellular zinc in axon formation and elongation, involving mammalian target of rapamycin complex 1 (mTORC1). To investigate the involvement of zinc on axon growth, we performed an ex vivo culture of mouse hippocampal neurons and administrated $ZnCl_2$ as a media supplement. At 2 days *in vitro*, administration of zinc induced the formation of multiple and elongated axons in the ex vivo culture system. A similar outcome was witnessed in callosal projection neurons in developing mouse brain. Treatment with extracellular zinc activated the mTORC1 signaling pathway in mouse hippocampal neuronal cultures. The zinc dependent enhancement of neuronal processing was moreover inhibited either by deactivation of mTORC1 with RAPTOR shRNA or by mTOR-insensitive 4EBP1 mutants. Additionally, zinc-dependent mTORC1 activation enhanced axonal translation of TC10 and Par3 may responsible for axonal growth. Collectively, we have identified a promising role of zinc in controlling axonogenesis in the developing brain, which in turn, may possess a novel role for the treatment of neurological disorders such as callosal agenesis.

Title: The effects of pyruvate kinase M2 (PKM2) gene deletion in astrocytes on global cerebral ischemia-induced neuronal death

Authors: *B. KANG, S. SUH, B. CHOI, A. KHO, S. LEE, D. HONG, S. LEE;
Dept. of Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of

Abstract: Ischemic stroke is one of the most severe brain diseases and is caused by insufficient supply of nutrients and oxygen when there is decreasing blood flow to the brain. The astrocyte has an important role in bidirectionally converting pyruvate generated via glycolysis into lactate, and supplying lactate to neurons through the astrocyte-neuron lactate shuttle (ANLS). Pyruvate kinase M2 (PKM2) is an enzyme that catalyzes dephosphorylation of phosphoenolpyruvate to pyruvate in astrocyte-specific glycolysis. To test whether astrocyte-specific PKM2 gene deletion influences energy production, and also exacerbates brain damage, we used PKM2 knock out (KO) mice. PKM2 gene was deleted by administrating tamoxifen to Aldh1l1-Cre^{ERT2}; PKM2$^{f/f}$ mouse. The global cerebral ischemia (GCI) performed blood flow restoration and resuscitation after occlusion of the bilateral common carotid artery (BCCA) for 20 min in mice. So, we hypothesized that the decrease in lactate supply over the ANLS in the astrocyte-specific PKM2 KO will lead to more widespread neuronal death compared to PKM2 wild-type mice after GCI. To confirm whether lactate administration in the astrocyte-specific PKM2 KO reduces neuronal death after GCI, sodium L-lactate (250mg/kg, i.p.) was injected immediately after GCI and then once daily for 3 days before sacrifice. We demonstrated that PKM2 KO exacerbates GCI-induced neuronal death and reactive oxygen species (ROS) production, and that these aberrant processes are attenuated by lactate administration. In conclusion, we suggest that lactate supply via the ANLS in astrocytes plays a crucial role in maintaining sufficient energy production in neurons, therefore lactate administration has a potential therapeutic effect on neuronal death after GCI.

Title: An acid sphingomyelinase inhibitor, imipramine, reduces hippocampal neuronal death after traumatic brain injury

Authors: *S. LEE, B. CHOI, A. KHO, S. LEE, D. HONG, B. KANG, M. PARK, S. SUH; Dept. of Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of

Abstract: Traumatic brain injury (TBI), broadly, is a decline in the normal function of the brain after experiencing a bump, blow or jolt to the head. It leads to aggravation of pre- existing brain dysfunction and promotes neurotoxic cascades that involve such processes as oxidative stress, dendritic loss, and zinc accumulation. Acid sphingomyelinase (ASMase) is an enzyme which hydrolyzes sphingomyelin to ceramide in the cells. Ceramide is involved in various physiological functions such as cell migration, differentiation and apoptosis. However, under pathological settings such as cerebral ischemia and Alzheimer's disease, excessively ceramide production causes activation of cell death mechanisms to occur. So, we hypothesized that inhibition of ASMase activity by the ASMase inhibitor, imipramine, could reduce ceramide formation and thus prevent TBI-induced neuronal death. To test our hypothesis, imipramine was injected (10mg/kg, i.p., once-daily for 7 days) after TBI. The experimental animals were sacrificed at 24 hour and 7 days following TBI. As the result, we confirmed that neuronal death, dendritic loss and oxidative stress were significantly reduced in the TBI-imipramine group compared to TBI-vehicle group at 24 hours. Additionally, we validated that the administration of imipramine for 7 days has neuroprotective effects on TBI, and that neurological behavior testing (mNSS test) confirmed that imipramine prevents cognitive dysfunction after TBI. Taken together, we suggest that imipramine, an ASMase inhibitor, decreases ceramide levels and thus prevents TBI-induced neuronal death. Consequently, ASMase inhibition may be therapeutic target for TBI-induced hippocampal neuronal death.

Biol., Sejong Univ., Seoul, Korea, Republic of; [4]Dept. of Neurol., Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of

Abstract: Previous studies in our lab revealed that chemical zinc chelation or zinc transporter 3 (ZnT3) gene deletion suppresses the clinical features and neuropathological changes associated with experimental autoimmune encephalomyelitis (EAE). In addition, although protective functions are well documented for AMP-activated protein kinase (AMPK), paradoxically, disease-promoting effects have also been demonstrated for this enzyme. Recent studies have demonstrated that AMPK contributes to zinc-induced neurotoxicity and that compound A or B, an inhibitor of AMPK, reduces zinc-induced neuronal death and protects against oxidative stress, excitotoxicity, and apoptosis. Here, we sought to evaluate the therapeutic efficacy of compound A or B against myelin oligodendrocyte glycoprotein 35-55-induced EAE. Compound A (5 ug/kg) or B (20 ug/kg) was intraperitoneally injected once per day for the entire experimental course. Histological evaluation was performed three weeks after the initial immunization. We found that Compound A or B profoundly reduced the severity of the induced EAE and that there was a remarkable suppression of demyelination, microglial activation, and immune cell infiltration. Compound A or B also remarkably inhibited EAE-associated BBB disruption, MMP-9 activation and aberrant synaptic zinc patch formation. Furthermore, the present study showed that long term-treatment with compound A or B also reduced the clinical course of EAE. Therefore, the present study suggests that zinc chelation and AMPK inhibition with compound A or B may have great therapeutic potential for the treatment of multiple sclerosis.

Title: Administration of an acidic sphingomyelinase (ASMase) inhibitor, imipramine, reduces hypoglycemia-induced hippocampal neuronal death

Authors: *A. KHO, B. CHOI, S. LEE, D. HONG, B. KANG, S. LEE, S. SUH;
Dept. of Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of

Abstract: Severe hypoglycemia (below 35 mg/dL) appears most often in diabetes patients who continuously inject insulin. To rapidly cease the hypoglycemic state, glucose reperfusion is conducted to restore blood glucose levels, which can induce a secondary neuronal death cascade following hypoglycemia. Acid sphingomyelinase (ASMase) hydrolyzes sphingomyelin into ceramide and phosphoryl choline. ASMase activity can be influenced by cations, pH, redox, lipids, and other proteins in the cells. In particular, severe hypoglycemia can lead to acidosis; oxidative stress; and excessive cation release—for example, the release of Ca^{2+} or Zn^{2+}. Therefore, we expect that ASMase is activated excessively after hypoglycemia. Ceramide is known to cause free radical production, excessive inflammation, calcium dysregulation, and lysosomal injury, resulting in apoptosis and the necrosis of neurons. Imipramine is mainly used in the treatment of depression and certain anxiety disorders. Additionally, it is known as ASMase inhibitor. In the present study, we hypothesized that imipramine can decrease hippocampal neuronal death by reducing ceramide via the inhibition of ASMase after hypoglycemia. In the present study, we found that the administration of imipramine significantly reduced hypoglycemia-induced neuronal death. Therefore, the present study suggests that imipramine may be a promising therapeutic tool for preventing hypoglycemia-induced neuronal death.

Title: Acid sphingomyelinase inhibitor, imipramine, increases the survival of newborn neurons after pilocarpine-induced seizure

Authors: *S. LEE[1], B. CHOI[1], A. KHO[1], D. HONG[1], B. KANG[1], S. LEE[1], H. SONG[2], H. CHOI[2], S. SUH[1];

Abstract: Acid sphingomyelinase (ASM) is an enzyme that hydrolyzes sphingomyelinase into ceramides, and the ceramides produced at this time can cause viral and bacterial diseases as well as a wide range of diseases such as cancer, cystic fibrosis, diabetes, Alzheimer's and depression. Ceramide metabolized from sphingomyelin by ASM are the simplest sphingolipids in the brain. Ceramide is known to cause reactive oxygen species (ROS) production, excessive inflammation and lysosomal damage. After epilepsy, excessive zinc release occurs in neurons, and ASM is activated to promote ceramide formation, which plays a pivotal role in inflammation, cell signaling and cell death, leading to apoptosis. ASM inhibitor, imipramine, can reduces the activity of ASM caused by epilepsy, thereby reducing ceramide production. In this study, we tested the hypothesis that imipramine can suppress excessive oxidative stress and improve the survival of newly generated neurons under pathological states such as epilepsy. This study used Sprague-Dawley rats (250-300g) and seizure was induced by pilocarpine (25 mg/kg, i.p.). Imipramine (10 mg/kg, i.p.) was continuously injected once per day for 4 weeks after seizures. Histological analysis and cognitive function (barnes maze) test was performed at 4 weeks after seizure. We found that long-term treatment of imipramine increased the number of $BrdU^+$ and $BrdU^+NeuN^+$ cells in the dentate gyrus of hippocampus after pilocarpine-induced seizure. In the barnes maze test, imipramine treatment improved seizure-induced cognitive impairment. The present study demonstrates that imipramine increases the survival of newborn neurons in the dentate gyrus of hippocampus and improved cognitive function after seizure. Therefore, this study suggests that imipramine may be a therapeutic tool that reduces neuronal death after seizure and increases the survival of newborn neurons.

Title: Targeting the AMP-activated protein kinase and zinc: a therapeutic target for global cerebral ischemia

Authors: *D. HONG[1], B. CHOI[1], J.-W. EOM[2], S. CHOI[1], A. KHO[1], S. LEE[1], B. KANG[1], S. LEE[1], Y.-H. KIM[2], S. SUH[1];
[1]Physiol., Hallym Univ., Chuncheon, Korea, Republic of; [2]Sejong Univ., Seoul, Korea, Republic of

Abstract: Ischemic stroke causes severe brain damage and it is a leading threat to the global population at large. Insufficient supply of glucose, oxygen and blood by blood clot-induced blockade of vessels or considerably reduced blood flow due to heart attack are two common examples of situations that can result in cerebral ischemia. These deleterious situations lead to activation of cell death cascades that involve production of reactive oxygen species (ROS), excitotoxicity and ionic imbalance. AMP-activated protein kinase (AMPK) has three subunits: catalytic unit alpha, regulatory unit beta and regulatory unit gamma. Under the physiological situations, AMPK is necessary for maintaining energy balance and processes such as glycolysis, gene transcription, glucose uptake and several other biological functions. However, central nervous system (CNS) injury-induced energy and metabolic stress, such as cerebral ischemia, increases AMPK phosphorylation. Highly phosphorylated AMPK contributes to excitotoxicity, oxidative and metabolic problems. As well, CNS injuries-induced excessively released chelatable zinc contributes to brain damage, including ROS production, apoptosis, and elevation of intracellular calcium levels. For this reason, we assert that regulation of abnormal AMPK activity and zinc release is necessary for prevention against brain damage under ischemic conditions. In compound C (a well-known AMPK inhibitor) structure-based screening, novel agent 2G11 significantly decreased zinc toxicity and AMPK activity. In this study, we verified whether novel AMPK inhibitor, 2G11 administration has neuroprotective effects via regulation of AMPK activity on the global cerebral ischemia (GCI). In order to demonstrate 2G11 effects, we used a GCI animal disease model (2G11: 20μg/kg) and oxygen glucose deprivation/reoxygenation (OGD/R, 2G11: 20μM) in primary cultured neurons. As a result, 2G11 reduced AMPK phosphorylation, the number of degenerating neurons, zinc accumulation, lipid peroxidation and astrocyte & microglia activation. These collective findings suggested that the novel AMPK inhibitor, 2G11 is a therapeutic candidate for cerebral ischemia-induced cell death cascades.

Title: Altered expression of peroxisomal markers in a mouse model of amyotrophic lateral sclerosis

Authors: *R. PRICE[1,2], S. SCARICAMAZZA[2], M. TERRICOLA[2], I. SALVATORI[2,3], G. TAGLIALATELA[4], R. KAYED[4], M. CERVELLI[1,2], F. BERARDINELLI[1,2], A. FERRI[2], C. VALLE[2], S. MORENO[1,2];

Abstract: Amyotrophic lateral sclerosis (ALS) is a degenerative disorder affecting both upper motor neurons in the neocortex, and lower motor neurons in the brainstem and spinal cord, and leading to skeletal muscle atrophy and weakness. As a multisystemic disease, alterations in one or more cellular pathways in extra-neural tissues have been considered fostering ALS onset and progression. Some of these include oxidative stress, mitochondrial dysfunction, axonal and vesicular transport defects, excitotoxicity, autophagic dysfunction, neuroinflammation and altered RNA metabolism. Increased energy expenditure and lipid metabolism alterations related to mitochondrial dysfunction manifest prior to motor neuron loss. Being a key determinant of whole-body metabolic rate, skeletal muscle plays a pathological role in ALS, contributing to defective energy metabolism and determining a derangement of basal metabolic rate, switching its metabolism towards an oxidative phenotype at the expense of a glycolytic one, and to the preferential use of fatty acids as fuel. Over the years, light has been shed on the tightly connected functions of mitochondria and peroxisomes, mainly in controlling lipid and reactive oxygen species (ROS) metabolism, so that (dys)-functions in either of the two determine altered metabolism of the other. Importantly, peroxisomes respond to physiological and pathological changes and extracellular stimuli, by altering their enzyme content, morphology, size, and abundance. These dynamic features are modulated by the activation of a subfamily of transcription factors, namely peroxisome proliferator activated receptors (PPARs), upon binding to their ligands, which in turn exert neuroprotective effects in ALS. The aim of this study is to address the role played by peroxisomes in ALS onset and progression, by analyzing the expression of peroxisomal markers in the spinal cord, muscle and liver of SOD1-G93A mouse model. Immunoblotting analysis of peroxisomal proteins and antioxidant enzymes shows an increase concomitant with pathology progression, suggesting an enhancement in the number of peroxisomes and in β-oxidation of very long chain fatty acids. This correlates with the increase of PGC1-α that, stimulating both peroxisomal and mitochondrial biogenesis, elicits an antioxidant response to cope with redox imbalance through the progression of the disease. This data is consistent with what observed by qRT-PCR analysis of the same markers. Overall, our data strongly suggests an involvement of both neural and non-neural peroxisomes in ALS onset and progression, possibly counteracting mitochondrial dysfunction.

Abstract: Organelle homeostasis is an intricate process, requiring axonal transport to relocate organelles between sites of high demand and their sites of biogenesis and eventual degradation. For example, mitochondria are transported anterogradely toward axonal branch tips and their synapses, where they provide local energy to drive neurotransmission - damaging mitochondria over time via reactive oxygen species (ROS) production. While some presynaptic mitochondria are eventually transported back toward the soma, a substantial residue is left behind, raising the question of how mitochondrial homeostasis - ‘mitostasis’ - is ultimately achieved. Although principal pathways for mitochondria degradation, such as bulk autophagy or selective mitophagy, are known, current models of mitostasis do not explain how these processes are compartmentalized and regulated in synapses *in vivo*. By measuring mitochondrial volume flux in mouse motor axons, we identified major sites of degradation near presynaptic compartments. Using pulse-chase tracking of photo-tagged synaptic mitochondria in *Thy1*-mitoDendra mice, we discovered that ~60% of mitochondria that attempted to leave neuromuscular synapses (NMJs) stopped and vanished close to the most distal node of Ranvier. Nodes located further proximally captured retrogradely, but not anterogradely moving mitochondria with decreasing frequency, indicating a selective mechanism acting on specific mitochondria only. In line with local

degradation, we found a high density of lysosomal markers at capture sites, and colocalization with captured mitochondria over time. Locally depolarizing presynaptic mitochondria using a photo-caged uncoupler increased capture rates, indicating that damaged mitochondria were preferentially targeted for capture. Accordingly, in mouse models of Amyotrophic lateral sclerosis (ALS), where synaptic mitochondria are prone to damage, we observed increased capture (SOD and dipeptide-repeat-protein based models). Our ongoing genetic analysis shows that ablating the disease-associated protein optineurin (*Optn*), but not the *Pink1-Parkin* pathway, led to reduced capture and higher retrograde transport of mitochondria in terminal branches, implying that the mitophagy receptor optineurin is involved. In summary, our data support a new model, where mitochondrial quality control occurs in distal axonal compartments. Perinodal sites serve as a cascade of checkpoints that filter out damaged mitochondria as they transit towards the soma for local degradation - a mitostatic system that establishes mitochondrial mass balance in healthy axons and is adjusted in degenerative axonopathies.

Title: Inositol hexakisphosphate kinase-2 regulates mitochondrial functions through creatine kinase-B

Authors: *L. NAGPAL, M. D. KORNBERG, S. H. SNYDER;
Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Inositol hexakisphosphate kinases (IP6Ks) regulate various biological processes. IP6Ks convert IP6 to pyrophosphates such as diphosphoinositol pentakisphosphate (IP7) and bis-diphosphoinositol tetrakisphosphate (IP8). IP7 is produced in mammals by a family of inositol hexakisphosphate kinases, IP6K1, IP6K2, and IP6K3, which have distinct biological functions. We explored the role of IP6K2 by elucidating its protein interactome. IP6K2 was found to robustly bind to creatine kinase-B (CK-B), a key enzyme in energy homeostasis. Cerebella of IP6K2-deleted mice (IP6K2-KO) produced less phosphocreatine and ATP and generated higher levels of reactive oxygen species and protein oxidative damage. In IP6K2-KO mice, mitochondrial dysfunction was associated with impaired expression of the cytochrome-c1

subunit of complex III of the electron transport chain. Overactive mitochondrial fission was observed in IP6K2 knocked down cells. We also observed upregulation of mitochondrial fission protein, Drp1, as well as mitochondrial biogenesis markers (PGC1α and Nrf-1). We reversed some of the effects of mitochondrial dysfunction by combined treatment with N-acetylcysteine and phosphocreatine. These findings establish a role for IP6K2-CK-B interaction in energy homeostasis associated with neuroprotection.

Title: Hydrogen peroxide-induced neurite degeneration via mitochondrial dysfunction

Authors: *K. FUKUI, M. WAKUZAWA, N. YOSHIDA, Y. KATO;
Shibaura Inst. Technol., Saitama, Japan

Abstract: Reactive oxygen species (ROS) induce neuronal cell death and deeply relate to the development of many severe neurodegenerative disorders such as Alzheimer's disease (AD), Parkinson's disease and dementia. These diseases show the same neuronal changes in the early stages, and neuronal axons cause alteration such as aggregation, shrinking and accumulation. If we find to the early sign of the neuronal change such as axon/neurite degeneration, it has a chance to improve neuronal functions. We tried to elucidate the mechanism of neurite degeneration in hydrogen peroxide-treated neuroblastoma cells. To clarify the mechanism of neurite degeneration in hydrogen peroxide-treated N1E-115 cells, we established neurite-isolation methods and analyzed proteins using LC/MS/MS and determined some specific proteins. HSP 60 which is one mitochondrial chaperon protein was increased in the isolated neurite of a low concentration hydrogen peroxide-treated cells. However, it expression was gradually decreased in AD-transgenic mouse brain in an age-dependent manner. It was confirmed that mitochondria accumulated to the neurite degenerated region and released superoxide in cultured cells. The fluorescent intensity of Mitosox in hydrogen peroxide-treated cells was significantly increased compared to the normal cells. 3-nitrotyrosin and nNOS expressions in the isolated mitochondria on AD-transgenic mouse brain tended to increase compared to the age-matched controls. SOD-2 and NMNAT-3 expressions tended to decrease in the isolated mitochondria on AD-transgenic mouse brain tended to increase compared to the age-matched controls. We also found that endoplasmic reticulum (ER) was also accumulated at neurite degenerated regions. Mitochondria and ER are famous calcium stores in the cells, and we

are focusing on the relation between changes in calcium homeostasis and ROS-induced mitochondrial dysfunction.

Title: Standardization of a low-cost western diet as a model for increased weight gain during pregnancy and overweight in offspring at birth in CD-1 mice

Authors: *R. PEDRAZA-MEDINA, S. ROSALES-HERRERA, M. ORTIZ-VALLADARES, J. GUZMÁN-MUÑIZ, N. MOY-LÓPEZ;
Univ. De Colima, Colima, Mexico

Abstract: Western diet (WD) is a set of processed foods, which are high in calories, fat, and sugar, low in fiber, but pleasant in taste and texture. In recent years, studies of WD have increased, however, in developing countries is hard to have access to a standardized model of WD. They are expensive and manufactured in other countries. We aimed to develop a low-cost western diet model capable to induce increased weight gain during pregnancy and overweight in the neonatal offspring of CD-1 mice. To develop our diet, we analyzed the composition of three commercial WD. Using the standard diet (SD) "Nutricubos" from Purina Mexico as a basis we defined the composition of the diet to be developed. Then we analyzed the diet for the next parameters: crude protein, fat, crude fiber, carbohydrates, and ash, following the official methods of analysis from the Association of Official Analytical Chemists. Finally, we realized two experiments in CD-1 mice, in the first one; we analyzed bodyweight on PND 5 and spatial learning and memory on Morris Water Maze on PND 90 in 27 mice from mothers exposed to our WD during pregnancy and lactation, and 27 from animals exposed to the SD (Nutricubos). In the second experiment, we analyzed bodyweight on PND 5 and brain weight on PND 26 in 20 mice from mothers exposed to the WD during pregnancy and lactation, and 10 from mothers with an SD. We registered maternal weight gain and food intake during pregnancy in both protocols. Analysis of WD shows that our diet has 4.30 Kcal/g^2, of which 41.39% were from fats, 15.28% from proteins, and 43.43% from carbohydrates. Mice exposed to WD during pregnancy show an increased intake of food, calories and have a greater weight gain. On the PND 5, offspring from a WD were heavier than control. We did not found differences in brain weight; however, WD decreased memory skills during adulthood. In conclusion, our diet proved to have the composition of a characteristic WD, in addition to being useful to increase weight gain during pregnancy and induce overweight in neonatal offspring of CD-1 mice.

Title: Disrupting glucose uptake rejuvenates neural stem cells in the aged brain.

Authors: *T. J. RUETZ, C. M. KASHIWAGI, B. MORTIN, R. W. YEO, D. S. LEEMAN, M. C. BASSIK, A. BRUNET;
Stanford Univ., Stanford, CA

Abstract: Neural stem cells in the aging mammalian brain are impaired in their ability to activate to produce new neurons and regenerate damaged tissue. Here we use a genome-wide CRISPR/Cas9 knockout screen to identify gene networks to improve neural stem cell activation in old mice. We establish a high throughput system to screen primary cultures of neural stem cells. We screened 600 million neural stem cells from 3 cohorts of young and old mice to identify gene knockouts that specifically boost old neural stem cell activation. We identify 300 gene knockouts that rescue old neural stem cell function. The top gene knockouts that boost old neural stem cell activation are involved in cilium organization, cytoplasmic granule structures, and glucose import, and include the glucose transporters GLUT4 and GLUT12. To identify rejuvenating gene knockouts most relevant for the aging brain, we developed an *in vivo* screening platform. We find that knockout of GLUT4 in the sub ventricular zone stem cell niche rejuvenates neural stem cell activity in old mice. The GLUT4 protein increases in expression in the stem cell niche during aging, and indeed old neural stem cells uptake ~2-fold more glucose than their young counterparts. Importantly, a brief glucose starvation increases the ability of old neural stem cells to activate, which is not improved with knockout of GLUT4. These results show that a shift in GLUT4 activity and increase in glucose uptake drives the decline in neural stem cell activity with age, thereby providing a robust target for rejuvenation strategies. Our work also identifies a large set of gene knockout interventions to boost neural stem cell activity in old brains, which should help counter cognitive decline during aging.

Title: A novel role for BRIP1/ FANCJ in neuronal cell health and in resolving oxidative and metabolic stress induced DNA lesions

Authors: *C. MANI[1], P. H. REDDY[2], K. PALLE[1];
[2]Dept. of Intrnl. Med., [1]TTUHSC, Lubbock, TX

Abstract: A novel role for BRIP1/ FANCJ in neuronal cell health and in resolving oxidative and metabolic stress induced DNA lesions

Chinnadurai Mani[1], P. Hemachandra Reddy[2] and Komaraiah Palle[1]. 1. Cell Biology and Biochemistry, 2. Internal Medicine, Texas Tech University Health Sciences Center, Lubbock, TX, 79430 USA.**Presenting Author: Chinnadurai Mani[1]**

Abstract: The purpose of our study is to understand the role of BRIP1/ FANCJ in neuronal cell health and oxidative/metabolic stress. DNA damage accumulation and mitochondrial abnormalities are elevated in neurons of AD patients, and contribute to neuronal dysfunction and AD pathogenesis/progression. BRCA1 interacting protein 1 or BRIP1 is a 5' to 3' DNA helicases that catalyzes abnormal DNA structures during replication, gene transcription, recombination, and contributes to genomic integrity. BRIP1 functions are well studied in DNA repair; however, there is limited data on its role and regulation during aging and neurodegenerative diseases.

Methods: We used immunohistochemistry, western blot and RT-PCR assays to analyze BRIP1 expression in mice and human brains. Immunofluorescence assay was used to study R-loop, ROS formation and mitochondrial morphology. Flow cytometry and Electron microscopy was used to evaluate mitochondrial ROS and mitochondrial structures, respectively. Seahorse assay was performed to study the OCR, and Prestoblue assay was used to evaluate cell viability.

Results: Our results show BRIP1 expression in the brain and in neuronal cells, and its levels were elevated in hippocampal region of brain, specifically in dentate gyrus. BRIP1 downregulation in human and mouse neuronal cells caused increased R-loop formation basally and in response to H_2O_2 treatment. Additionally, knocking down BRIP1 in neuronal cells caused downregulation of BRCA1, increased DNA damage and cell death both in cycling and terminally differentiated cells. Furthermore, in BRIP1 deficient cells, elevated levels of excitotoxicity was observed in response to L-Glutamic acid exposure as evidenced by mitochondrial ROS levels, deteriorated mitochondrial health, and cell death.

Conclusions: Overall, our results indicate that BRIP1 plays important role in maintaining neuronal cell health and homeostasis by suppressing cellular oxidative stress, resolving abnormal

DNA structures, and protects mitochondria. As these metabolic stress conditions are common during aging and neurodegenerative conditions, our data suggests BRIP1 contributes to healthy aging and may have protective role in neurodegenerative diseases.

Title: Molecularly distinct mitochondria display synapse-specific localization

Authors: *K. PANNONI[1], D. GIL[1], L. CAMPBELL[1], S. FARRIS[1,2];
[1]Fralin Biomed. Res. Inst., Virginia Tech., Roanoke, VA; [2]Virginia-Maryland Col. of Vet. Med., Virginia Tech., Blacksburg, VA

Abstract: CA2 is an understudied subregion of the hippocampus that is critical for encoding social memories. To uncover which genes play a role in CA2 function, we transcriptionally profiled subregions of the mouse hippocampus and found that genes encoding mitochondrial proteins involved in energy generation and calcium uptake have higher expression in CA2 compared to CA1. In particular, multiple components of the mitochondrial calcium uniporter (MCU) complex are selectively enriched in CA2. The MCU complex regulates calcium entry into mitochondria, which in turn can regulate bioenergetics, mitochondrial transport and localization to active synapses. We hypothesize that mitochondria in CA2 are molecularly and functionally distinct from mitochondria in CA1, which may confer unique synaptic and circuit properties underlying CA2 function. It is well-known that CA2 synapses in stratum radiatum (SR) that receive input from CA3 are resistant to long-term potentiation (LTP). Conversely, CA2 synapses in stratum lacunosum moleculare (SLM) that receive input from entorhinal cortex layer II readily express LTP. To determine if there are circuit-specific differences in mitochondria across dendritic layers, we immunostained for MCU and quantified the size, fluorescence, number, and percent area of mitochondria. We found that MCU fluorescence is strikingly enriched in CA2 SLM compared to SR. Furthermore, the MCU-enriched mitochondria in CA2 SLM are larger compared to MCU-labeled mitochondria in SR. This suggests that larger mitochondria preferentially localize to distal and/or more plastic synapses, perhaps due to enriched MCU expression. To determine if MCU expression regulates mitochondrial size and/or localization, we used adeno-associated viral vectors to overexpress MCU or GFP in CA1, which

normally has 4-fold less MCU than CA2. MCU overexpression led to larger MCU-labeled mitochondria in CA1 SR and SLM compared to GFP controls, with a preferential enrichment in SR compared to SLM. Our findings demonstrate that mitochondria are molecularly diverse across hippocampal cell types and circuits and that MCU is a key regulator of mitochondrial size and localization at synapses. Ongoing studies are using a CA2-specific MCU conditional knockdown mouse line to investigate whether there is bi-directional effect on mitochondrial size and localization in CA2 that could impact circuit-specific function.

Title: The relationship between obesity and cognitive dysfunction; Prevention by tocotrienols

Authors: *Y. KATO, J. BEN, K. FUKUI;
Shibaura Inst. of Technol., Saitama, Japan

Abstract: Recently, it is social problem to increasing of the people with cognitive dysfunction such as Alzheimer's (AD) and Parkinson's disease. Obesity is also increasing all over the world. Obesity raises a risk of secondary diseases such as type-2 diabetes and cardiovascular disease. It has been reported that obesity induces cognitive dysfunction. However, detailed mechanisms of it have been yet unclear. The diseases induced by obesity strongly related to accumulation of oxidative damages by reactive oxygen species. In fact, the amount of lipid peroxide in AD model mice cortex and hippocampus are higher than that of control mice. We expected that obesity may induce cognitive dysfunction via elevation of brain oxidation.
Vitamin E is one of lipophilic vitamins and have chroman ring structure with side chain. Tocotrienols (T3s) are the vitamin E homologs with unsaturated side chain and have strong antioxidant function. It was reported that T3s but not the saturated vitamin E (tocopherols) have beneficial functions such as anti-cancer and neuroprotective effects. In addition, antioxidant activity of T3s is higher than that of tocopherols. Additionally, we demonstrated that T3s have anti-obesity effects such as inhibition of body weight gain and decrease of serum cholesterols. So, it is possible that T3s can prevent obesity-induced cognitive impairment via antioxidant and/or anti-obesity effects.
We fed a high-fat diet or high-fat high-sucrose diet in the presence or absence of T3s. We prepared some experimental conditions (diets, treatment duration, age of mice, treatment volume of T3s, etc.). We measured body weight at once a week. After duration, we assessed the effects of obesity and T3s on mice cognition by the Morris water maze, rota rod, Y-maze and Open filed

test. Furthermore, we measured oxidative stress makers and the expressions of antioxidative enzymes, neurotrophic factors and acetylated histone H3 in the high-fat diet and high-fat high-sucrose diet-treated mice brain. We would like to present the detailed-results and comparison between each experimental condition.

Title: The role of oxidative stress in microtubule regulation and neuronal ageing

Authors: *S. SHIELDS, O. R. WILKES, N. SANCHEZ-SORIANO;
Inst. of Systems, Mol. and Integrative Biol., Univ. of Liverpool, Liverpool, United Kingdom

Abstract: In healthy axons, microtubules are arranged into parallel bundles providing the structural backbones and highways for life-sustaining transport from and to the cell body. During ageing and across different species, neurons experience changes at the subcellular level including decay of the microtubule (MT) cytoskeleton and a rise in reactive oxygen species (ROS) leading to oxidative stress (OS). We intend to understand the nexus between oxidative stress and microtubule damage and the contribution to axonal and synaptic decay during neuronal ageing. Using primary neuronal cultures derived from *Drosophila*, we show that OS (induced by loss-of-function of superoxide dismutases, Sod; Gss1 and Gss2 knockdown, the enzymes catalysing the antioxidant glutathione; or treatment with ROS-inducing compounds) disrupts microtubule organisation within axons in vitro and is rescued via administration with the antioxidant vitamin E analogue trolox. At the mechanistic level, we find that the association of Eb1 (end binding protein) to microtubules is reduced in conditions of OS. Since Eb1 is a master regulator of microtubule polymerisation, dysregulation of Eb1 could explain MT defects observed in conditions of OS in vitro. Confirming the latter, we find that the neuroprotective peptide NAP, which enhances Eb1 binding to MTs, fully rescues ROS-induced MT disorganisation. To assess the importance of our findings for neuronal ageing, we established a novel in vivo model within the fly optic lobe, to study the cell biology of ageing. Within neurons, we observed the

accumulation of MT defects within axons and synaptic terminals during ageing and such changes preceded the thinning of axons and the appearance of membrane swellings. All these ageing phenotypes were exacerbated in both paraquat and diethyl maleate-fed flies. Conversely, the deterioration of axons and synapses could be improved upon knockdown of the NRF2 inhibitor Keap1 and by the overexpression of Eb1. We propose that age-related OS alters the functions of key MT regulators, such as Eb1, leading to the formation of MT aberrations and, in turn, axon and synapse decay. From this, enhancing the function or stability of Eb1 provides an effective strategy for combatting OS-induced neuronal decay during ageing.

Title: An efficient iPSC-derived “brain-in-a-dish” tri-culture model identifies a role for TREM2 in modulating a neuroinflammatory cascade implicated in neurodegeneration

Authors: M. OHSHIMA, T. WAKUI, **M. GOEDLAND**, M. LIVINGSTON, S. BURTON, C. B. CARLSON, *W. W. POON, S. HILCOVE, D. RAJESH;
FUJIFILM Cell. Dynamics, Inc., Madison, WI

Abstract: Neuron-glia interactions play a pivotal role in normal brain homeostasis in which perturbations to disrupt this delicate balance are implicated in neurodegenerative disease pathogenesis. Although mouse models have uncovered many aspects related to the role of brain neuroinflammation in disease etiology, salient features are not captured due to species differences. Hence, there is a critical need to develop human disease models that are more translatable to the clinic. Here, we describe a defined, scalable *in vitro* tri-culture model combining human induced pluripotent stem cell (iPSC)-derived GABAergic neurons, astrocytes, and microglia that can be used to study cellular interactions and cell type-specific genetic contributions to model neurodegeneration for drug screening applications. This “brain-in-a-dish” system was used to investigate the role of TREM2 in neuroinflammation, as TREM2 mutations are implicated in Alzheimer’s Disease (AD) risk. By examining these tri-cultures that contain iPSC-derived microglia differentiated from either an apparently healthy donor (AHN), an engineered heterozygous (HZ) TREM2 knockout (KO) iPSC line, or a homozygous (HO) TREM2 KO line, we found intrinsic differences between the AHN and TREM2 engineered lines and that LPS treatment led to neurotoxicity in tri-cultures, as analyzed by an image-based quantification system coupled to immunocytochemistry. Further analysis of tri-cultures with either TREM2 HZ or TREM2 HO KO microglia revealed a several fold increase in

neuroinflammatory cytokines and chemokines (TNF-alpha, IL-6, IL-10, IL-12, CCL2, CCL3, CCL4 and CX3CL1), and augmented the generation of A1 astrocytes, implicating a role for TREM2 in restraining the A1 astrocyte phenotype. Importantly, we identified intrinsic differences in complement component production (C3 and C1q) due to TREM2 loss of function in microglia in mono-culture compared to when in tri-culture. Thus, iPSC-based tri-cultures can serve as a powerful tool to screen for therapeutics to rescue neuroinflammation-mediated neurotoxicity, as well as to study autocrine and paracrine signaling pathways involved in neuronal dysfunction, synaptic pruning, and provide mechanistic insights into pathways disrupted by disease associated microglia (inherited genetic mutations) in the context of a more relevant brain environment.

Abstract: Alzheimer’s disease (AD) is the most common neurodegenerative disorder. It has complex neuropathology which includes an accumulation of amyloid beta (Aβ) plaques, hyper-phosphorylated tau tangles, and neuroinflammation. Our lab has identified that expression of the interferon response protein IFITM3 is upregulated in human AD brain as well as in 5xFAD mouse brain, which expresses human APP and PSEN1 transgenes. We have shown that IFITM3 regulates γ-secretase activity in neurons and astrocytes, and a deficit in IFITM3 results in decreased γ-secretase cleavage of APP. Further, IFITM3 is highly expressed and inducible in

microglia. Research has indicated that microglia play a critical role in AD progression. Our current focus is on investigating the function of IFITM3 in the phagocytic clearance of Aβ by microglia and its interplay with TREM2 and downstream signaling in the context of neuroinflammation. For this, we have generated 5xFAD ; IFITM3$^{-/-}$; TREM2$^{-/-}$ mice and have established stem cell-derived IFITM-deficient microglial cells. With our studies, we hope to determine the role of IFITM3 in microglia, which has not been previously described before, using cellular assays and mouse models.

Abstract: **Background:** Recently, transcriptomic profiling has helped identify the diverse heterogeneity and distinct molecular states of astrocytes in different disease models. Mouse astrocytes adopt an ‘A1’ neurotoxic phenotype, characterized by the increase expression of complement 3 (C3), after exposures to specific cytokines secreted by microglia, whereas they acquire an ‘A2’ neuroprotective phenotype in a model of ischemic stroke. Although, now it is unclear if these binary divisions are fixed and if A1 and A2 phenotypes are all encompassing, suggesting a much more complex disease specific interplay. Interestingly, we and others have reported in response to the cerebrovascular deposition of amyloid in CAA, severe astrogliosis with an C3^{+}-astrocytic phenotype without reactive microgliosis, suggesting that other cell types

may be responsible for A1 astrocytic induction independent of microglia activation. **Methods:** Here, we use LPS-mediated inflammation of microglia and endothelial cells to identify distinctive reactive astrocytic profiles in primary culture assays and in mouse models and AD/CAA patients. **Results:** We show that LPS-mediated inflammation of endothelial cells induces the formation of $C3^+$-reactive astrocyte with a strong extracellular matrix remodeling profile, distinct from astrocytes classically activated by neuroinflammatory microglia. We show that activated endothelial cells strongly induce C3 positive astrocytes enriched in A1-astroctyic genes and exhibit a gain of neurotoxic function while retaining homeostatic phagocytic capacity. Additionally, the transcriptomes of astrocytes differ between endothelial and microglial inflammatory stimulus and GBP2 and extracellular matrix remodeling gene Decorin stratify to molecular subtypes of $C3^+$-astrocytes. Finally, we demonstrate $Decorin^+$ $C3^+$ astrocytes are associated to vascular amyloid deposits but not amyloid plaques in mouse models and AD/CAA patients showing the existence of potentially extensive and subtle functional diversity of $C3^+$-reactive astrocytes and the multidimensional roles of reactive astrocytes after CNS injury and neurodegenerative diseases. **Conclusion:** The presence of $C3^+Decorin^+$ astrocytes associated to vascular amyloid deposits suggests vascular damage induces reactive astrocytes with an extracellular matrix remodeling profile in mouse models and AD/CAA patients that are distinct from astrocytes classically activated by neuroinflammatory microglia demonstrating the existence of potentially extensive and subtle functional diversity of neurotoxic A1- astrocytes.

Title: Tnf-mediated neuroinflammation linked to neuronal necroptosis signaling in alzheimer's disease hippocampus

Authors: *A. JAYARAMAN[1], T. T. HTIKE[1], R. JAMES[2], C. PICON[2], R. REYNOLDS[1,2]; [1]Lee Kong Chian Sch. of Med. - NTU, Singapore, Singapore; [2]Div. of Neuroscience, Dept. of Brain Sciences, Fac. of Medicine, Imperial Col. London, London, United Kingdom

Abstract: Neuroinflammation has been implicated in the pathogenetic mechanisms underlying neuronal death and dysfunction in Alzheimer's disease (AD). In chronic inflammatory

environments, TNF-TNFR1 can lead to cell death via necroptosis. Although necroptosis has recently been demonstrated in AD, its significance in neuronal death and the role of TNF signaling is unclear. Using post-mortem human brain tissues and human iPSC-derived glutamatergic neurons, we demonstrate that TNF signaling is linked to neuronal necroptosis. We show evidence of altered expression of ESCRT III components, which antagonize necroptosis and provide a possible mechanism for cell survival after necroptosis. Snap-frozen post-mortem hippocampal tissue blocks from AD (n=30) and non-neurological control subjects (n=11), were compared. For RNA/protein work, 5-10 serial 30µm cryosections of grey matter tissue were pooled for each sample. The differential spatial distribution and cellular source were examined by multiple immunolabelling on 10µm cryosections. All imaging data were correlated with pathological and clinical outcomes. Human iPSC-derived glutamatergic neurons were treated with TNF+Smac-mimetic+zVAD, with or without pretreatment with RIPK1, RIPK3 or MLKL inhibitors. LDH assays were used to determine the extent of neuronal death. qRTPCR analysis showed 2–3-fold upregulation of TNF and necroptosis pathway genes in AD. Immunolabelling showed increases in TNFR1, RIPK1, pRIPK3 and pMLKL expression in the AD hippocampus, predominantly in CA1-2 pyramidal neurons. Western blot analysis showed significant increases in pMLKL, pRIPK3, TNFα, FADD, and TNFR1 expressions in AD. Colocalization of pMLKL with pRIPK3/RIPK1, and co-immunoprecipitation of pRIPK3-MLKL in the AD hippocampus further provided evidence for neuronal necroptosis and necrosome formation. We showed chronic inflammatory factors (CD8+ T-cells and activated microglia) around pMLKL+ neurons. ESCRT-III components showed a significant overlap at the subcellular level in pMLKL+ neurons. TNF+Smac-mimetic+zVAD exposure induced necroptosis in human iPSC-derived glutamatergic neurons with ~67% neuronal death at 24 h, and significant increase in ROS production by 6 h, both of which were effectively decreased by inhibitors. Our results suggest that increased TNF/TNFR1-mediated inflammatory signaling leads to necroptotic cell death in AD brains. Demonstration of TNF-mediated necroptosis in human iPSC derived neurons and its reduction with small molecule inhibitors targeting RIPK1, RIPK3 or MLKL suggests that this pathway could potentially be therapeutically manipulated in AD.

Title: Identification of state-specific proteomic characteristics of microglia-derived exosomes

Authors: *J. SANTIAGO[1], S. RAYAPROLU[1], H. XIAO[1], N. T. SEYFRIED[2], S. RANGARAJU[1];
[1]Neurol., [2]Biochem., Emory Univ., Atlanta, GA

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder defined by progressive pathological protein aggregation (amyloid-beta and tau) and deterioration of cognitive function. Microglia-mediated neuroinflammation is a key pathological component of AD; however, there are critical gaps in our understanding of how microglia perpetuate AD pathology. One proposed mechanism of microglia-mediated neuroinflammation and neurodegeneration is exosome release because of their critical role in the transport of macromolecules between cells to facilitate intercellular communication. Thus, it is possible that microglia-derived exosomes transfer pathogenic cargo which could perpetuate AD pathology. The proteomic profiles and influence of different microglia-derived exosomal populations on AD pathology remain unknown. We hypothesize that different microglia states determine the molecular composition of exosomes. To test this, we treated a murine microglia cell line, BV2 cells, with various cytokines to polarize them and collect their exosomes for downstream mass spectrometry (MS) analyses. Three groups of BV2 cells (n=4/group) were treated with either lipopolysaccharide (LPS) to polarize to a pro-inflammatory state, interleukin 10 (IL-10) to polarize to an anti-inflammatory state, or transforming growth factor beta (TGF-β) to polarize to a homeostatic state. Untreated BV2 cells served as a control group. Following 72 hours of treatment, BV2 cells were lysed and cell culture media was collected for exosome isolation. Transmission electron microscopy images and western blotting for exosomal marker, CD9, confirmed exosome purification by our isolation method. In MS studies, we identified 533 proteins in exosome fractions and 1,866 proteins in BV2 cell proteomes. We found that known exosome related proteins, Sdcbp and Igsf8, were significantly increased in the exosomal proteome compared to the whole cell proteome. We identified proteins that are differentially expressed across polarization with unique proteins increased in exosomes derived from LPS, IL-10, and TGF-β treated BV2 cells. Validation studies of these top hits are ongoing, and studies are underway to replicate these findings in primary microglia. Our results indicate that exosomes derived from microglia adopt distinct state-associated protein profiles which may have differential effects on other cell types. This work will guide future studies concerning the role of exosomal cargo in perpetuating AD pathology.

Title: Exploring cell signaling pathways engaged by two novel small molecule drug candidates (MW151 and MW189) that selectively modulate stressor-induced neuroinflammation

Authors: *E. D. ROEPKE, D. J. BRAUN, L. J. VAN ELDIK;
Sanders Brown Ctr. on Aging, Univ. of Kentucky, Lexington, KY

Abstract: Neuroinflammation plays an important role in many different brain pathologies and injuries and therefore may represent a beneficial therapeutic target across neurological conditions. Two brain-penetrant, anti-inflammatory small molecule drug candidates, MW151 and MW189, are in or have completed Phase 1 clinical trials for safety (clinicaltrials.gov ID NCT04120233 and NCT02942771, respectively). MW151 and MW189 are structural analogs, and both ameliorate neuroinflammatory effects across a broad range of preclinical animal models, such as reducing glial activation and pro-inflammatory cytokine production. However, their molecular target(s) are not defined. To maximize the likelihood of eventual clinical success for one or both drugs (or similar compounds), we have started exploring potential target pathways *in vitro*. For these studies, we are utilizing the BV-2 mouse microglial-type cell line. It is already known that these drugs do not inhibit the p38 MAPK pathway, so other major inflammatory pathways such as NFκB, STAT3, JNK, and ERK are currently being explored. We found that MW151 and MW189 inhibit lipopolysaccharide (LPS)-induced iNOS stimulation and LPS-induced cytokine secretion, which may occur in part via inhibition of NFκB signaling. Both drugs also block extended IL-6 induced STAT3 phosphorylation (1 to 4 hours post-stimulation), with no effect on the early phase (30 minutes or less). While these findings offer intriguing clues, an unbiased proteomic exploration of BV-2 cells exposed to MW151 and MW189 is being undertaken to more clearly identify the molecular mechanism(s) and target pathway(s) of these drugs. Successful identification of the signaling pathways and proteins modulated by MW151 and MW189 *in vitro* will provide the biological rationale for design of future clinical trials, and possibly open new avenues of exploration in future drug development programs.

Informatics, Intrnl. Medicine, Univ. of Kentucky Col. of Med., Lexington, KY; [5]Dept. of Neuroscience, Mayo Clin., Scottsdale, AZ; [6]Neurosci. Grad. Program, Mayo Clin. Grad. Sch. of Biomed. Sci., Scottsdale, AZ

Abstract: Complement receptor 1 (*CR1*) was implicated as a top Alzheimer's Disease (AD) risk factor in 2009, yet its role in AD remains an enigma. *CR1* encodes a transmembrane, regulatory protein with an extracellular binding domain that binds complement cascade proteins (C3b, C4b, and iC3b), and is thought to improve Aβ clearance. Oddly, while *CR1* RNA and proteins are highly expressed in various blood cells, *CR1* RNA is not expressed in brain tissue at a meaningful level, making it difficult to understand *CR1*'s involvement in AD. A study by Crehan et al. suggests CR1-homologue proteins (Cr2) are present on rat microglia, and that blocking Cr2 significantly decreases microglial phagocytosis of $A\beta_{42}$. A major challenge here, however, is whether murine *Cr2* in fact encodes a valid human *CR1* homologue.Adding to the peculiarity of *CR1* involvement in AD, the gene has been genetically linked as a potential loss-of-function risk gene, yet certain apparent gain-of-function variants are also associated with AD risk. Specifically, CR1 variable C3b/C4b binding domains in the population, where more binding domains are associated with increased AD risk. Furthermore, we recently demonstrated the *CR1* binding domains are "camouflaged," meaning they are entirely overlooked by standard short-read sequencing methods and likely have undiscovered DNA variants. In fact, by rescuing mutations from these regions in *CR1* in the Alzheimer's Disease Sequencing Project (ADSP), we identified a rare 10-nucletotide loss-of-function frameshift deletion that could be involved in disease. In short, significant evidence suggests *CR1* plays a major role in AD pathogenesis, yet exactly how *CR1* is involved remains an enigma, demonstrating the importance of research into *CR1*'s involvement. We propose a future study to clarify *CR1*'s apparent enigmatic role in AD. Using a combination of human tissue, cell lines, and murine models, our primary goals are to: (1) determine whether CR1 proteins are present in human brain tissue, and assess function in the brain; and (2) experimentally modify the binding domain by increasing, decreasing, and mutating the region, including the 10 bp frameshift to test its effects on AD phenotypes. We hope these experiments clarify the enigmatic nature of CR1's involvement in AD.

Title: Altering microglia phenotype in Alzheimer's disease by blockade of L-type calcium channels in 5XFAD mouse model with isradipine

Authors: *J. WICKLINE[1], S. SMITH[1], K. ODFALK[1], R. SHIN[2], J. SANCHEZ[1], M. JAVORS[1], B. GINSBURG[1], S. C. HOPP[3];
[1]Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX; [2]Univ. of Texas at Austin, Austin, TX; [3]Biggs Inst. for Alzheimer's and Neurodegenerative Dis., UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Alzheimer’s disease (AD) is the sixth leading cause of death in the United States and is pathologically characterized by tau tangles and amyloid beta (aβ) plaques. In AD, microglia take on a neurodegenerative phenotype characterized by toxic gain-of function (e.g., proinflammatory cytokine production) and loss-of-function (e.g., reduced ability to remove aβ). Intracellular calcium (Ca^{2+}) dysregulation is a key factor that may drive the microglia neurodegenerative phenotype in AD. Microglia display dysregulated intracellular Ca^{2+} near plaques. Epidemiological studies show that use of Ca^{2+} channel blockers targeting L-type Ca^{2+}channels (LTCCs) reduce the incidence of neurodegenerative diseases, but the mechanism of this observation is unknown. We hypothesize that LTCCs on microglia mediate their Ca^{2+} dysregulation and neurodegenerative phenotype near aβ plaques. To test this hypothesis, we treated male and female 5XFAD plaque pathology model mice with the LTCCs antagonist isradipine (3 mg/kg/day) using three different drug delivery methods: osmotic minipumps, mouse chow and subcutaneous slow-release pellet. Following three weeks of treatment, we tested whether isradipine treatment could improve learning and memory behavior measured using novel object recognition and Morris water maze (MWM). We also measured markers of neurodegenerative microglia using qPCR, immunohistochemistry (IHC) and protein biochemistry. qPCR was used to measure phenotypic markers of neurodegenerative microglia such as IL1β, iNOS, TNFα, TREM2 and CD68, and the LTCCs Cav1.2 and 1.3. IHC was used to examine the relationship between microglia and aβ plaques and the presence of dystrophic neurites. Finally, protein biochemistry was used to quantify the ratio of aβ 42/40. All data was analyzed with a two- or three-way ANOVA using post hoc Tukey HSD and G-power was used

to calculate the correct sample size for behavior assays at a power of 0.80. We observed a genotypic difference in 5XFAD and wild-type (WT) littermates in the MWM but observed no effect of isradipine treatment. However, mass spectrometry revealed subtherapeutic levels of drug in the plasma and brain for 2 out of 3 delivery methods. Our studies showed that previously published literature using isradipine in osmotic minipumps was not reproducible and that a novel chow delivery of isradipine is not effective. We show the most reliable drug delivery method for isradipine is the subcutaneous pellet; future studies will focus on understanding the gene expression, histological, and biochemical changes following this treatment paradigm in the 5XFADs.

Title: Early changes in nmda receptors in 5xfad mice are enhanced through the treatment of ibuprofen in females but not males

Authors: *E. SACKINGER[1], J. RAUENHORST[1], T. VU[1], A. RADKE[1], F. NIGUSSIE[2], K. R. MAGNUSSON[3];

Abstract: Changes in amyloid occur early in Alzheimer's disease (AD), before behavioral signs. Based on this, and early changes seen in N-methyl-D-aspartate receptors (NMDARs) in presenilin models, we aimed to study the development of changes in α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs) and NMDAR prior to behavioral signs of amyloid-related degeneration in 5xFAD mice. We performed 2 studies to examine glutamate receptor responses, with and without ibuprofen (IBU) intervention. In order to assess early changes in 5xFAD mice at 15-days, 1, 2 or 4 months old, we examined the field excitatory postsynaptic potentials (fEPSPs) of CA1 synapses in hippocampal slices using a MED64 multielectrode array system. Antagonists of AMPAR, GluN2A and GluN2B NMDAR subunits, and full NMDARs were applied. Hippocampal slices began in regular artificial cerebrospinal fluid (aCSF), followed by 1) 30μM DNQX (AMPAR antagonist), 2) 0.5mM $MgSO_4$ aCSF,

30μM DNQX & 10μM picrotoxin (γ-aminobutyric acid (GABA) receptor antagonist) solution; 3) 4μM Ro-25-6981 (GluN2B antagonist), 4) 500nM PEAQX (GluN2A antagonist), and 5) 50μM AP5 (NMDAR antagonist). A stimulus response was performed after each step and input (fiber volley amplitude) / output (fEPSP amplitude) was analyzed. At 4 months old, both male and female hemizygous (5xFAD) mice showed increases in I/O responses for GluN2A, GluN2B and all NMDARs (p = .014-<.0001) but decreases at 15 days in AMPARs (p =.015, <.0001), and at 2 months for AMPARs and GluN2A (p <.0001). 5xFAD females showed increased I/O responses for AMPARs (1 and 4 months, p <.0001), GluN2B and NMDAR (1 month, p=.02), but decreases at 2 months for GluN2B (p <.0001). 5xFAD males had increased I/O responses for GluN2B (p=.0003) at 15 days, but decreased responses for NMDAR (p. <.0001) at 1 month and GluN2B and NMDAR (p =.001- <.0001) at 2 months. There appeared to be early increases in glutamate transmission at .5-1 month, followed by a reduction and subsequent return to hyperresponsive NMDARs by 4 months in 5xFAD mice. Previously, our lab determined IBU can decrease NMDAR expression in male mice. We treated 2 month old 5xFAD mice with IBU (375 ppm in chow) for 2 months, in order to reduce the increased synaptic NMDAR responses that we saw at 4 months in 5xFAD mice. Both male and female 5xFAD showed increased I/O responses for NMDAR and GluN2A (p=.007-<.0001). IBU increased responses for NMDAR, GluN2A and AMPAR in both WT (p<.0001) and 5xFAD (p=.02-.0009) females, but decreased responses to GluN2B and AMPAR in 5xFAD males (p=.045-.0002). IBU had small reducing effects on glutamate receptor responses in males, but enhanced NMDAR responses in females.

Title: Modeling the Impact of AD Genetic Risk on Microglia States and Function

Authors: *M. THERRIEN[1], M. J. DOLAN[2], S. JEREB[2], T. KAMATH[2], N. LOJEK[2], T. ATKESON[2], S. E. MARSH[4], M. B. JOHNSON[5], K. EGGAN[6], E. MACOSKO[3], B. A. STEVENS[7];

Neurobio., Boston Children's Hosp., Boston, MA

Abstract: Microglia, the brain's resident immune cells, are highly dynamic and reactive to environment and genetic challenges. More than 40 genomic loci have been linked to late onset Alzheimer's disease (AD) and many risk genes are highly expressed in microglia. Our goal is to connect insights from genetic association studies to new ways of functionally modeling the cellular and molecular causes of disease to enable predictive tracking and targeting of detrimental immune cell states in patients in the early stages of disease. Single cell transcriptomic studies reveal diverse microglial states in human and mouse brains, however we currently lack specific approaches to track and manipulate specific populations of microglia in Alzheimer's and other diseases. To answer this question, we turned toward human iPSC-induced microglia (iMGL) and single cell transcriptomics.Single cell transcriptomics revealed the presence of multiple microglia states when iMGLs are stimulated with different brain-relevant challenges, including apoptotic neurons, synaptosomes, myelin and amyloid. Moreover, alignment of these data using LIGER (Welch et al. Cell 2019) shows these states are similar to the ones observed in human and mouse in vivo, revealing several disease associated states, including disease-associated microglia (DAM). We also observed changes in microglia states depending on the challenge and genetic background.Together, our data identified key elements causing the formation of DAM and how AD risk genes affect disease-associated states and functions. This work will open the door to the identification of modulators of DAM and highlight new therapeutics avenues of AD.

Title: Microglia internalize tau monomers and preformed fibrils via macropinocytosis and clathrin-mediated endocytosis

Authors: *K. F. ODFALK[1], C. M. BYRNE[1], D. LIM[2], S. C. HOPP[1];
[1]Biggs Inst. for Alzheimer's and Neurodegenerative Dis., [2]Univ. of Texas Hlth. San Antonio, San Antonio, TX

Abstract: Aggregation of misfolded tau is a hallmark of many neurodegenerative diseases including Alzheimer's disease (AD) and is correlated with cognitive decline. Neurons release tau which enters nearby cells and serves as a template for tau aggregation, thus propagating the progression of tau pathology through the brain. Microglia do not express the tau gene. Yet, microglia containing tau are observed in brains of AD patients and mouse models of tauopathy. This suggests that microglia take up neuronal tau, but how this occurs is unclear. Microglia undergo constitutive macropinocytosis and thus efficiently internalize liquid-phase particles in their extracellular milieu. We hypothesized that microglia employ macropinocytosis to internalize free extracellular tau. To test this hypothesis, we treated microglial cells (BV2) in culture with different endocytic pathways inhibitors and probed their uptake of fluorescently conjugated monomer and preformed fibril (PFF) tau. These compounds include: cytochalasin D (CTD), dynasore, chlorpromazine (CPZ), and methyl-β-cyclodextrin (MβCD), inhibitors of actin polymerization, dynamin, AP2, and lipid rafts, respectively. As predicted CTD robustly inhibited tau uptake in BV2 microglia, suggesting an actin-dependent process is involved. Interestingly, CPZ and dynasore also inhibited monomer and PFF uptake but neither as robustly as did CTD. This suggests that macropinocytosis, an actin-dependent but dynamin-independent process, and clathrin-mediated endocytosis (CME), an AP2- and dynamin-dependent process, constitute the two potential endocytic pathways of tau uptake in BV2 microglia. We next asked whether microglia tau uptake was a saturable, receptor-mediated process. To test this, examined whether increasing concentrations of unlabeled tau altered the internalization of a constant concentration of labeled tau. Here we observed that labeled tau monomer uptake decreased with the addition of unlabeled tau, but tau PFFs uptake did not. This suggests that tau monomer uptake in BV2 microglia is receptor mediated. In future experiments we will co-administer tau with 70 kDa dextran or transferrin, positive controls for macropinocytosis and CME, respectively, and measure co-localization within endosomal compartments. The literature suggests that microglia play a dual-role role in tau pathology, as they have been implicated in both tau clearance and spread. By determining the tau uptake mechanisms employed by microglia, we hope to advance our understanding of microglia-tau interaction and aid in the development of therapies aimed at preventing pathological tau progression and cognitive decline.

Title: The roles of oligodendrocytes in the pathogenesis of Alzheimer's disease

Authors: *K. YASUDA[1], T. MAKI[1], M. TOYOKAWA[2], S. TODA[1], Y. KUWATA[1], R. TAKAHASHI[1];

Abstract: [Aim] Neuron-centric view cannot explain entire aspects of Alzheimer's disease (AD). Among non-neuronal cells, disruption of oligodendrocytes (OLs) and myelin has been reported as an early sign in the AD. Given that oligodendrocyte precursor cells (OPCs) regulate brain homeostasis by interacting with neuronal, vascular, glial, and immune system, pathological OPCs/OLGs could be associated with the onset and progression of AD. However, the mechanisms by which OLs exert harmful effects in AD remain elusive. Therefore, the purpose of present study is to examine the roles of OLs on the pathogenesis of AD. [Methods]For *in vitro* experiments, we examined the effect of Aβ oligomers on OLs as well as the expression levels of Aβ and its related factors in primary cultured OLs. Quantitative RT-PCR was performed to confirm the effects of Aβ oligomers on the phenotype of OPCs. For *in vivo* studies, we evaluated the behaviour of OLs in AD model mice (Tg-SwDI) and postmortem human brains with AD. [Results] *In vitro* studies showed that Aβ oligomers induced cytotoxicity in OPCs in a dose-dependent manner. In addition, OLs themselves produced Aβ40/42, which are pathogenic for AD, via amyloidogenic pathway, and secreted sAPPα, which has neuroprotective and neurogenic functions, via non-amyloidogenic pathway. RT-PCR revealed that Aβ42 oligomers increase the multiple gene expression levels of inflammation-related factors and metalloproteinases in OPCs. In AD model mice and patients, OPCs were located in close proximity with Aβ depositions. [Conclusions] The present study indicated the bi-directional relationship between APP processing and OLs in AD. Further studies are warranted to elucidate the pathological shift in OLs from beneficial non-amyloidogenic process to detrimental amyloidogenic process during AD progression.[Grant/Other Support] ISHIZUE 2021 of Kyoto University Research Development Program.

Title: Cxcl14 as a Potential Modulator for Amyloid Beta Clearance and Cell Death in Alzheimer's Disease

Authors: J. GALSKE, J. ZHOU, R. YAN;
Dept Neurosci, Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: The abnormal accumulation of beta-amyloid (Aβ) plaques is viewed to initiate events that eventually cause Alzheimer's Disease (AD) neuronal cell death. In AD, both cytokines and chemokines are responsible for recruiting astrocytes and microglia towards Aβ plaque sites for uptake and degradation. Activated microglia and reactive astrocytes are known to regulate the expression and/or secretion of certain cytokines and chemokines that may play beneficial or detrimental effects on the development of AD pathology. We have now found higher levels of CXCL14 localized around Aβ plaques in the 5XFAD mouse model. CXCL14 is a chemokine possessing a C-X-C domain and has been identified as an inflammatory modulator in the periphery. However, its' role in neurodegeneration and AD is unknown. In this study, we explored whether CXCL14 is a chemoattractant to microglia migration in AD mouse models. We showed that in vitro administration of Aβ increased CXCL14 levels in primary astrocytes. A transwell migration assay revealed that CXCL14 recruited microglia in a dose-dependent manner, but not astrocytes. CXCL14 also enhanced Aβ uptake in primary microglia with both acute and recurrent Aβ treatments. Furthermore, CXCL14 protects both microglia and neurons from recurrent Aβ insults. The interaction between CXCL14 and one of its putative receptors CXCR4 mediates neuronal protection. In summary, our study suggests that CXCL14 may serve as a potent chemokine by recruiting microglia to Aβ plaques to enhance Aβclearance and to prevent cell death in AD.

Abstract: Functional synapses are crucial for memory formation and learning processes. Synaptic dysfunction is an early biological mechanism in neurodegenerative diseases such as Alzheimer's Disease (AD). Previous post-mortem studies suggest that changes in synaptic proteins such as zinc transporter protein 3 (ZnT3), dynamin1 (Dyn1) and AMPA glutamate receptor 3 (GluA3) are associated with cognitive decline in AD. We aimed to evaluate the diagnostic value of ZnT3, Dyn1 and GluA3 in cerebrospinal fluid (CSF) of Mild cognitive impairment (MCI) and AD patients. In addition, we aimed to assess the translational potential of these synaptic proteins in two established App knock-in AD animal models by assessing the CSF, hippocampal and cortical synaptic protein concentrations within the same animal. ELISA immunoassay was used to measure the concentration of ZnT3, Dyn1 and GluA3 in CSF from a cohort of 54 MCI, AD and control patients, as well as in CSF and/or brain of 12 and 24 months old App^{NL-F}, App^{NL-G-F} and wild-type mice. Furthermore, age and brain regional- distribution (12 months and 24 months) and expression changes of these proteins were further explored in App knock-in models by immunofluorescence. We found a significant increase in ZnT3 and GluA3 concentrations both in MCI and AD patients as compared to control patients. Dyn1 concentration was significantly higher in AD patients only. MCI patients converting to AD exhibited more elevated CSF ZnT3 concentrations than stable MCI patients. CSF GluA3 concentration was significantly higher in App^{NL-G-F} knock-in mice as compared to wild-type controls. Furthermore, we have detected age and brain regional specific changes of the synaptic proteins in both App^{NL-F} and App^{NL-G-F} knock-in mice. Notably, the concentrations of all the three synaptic proteins correlated negatively with their concentrations in brain hippocampal lysates. We have also observed age dependent neuroinflammation and distinct accumulation of these synaptic proteins around amyloid-beta plaques. The pronounced synaptic dysfunction in MCI and AD patients reflected by increased CSF concentrations of synaptic proteins was a discerned characteristic of the App knock-in mouse models highlighting the translational potential of these AD mouse models. These translatable synaptic biomarkers could potentially help reducing the current disparities between human and animal models-based studies aiding the translation of preclinical discoveries of pathophysiological changes into clinical research.

Title: Alternative treatment strategy and validation of a novel brain target for deep brain stimulation in neurodegenerative disease

Authors: *S. C. L. CHAN[1], G. KUMAR[1], C. H. E. MA[1,2];
[1]Dept. of Neurosci., City Univ. of Hong Kong, Kowloon Tong, Hong Kong; [2]City Univ. of Hong Kong Shenzhen Res. Inst., Shenzhen, China

Abstract: Alzheimer's disease (AD) is the major cause of dementia worldwide. AD progression significantly affects mental and physical health of patients as well as families and resulting in a heavy financial burden to Public Health Services. AD patients with disease progression fails to respond conventional drug therapy after long-term medication, and therefore new therapeutic strategies has been explored. Deep brain stimulation (DBS) has been emerging as a potential alternative treatment for AD. Applying DBS to fornix (fornix-DBS) was found therapeutically effective in improvement of cognitive symptoms. However, significant cognitive impairments were reported in patients below 65 years old during phase II clinical trial. Moreover, no tangible evidence supported the long-term efficacy and delay of disease progression. Therefore, we proposed a novel brain target of DBS (novel target-DBS) in brain stem for AD treatment due to its strategic anatomical location and indirect projection to hippocampus. In our exploratory study, we used streptozotocin (STZ) induced and transgenic APP/PS1 (2xTg) mice model of AD to evaluate the therapeutic potential of DBS at novel area in the brain stem for amelioration of learning and memory. To assess the spatial and recognition memory, we conducted neurobehavioral tests, including Y-maze test, object recognition (NOR) test and Barnes maze test in the STZ and transgenic mice model of AD. All the neurobehavioral experiments were performed in a quiet room and observer was blinded to the mouse genotypes, surgery and treatment group. Our results showed that acute treatment (1 week) in STZ model and chronic treatment (3 weeks) in transgenic mice model significantly improved spatial and recognition memory as assessed by Y-maze, NOR test and Barnes maze test from day 7 or day 21 of the experimental paradigm of STZ or transgenic mice respectively. We also performed immunohistology of Nissl and BrdU staining for quantification of newly proliferated cell to evaluate the activity of neurogenesis and delineate the mechanism of DBS efficacy. Neurogenesis is one of the potential mechanisms of DBS for memory formation. We observed that the novel target-DBS significantly increased the number of Nissl positive and BrdU positive cells in the hippocampus. Interestingly, a wide migration of BrdU positive cells towards the vital nuclei of memory formation, suggesting the widespread therapeutic effect on neuronal circuit for enhancement of memory function. In conclusion, our novel target-DBS showed better

therapeutic efficacy than conventional DBS (fornix-DBS) to improve learning and memory in mice model of AD.

Title: Mechanisms of Mitochondrial Disruption by Amyloid Beta 42 Identified by Proteomics and Pathway Mapping

Authors: *P. L. SINCLAIR[1], T. SEPAHPOUR[2], A. BARANOVA[3], N. KABBANI[4]; [1]Interdisciplinary Program in Neurosci., George Mason Univ., Annandale, VA; [2]Biosci., [3]Sch. of Systems Biol., George Mason Univ., Fairfax, VA; [4]Mol. Neurosci, Krasnow Inst., Fairfax, VA

Abstract: Abstract
Alzheimer's Disease (AD) is marked by chronic neurodegeneration of the human brain that correlates with the occurrence of the pathogenic amyloid beta $A\beta_{42}$ peptide, the primary component of plaques. With limited symptom management and new drugs that target amyloid peptides a fundamental understanding of early cellular changes that occur as a result of amyloids. This problem is not unique to AD, but pertinent to other human neurodegenerative disorders such as Parkinson's and Lewy body dementia, which are also marked by amyloid protein pathology. Here we examined the effect of 3-day $A\beta_{42}$ exposure on differentiated PC12 cells using liquid-chromatography electrospray ionization mass spectrometry (LC-ESI MS/MS) coupled to protein identification and precursor ion peptide quantification. Gene set enrichment analysis (GSEA) of the resulting $A\beta_{42}$ proteome was conducted using Pathway Studio to identify differentially represented gene ontology (GO) pathways. Findings indicate a critical role for mitochondrial signaling, bioenergetics, and morphology in $A\beta_{42}$ cellular responses and provide potential new biomarkers for AD. Mitochondrial adaptation to $A\beta;_{42}$ mediated high calcium load within the matrix compartment may be achieved by stemming ER calcium transfer with an aid of FK-506 binding protein 1a (FKBP1a).

Title: The simple and cost-efficient workflow of small molecule-induced amyloid-beta production in neuronal cell culture encapsulated in a three-dimensional agarose-laminin hydrogel scaffold

Authors: *P. NAMCHAIW[1], P. BUNREANGSRI[2];
[1]Biol. Engin. Program, Fac. of Engin., [2]Neurosci. Ctr. for Res. and Innovation, Learning Inst., King Mongkut's Univ. of Technol. Thonburi, Thung Kru, Thailand

Abstract: A 3D culture is now considered a relevant in vitro culture model for studying neurological diseases such as Alzheimer's disease (AD). In the past several years, hiPSC derived from familial AD (FAD-hiPSC) was used to generate an in vitro AD model. However, 90% of all AD cases are sporadic AD (SAD), which is not inherited genetic mutations. While the cause of the disease is still not fully understood, the amyloid-β accumulation has been thought to be the key event explaining the impairment of neurons and cognitive functions in both AD. Herein, we utilize Aftin-4, a small molecule β- and γ-secretase modulator to induce the amyloidogenic pathway in the neuronal-like cell encapsulated in agarose-laminin hydrogel scaffolds. We present here a small molecule-induced amyloidogenic condition in 3D neuronal culture workflow and provide the methods to isolate cells, RNAs, and proteins from a hydrogel scaffold. The isolated RNA and protein are suitable for real-time PCR and ELISA to study the expression profile in 3D neuronal culture. Besides the isolated cells from a hydrogel scaffold is suitable for flow cytometry analysis. Our results show that at 7 days in vitro, neuroblastoma cell lines become neuronal-like cells expressing TUJ1+. The real-time PCR analysis revealed the amyloid beta-linked genes expression *APP, BACE1, PS1,* and *PS2* in 3D culture. The secreted amyloid beta-40 and -42 (Aβ40, Aβ42) diffuse into an agarose-laminin hydrogel part and culture medium, which Aftin-4 specifically increases the level of Aβ42 but not Aβ40 in both parts. This increases Aβ42/Aβ40 ratios to 0.24-fold and 0.27-fold upon treatment when compared with vehicle control of 0.19-folds and 0.23-folds in cell culture medium and agarose-laminin hydrogel, respectively. The alteration of the Aβ42/Aβ40 ratio tightly correlates with a pathological hallmark of AD. The results presented here demonstrate the feasible and cost-efficient method to generate amyloidogenic induction in a 3D neuronal-like culture. Besides the isolated RNAs, proteins, and cells from the 3D scaffold would facilitate the drug screening and drug development to slow the progression or delay the onset of AD.

Title: Cellular proteomic profiling using proximity labeling by TurboID in microglial and neuronal cell lines

Authors: *S. SUNNA[1], S. RAYAPROLU[1], C. BOWEN[1], P. BAGCHI[1], N. T. SEYFRIED[2], S. RANGARAJU[1];
[1]Emory Univ., Atlanta, GA; [2]Biochem., Emory Sch. Med., Atlanta, GA

Abstract: Proximity labeling of proteins by promiscuous biotin ligases such as TurboID, coupled with mass spectrometry (MS) analyses of biotinylated proteins, can potentially resolve cell-type specific proteomes from complex tissues such as brain without cell type enrichment. Before *in vivo* applications, it is important to characterize the types of proteins preferentially labeled by TurboID in mammalian cells, and directly compare biotinylated proteomes with whole cell proteomes. We determined whether TurboID-labeled proteomes in microglial (BV2) and neuronal (N2A) cell lines are representative of total cellular proteomes under homeostatic and activated conditions. We generated N2A and BV2 cell lines that stably express TurboID fused to a nuclear export sequence, and treated cells with 200μM biotin and 1μg/mL lipopolysaccharide (LPS) for 48hrs to mimic inflammatory stress. Whole cell lysates (inputs) and streptavidin bead-enriched biotinylated proteins were used for western blot and label free quantitation MS (LFQ-MS). After confirming robust proteomic biotinylation in TurboID N2A and BV2 cell lines by western blot, LFQ-MS quantified >3,000 proteins in inputs and >2,400 proteins in biotinylated proteomes from both cell types. In BV2 and N2A inputs, TurboID expression and biotinylation did not impact the proteome, evidenced by very few differentially-expressed proteins and absence of cellular respiration measures in mitochondrial stress tests, comparing TurboID and non-TurboID cells. Of all the proteins quantified in BV2 and N2A TurboID inputs, over 50% were also quantified in the biotinylated proteomes in both cell types. As compared to input proteomes of both cell types, the biotinylated proteome was enriched in vesicular transport, ribosomal, mitochondrial, cytoplasmic and cytoskeletal proteins. The biotinylated proteome successfully differentiated BV2 and N2A cells, similar to the input proteomes. LPS stimulation altered levels of 488 proteins in BV2 cells in the input proteome, of which the top increased (e.g. Irg1, Oasl1, Cyb5a) and decreased (e.g. Mrc1, Mgl2, Arg1) proteins showed concordant changes in the biotinylated BV2 proteome. Our analyses show that

cellular proteomic labeling by TurboID in microglial and neuronal cell lines does not disrupt cellular function, and the resulting biotinylated proteomes are reasonably representative of the whole cell proteome and is able to capture the most robust alterations induced by immune stimuli in microglia. These represent foundational data to guide future applications of proximity-labeling for cell type specific proteomics *in vivo*.

Title: Relationships between potassium, copper, iron, and zinc in plaques in a mouse model for Alzheimer's disease

Authors: *P. KAKALEC[1], K. BOGGS[1], C. M. GROEBER TRAVIS[3], A. LANZIROTTI[4], J. M. FLINN[2];
[2]Psychology, [1]George Mason Univ., Fairfax, VA; [3]BTNN, Walter Reed Army Inst. of Res., Silver Spring, MD; [4]Univ. of Chicago, Chicago, IL

Abstract: One of the hallmarks of Alzheimer’s disease is the presence of amyloid plaques in the brain. While these plaques are primarily composed of amyloid, the presence of several trace metals has been detected within these plaques. Given the presence of these trace metals, it is probable that metal dyshomeostasis plays a role in the disease process and could indicate a mechanism by which the dietary intake of trace metals could affect disease progression. To better understand the role of dietary metal intake in Alzheimer’s disease pathology we administered waters supplemented with copper, iron, and copper + iron to CRND8 animals expressing the Indiana and Swedish mutation of the human APP gene, with transgenic animals administered lab water serving as a control. Following 5 months of supplementation, unfixed brain tissue was analyzed at Brookhaven National Laboratory to quantify the metal distribution in the tissue using synchrotron X-ray fluorescent microscopy. Fixing tissue results in the washing of potassium, thus our use of unfixed tissue allowed us to visualize the potassium content of plaques. These data were then used to model the relationships between potassium, iron, zinc, and copper, as well as the changes in plaque metal content observed in response to dietary metal supplementation. Results indicated that potassium content correlated positively with both iron

and zinc, but a relationship was not observed between iron and zinc. We also observed that the administration of copper- and iron-supplemented waters reduced the presence of potassium in the plaques relative to plaques in animals administered lab water ($p < 0.05$), and that the administration of copper water increased the zinc content of plaques relative to lab water ($p < 0.05$).

Title: Brain regional proteomics reveals mechanistic insight to the progression of distinct pathologies in the rTg-DI rat model of cerebral amyloid angiopathy.

Authors: *J. M. SCHRADER, F. XU, W. E. VAN NOSTRAND;
Col. of Pharm., Univ. of Rhode Island, Kingston, RI

Abstract: Cerebral amyloid angiopathy (CAA), characterized by cerebral vascular amyloid accumulation, intracerebral hemorrhages and microbleeds, and cerebral infarction, is a prevalent comorbidity in Alzheimer’s disease (AD) and prominent contributor to vascular cognitive impairment and dementia (VCID). rTg-DI rats, a preclinical model of CAA, develop varying degrees of microvascular amyloid deposition and neuroinflammation in several brain regions, while thrombotic events of occluded vessels and microbleeds are mainly restricted to the thalamus. We employed liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) using a sequential window acquisition of all theoretical mass spectra (SWATH) method to report numerous brain regional specific proteomic changes in the cortex, hippocampus and thalamus of rTg-DI rats, followed by Ingenuity Pathway Analysis (IPA) to connect these changes with specific pathways and disease functions. IPA suggested TNFα activation, abnormal nervous system morphology, and neutrophil degranulation in all three regions, TGFβ activation in the hippocampus and thalamus, and thrombin activation in the thalamus. Proteomics analysis and immunostaining also revealed the presence of neutrophil extracellular traps (NETs) specifically

in the thalamus, a potentially important mechanism in the progression of the more severe vasculopathies observed in that region. Thus, we report new and significant insight linking specific proteomic changes to differential CAA-pathologies, and present potential mechanisms for the regionally distinct disease progression.

Title: Validation of PAL test in 3xTG and APP/PS1 transgenic AD mouse model

Authors: *T. SYEDA[1,2], S. ENKH-AMGALAN[3], M. HADDAD CORREA[4], J. M. BROWN[1,2], J. R. CANNON[1,2], W. A. KOSS[2];
[1]Sch. of Hlth. Sci., [2]Purdue Inst. for Integrative Neurosci., Purdue Univ., West Lafayette, IN; [3]Dept. of Psychological Sci., Purdue Univ., Wet Lafayette, IN; [4]Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: Alzheimer's disease (AD) is characterized by the accumulation of amyloid-beta plaques, intracellular neurofibrillary tangles, and progressive cognitive decline. Despite the significant public health crisis that it poses, there is no clinically available disease-modifying therapy. The behavioral tasks used currently, such as the morris water maze, novel object recognition, and battery of spatial mazes in rodents, do not detect early mild cognitive deficits and do not detect the nuances of deficits seen in AD patients; this major translational weakness limits preclinical AD modeling, particularly evaluating early diagnostic markers of disease and efficacy testing of novel therapeutics. The Cambridge neuropsychological test automated battery (CANTAB) is one of the most popular tests to assess cognition in AD patients. Paired-associates learning (PAL) task, part of the CANTAB, requires the subject to learn to associate a given object with a particular location. A touchscreen automated object-in-place PAL task has been recently adapted for mice and rats. PAL touchscreen task has not been tested and validated in the most commonly used 3xTG and APP/PS1 transgenic AD mouse model. In the present study, we hypothesized that the PAL test effectively detects cognitive deficits in this model earlier than the traditional cognitive test. If the PAL test is found to be more effective than other traditional cognitive tests, we will further validate rodent cognitive tests with higher translational value to aid the AD studies and drug discovery. In the present study, we will validate the PAL test in Bussey-Saksida touchscreen chambers using two transgenic 3xTG (4 months old) and APP/PS1

(5.5 months old) AD mouse models. We will validate this test by comparing it with traditional cognitive tests (water maze, Y-maze, and object recognition test). Since cognitive deficits are more significant in females than males in both of these mouse strains, we will use female mice for the study. Preliminary data show that the behavioral performance of 3xTG performed poorer in the training; the average number of trials in the PAL test completed was significantly lower compared to C57BL6 mice. Other test will be done to analyze whether the non-performance in the PAL test is associated with motivation. Collectively, our preliminary data suggests that PAL can detect cognitive deficits sooner in 3xTG mice compared to the traditional cognitive test.

Title: Generation of PSEN1 gene-manipulated common marmoset using the base-editor system

Authors: *W. KUMITA[1], H. SASAGURI[2], K. SATO[1], N. OURA[1], T. C. SAIDO[2], E. SASAKI[1];
[1]Central Inst. For Exptl. Animals, Kawasaki-Shi, Japan; [2]Lab. for Proteolytic Neurosci., RIKEN Ctr. For Brain Sci., Wako-Shi, Japan

Abstract: Animal models are beneficial in elucidating the pathogenic mechanism of neurodegenerative diseases and in developing treatment methods and effective drugs. Rodent models have contributed substantially to advancements in neuroscience research. However, the brain structure differs significantly between rodents and humans, limiting the use of rodents as models of neurological disorders. The use of non-human primates that are neurologically similar to humans could be valuable to study psychiatric and neurological disorders. The common marmoset (*Callithrix jacchus*) is a small non-human primate for which a genetic modification method has been established. In 2016, we developed a marmoset model of X-linked severe combined immunodeficiency model generated by gene editing. The presenilin 1 gene (*PSEN1*) is associated with Alzheimer's disease (AD), and many *PSEN1* mutations have been reported in AD patients. Especially the P117L amino acid mutation of the *PSEN1* (*PSEN1*-P117L mutant) is found in early-onset familial AD patients. In this study, the *PSEN1*-P117L mutant was targeted for gene editing to develop a marmoset model of AD using the base-editor system, which can generate single-nucleotide changes in DNA or RNA without double-strand breaks. First, *PSEN1*-

P117 sequence-targeted guideRNA mRNA and base-editor mRNA were injected into 896 marmoset embryos with nine injection conditions. Injected embryos were analyzed, and efficient conditions were established to cause *PSEN1*-P117L modification. Next, 69 of the injected embryos were transferred into the uterus of surrogate female marmosets resulting in 4 neonates (4.7% of the transferred embryos). The sub-clones of the PCR products derived from the genome of hair root cells from each neonate were analyzed. The *PSEN1*-P117L modification was detected in all 4 neonates (100%). The *PSEN1*-P117L mutant marmosets are expected to be early-onset of the AD, and could be valuable in elucidating the peculiar mechanism of AD in primates.

Title: Hy209 regulates p2x7r-mediated nlrp3 inflammasomal activation of microglia in mice with alzheimer’s diseases

Authors: *J. ISLAM[1,2,3], J.-A. CHO[1], J.-Y. KIM[1], K.-S. PARK[1], Y.-J. KOH[3], C. CHUNG[3], S.-Y. SEONG[1,4,2,3];

Col. of Medicine,, Seoul, Korea, Republic of; [3]Shaperon Inc. Ltd., Seoul, Korea, Republic of; [4]Dept. of Microbiology and Immunology, Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: NLRP3 inflammasome (N3I) activation by P2X7R of microglia is crucial in neuroinflammation of Alzheimer’s disease (AD). Damage-associated molecular patterns such as Amyloid β (Aβ) and/or ATP activates N3I thru P2X7R pathway. Inhibitors for N3I have been

tested to alleviate progression of AD in animal models. Due to polymorphisms, subtypes, and ubiquitous expression of P2X7R and N3I components (NLRP3, ASC or pro-caspases etc.), clinical benefits have been controversial. G-protein coupled receptor 19 (GPCR19) is preferentially expressed on myeloid immune cells including microglia. For the first time, we found that GPCR19 co-localized with P2X7R on the membrane of microglia and regulates P2X7R-mediated N3I activation. HY209, a GPCR19 ligand suppressed IL-1β production in WT mice but not in GPCR19KO and P2X7RKO microglia. Ca++ mobilization of microglial in response to ATP or BzATP was diminished in GPCR19KO and P2X7RKO cells when compared with WT cells, suggesting GPCR19 is crucial for P2X7R mediated N3I activation which is essential for production of IL-1β/IL-18. HY209 also inhibited the priming phase of N3I activation via GPCR19-cAMP-PKA-NF-kB pathway. Further, HY209 suppressed expression of P2X7R, enhanced phagocytosis of Aβ, and decreased number of Aβ plaque in the brain of 5xFAD mice. HY209 also reduced microgliosis, prevented neuronal loss, and improved memory function of 5xFAD mice. Aβ and/or ATP enables the open state of the P2X7R on the cell membrane, thereby increases exchange of cytosolic and extracellular cations. The crystal structure of the P2X7 receptor displays clear differences between the open and closed pore state. Taken together with colocalization of GPCR19-P2X7R, HY209 might inhibit N3I activation by changing configuration of GPCR19 which hampers opening of P2X7R necessary for cation exchange. In summary, GPCR19 ligands might be a novel option for ameliorating neuroinflammation as Alzheimer’s disease to prevent neuronal loss which is crucial to preserve cognition and memory.

Title: Apocynin a nootropic, neurotrophic and neuroprotective treatment modality for Alzheimer's disease

Authors: *N. CHIMTHANAWALA, S. SATHAYE, S. BAGLE;
Inst. of Chem. Technology, Matunga, Mumbai, India

Abstract: Learning from daily life experiences, and their reconstruction in the form of memories, remain a crucial facet of our personality. This ability gets eroded in Alzheimer's disease (AD). A multifactorial disease with a complex etiology, AD presents extracellular amyloid beta (Aβ) deposits and intracellular hyperphosphorylated tau as hallmark features. Pathologically, immense oxidative stress, mitochondrial dysfunction, impaired mitochondrial biogenesis, altered oxidative phosphorylation system, perturbed calcium homeostasis, hampered adult neurogenesis, inflammation, etc. are observed. Progressive degenerative nature of the disease demands exploration of a molecule possessing multifaceted activity to offer a better quality of life. We evaluated the role of apocynin (phytoactive), an NADPH oxidase inhibitor, obtained from Picrorhiza kurroa, possessing anti-inflammatory and antioxidant activity, in the AD pathology in an $A\beta_{1-42}$ peptide-induced AD rodent model. Male Wistar rats were subjected to intrahippocampal $A\beta_{1-42}$ administration in N=12 per group using stereotaxy in the study. Further, per-oral treatment with 3 graded doses of apocynin for 28 days was done. Neurobehavioral activity was evaluated using Barnes maze test (BMT), Open field test (OFT). Biomarkers like anti-oxidants [Superoxide dismutase (SOD), reduced glutathione (GSH), Catalase], membrane peroxidation [Lipid peroxidation (LPO)], inflammatory parameter (TNF-α), immunohistochemistry for $A\beta_{1-42}$ peptide were measured. RT-PCR analysis for caspase-3, and RAGE (receptor for advanced glycation end-products) gene expression was performed. Histopathological staining using Congo red, Nissl and H&E was also carried out. Our data revealed that apocynin had a multidimensional role showing nootropic, neuroprotective, anti-inflammatory, and anti-oxidant effects. Our aim was to stop the overall progression of disease and explore the synaptogenic and neurogenic potential. We assessed the activity of apocynin on adult hippocampal neurogenesis [using BDNF, Ki-67, DCX (doublecortin), NeuN, synaptophysin, and ChAT (choline acetyltransferase) as markers] in the same AD model. Apocynin enhanced the proliferation and differentiation of the neuronal stem cells, instigating adult hippocampal neurogenesis. Lastly, apocynin restored the impaired mitochondrial biogenesis in the same model, modulating levels of PGC-1α (PPAR-$_\gamma$ coactivator) and Mt-CO1 (cytochrome c oxidase I) as the parameters expressed providing neuroprotective effect. We hence propose a novel treatment modality for AD that can be further upscaled for clinical studies as a disease modifying agent.

Title: Evaluating the Effect of Angiotensin Receptor Blocker Treatment in Mice that Express Human APOE4

Authors: *S. B. SCHEINMAN, L. M. TAI;
Univ. of Illinois at Chicago Dept. of Anat. and Cell Biol., Chicago, IL

Abstract: Human *APOE4* is the greatest genetic risk factor for the development of Alzheimer's disease (AD), the most common form of dementia. In addition to earlier AD onset and more rapid cognitive decline in human *APOE4* carriers, *in vivo* data support that *APOE4* is associated with memory-relevant behavioral deficits, higher Aβ levels, and greater neuroinflammation as compared to *APOE3*. These same dysfunctions have also been linked to activation of the Angiotensin II Type 1 (AT1) receptor in the brain. As such, antagonism of the AT1 receptor could represent a potential therapeutic strategy for *APOE4*-associated AD risk and progression. In fact, Angiotensin receptor blockers (ARBs), a class of pharmaceuticals commonly used to treat hypertension, have been shown to have beneficial effects in both human AD patients and AD-relevant rodent models, although results are mixed. However, the effect of ARBs in the context of *APOE* genotype remains unknown and understanding this interaction could inform the effective development of ARBs for AD therapy. Therefore, we treated both male and female mice that express the human *APOE4* gene, either with (E4FAD+) or without (E4FAD-) high Aβ levels, with the ARB candesartan for a period of 4 months. We found that in female, but not male, E4FAD- and E4FAD+ mice, ARB treatment resulted in greater performance on the novel object recognition (NOR) task of memory-relevant behavior as well as higher levels of synaptophysin, SV2A, and SNAP25 in the hippocampus. Further, female E4FAD- and E4FAD+ mice treated with ARBs also had lower hippocampal GFAP levels (16-43%) and lower Iba1 levels (30-43%), the latter of which correlated with enhanced NOR performance. Overall, these results suggest that ARB treatment modulates behavior, synaptic protein levels, and hippocampal gliosis in female mice, but not male mice, that express human *APOE4*, most likely through an Aβ independent pathway as similar results were observed in both E4FAD- and E4FAD+ mice. Findings support the therapeutic potential of ARBs for the targeting of neuroinflammation in AD, in particular for female *APOE4* carriers.

Title: Inhibition of EV biogenesis reduces tau propagation in seeded tau model of Alzheimer's Disease

Authors: *B. BELL[1], C. TALLON[1], M. M. MALVANKAR[1], K. COLEMAN[1], T. JOE[1], A. SHARMA[1], E. EREN[2], K. RANGARAMANUJAM[1], D. KAPOGIANNIS[2], B. S. SLUSHER[1]; [1]Johns Hopkins Med. Institutions, Baltimore, MD; [2]NIH Natl. Inst. on Aging, Baltimore, MD

Abstract: Alzheimer's Disease (AD) is the most common form of dementia worldwide, yet no effective therapeutics are available despite extensive research. AD is characterized by progressive neurodegeneration and cognitive decline, as well as the accumulation of putatively pathological Amyloid-β (Aβ) and hyperphosphorylated Tau. Numerous clinical trials which reduced levels of aggregated Aβ plaques in patient brains were unsuccessful in alleviating cognitive symptoms. These results renewed focus on tau, which spreads throughout the brain along characteristic pathways and correlates strongly with the severity of disease progression. Recent evidence highlights the importance of extracellular vesicles (EVs) in enabling the transcellular transmission of pathological tau in the brain in a 'prion-like' manner and identified the inhibition of EV biogenesis via small-molecule inhibitors of nSMase2 as a potential avenue for clinical intervention. However, the presently available tool inhibitors are unsuitable for clinical development. To assess this, our lab performed a >350K high-throughput screen against human nSMase2 and identified two new inhibitor chemotypes. After substantial medicinal chemistry efforts on these hit clusters, two lead nSMase2 inhibitors were identified - PDDC (IC_{50}=300 nM) with excellent oral bioavailability (F%=87) and brain penetration (AUC_{brain}/AUC_{plasma}=0.6) and DPTIP (IC_{50}=30 nM) with poor oral availability and limited brain exposure. To circumvent the pharmacokinetic limitations of DPTIP, we conjugated it to a brain-penetrable hydroxyl dendrimer system and subsequently demonstrated CNS target engagement following oral dosing. To characterize the potential of these two inhibitors as AD therapeutics *in vivo*, we optimized a rapid seeded tau mouse model in which we stereotaxically injected an AAV vector containing mutant human tau (P301L) into the CA1 region of the left hippocampus in young WT mice (male and female), and quantified the degree of tau and phosphorylated tau species in the contralateral dentate gyrus (DG) region after 6 weeks. Mice were immediately dosed following injection with PDDC-containing chow or oral dendrimer-DPTIP (100mg/kg each), as well as matched vehicle controls. Both treatment paradigms significantly reduced pThr181 phosphorylated tau fluorescence intensity in the contralateral DG. Similarly, drug treatments suppressed tau-containing neuronally-derived EVs circulating in plasma compared to vehicle-treated controls. These results confirm the efficacy of nSMase2 inhibition at retarding tau propagation through EVs, and highlight these promising therapeutics as treatments for AD.

Title: Small-molecule Shc Blockers as Novel Therapeutics for Alzheimer's Disease

Authors: *G. CORTOPASSI[1], A. TOMILOV[1], C. GARCIA[1], C. MONTGOMERY[1], D. KOVALSKYY[2], I. MAEZAWA[3], L.-W. JIN[3];
[1]Univ. of California, Davis, Davis, CA; [2]Resistomix, San Antonio, TX; [3]M.I.N.D. Inst. UC Davis, Davis, CA

Abstract: Background. The human Shc locus has recently been identified as extremely important in the conversion from Mild Cognitive Impairment (MCI) to full Alzheimer's Disease (AD) [PMID: 33172501], and Shc is ranked as the 12th most important locus in AD, ahead of BACE, to which substantial drug development effort has been expended [PMID: 30944912]. Shc is more highly expressed in Hippocampus of human AD cases vs. Controls [PMID: 12084708] and activated A-beta binds to and increases Shc activity and gene expression in cells, and Shc knockdown reduces A-beta toxicity [PMID: 30459314]. PSAPP mice with genetically reduced Shc reduction resist cognitive deficits, memory loss and age-related cerebrovascular dysfunction [PMID: 25012499] in an interesting way**.** These Shc-deficient PSAPP mice have improved memory and cognition and survival relative to PSAPP mice, *with the same amyloid burden* [PMID: 27431297]. Thus Shc reduction is neuroprotective, *downstream* of the toxic A-beta signal. Under MTA we have received small molecule Shc Blockers from Buto Corp, to identify their relative efficacy in cell and animal models of disease.**Method.** We tested the neuroprotective potency of Shc blockers to rescue N2A cells challenged with A-beta in 384-well plates. We also tested the anti-inflammatory potency of Shc blockers in human and mouse microglial cells challenged with pro-inflammatory A-beta or LPS and observe decreased inflammatory gene expression (IL-6, IL-10, and Nos). The impact of Shc Blockers on memory loss by Barnes Maze and Novel Object Recognition was also tested in the ApoE4 and PSAPP mouse models of AD is ongoing. **Results.** We observe significant protection of several Shc blockers from A-beta-dependent neurotoxicity to N2a cells. We observe significant protection of multiple Shc blockers from A-beta or LPS mediated microglial inflammation. We observe

protection from memory loss in the ApoE4 mouse model of AD in vivo by a molecule that protects N2a cells from A-beta toxicity and inflammation in vitro. **Conclusion.** These preclinical data suggest that small-molecule Shc blockers are a novel therapeutic strategy of potential utility for AD.

Abstract: Age is the predominate risk factor for developing neurodegenerative diseases, including Alzheimer's disease (AD). We have recently shown in mouse models of AD that changes in glutamatergic neurotransmission are altered as a function of age and disease progression, and that the glutamatergic system can be targeted prior to cognitive decline to positively influence cognitive outcome. However, the underlying mechanisms responsible for these changes are currently unknown, and may be influenced from additional factors both internal and external to the brain, such as glucose metabolism, body composition, cell senescence, and environmental factors. Their impact on disease progression and interventional strategies was assessed in AβPP/PS1 (transgenic) and $APP^{NL\text{-}F/NL\text{-}F}$ (knock-in) mouse models of

AD, and their shared genetic background controls, C57BL/6 mice. Separate groups of mice underwent a single early intervention strategy beginning at 2-6 months of age, including oral riluzole treatment (356 µM or vehicle control), visceral fat removal (VFR; or sham surgery control), oral senolytic treatment (100 mg/kg bw fisetin, 5 mg/kg bw dasatinib + 50 mg/kg bw quercertin (D+Q; or vehicle control), or altered environmental temperature (chronic housing at 30 or 23°C control). Sex was also probed as a biological variable in all experiments. At approximately 12 or 18 months of age, all mice underwent insulin and glucose tolerance tests (ITT and GTT, respectively) to assess glucose metabolism, body composition measures, and cognitive testing using the Morris water maze. Brain (hippocampus) and peripheral (white and brown adipose and hepatic) tissues were assed for markers of glutamatergic neurotransmission, cell senescence, and glucose metabolism. Data support sex differences in disease progression and response to intervention across all groups. Riluzole treatment resulted in improved long-term memory compared to control mice in males, but not females. VFR intervention altered insulin sensitivity in female AD mouse models, but not males; however, preliminary data do not support cognitive improvement in either sex. Senolytic treatment with D+Q reduced abdominal white adipose depots and improved long-term memory in female mouse models of AD, but not males. Chronically housing mice at 30°C improved insulin sensitivity and glucose tolerance in both sexes, but procognitive effects were only observed in male AD models. Observed sexual dimorphic effects may indicate differences in disease progression profiles, which supports a need for sex-based, disease-stage specific therapeutic strategies.

Title: Sigma-1 receptor is critical for UPR response and mitochondrial activity in larval zebrafish

Authors: *B. DELPRAT, L. CROUZIER, M. DENUS, E. M. RICHARD, A. TAVERNIER, C. DIEZ, N. CUBEDO, T. MAURICE;
MMDN, Univ. Montpellier, EPHE, INSERM, Montpellier, France

Abstract: The sigma-1 receptor (S1R) is a highly conserved transmembrane protein highly enriched in mitochondria-associated endoplasmic reticulum (ER) membranes (MAMs), where it

interacts with several partners involved in ER-mitochondria Ca^{2+} transfer and/or activation of the ER stress pathways. By stabilizing the conformation of inositol 1,2,4-trisphosphate receptor type 1, S1R enhances the efflux of Ca^{2+} from the ER into the mitochondria, thus improving mitochondria function. Very interestingly, S1R can be activated/inactivated by small molecules and accumulating preclinical data suggest that S1R agonists are protectants in neurodegenerative diseases. In addition, mutations in S1R led to juveniles ALS and distal Hereditary Motor Neuropathies (dHMN), underlying the critical role of S1R in motor neurons function and survival. Even if deficient S1R mice model shed light on its role on motor deficits and muscle weakness associated with denervation at the neuromuscular junction and loss of motor neurons in the spinal cord, the precise function of the protein is still not fully understood. In order to determine the physiological role of S1R, we characterized a new S1R deficient zebrafish line at 5 days post fertilization (dpf). We analyzed the impact of S1R deficiency on the visual, auditory and locomotor functions using the technology developed by Viewpoint. The *sigmar1*$^{+25/+25}$ deficient line showed impairments in its visual and/or locomotor functions compared to *sigmar1*^{WT}. Indeed, the locomotion of the larvae is increased in the light and dark phases of the visual motor response in *sigmar1*$^{+25/+25}$. In contrast, no deficit was observed in acoustic startle response. In addition, we demonstrated the critical role of S1R in the ER stress response and mitochondrial activity. By analyzing the unfolded protein response (UPR) genes using qPCR, we observed that loss of S1R leads to decreased levels of ire1, xbp1s, perk and atf4b (in physiological condition) and increased upregulated levels of bip, atf6, perk ire1, xbp1s and chop after tunicamycin treatment (stressed condition). Finally, using a Seahorse analyzer, we observed that S1R deficiency leads to a decrease in basal respiration, ATP-linked respiration and non-mitochondrial respiration. In conclusion, this model will be highly valuable to decipher S1R cellular functions in vivo and a useful tool to deeply analyze the physiopathological roles of S1R.

Title: Inhibition of histone deacetylase mitigates spatial memory performance deficits and disease associated neuroinflammation in an Alzheimer’s disease transgenic rat model

Authors: *K. NDUKWE[1,2], L. XIE[4], P. SERRANO[3], P. ROCKWELL[2], M. E. FIGUEIREDO-PEREIRA[2];
[1]Neurosci. Collaborative program, The Grad. Ctr. City Univ. of New York, New York, NY; [2]Dept. of Biol. Sci., [3]Dept. of Psychology, Hunter College, CUNY, New York, NY; [4]Computer Sci. Dept, Hunter Col. CUNY, New York, NY

Abstract: Alzheimer's disease (AD) is one of the most common causes of dementia. In the United States, AD affects about 5.8 million Americans and is projected to reach 13.8 million individuals by 2050. Epigenetic alterations such as histone-modifications play a role in memory function, and disruption in the epigenetic processes is linked to the pathogenesis of neurodegenerative and neuropsychiatric diseases. Currently, there are no effective therapies for AD, and therapies targeting epigenetic mechanisms such as pharmacologic inhibitors of histone deacetylases (HDACs), are effective in improving cognitive performance in animal models of AD. The effects of histone deacetylase inhibitors on AD pathology and brain immune resident cells and neurons in an AD brain are not well understood. In this study, we treated Fisher transgenic 344-AD (TgF344-AD) rats, a model of AD, with the brain-penetrant inhibitor of histone deacetylase RG2833 for 5 months starting at the age of 6 months, and evaluated the rats for spatial memory performance and AD pathology. Using an active place avoidance test we identified a significant hippocampal-dependent spatial memory performance deficit in TgF344-AD rats compared to wild type littermates at 11 months of age. Notably, this deficit was mitigated in the RG2833 transgenic treated rats. Furthermore, RNAseq analysis of hippocampal tissue from TgF344-AD rats, revealed that treatment with RG2833 upregulated the expression of immediate early genes Arc and c-Fos, which are involved in synaptic plasticity and memory consolidation. We also found that RG2833 treatment failed to decrease amyloid beta or tau paired helical filament accumulation. However, RG2833 treated TgF344-AD rats exhibited a decrease in gliosis manifested by fewer amoeboid and ramified microglia in the hippocampal CA1 region compared to the untreated TgF344-AD littermate controls. These data indicate that histone modifying therapies can improve cognitive behavior by improving the expression of neuroprotective genes and by modulating the activation of immune cells and possibly dampening inflammatory response. Based on our data, we propose that RG2833 could be an effective therapeutic to treat disorders such as AD.

Title: Inhibition of p38 alpha MAPK signaling provides benefit in a mouse model of mixed dementia

Authors: *D. J. BRAUN[1], M. J. COLEMAN[1], V. A. DAVIS[1], S. M. ROY[2], D. M. WATTERSON[3], L. J. VAN ELDIK[1];
[1]Univ. of Kentucky, Lexington, KY; [2]Dept. of Pharmacol., [3]Northwestern Univ., Chicago, IL

Abstract: Background: The p38α MAPK signaling pathway is a well-established regulator of neuroinflammation that is aberrantly activated in Alzheimer's disease (AD). However, there is a lack of insight into the p38α MAPK signaling pathway involvement in non-AD comorbidities found in roughly 80% of probable AD patients. The most common of these co-morbidities is vascular pathology. Therefore, we explored the potential pharmacodynamic effects of MW150, a p38α MAPK isoform selective inhibitor currently in clinical trials, on neuroinflammation in a co-morbid environment with both AD and vascular pathology. To this end, we used a mouse mixed dementia (MD) model that combines amyloid pathology with vascular pathology induced by hyperhomocysteinemia (HHcy). **Method:** The 5xFAD mouse model of amyloid pathology (MMRRC No. 34848-JAX) was used. 5-month-old animals were placed for 8 weeks on a B-vitamin deficient and methionine-supplemented diet (Envigo TD.97345) to induce HHcy and generate the MD model. In a preventative treatment paradigm (treatment before vascular pathology is present), the MD mice were given intraperitoneal injections of saline vehicle or varying doses of MW150. For baseline comparisons, WT littermates on a control diet and administered saline were included. At the end of the 8 weeks, mice underwent testing in the Morris Water Maze (MWM) at the Jackson Laboratory or were sacrificed in-house for pathological analyses, including measurement of pro-inflammatory cytokines and changes in various RNA transcript levels. **Results:** In the MD mice, MW150 was able to rescue deficits in the MWM task, prevent proinflammatory cytokine IL-1β overproduction, and reduce several markers of microglial activation in a manner consistent with its known anti-inflammatory activity in other models. **Conclusions:** These data indicate that early intervention with MW150 might be an efficacious strategy in the context of co-morbid amyloid and vascular pathologies. Work to test the efficacy of MW150 when administered in a therapeutic as opposed to preventative paradigm is currently ongoing.

Title: Low-dose Intranasal Deferoxamine modulates memory, neuroinflammation, and the transcriptome in a rodent model of Alzheimer Disease

Authors: *J. KOSYAKOVSKY[1], J. M. FINE[2], W. H. FREY, II[2], L. R. HANSON[2]; [1]Sch. of Med., Univ. of Virginia, Charlottesville, VA; [2]Alzheimer's Res. Ctr., HealthPartners Neurosci. Ctr., Saint Paul, MN

Abstract: Intranasal (IN) Deferoxamine (DFO) has emerged as a remarkably promising candidate therapeutic across neurodegenerative and cerebrovascular disease. As an iron chelator, its mechanisms are multimodal and involve the binding of brain iron with the consequent engagement of several disease-nonspecific pathways. We and other research groups have shown that IN DFO rescues cognitive impairment in several rodent models of Alzheimer Disease (AD). We designed the present study in an effort to ease the translation of IN DFO to clinical trials, probing dosing regimes and mechanisms within the inducible intracerebroventricular (ICV) streptozotocin (STZ) rat model of AD. We found that a 1% solution of IN DFO rescued cognitive impairment caused by ICV STZ administration as measured by the Morris Water Maze (MWM) test. IN DFO rescued STZ-induced hippocampal neuron loss and decreased hippocampal apoptosis. Furthermore, IN DFO modulated several aspects of the neuroinflammatory milieu of the ICV STZ model which we assessed through a novel panel of brain cytokines and immunohistochemistry. Using RNA-sequencing and pathway analysis, we found that STZ induced several pathways of cell death and neuroinflammation, and that IN DFO engaged multiple transcriptomic pathways involved in hippocampal neuronal survival. In sum, to our knowledge this study is the first to assess the transcriptomic pathways and mechanisms associated with either the ICV STZ model or DFO treatment using RNA-sequencing and the first to demonstrate this therapeutic's efficacy at low doses. Additionally, we significantly elucidate the mechanisms and role of the ICV-STZ rodent model of AD.

Hlth., Baltimore, MD

Abstract: A major challenge in effectively treating Alzheimer's Disease (AD) is the presence of disease subtypes with highly heterogeneous underlying biology. Identifying AD subtypes is critical for advancing patient care and subtypes related to cognitive and neuropsychiatric characteristics have been identified using data- and hypothesis-driven clustering approaches. Current approaches to subgroup identification, however, are based on research-quality neuroimaging limiting the feasibility, generalizability, and impact on decision-making in the clinical space. In this work, we process clinical structural brain MRI data via a high-throughput image parcellation algorithm and cluster the resulting parcellations along with readily available data from the electronic medical record. Our methods and results provide a connection between the identification of AD subtypes via neuroimaging and clinical data. Additional clinical features may be added to contextualize and operationalize meaningful AD subtypes towards informing and improving clinical care.

Title: Subgroup classification of delirium and CSF amyloid beta and tau status in relationship to preoperative and postoperative cognitive decline

Authors: *M. REESE[1], M. BERGER[1,2,5], J. N. BROWNDYKE[3,2,5,6], M. COOTER[1], W. M. BULLOCK[1], M. J. DEVINNEY[1], E. W. MORETTI[1], D. T. LASKOWITZ[1,1], L. SHAW[7], H. E. WHITSON[4,2], H. J. COHEN[4,2], J. P. MATHEW[1];

Ctr., Durham, NC; [5]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [6]Duke Brain Imaging and Analysis Ctr., Durham, NC; [7]Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Introduction
Patients who experience postoperative delirium and those who meet ATN criteria established by the National Institute on Aging Alzheimer's Association are at increased risk of developing Alzheimer's disease and related dementias (ADRD). It is unclear whether delirium and ATN status are dissociable in their neurophysiological mechanisms, particularly in risk of postoperative cognitive decline associated with preclinical ADRD. Thus, existing data from preoperative and postoperative cerebral spinal fluid (CSF) AD biomarkers, the Confusion Assessment Method (CAM), and a neurocognitive test battery were used to characterize relationships between ATN status, delirium, and cognitive outcomes before to 6 weeks after surgery.
Method
Screening included 1,690 Duke University Medical Center English-speaking patients age ≥60 and scheduled for non-cardiac, non-neurologic surgery with a planned hospital stay of ≥1 night. 110 patients met inclusion criteria and completed baseline through 6-week CSF testing, a neurocognitive battery factor analyzed into 4 domains alongside the Mini-Mental State Exam

(MMSE), and CAM. ATN subgroups were identified at baseline using established immunoassay thresholds (Aβ <249 pg/ml or tau >93 pg/ml). The p-tau cutoff (>23 pg/ml) has low specificity for our AlzBio3 platform (N=66 p-tau+); thus, p-tau was excluded from subgrouping. Delirium+ included a positive CAM score or delirium chart review within 5 days post-surgery. Analyses included t-tests, ANOVAs, and non-parametric equivalents to study the association between subgroups and cognition from baseline to 6 weeks post-surgery.

Results

Delirium+ classification (N=13) was associated with worse cognition than delirium- (N=97) (baseline p=.030; 6-weeks post-surgery p=.020), particularly for visual memory (baseline p=.018; 6-weeks p=.015) and MMSE scores (baseline p=.088; 6-weeks p=.016). Baseline Aβ+ or tau+ patients (N=18) generally had a lower cognitive index (baseline p=.072; 6-weeks p=.021) and less visual memory (baseline p=.009; 6-weeks p=.002) than Aβ- and tau- patients (N=83). Delirium had no significant association with CSF Aβ, tau, or p-tau levels at any time point, and baseline CSF Aβ and tau status had no significant association with delirium incidence.

Conclusion

Exploratory analysis of subgroups differentiated CSF Aβ and tau from delirium, showing a 3 patient overlap and no significant association between baseline AD biomarkers or delirium status. Findings may suggest distinct underlying mechanisms for ATN and delirium despite similar patterns of cognitive impairment, which is an important consideration for future ADRD research.

Title: Identification and characterization of endogenous neuropeptide proteoforms, including VGF, in dementia pathophysiology

Authors: *J. P. QUINN, E. C. ETHIER, S. E. KANDIGIAN, B. A. TROMBETTA, S. E. ARNOLD, B. C. CARLYLE;
Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Neuropeptides are neurotransmitter-like molecules with multiple roles in neuronal activity that are processed into functional peptides (aka proteoforms) by prohormone convertases and as yet unidentified proteases. The neuropeptide neurosecretory protein VGF was the most nominated potential therapeutic target for Alzheimer's disease (AD) in a survey by the Accelerating Medicines Partnership-AD (AMP-AD), due to its levels being decreased in cerebrospinal fluid (CSF) and brain from patients with AD. Neuropeptides and their proteoforms remain understudied in their physiological processing pathways, their contribution to dementia pathogenesis and their potential use as a biomarker of dementia. Using mass-spectrometry and recombinant proteolysis assays we aimed to; 1) validate if specific neuropeptide proteoforms represent CSF biomarkers of synaptic health in dementia and 2) investigate their proteolytic processing. CSF was collected from 50 patients with AD, 64 with mild cognitive impairment (MCI), 18 who were cognitively resilient to AD pathology and 45 age-matched cognitively unimpaired controls. CSF samples were tandem mass tag (TMT)-labeled and pooled into thirteen 16-plex experiments. Pooled samples were size-filtered to eliminate peptides larger than 30kDa, and analyzed using a data-dependent acquisition workflow with a previously defined inclusion list of 241 endogenous non-tryptic neuropeptide proteoforms. Neuropeptide proteoforms from CHGA, CHGB, SCG2, SCG3, SCG5 and VGF were robustly detected (replicate coefficient of variation from 0.2-6.5%) from pooled samples run on every plex. Of those detected with less than 35% missing values across all samples, a majority were significantly associated with age, which was included as a co-variate in the linear modeling. 42 unique proteoforms detected had significant differential abundance between diagnostic groups, mainly between controls and AD. 7 VGF peptides and 5 SCG1 peptides were significantly different between AD and MCI while 9 VGF and 6 SCG1 peptides were significantly different between resilient subjects and AD. Using Proteasix, the MEROPS and human protein atlas database, 22 neuronally expressed proteases previously linked to dementia were identified that may cleave neuropeptides. Assays using recombinant proteins identified that ADAMTS4, calpain-1, cathepsin S, granzyme A and MMP-3 cleaved neuropeptides into N-terminal, mid-region, and C-terminal neuropeptide proteoforms. Overall, this work provides mechanistic insight into neuropeptide processing and how neuropeptide proteoforms could represent a novel biomarker for synaptic health in dementia.

Title: Associations between psychophysiological stress responses, inflammatory markers, and CSF biomarkers in the spectrum of Alzheimer's Disease

Authors: *H. OH[1], H.-C. LEUNG[3], T. CANLI[4], E. PARK[2];
[1]Psychiatry and Human Behavior, [2]Brown Univ., Providence, RI; [3]SUNY Stony Brook, Stony Brook, NY; [4]Dept Psychol, Stony Brook Univ. Dept. of Psychology, Stony Brook, NY

Abstract: Background: Although genetic factors associated with the aggregation of misfolded proteins clearly play a role in Alzheimer's disease (AD), several individual difference factors have been seen to confer an increased risk for the clinical manifestation of AD as well as the development of AD pathology. One of the key factors is an individual's susceptibility to psychological stress. The goal of this study was to examine the relationships between psychophysiological stress responses measured by plasma stress hormones and neuropsychiatric symptoms, inflammatory markers, and AD pathology along the spectrum of AD.**Method:** Alzheimer's Disease Neuroimaging Initiative (ADNI) consists of 819 adult subjects— 229 cognitively normal older adults (CNs), 398 participants with mild cognitive impairment (MCIs), and 192 patients with AD. Of these subjects, we included 58 CNs, 396 MCIs, and 112 AD patients whose plasma stress measures were available. Plasma cortisol and cytokines and CSF Aβ1-42, t-tau, and p-tau181 data were downloaded from ADNI. Neuropsychiatric Inventory (NPI-Q) total scores were used to indicate a psychological stress level.**Result:** AD stages were significantly related to the level of plasma cortisol and NPI-Q total scores showing that AD patients exhibit the highest level of cortisol and greater severity of psychological symptoms followed by MCIs and CNs. AD stages were also significantly related to the level of inflammatory markers measured by cytokines, although the level of inflammatory markers in relation to the diagnostic groups varied across different types of cytokines. Plasma cortisol levels did not relate to concurrent levels of CSF Aβ1-42 either across diagnostic groups or within diagnostic groups. Higher plasma cortisol, however, corresponded to higher CSF p-tau among CNs, but not in MCIs and ADs.**Conclusion:** Psychophysiological stress responses and inflammatory markers are significantly associated with the disease severity. A positive relationship between plasma cortisol level and CSF p-tau in CNs may indicate a role of individuals' susceptibility to stress in neuronal hyperexcitability in the early stage of AD and confer a risk of neurodegeneration and the development of AD. Alleviating stress and regulating stress responses may be important modifiable factors that help prevent AD.

Title: Extracellular vesicle enriched miRNA-biomarkers show increased predictive potential for alzheimer's dementia and medial temporal atrophy

Authors: Y. CHAI[1], L. STROHM[1], Y. ZHU[1], R. CHIA[1], J. CHONG[1], L. ZHOU[1], H. TOO[1], M. LAI[1], E. KOO[1], C. CHEN[1], ***G. H. POPLAWSKI**[2];
[1]Natl. Univ. of Singapore, Singapore, Singapore; [2]Duke-NUS Med. Sch., Singapore, Singapore

Abstract: "Liquid biopsies" have emerged as a new technique in the field of biomarker discovery. These non-invasive techniques, utilizing blood-derived extracellular vesicles (EVs), are especially promising in diagnosing dementia and neurodegeneration where brain biopsies are not practical. Investigation of blood EV-enriched biomarkers harbour the potential advantage of protecting miRNAs from degradation and could such increase the specificity of miRNA-biomarkers compared to serum-derived miRNAs. Here we show that indeed miRNAs isolated from blood-derived EVs are more predictive of Alzheimer's Disease as well as its neuropathological feature (namely medial temporal atrophy) compared to those isolated from serum samples. We further identified several novel miRNAs in AD patient derived EVs that have not been associated with AD beforehand. These data support the further utilization of EV-biomarker discovery for neurodegenerative diseases and provide potentially new biomarkers for the diagnosis of Alzheimer's Disease.

Title: Enlarged perivascular spaces in the centrum semiovale predict MoCA scores among cognitively normal older adults

Authors: *T. J. LIBECAP[1], B. RODOLPHO[1], F. D. RASLAU[2], B. T. GOLD[1];
[1]Neurosci., [2]Radiology, Univ. of Kentucky, Lexington, KY

Abstract: Cerebral small vessel disease (cSVD) is an important risk factor leading to the development of vascular contributions to cognitive impairment and dementia (VCID). cSVD is characterized by several in-vivo neuroimaging biomarkers including enlarged perivascular spaces (ePVS). PVS are fluid-filled spaces believed to play a role in the glymphatic system's removal of waste from the brain. Reduced clearance may cause backup and enlargement of the PVS and subsequent accumulation of toxic solutes characteristic of neurodegeneration, including Aβ. Evidence supports ePVS role in aging and dementia, but the relationship between ePVS and cognitive function remains unclear**.** Due to their presence in brain regions that support cognition, we hypothesized that quantitative, cross-sectional ePVS counts in cognitively normal older adults would predict baseline cognitive performance. We explored the relationship between ePVS and the Montreal Cognitive Assessment (MoCA) in 71 cognitively normal older adults ranging in age from 60-86. Participants were scanned on a 3T Siemens Prisma scanner with a 64-channel head coil. All ePVS counts were performed on T1 MPRAGE and T2 FLAIR images by an experienced rater blinded to participant demographics and under the direction of a trained neuroradiologist. In line with previously established guidelines, ePVS were defined as regions of hypointensity less than 3mm in diameter on T1 imaging and were distinguished from lacunar infarcts by the absence of T2 FLAIR hyperintensity. ePVS were individually and manually counted in a single, representative slice in the axial plane of the white matter centrum semiovale (CSePVS), basal ganglia, hippocampus, and midbrain. Linear regression analyses controlling for age, sex, intracranial volume, and education demonstrated a significant, negative relationship between total ePVS counts combined across the four regions of interest and MoCA score ($\beta = -0.282$, $P = 0.022$). The strongest relationship was found among CSePVS and MoCA ($\beta = -0.337$, $P = 0.005$). These findings suggest that ePVS burden, driven primarily by CSePVS, is associated with cognitive performance at baseline. Ultimately, our results support the continued investigation of ePVS as an early neuroimaging biomarker of cSVD-related cognitive dysfunction. In particular, additional work that addresses the longitudinal relationship between ePVS and MoCA is needed to strengthen the findings that ePVS predict cognitive dysfunction.

Abstract: Blood transcriptome has emerged as a powerful resource for studies of human diseases. However, the changes of blood transcriptome in patients with Alzheimer’s disease (AD) have not been well studied. We undertook transcriptome profiling of 422 participants 208 normal controls and 214 patients with AD) from the Hong Kong Chinese population. WGCNA (weighted correlation network analysis) was performed to construct co-expression network to identify modules that associated with AD. Co-expression modules are significantly associated with AD and plasma biomarkers of AD (i.e. Aβ and NFL). Pathway enrichment analysis revealed their possible involvement in specific biological pathways. Motif analysis identified potential mechanisms that drive the transcriptomic change in AD blood. Co-expression network analysis of AD blood transcriptome results in a better understanding on the disease mechanisms, as well as identification of potential targets for disease intervention and monitoring.

Title: Striatal compartmentalization and clustering of different subtypes of astrocytes is altered in Huntington's disease

Authors: *T. BROWN[1], M. THAYER[2], N. ZARATE[1], R. GOMEZ-PASTOR[2];
[1]Univ. of Minnesota Grad. Program In Neurosci., Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Huntington's disease (HD) is a devastating neurodegenerative disease that manifests as motor, cognitive, and psychiatric impairments. HD preferentially affects medium spiny neurons (MSNs) of the striatum, but it also causes astrogliosis, which is defined by an increased density of astrocytes. Striatal astrocytes are not homogeneous, and they can be classified into different subpopulations characterized by the expression of different markers including glutamine synthetase (GS), glial fibrillary acidic protein (GFAP), and S100 calcium-binding protein beta (S100β). It has been suggested that these subpopulations have different functions and could differentially contribute to HD. We conducted a comparative analysis of the abundance of different subpopulations of astrocytes (GFAP, GS and S100β) in the heterozygous zQ175 HD mouse model. Our data using 2D fluorescent imaging showed increased marker expression and abundance of all three subpopulations in the striatum of zQ175 mice. To analyze whether there is a differential spatial distribution of any of these subpopulations, we developed an unbiased brain compartmentalization approach and found that while GS and S100β are more homogeneously distributed throughout the striatum, GFAP+ astrocyte accumulation is specifically enhanced in the dorsomedial striatum of HD mice, a region involved in integration of heterogeneous inputs from both thalamic and cortical subregions. In addition, GFAP+ astrocytes showed increased clustering in HD mice compared to wildtype, a parameter that may indicate areas of highly localized secretion of inflammatory molecules. Our data suggest a distinct striatal compartmentalization of different populations of astrocytes in HD that could

contribute to striatal dysfunction and behavioral deficits. These results have major implications for our understanding of functional compartmentalization of the striatum and its relevance in contributing to the different HD symptoms.

Title: Genome-wide transcriptome profiling in striatum of HD mice exposed to a super-enriched environment

Authors: *H. KIM[1], S. H. WEE[1], J.-C. CHAI[2], T. YOO[1], R. ZUKIN[3], J.-Y. HWANG[1];
[1]Dept. of Pharmacol. and Neurosciences, Creighton Univ. Sch. of Med., Omaha, NE; [2]Dept. of Epidemiology and Population Hlth., [3]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., New York, NY

Abstract: Huntington’s disease (HD) is an autosomal dominant inherited neurodegenerative disorder characterized by progressive motor, psychiatric and cognitive decline. Marked neuronal loss in the striatum and cerebral cortical structures is the main neuropathological hallmark of HD. Environmental factors can alter gene expression through epigenetic responses such as DNA methylation and histone modification, which are critical to genome reprogramming during brain development, tissue-specific gene expression, and global gene silencing under physiological and pathological conditions. An enriched environment has been shown to delay the onset and progression of motor symptoms and to improve neurological function and cognitive performance in animal models of HD. However, the impact of an enriched environment on transcriptional changes in the R6/2 transgenic mouse model of HD is, as yet, unclear. To address this issue, we performed genome-wide transcriptome analysis using next generation RNA-seq in striatal tissue from HD and wild-type mice reared in either a stark or super-enriched environment. Volcano plots demonstrate that an enriched environment has a very strong influence on gene expression changes in both HD and WT mice. The differentially expressed genes were analyzed by the Ingenuity Pathway Analysis software. Canonical pathway analysis reveals that autophagy related pathways such as elF2 signaling, mTOR signaling, and regulation of elF4 and p70S6K signaling are activated and mitochondrial dysfunction is inhibited in HD mice exposed to the super-enriched environment in comparison to HD mice reared in the normal environment. We

anticipate that the identification of genes and gene networks that are altered in HD mice in response to enriched environments will assist us in understanding how enriched environments can improve HD symptoms and neurological function and will contribute to the development of novel therapeutic strategies to ameliorate motor and cognitive deficits associated with this debilitating and devastating disease.

Title: Tumor suppressor p53 regulates Heat Shock Factor 1 protein stabilization in Huntington's disease

Authors: R. MANSKY, D. YU, ***E. GREGUSKE**, N. ZARATE, T. INTIHAR, W. TSAI, M. THAYER, R. GOMEZ-PASTOR;
Univ. of Minnesota, MINNEAPOLIS, MN

Abstract: In contrast to cancer, increased levels of tumor suppressor p53 have been reported in the brains of patients with Huntington’s disease (HD), a neurodegenerative disorder caused by a polyglutamine expansion in the Htt gene (mtHTT). It is known that elevated p53 plays a detrimental role in HD with evidence demonstrating that a systemic lack of p53 provides neuroprotection in a mouse model of HD. However, the molecular mechanisms that regulate p53 levels in HD and the cellular processes affected by p53 upregulation remain unknown. We have found that mtHTT enhanced p53 levels by altering the interaction between p53 and Mdm2, an E3 ligase responsible for p53 degradation, resulting in increased p53 stabilization. We also found that elevated p53 stabilization preferentially occurred in medium spiny neurons (MSNs) of the basal ganglia, a type of neuron highly susceptible to mtHTT accumulation and aggregation. Additional analyses revealed that increased p53 stabilization activated a unique transcriptional program that further contributed to enhance protein aggregation by promoting the degradation of the stress protective transcription factor HSF1. We developed a conditional deletion of p53 in MSNs of the heterozygous zQ175 HD mouse model and demonstrated that specific deletion of p53 in this cell type was sufficient to restore HSF1 levels, protein homeostasis, and synaptic

density. Overall, our data identified a novel molecular pathway connecting mtHTT with p53 and HSF1 protein stabilization in HD.

Title: Mutant huntingtin originating from the striatum contributes to its presence in the cerebrospinal fluid in Huntington disease

Authors: N. S. CARON[1], R. BANOS[2], A. E. ALY[1], Y. XIE[2], S. KO[1], N. POTLURI[2], C. ANDERSON[1], H. FINDLAY BLACK[1], B. GORDON[2], M. R. HAYDEN[3], ***A. SOUTHWELL**[2];
[1]Med. Genet., Ctr. for Mol. Med. and Therapeut., Vancouver, BC, Canada; [2]Univ. of Central Florida, Orlando, FL; [3]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington disease (HD) is a neurodegenerative disease caused by a trinucleotide expansion in the *HTT* gene which codes for an elongated polyglutamine tract in the huntingtin protein (HTT). Expanded mutant HTT (mHTT) is toxic and leads to regional atrophy and neuronal cell loss in the brain, which is most pronounced in the striatum. Therapeutic lowering of mHTT in the central nervous system (CNS) has shown promise in preclinical studies, with multiple approaches currently in clinical development for HD. Concentration of mHTT in the cerebrospinal fluid (CSF) is being used in clinical trials as a pharmacodynamic biomarker of target engagement in the CNS. We have previously shown that the CNS is a major source of mHTT in the CSF, however, little is known about the specific brain regions and cell types that contribute to this pool of CSF mHTT. Therefore, a better understanding of the source of CSF mHTT is important for our interpretation of clinical CSF mHTT data since many of the mHTT lowering agents are expected to have limited distribution to the deeper regions of the brain, including the basal ganglia. Here, we use complementary pharmacological and genetic approaches to evaluate the contribution of the striatum to the pool of mHTT in the CSF. We show that viral expression of a HTT fragment with transduction restricted to the striatum leads to detectable mHTT in the CSF. We demonstrate that targeted delivery of an antisense

oligonucleotide against mHTT restricted to the striatum leads to a significant reduction of mHTT in the CSF of HD mice. Furthermore, using a transgenic mouse model of HD that expresses full length human mHTT and wild type HTT (Hu97/18), we show that genetic inactivation of mHTT selectively in the striatum results in a significant reduction of mHTT in the CSF. Taken together, our data support the findings that the striatum contributes sufficiently to the pool of mHTT in the CSF that therapeutic levels of HTT lowering in the striatum can be detected by this measure in mice, which suggests that CSF mHTT may represent a pharmacodynamic biomarker for therapies that lower mHTT in the striatum.

Abstract: Dysregulated autophagy relates to neurodegenerative diseases, in particular the *C9orf72*-ALS. In *C9orf*72-ALS, (G4C2)-hexanucleotide repeats expansion (HRE) does so by disrupting the nucleocytoplasmic transport of TFEB required for autophagy. However, the exact mechanism underlying the dysregulated autophagy caused by HRE remains unclear. The sigma-1 receptor (Sig-1R) is a multiple-functional chaperone protein that can affect the nuclear pore stability. Here we found that the Sig-1R regulates autophagy by chaperoning nucleoporin POM121 for the recruitment of importinβ1 that transports nucleus-bound TFEB. In NSC34 cells, the Sig-1R interacts and colocalizes with nucleoporin POM121 and Importinβ1. The Sig-1R as a chaperone stabilizes POM121 but not importinβ1, suggesting that Sig-1R interacts with POM121 that in turn binds importinβ1. HRE causes the dissociation of Sig-1R from POM121 and results

in a deficiency of nuclear importinβ1, TFEB, and an autophagy marker LC3-II. Overexpression of Sig-1R or POM121 rescues all of those deficits. Pridopidine is a potent and highly selective Sig-1R agonist currently under phase 2/3 clinical trials for ALS. But pridopidine's molecular mechanism of action against ALS remains unclear. We found that in the Sig-1R-BiP cellular assay, pridopidine acts as an agonist causing the dissociation of Sig-1R from BiP. In a chemical assay examining the chaperone activity of Sig-1R against the aggregation of citrate synthase, we found that pridopidine enhances the innate chaperone activity of Sig-1R and that the Sig-1R antagonist BD1063 blocks this action of pridopidine. Lastly, treatment of HRE-transfected NSC34 cells with pridopidine rescues all of the HRE-caused deficits mentioned above. Our results demonstrate that the Sig-1R is a ligand-regulated chaperone that controls autophagy by chaperoning a nucleoporin POM121. Results also suggest that pridopidine may be beneficial for the *C9orf72*-ALS patients through its action on the restoration of cellular autophagy. (Supported by the IRP, NIDA, NIH).

Abstract: RTP801/REDD1 is a stress-regulated protein whose levels are increased in several neurodegenerative disorders such as Parkinson's disease (PD), Alzheimer's disease (AD) and Huntington's disease (HD). Neuronal RTP801 downregulation *in vivo* ameliorates behavioral alterations in several mouse models of these disorders. Moreover, RTP801 silencing in hippocampal neurons in the 5xFAD mouse model of AD reduced several gliosis markers and inflammasome proteins, suggesting a novel role of RTP801 in neuroinflammation. In HD, RTP801 mediates mutant-huntingtin toxicity in cellular models and its levels are increased in human HD-iPSCs, postmortem putamen samples of HD patients and in striatal synaptosomes from mouse models. Moreover, RTP801 silencing in the striatum of the R6/1 mice prevented motor learning deficits and loss of synaptic proteins. Both HD patients and mouse models develop psychiatric and cognitive alterations before the onset of motor dysfunction. However, the potential role of RTP801 in the hippocampal pathophysiology in HD has not yet been elucidated. Hence, here, we investigated whether RTP801 is involved in hippocampal cognitive dysfunction and neuroinflammation in HD. We found that RTP801 levels are increased in the hippocampus of HD patients and that the levels of the protein correlate with gliosis markers. Although RTP801 expression is not altered in the hippocampus of the R6/1 model, RTP801 silencing in hippocampal neurons using shRNA-containing AAV particles ameliorates cognitive alterations. This recovery is associated with a partial rescue of synaptic markers and with a reduction of inflammatory events, particularly microgliosis. Altogether, our results indicate that RTP801 could be a biomarker for hippocampal neuroinflammation in HD patients and a therapeutic target to ameliorate the hippocampal-associated cognitive dysfunction in the disease.

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disease caused by a cytosine-adenosine-guanine (CAG) trinucleotide expansion coding for a polyglutamine (polyQ) in the huntingtin (Htt) protein. Although the genetic mutation that causes HD is well-characterized, the pathogenic mechanisms leading to neuronal loss are not yet completely understood. It has been reported that alterations in mitochondrial function and oxidative stress play an early pathogenic role in HD. However, clinical trials involving antioxidant drugs in HD patients have been unsuccessful, highlighting the importance of unraveling the molecular pathways leading to increases in oxidative stress in HD. One such candidate is the WW domain-containing oxidoreductase (WWOX). WWOX is altered in Alzheimer's disease (AD) post-mortem brains, and mutations in the WWOX gene cause cerebral ataxia, seizures, and epilepsy. Additionally, WWOX plays a role in regulating the mitochondrial electron transport chain (mtETC) through its short-chain alcohol dehydrogenases (SDR) domain. Therefore, we hypothesized that alterations in WWOX may contribute to oxidative stress and mitochondrial dysfunction in HD. As described previously, we found a significant increase in complex I (NDUFB8) and III (UQCRC2) mtETC proteins in a large cohort of HD human post-mortem prefrontal cortex (PFC) samples, indicating increases in oxidative stress in HD brain. There was also a concomitant and significant increase in WWOX and its phosphorylated and activated form, pWWOX-Y33, in HD PFC compared to controls. Similarly, WWOX and pWWOX-Y33 levels were significantly increased in HD isogenic embryonic stem cell (ESC)-derived cortical neurons compared to control cells. Lastly, using a recombinant WWOX protein, we demonstrated a significant increase in cell death in vitro as measured by an MTT assay. Collectively, our findings suggest that increases in WWOX levels may contribute to mitochondrial dysfunction and neuronal loss in HD.

Title: Spatial mapping of brain metabolism in a mouse model of Huntington's disease reveals markers of ER stress pre-symptomatically followed by neuronal deterioration

Authors: F. FARZANA[1], M. MCCONVILLE[2], T. RENOIR[1], *A. J. HANNAN[1], D. HATTERS[2], B. A. BOUGHTON[3];
[1]Florey Inst. of Neurosci. and Mental Health, Univ. of Melbourne, Melbourne, Australia; [2]Univ. of Melbourne, Melbourne, Australia; [3]Murdoch Univ., Perth, Australia

Abstract: A key pathological signature of Huntington's disease is the formation of intracellular inclusions formed by fragments of the huntingtin protein. In immortalized cell culture models, we previously showed that cells that had formed inclusions became functionally quiescent [Ramdzan et al., 2017, Cell Reports 19:919-927]. To determine whether inclusions played a role in establishing quiescence in vivo, we spatially monitored metabolism in the brains of a transgenic mouse model (R6/1) of HD at time points both before (6 weeks of age) and after inclusions manifested (12 and 16 weeks of age). MALDI-imaging mass spectrometry (MALDI-IMS) was used to monitor changes in metabolite abundances, and turnover, via deuterium isotope incorporation into lipids, introduced via drinking water and an intraperitoneal injection, in one brain hemisphere. The matched brain hemispheres were assessed in more detail by liquid-chromatography mass spectrometry (LC-MS). We found that in hippocampus regions dense with inclusions, there was a reduction in the relative abundance of neuronal-enriched lipids known to play a critical role in ER-stress protection, neurotransmission, synaptic plasticity, and neurogenesis. However, certain lipid synthesis rates were also increased in regions enriched with inclusions. These increased lipid synthesis rates were also apparent in mice at 6 weeks of age, which are asymptomatic and lack inclusions. Interestingly, elevated lipid synthesis has been previously recognized as a mechanism used by cells to cope with ER stress. Our data therefore suggests that increased lipid synthesis earmarks early-stage adaptive response to ER stress but, as HD progresses, a failure results in broader cellular collapse of neurotransmission, synaptic plasticity and neurogenesis. These findings provide new insight into the cascade of molecular events in brain regions spanning the development of inclusions.

Title: Neurotrophic and epigenetic mechanisms underlying the antidepressant action of ketamine in a rat model for Gulf War Illness

Authors: A. C. R. RIBEIRO[1], E. H. HAWKINS[1], F. JAHR[2], J. L. MCCLAY[2], *L. S. DESHPANDE[1];
[1]Virginia Commonwealth University, Sch. of Med., Richmond, VA; [2]Virginia Commonwealth University, Sch. of Pharm., Richmond, VA

Abstract: Over a third of the First Gulf War Veterans suffer from Gulf War Illness (GWI) with depression and memory impairment among its chief complaints. War-time exposure to organophosphate (OP) compounds has been implicated for GWI development. Following repeated, low-dose exposures to an OP and a nerve agent surrogate diisopropyl fluorophosphate (DFP), we previously identified signs of chronic depression in rats. We subsequently reported reduced levels of brain derived neurotrophic factor (BDNF) along with epigenetic histone dysregulations in this GWI model. Furthermore, ketamine (KET) boosted BDNF levels and produced an antidepressant effect in GWI rats. In this study, we further investigated the molecular consequences of reduced BDNF and investigated mechanisms by which KET was upregulating BDNF in our GWI model. Male Sprague-Dawley rats (3-m age) were injected with DFP (0.5 mg/kg, sc, 1x daily for 5-days). After about 6-m, rats received either a single dose of KET (10 mg/kg, ip) or saline. Twenty-four hours later, rats were either euthanized and rapidly dissected to obtain hippocampi for antibody-specific protein determinations or they were perfused with 4% paraformaldehyde, hippocampal slices subjected to Dil staining and confocal imaged to visualize dendritic spines. In agreement with our published data, GWI rats exhibited a significant decrease in BDNF levels that were significantly higher after KET treatment. Similarly, increased histone deacetylase (HDAC) activity along with a significant increase in HDAC1 and higher levels of HDAC3 and HDAC5 proteins were noted. In the KET-treated GWI samples, decreases in HDAC3 and HDAC5 levels were observed but only HDAC3 expression was deemed significantly lower. Confocal imaging revealed a significant decrease in dendritic spine density in GWI rats compared to age-matched control rats. Moreover, KET-treated GWI rats exhibited a significant increase in spine density over saline-treated GWI rats. BDNF has come to the forefront both as a molecule that not only affects spine maturation and synaptic mechanisms but also as a biomarker of depression and as a key transducer of antidepressant and memory effects. Our prior studies indicate that DFP exposures leading to GWI-related depression are associated with epigenetic HDAC modifications that affect BDNF protein expression. We now show that reductions in BDNF affect spine density that could underlie the pathological synaptic plasticity that precipitates as GWI neurological symptoms. KET may reverse this by decreasing HDAC activity, allowing for increased BDNF expression and spine density to produce long-lasting antidepressant effects in GWI rats.

Title: A cellular approach to understanding and treating Gulf War Illness

Authors: P. L. YATES[1], A. PATIL[1], X. SUN[1], A. NICEFORO[1], R. GILL[1], P. CALLAHAN[2], W. BECK[2], E. PIERMARINI[1], A. V. TERRY, JR[2], K. SULLIVAN[3], P. W. BAAS[1], ***L. QIANG**[1];

Abstract: Gulf War Illness (GWI), a disorder suffered by approximately 200,000 veterans of the first Gulf War, was caused by exposure to low-level organophosphate pesticides and nerve agents in combination with battlefield stress. To elucidate the mechanistic basis of the brain-related symptoms of GWI, human induced pluripotent stem cells (hiPSCs) derived from veterans with or without GWI were differentiated into forebrain glutamatergic neurons and then exposed to a Gulf War (GW) relevant toxicant regimen consisting of a sarin analog and cortisol, a human stress hormone. Elevated levels of total and phosphorylated tau, reduced microtubule acetylation, altered mitochondrial dynamics/transport, and decreased neuronal activity were observed in neurons exposed to the toxicant regimen. Some of the data suggest that neurons from veterans with GWI may be especially susceptible to developing GWI phenotypes compared to neurons from their counterparts without GWI. Wistar rats exposed to a similar toxicant regimen showed a mild learning and memory deficit, as well as cell loss and tau pathology selectively in the CA3 region of the hippocampus. These cellular responses offer a mechanistic explanation for the memory loss suffered by veterans with GWI and provide a cell-based model for screening drugs and developing personalized therapies for these veterans.

Title: How to measure and modulate the rewiring of automatic behaviors by non-invasive brain stimulation

Authors: *T. VÉKONY[1], F. PEDRAZA[1], R. PHELIPON[1], K. JANACSEK[2], F. HAESEBAERT[1], B. TILLMANN[1], D. NEMETH[1];

Abstract: Habits are recurring, automatic behaviors that strongly rely on statistical learning. To change the existing and sometimes harmful behaviors, we need to overwrite the old associations with new ones (rewiring). To date, little research has been done to explore the neurocognitive mechanisms underlying rewiring and possible approaches to facilitate successful rewiring. Previous research has shown an antagonistic relationship between executive, control function and statistical learning performance. The dorsolateral prefrontal cortex (DLPFC) has been proposed to play a "switching role" in this antagonistic relationship. This claim was supported by scientific evidence proposing that suppressing DLPFC-activity - thus, mitigating the control - might improve the acquisition of statistical knowledge. However, the question of whether we can influence the rewiring of already existing statistical associations by non-invasive brain stimulation of the prefrontal cortex remains elusive. Sixty-seven healthy young adults were enrolled in our study to test this question. On the first day of our experiment, participants practiced a probabilistic sequence learning task (Alternating Serial Reaction Time task) to measure their statistical learning performance. After a 24-hour delay period, they practiced the same task again with partly overlapping regularities, requiring them to overwrite their already existing statistical knowledge. During the acquisition of the new regularities (offline during breaks), we applied 1 Hz repetitive transcranial magnetic stimulation or sham stimulation over the left or right DLPFC. Our results demonstrate that participants were able to rewire their

knowledge of statistical regularities and acquire new associations. The old and the new knowledge can coexist, providing evidence for the compelling flexibility of the human mind in a changing environment. Moreover, we observed that the stimulation of the left DLPFC boosted the rewiring process by speeding up the acquisition of the new regularities. These findings are in line with previous results showing the mediating role of DLPFC in statistical learning. Our study provides further insights into the neurocognitive underpinnings of habit change and can contribute to a better understanding of the role of DLPFC in statistical learning.

Title: Does 1 Hz transcranial magnetic stimulation over the left DLPFC affect declarative and procedural knowledge?

Authors: *L. SZÜCS-BENCZE[1], T. VÉKONY[2], O. PESTHY[3,4], N. SZABÓ[1], D. NEMETH[2,4,5];

Group, Inst. of Cognitive Neurosci. and Psychology, Res. Ctr. for Natural Sci., Budapest, Hungary

Abstract: Different memory systems can support but also inhibit each other. Long-term memory representations of declarative memory can be detrimental in extracting completely new patterns from the environment, processes related to procedural learning. Previous non-invasive brain stimulation (NiBS) studies pinpointed the „neural switch" role of the dorsolateral prefrontal cortex (DLPFC) in this antagonistic relationship. They showed that inhibitory stimulation had improved implicit procedural learning. In contrast to previous studies that typically modulated the learning phase by NiBS, here, we examined the role of the DLPFC in the retrieval phase of already acquired declarative and procedural knowledge. In our study, participants performed

declarative learning (Paired Associate Learning Task) and implicit procedural learning (Alternating Serial Reaction Time Task) in the learning phase. After a 24-h offline period, we applied 1 Hz repetitive transcranial magnetic stimulation (rTMS) or sham stimulation for ten min over the left DLPFC just before retesting the declarative and procedural knowledge. A similar level of knowledge was measured following left DLPFC and sham stimulation for both tasks. Here, we focused only on the left hemisphere; the study of the right hemisphere and bilateral stimulation is ongoing. The lack of difference between groups may be due to interhemispheric compensatory mechanisms. More targeted NiBS studies are necessary to determine the functional role of the DLPFC in the retrieval of declarative and procedural knowledge.

Neurosciences, Budapest, Hungary

Abstract: Behavioral memory performance can be a result of different interacting memory processes. This interaction can be cooperative, or competitive in nature. The balance of memory processes might depend on the dorsolateral prefrontal cortex (DLFPC). A recent study has shown that reduced functioning of the DLPFC results in better learning of probability-based regularities (i.e., statistical learning). However, the question remains if this improvement in statistical learning interferes with declarative learning and whether there is a hemispheric asymmetry in the role of DLPFC. Based on earlier neuropsychological studies, we hypothesized that disrupting the left DLPFC benefits statistical learning and inhibits declarative performance, while the right DLPFC has the opposite effect. Sixty-three healthy young adults participated in our sham-controlled, single-blind brain stimulation study. We used a probabilistic sequence learning task (Alternating Serial Reaction Time task) to measure statistical learning and the Paired Associate Learning task to measure declarative memory. We applied 1 Hz inhibitory repetitive transcranial magnetic stimulation over either the left or the right DLPFC throughout learning, during the breaks of the tasks. We tested the performance after a 24-hour delay period as well. We found that right DLPFC stimulation weakened statistical learning, but did not affect declarative memory. Furthermore, we did not find any effect of the left stimulation. Bayesian statistics also supported these results. Our findings are in line with previous literature on the benefit of the right DLPFC in statistical learning, however, we could not show evidence for competing memory processes on the behavioral level. We suggest that these results might be due to the compensation of the non-stimulated hemisphere.

Title: The insect olfactory receptor-coreceptor Orco controls spontaneous activity and, thus, kinetics and sensitivity but not primary events of hawkmoth pheromone transduction

Authors: K. SCHROEDER[1], E. A. SOUFI[1], ***M. STENGL**[2];
[1]Biology, Animal Physiology/Neuroethology, [2]Univ. of Kassel, Kassel, Germany

Abstract: The roles of Orco in insect odor transduction are still not completely comprehended. As established in *Drosophila* in the hawkmoth Orco is a chaperon that is obligatory for locating

and maintaining olfactory receptors (ORs) to ciliary membranes of olfactory receptor neurons (ORNs). Furthermore, if expressed in heterologous expression systems Orco from both *Drosophila* and hawkmoths forms a slow, spontaneously opening non-specific cation channel that fulfills criteria of pacemaker channels comparably to HCN channels. In contrast to *Drosophila* in the hawkmoth Orco is not involved in the primary events of pheromone transduction as ligand-gated olfactory receptor-ion channel complex. It activated about one second later during the late, long-lasting pheromone response, when membrane potential, Ca^{2+}, and cGMP levels are rising pheromone-dependently. Thus, we hypothesize that Orco acts as voltage- and second messenger-gated pacemaker channel that controls kinetics and sensitivity of pheromone responses via resonance. Indeed, with heterologous expression and extracellular tip-recordings of pheromone-sensitive antennal sensilla in *M. sexta in vivo* we found that Orco is a voltage-dependent non-specific cation channel. Since it opens at hyperpolarized potentials it drives spontaneously occurring membrane potential oscillations providing temporal selectivity for the detection of pheromone pulses that guide the males to the calling females. Furthermore, since hawkmoths' pheromone-guided mating behavior is under strict circadian control we performed long-term recordings over several days and established that spontaneous activity is controlled via a circadian clock in ORNs. Neither cAMP, nor phosphorylation via protein kinase C alone affect spontaneous activity, while after previous phosphorylation cAMP increases spontaneous activity only during the hawkmoth's activity phase. In addition, cGMP increases spontaneous activity phosphorylation dependently only during the resting phase. In summary, Orco is a target for second messenger- and circadian clock-dependent modifications to control resonance properties, sensitivity, and kinetics of hawkmoth ORNs.

Title: Rapid transcuticular imaging of olfactory sensory neuron activity in the yellow fever mosquito Aedes aegypti

Authors: *D. GIRALDO[1,2], C. J. MCMENIMAN[1,2,3];
[1]W. Harry Feinstone Dept. of Mol. Microbiology and Immunol., Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD; [2]Johns Hopkins Malaria Res. Inst., Baltimore, MD; [3]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The yellow fever mosquito *Aedes aegypti* uses different physical and chemical cues emanating from the human body to locate a potential host. Carbon dioxide (CO_2) present in

human breath is an important behavioral activator, and this gas also synergizes with other volatile chemicals such as L-(+)-lactic acid found in human body odor to trigger mosquito host-seeking behavior. The dendrites of olfactory sensory neurons (OSNs) that detect these chemicals are housed in specialized sensilla on the mosquito antennae and maxillary palps. To date, electrophysiological approaches such as single sensillum recordings have only facilitated studies of the ligand tuning dynamics of a limited subset of OSNs from the *Aedes aegypti* olfactory system. This is primarily due to thick cuticle hampering electrode penetration of olfactory sensilla during these extracellular recordings, and the large number of sensilla present on the mosquito olfactory organs. Recent advances in mosquito genome editing allowed us to generate transgenic lines that express genetically encoded calcium indicators (GECI) targeted to specific tissues and permitted recording of activity from multiple neurons at the same time. Using the QF2-QUAS system we targeted the expression of GCaMP6s to a set of neurons that respond to CO_2 and another set that respond to carboxylic acids. We found that in peripheral sensory organs from wild-type mosquitoes, calcium-induced fluorescence is strongly attenuated given the highly melanized nature of the *Aedes aegypti* cuticle. To overcome this challenge, we introgressed our driver and effector lines to mosquitoes with a mutation that reduces melanization of the cuticle, which allowed for efficient detection of GECI fluorescence. This optimized method facilitates rapid transcuticular imaging of CO_2 receptor neuron responses and other OSNs that detect human related odorants such as L-lactic acid and butyric acid. It is further less invasive and enhances experimental throughput relative to other neurophysiological recording methods available in this non-model species. This technological advance stands to improve our fundamental understanding of the ligand tuning dynamics of the *Aedes aegypti* olfactory system.

Title: Diversity of odor responses in maxillary palps of Aedes aegypti

Authors: *S. S. SINGH[1], A. AIRAN[1,2], S. GUPTA[1], N. GUPTA[1];
[1]Dept. of Biol. Sci. and Bioengineering, [2]Dept. of Physics, Indian Inst. of Technol., Kanpur, India

Abstract: Aedes aegypti mosquito is a vector for some of the deadliest diseases like dengue fever, zika fever, yellow fever, and chikungunya. Female mosquitoes use olfactory cues like body odors and carbon dioxide to find human hosts for blood-feeding. One of the main olfactory organs, the maxillary palp, detects these odors through several small sensilla present on its surface. These sensilla, known as the capitate pegs, house three sensory neurons within them. It is crucial to study the responses of these sensory neurons to understand how host odors are represented and processed in the mosquito brain. We recorded the responses of these neurons to carbon dioxide, 1-octen-3-ol, and 13 other odors, along with solvent controls, using single sensillum recordings (SSRs) in Aedes aegypti. We observed three types of spikes differing in their spike amplitudes and second-time derivatives within the SSR responses. Using second-time derivatives for thresholding, we characterized the spikes as A (biggest), B (middle-sized), and C (smallest), corresponding to the three neurons in the capitate peg sensilla. Consistent with previous reports, neuron A responded strongly to carbon dioxide, cyclopentanone, butanone, and 3-methyl cyclopentanone. There was some response to all the tested odors except L-lactic acid. In contrast, neuron B responded to only 4 out of 16 odors tested (4-methyl-cyclohexanol, triethyl amine, 1-hexen-3-ol, and (S)-limonene). Neuron C responded to all the odors but showed a relatively stronger response to 1-octen-3-ol. Interestingly, neuron A exhibited highly diverse responses to 1-octen-3-ol in different SSR recordings. These responses ranged from excitatory to inhibitory to no response and even temporally patterned responses in some cases. We found that this patterned activity was a combination of the intrinsic excitatory activity of neuron A and an inhibitory activity due to ephaptic coupling with neuron C. We observed reduced or no inhibition in the activity of neuron A of mosquitoes that lacked the receptors for 1-octen-3-ol. This result confirmed that the inhibition in neuron A was caused by ephaptic coupling in the sensillum through neuron C. The current study contributes to the understanding of the olfactory processing in the maxillary palps of Aedes aegypti. A deeper understanding of sensory processing may help in devising strategies to perturb mosquito-host interactions and control the spread of mosquito-borne diseases.

Title: Dynamic switch between ON and OFF responses in an olfactory receptor neuron

Authors: *M. DEMIR[1,2], S. GORUR-SHANDILYA[1,3], T. EMONET[1,2,3,4];
[1]MCDB, [2]Inst. for Quantitative Biol., [3]Interdepartmental Neurosci. Program, [4]Dept. of Physics, Yale Univ., New Haven, CT

Abstract: Sensory neurons are either activated or inhibited by stimuli. Here we demonstrate the existence of a third response modality in the *Drosophila* olfactory receptor neuron ab2A, which in response to a single odorant can dynamically invert its polarity from excitatory to inhibitory. ab2A increases its spike rate in response to an initial increase in odor intensity, behaving like an "on" response. However, further increases in stimulus intensity elicit a decrease in the spike rate, whereas decreases in intensity elicit an increase in the spike rate, reminiscent of "off" responses. This on/off polarity inversion is dose-dependent and modulates olfactory behavior. It is specific to a subpopulation of acetate esters that are abundant in flies' natural settings, and is conserved across multiple *Drosophila* species that diverged at least 10 million years ago, suggesting broad occurrence and ethological relevance. Polarity inversion is independent of ephaptic coupling between sensory neurons, and does not rely on the most abundant odorant binding proteins and odor degrading enzymes. Inversion is observed at the level of signal transduction, upstream of action potential generation. Moreover, it is qualitatively recapitulated by a biophysical model with two binding sites, suggesting it might take place at the level of the receptor. Together, these results establish polarity inversion as an important property of olfactory receptor neurons, and provide a quantitative framework for future studies of this new dimension in odor coding.

Title: Amplification of Olfactory Transduction Signals by Anoctamin 9/TMEM16J is Essential for Mammalian Olfaction

Authors: *H. KIM, H. KIM, N. T. LUAN, T. HA, U. OH;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Sensing smells of food, prey, or predators determines animal survival. Olfactory sensory neurons(OSNs) in the olfactory epithelium(OE) detect odorants. cAMP and Ca^{2+} play a major role in transducing odorant inputs to electrical activity in OSNs. Here we show ANO9, a cation channel activated by cAMP/PKA pathway amplifies OSN responses. ANO9, expressed in OE, specifically the cilia of OSN, is activated by odorants through their respective receptors. *Ano9*-deficient mice elicited reductions in olfactory behavioral sensitivity, electro-olfactogram

signals, and neural activity in the olfactory bulb. ANO9 amplified the cAMP-evoked CNG currents in OSNs. Thus, the signal amplification by ANO9 contributes to mammalian olfactory transduction.

Title: Inheritance of Learned Fear: cell proliferation in response to stress

Authors: *Y. R. AYMAN[1], E. JAEGER[2], H. LEE[3], C. LIFF[1], B. J. MARLIN[1], R. AXEL[1]; [1]Neurosci., Columbia Univ. Zuckerman Inst., New York, NY; [2]Columbia Univ., New York, NY; [3]Weill Cornell, New York, NY

Abstract: The precise mechanism behind epigenetic regulation in the olfactory epithelium is unknown although morphological changes in response to fear conditioning have been observed. Namely, after a chosen odor (acetophenone) is presented, an increase in the specific olfactory sensory neurons (OSNs) is observed in the parental generation (F0) and their offspring (F1) following a 3 day fear conditioning paradigm in which this odor is paired with a foot shock. It has been also shown that more receptors being expressed in response to an odor that is predictive of a shock may make the mice more sensitive to said odor. Here we provide evidence for the mechanism underlying these epigenetic changes by answering two key questions. Firstly, does fear conditioning extend the OSN lifespan or increase cell proliferation of the specific receptors to the conditioned odor. Secondly, is activation of the receptors to the conditioned odor necessary and/or sufficient for the epigenetic phenotype in F0 and F1. We use 5-ethynyl-20-deoxyuridine (EdU) to birth date OSNs at single cell resolution in the olfactory epithelium, and DREADDS (HM4Di and HM4Dq) to stimulate the OSNs in vivo in order to test the causal relations between the mature OSNs and the increase in OSN expression. Our data indicate a potential mechanism for how environmental signals are conveyed to somatic cells in sensory systems, before being transmitted to germ cells and subsequently to future generations.

Title: A transcriptional rheostat couples past activity to future sensory responses

Authors: *T. TSUKAHARA[1], D. H. BRANN[1], S. L. PASHKOVSKI[1], T. BOZZA[2], S. R. DATTA[1];
[1]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [2]Neurobio. and Physiol., Northwestern Univ., Evanston, IL

Abstract: Animals traversing different environments encounter both stable background stimuli and novel cues, which are thought to be detected by primary sensory neurons and then distinguished by downstream brain circuits. Here we show that each of the ~1000 olfactory sensory neuron (OSN) subtypes defined by the expressed odorant receptors (ORs) in the mouse harbors a distinct transcriptome whose content is precisely determined by interactions between its odorant receptor and the environment. The expression of more than 70 genes relevant to sensory function (such as GPCR signaling factors, calcium binding proteins and ion channels) varies continuously and systematically across OSN subtypes. Consistent with a role in adaptation, levels of these genes accurately predict acute odor responses and dynamically adjust to novel odor environments over hours to days. The sensory periphery therefore separates salient signals from predictable background via a transcriptional rheostat whose moment-to-moment state reflects the past and constrains the future; these findings suggest a general model in which structured transcriptional variation within a cell type reflects individual experience.

Title: Comprehensive characterization of chemical-receptor relationship in vivo in olfactory sensory neurons

Authors: *D. H. BRANN[1], T. TSUKAHARA[1], T. BOZZA[2], S. R. DATTA[1];
[1]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [2]Neurobio. and Physiol., Northwestern Univ., Evanston, IL

Abstract: Animals detect chemicals in the environment by odorant receptors (ORs) expressed in olfactory sensory neurons (OSNs). In contrast to other sensory systems, the olfactory system detects and distinguish between large numbers of volatile odorants, and these sensory stimuli span a high-dimensional chemical space. Mammalian genomes have a vast array of ORs to deal with this complexity (>1000 in mice and ~400 in humans). A comprehensive understanding of chemical-receptor relationships is essential for understanding how animals interact with the chemical world. However, due to large number of stimuli and ORs, most ORs have no known ligands, making it difficult to understand general questions about how the nose filters the olfactory world and how OR activation is linked to sensory perception. To overcome these issues, we applied single cell RNA sequencing (scSeq) to identify activated OSNs and ORs in vivo. Activation was OR-specific and different odors activated different sets of ORs, with overlapping sets or ORs for similar odorants. Additionally, exposure to odors consistently up or down regulated hundreds of genes in activated OSNs. scSeq reliably identified ~100 ORs activated by acetophenone (~15% of the detected ORs in our dataset), including almost all previously identified ones and many novel acetophenone-responsive ORs. Since scSeq captures the transcriptional changes for cells expressing each OR, we further developed a metric, activation score, to quantify the degree of odor response in an analog fashion on an OR-by-OR basis. Activation scores were reliable across animals, varied continuously across OSNs expressing different ORs, and were concentration-dependent. These results show that scSeq is a powerful tool to characterize how the entire repertoire of ORs is activated by odorants.

Title: Effects of early auditory deprivation on audiovisual processing: An EEG investigation of audiovisual stimulation in cochlear implant using children

Authors: *B. M. BORMANN, S. COFFEY-CORINA, L. M. MILLER, D. P. CORINA;
Ctr. for Mind and Brain, Univ. of California, Davis, Davis, CA

Abstract: Early auditory sensory deprivation may have cascading effects on language and cognition in profoundly deaf children. Some studies have suggested these effects may be driven by cross-modal plasticity whereby auditory regions show additional preferential processing of visual information. However, little is known about how these children process concurrent auditory and visual stimulation. We make use of EEG to investigate the effects of concurrent sensory stimulation in CI using children (n = 39, m = 75 mos.) and typically developing controls (n = 30), m = 85 mos.). We recorded EEG while participants were presented with auditory only stimulation (continuous speech), visual stimulation (peripherally presented flashing checks) or these signals in combination. We characterized positive ERP responses in the time window of 80-210 msec, capturing responses known to be sensitive to auditory and visual stimulation. We examined audio only, visual only, and audiovisual stimuli in reference to two different time points. The first condition compared audio only stimuli to AV stimuli, time locked to the onset of the auditory events (AV-a). The second condition compared visual only stimuli to AV stimuli in reference to the onset of a visual events (AV-v). For both conditions, AV stimulation resulted in increased positivity for all groups. (Condition 1 p. < .009, Condition 2 p < .003). Our results indicate that for condition 1, CI using children show peak amplitude of the auditory-only response comparable to typically developing children (TD: 2.6 μV, CI: 2.4 μV, p = .306). We observed a greater positive amplitude for TD participants in this time window during concurrent audiovisual stimulation (AV-a) TD: 4.3 μV, CI 2.9, p < .008). In condition 2, a robust positive response for visual only stimuli was found for both groups of participants (TD: 7.5 μV; CI 4.8, μV p < .001). During concurrent audiovisual stimulation (AV-v) we observed a larger positive peak during this time window. This effect was more pronounced in TD subjects compared to CI subjects (TD:12.5 μV, CI 6.9 μV; p < .0001.). Taken together this data suggests that early auditory deprivation may differentially impact audiovisual processing.

Title: Characteristics of speech perception by distantly-presented bone-conducted ultrasound assessed by phonetic-feature transmission analysis

Authors: *S. NAKAGAWA[1,4], K. DOI[2], S. OTSUKA[3];
[1]Ctr. for Frontier Med. Enginrering, Chiba Univ., Chiba, Japan; [2]Dept. of Med. Engin., [3]Ctr. for Frontier Med. Enginrering, Chiba Univ., Yayoi-chi 1-33, Inage-ku, Chiba, Japan; [4]Chiba Univ. Hosp., Chiba, Japan

Abstract: Bone-conducted ultrasound (BCU) is perceived even by the profoundly sensorineural deaf. A novel hearing aid using the perception of amplitude-modulated BCU (BCU hearing aid: BCUHA) has been developed. In BCUHA, the vibrator is usually pressed against a part of the cranial bone behind the ear (mastoid process); however, BCU presented to parts of the body distant from the head can be perceived.In this study, to evaluate this “distantly-presented BCU” hearing, Japanese monosyllable articulation tests were conducted. Additionally, sequential information transfer analyses (SINFA) were conducted to determine what type of articulatory features were well transmitted.10 Japanese adults (males, 22-26 years), with normal-hearing participated in the monosyllable articulation test. 100-Japanese monosyllables recorded in a female voice were used as modulator signals. 30-kHz ultrasonic carrier was amplitude-modulated (AM) by the monosyllables and presented using a vibrator to following three locations: (a) mastoid process of the temporal bone, (b) sternocleidomastoid muscle (muscle of the neck), and (c) clavicle. The vibrator was fixed using an over-the-head-type steel band (mastoid), an elastic band (sternocleidomastoid muscle) or a shoulder supporter band (clavicle) with presentation pressure of 2 N (sternocleidomastoid muscle) or 5 N (mastoid and clavicle). Additionally, air-conducted (AC) monosyllables, i.e., the modulator signal itself, was presented to the same side as the BCU stimuli for comparison.In the monosyllable articulation test, the score for AC condition was higher than that of BCU condition. Confusion (miss-recognization of monosyllable) was more prevalent in the BC than in the AC condition. Differences in the percent correct between AC and BCU were significant in the clavicle for vowels and in all locations for consonants. Additionally, the phonetic features transfer ratios of vowels varied depending on the stimulus placements. Moreover, the “contracted sound” and “nasality” phonetic features of consonants were well transmitted when the stimuli were presented onto the sternocleidomastoid. The results obtained suggested that a practical speech transmission, comparable to ordinary

BCUs, presented onto the head, can be obtained by distantly-presented BCU. Additionally, it is also suggested that the feature information transmission may depend on the characteristics in the biological tissues such as attenuation rate and frequency characteristics.

Title: Auditory perception elicited by the infrared neural stimulation of cochlear nerves in Mongolian gerbils

Authors: *M. UENAKA[1], Y. TAMAI[1], Y. ITO[1], K. TODA[2], S. HIRYU[1], K. I. KOBAYASI[1]; [1]Doshisha Univ., Kyoto, Japan; [2]Keio Univ., Tokyo, Japan

Abstract: Cochlear implants allow hearing-impaired individuals to regain auditory perception by electrically stimulating the cochlear nerves, bypassing damaged hair cells. One of the most significant drawbacks of the device is it requires surgical intervention for implanting. Infrared neural stimulation has been investigated for overcoming the disadvantage because the laser can elicit neural activity without contacting tissues. No study, however, has proven the feasibility of the laser auditory prosthesis at the perceptual level. The purpose of this study was to examine laser-evoked auditory perception using classical conditioning in head-fixed Mongolian gerbils (*Meriones unguiculatus*). A click-train of 4000 Hz (sound pressure level: 70 dB SPL) was presented as a conditioned stimulus for a reward (a drop of water), and licking behavior was recorded as a conditioned response. After the training was completed, an optic fiber was inserted into the gerbil's ear canal. The lateral side of the cochlea was irradiated with a 4000Hz pulsed laser from an outer ear (radiant energy: 0.2, 10.1, 19.1 mJ/cm^2) without the paired water. As results, laser stimulation increased the licking rate in the same way as auditory stimulation. Furthermore, an increase in the licking rate was observed with radiant energy of laser stimuli increased, which was similar to the increase in the licking rate with the sound pressure level of auditory stimuli increased. In a subsequent experiment, we trained head-fixed Mongolian gerbils with the 4000Hz repetitive infrared laser pulses (radiant energy:14.8mJ/cm^2) as a conditioned stimulus. After the training, white noise (sound pressure level: 35, 50, 65, 80, 95 dB SPL) was presented as a masking stimulus during the laser stimulating period. The laser-evoked licking significantly decreased as the masking stimulus intensified ($r=-0.70$, $p<0.001$). These results indicate that the infrared laser irradiation to the cochlea can evoke auditory perception, and the

perceptual level can be controlled by changing the radiant energy. This research will be an essential step for the clinical application of laser stimulation to cochlear implants.

Title: Mechanisms Underlying the Enhancement of Medial Olivocochlear Reflex Associated with Rhythm-based Prediction: A Study Based on Temporal Correlation with Cortical Auditory Evoked Potential

Authors: *Y. ISHIZAKA, S. OTSUKA, S. NAKAGAWA;
Chiba Univ., Chiba, Japan

Abstract: Medial olivocochlear (MOC) fibers are efferent projections that emerge from the superior olivary complex and extend to the outer hair cells (OHCs). The MOC fibers are activated by acoustic stimulation and exert an inhibitory effect on OHC motility; this effect has been termed the medial olivocochlear reflex (MOCR). We have previously reported that MOCR is enhanced by anticipation based on the regularity of preceding sound sequence. Since there are efferent projections from the auditory cortex to the medial olivocochlear bundle, it is possible that processing at cortical levels involves the proactive control of MOCR. To elucidate the possibility, we measured the cortical auditory evoked potential (CAEP) and MOCR simultaneously and analyzed their temporal correlation. A broad-band noise for the MOCR and CAEP elicitation was presented in two conditions alternately. In the regular condition, interstimulus interval among the noises was fixed at 500 ms. In the irregular condition, the onset of the noise was randomly delayed or front loaded by 200 ms compared to the regular condition. The sound pressure level (SPL) and duration of the noise were set to 60 dB and 508 ms, respectively. Eight minutes-long measurements were performed, and the time fluctuations of the MOCR and CAEP were estimated.MOCR was assessed noninvasively using otoacoustic emissions (OAEs), which are sounds that originate in the cochlea and reflect OHC motility. We measured OAEs evoked by clicks presented right after the noise offset. Clicks were presented at the rate of 40 clicks per second and at a peak equivalent SPL of 60 dB. OAE level differences between the irregular and regular condition can be considered as MOCR changes associated with the timing predictability of the stimulus appearance (ΔMOCR_reg). CAEPs synchronized with the noise onset were measured. The recorded signals were band-pass filtered between 0.5-30 Hz to extract the cortical evoked response. The potential difference between the peaks of N1 and P2

was calculated from the average waveform.The time variation of ΔMOCR_reg was negatively correlated with that of N1-P2 amplitude: MOCR strength in the regular condition increases compared to the irregular condition, when N1-P2 amplitude decreases. This result suggests that the activity of auditory cortex is involved in the increase of MOCR strength associated with temporal expectation.

Title: Interhemispheric auditory white matter tract and impulsivity

Authors: T. E. STANSBERRY, ***T. IKUTA**;
Univ. of Mississippi, Oxford, MS

Abstract: The association between auditory processing and impulsivity has been consistently shown. However, the exact mechanism and pathological relations are not clear. The posterior part of the corpus callosum body has been repeatedly found to be affected in bipolar disorder, whose association to impulsivity is also well known. Although this part of the corpus callosum corresponds to the Interhemispheric Auditory white matter Tract (IAT), it has not been tested whether IAT is responsible for impulsivity. In this study, we first isolated the IAT and tested the association between IAT's integrity and impulsivity using diffusion tensor imaging (DTI) data from Nathan Kline Institute - Rockland Sample. Fractional Anisotropy (FA) was used as an index of white matter integrity. Out of 446 individuals, probabilistic tractography of IAT was successful in 390 individuals. FA of the IAT showed positive association with impulsivity scale, measured by UPPS (urgency, premeditation, perseverance, and sensation seeking) Impulsive Behavior Scale total score. Our results show that IAT is associated with impulsivity. Higher IAT FA is associated with higher impulsivity. This is inconsistent with the findings in bipolar disorder, where lower IAT FA is found and higher impulsivity is known. It is suggested that the IAT may not be a part of pathology in bipolar disorder.

Title: Optimized 40Hz ASSR in rodent cortical EEG - validation using a ketamine model of NMDA receptor hypofunction

Authors: *J. R. HUXTER, S. KANTOR, L. GIGGINS, M. DUXON;
Transpharmation Ltd., London, United Kingdom

Abstract: The auditory steady state response (ASSR) is impaired in patients with schizophrenia, reflecting a deficit in cortical-level sensory processing which may underlie common symptoms such as auditory hallucinations. ASSR is also easily measured in rodents, making it a powerful translational tool. Our aims were to 1) test ASSR detection in rats using near-midline frontal-parietal EEG, 2) to determine the sensitivity of ASSR to stimulus parameters, and 3) to test the

ability of atypical antipsychotics to reverse a ketamine-induced deficit in ASSR. Adult male Sprague-Dawley rats were implanted with epidural electrodes paired with wireless intraperitoneal transmitters (HD-S02, DSI USA). After recovery, animals were tested in sound-attenuating chambers in which blocks of click-trains were played for approximately 1 hour, using 1ms clicks with a 25ms inter-click interval. Our results indicate that by normalising responses to the 1-second baseline before each click-train, a robust ASSR signal (FFT-derived amplitude change at 40Hz, ~125% of baseline) emerged, even though the induced oscillations were not visually discriminable in the raw traces. The ASSR magnitude was replicated using tones as low as 25% of the volume typically used (75 dB) in human and rodent studies. Using a 75 dB stimulus, ketamine (0.3-10 mg/kg s.c.) induced a dose-dependent reduction in ASSR which was near 100% at 10mg/kg and returned to baseline after approximately 1 hour. The 10 mg/kg ketamine deficit was replicated in a separate cohort of animals, but not reversed by pre-dosing with aripiprazole (10 mg/kg s.c.) or clozapine (10 mg/kg s.c.), common antipsychotic medications. We conclude that with the appropriate stimulus and normalization, ASSR can be reliably detected using a frontal-parietal rodent cortical EEG montage, as opposed to recording from (or near) the auditory cortex itself. While ketamine-induced deficits were not reversed using atypical antipsychotics targeting 5-HT2A receptors, targeting alternative receptors and pathways may prove to be more effective. Alternatively, combining lower-amplitude stimuli with lower-doses of ketamine may yield a more reversible deficit.

Title: Modulating auditory perception using individualized tACS protocols

Authors: Y. CABRAL-CALDERIN, *M. J. HENRY;
Max Planck Inst. for Empirical Aesthetics, Frankfurt Am Main, Germany

Abstract: Auditory stimuli are often rhythmic in nature, and brain activity synchronizes to the rhythms in sounds. Stimulus-brain synchrony is advantageous for perceiving auditory information. Therefore, a clear hypothesis is that improving neural tracking, e.g., via transcranial alternating current stimulation (tACS), can aid auditory perception. In the present study we aimed to modulate auditory perception by using tACS to interfere with stimulus-brain synchrony. The effects of tACS on brain activity often show high inter-subject variability, due to

individual differences in brain anatomy and functional localization. Here, we used individualized electrode montages that were optimized to obtain the strongest electric field at individualized target regions determined based on functional imaging. In the first experiment, healthy human participants underwent an fMRI session where the BOLD signal was measured while they listened to frequency-modulated (FM) sounds. Regions showing higher activity during auditory stimulation when compared to rest, in bilateral temporal regions, were chosen as individual target regions for tACS. Individual FEM head models were created using structural MRI data and the electrode montage was optimized for each individual using Simnibs. In experiment 2, participants took part in two tACS sessions. In each session, participants listened to the same FM sounds modulated at 2Hz, while 2Hz tACS (using the individually optimized electrode montages) was applied at different phase lags relative to the auditory stimulus; we also included a sham condition. While listening to the sounds, participants detected silent gaps that were presented at different phases of the FM cycle. During the sham condition, gap detection was sinusoidally modulated by the FM-stimulus phase into which the gap fell. We hypothesized that, depending on the phase lag between tACS and the FM-stimulus, tACS could modulate gap detection in two different ways, 1) either by changing the FM-stimulus optimal phase for gap detection or 2) by changing the amplitude of the FM-stimulus-induced behavioral modulation. Cosine functions were fitted to hit rates to determine the optimal FM-stimulus phase and the amplitude of the stimulus-driven behavioral modulation. Best FM-stimulus phase for gap detection was not modulated by the tACS-sound phase lag. Compared to sham, we observed that amplitude of the FM-stimulus induced behavioral modulation was significantly smaller in the phase-lag opposite to the “best lag”. The results suggest that while tACS cannot overwrite neural tracking of the FM stimulus (no modulation of best phase), it can modulate its amplitude.

Title: Choice activity moderates sensorimotor associations within the V3A to CIP hierarchy

Authors: *R. DOUDLAH[1], T.-Y. CHANG[1], B. KIM[1], A. SUNKARA[2], A. ROSENBERG[1]; [1]Dept. of Neuroscience, Sch. of Med. and Publ. Hlth., Univ. of Wisconsin-Madison, Madison, WI; [2]WiSys Technol. Fndn., Madison, WI

Abstract: Visually guided behaviors require the brain to transform sensory signals into motor commands. To accurately and precisely represent an object, the visual system must solve the inverse problem of dissociating its three-dimensional (3D) orientation and position (i.e., 3D pose), which are confounded in retinal projections. To achieve desired goals, the 3D visual representations must then be associated with appropriate motor responses. We hypothesize that these transformations co-occur within a primary visual cortex (V1) to V3A to caudal intraparietal (CIP) area hierarchy. To test this, we used laminar probes to record from 692 V3A and 437 CIP neurons in three rhesus macaque monkeys while they simultaneously performed 3D orientation discrimination (3DOD) and visually guided (pop-up) saccade tasks. For the 3DOD task, planar surfaces were presented at different orientations and distances to investigate the sensory representation of 3D surface pose. Consistent with the hypothesized hierarchy, we found that 3D orientation and position were more dissociated in the responses of CIP neurons than V3A neurons. This finding implies that CIP encodes a higher-level, more robust 3D visual representation than V3A. Likewise, we found that a higher proportion of CIP neurons (44%) carried choice-related activity during the 3DOD task than V3A neurons (22%). Importantly, that difference was not explained by differences in inter-neuronal correlations within the areas. In both areas, neurons with more robust 3D selectivity tended to carry choice activity, suggesting that neurons which have resolved inherent sensory ambiguities may preferentially contribute to perceptual decisions. To explore potential sensorimotor associations, we first assessed if the neurons showed motor-related activity during the pop-up saccade task. Both areas contained similar proportions of neurons with saccade-related activity (V3A: 60%; CIP: 63%). Relative to the onset of the eye movement, saccade-related activity started in V3A (-108 ms) before CIP (-102 ms), suggestive of a feedforward saccade signal. We then compared the 3D orientation and saccade direction preferences to test for a sensorimotor association. In V3A, we found that sensory and motor preferences were aligned according to the task training, but only for neurons with choice activity. In CIP, both neurons with and without choice activity showed this association, but the relationship was stronger for neurons with choice activity. These findings imply a novel role for choice activity in moderating sensorimotor associations within the V3A to CIP hierarchy and call into question classical notions of sensory-motor dichotomies.

Title: Protracted development of visual category representation in human prefrontal cortex underpinned by cortical tissue changes

Authors: *J. K. YAO, Z. YAZDANI, J. GOMEZ;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: While occipitotemporal visual cortex has been the focus of studies examining how experience and development sculpt brain structure and function, little attention has been paid to the frontal lobe despite the known role it plays in visual processing. Here, we ask if prefrontal responses to ecologically relevant visual categories can be reliably observed relative to cortical folding patterns, and how functional responses may develop as children learn to read and improve face recognition skills. 29 children (ages 5-11) and 33 adults (ages 17-28) completed three runs of a visual category localizer while performing an oddball detection task. Contrast maps of faces, bodies, and words versus all other categories were produced for each subject, and volume of selectivity from thresholded t-value maps ($t>2.5$) on the cortical surface are quantified within regions of interest. We focus on ventrolateral prefrontal cortex (VLPFC), including cortex surrounding the precentral sulcus (PCS) and inferior frontal sulcus (IFS). We find that VLPFC is visually driven and shows prolonged functional development. Words and faces exhibit a hemispheric interaction: while face selectivity increases in the right hemisphere and is pruned from the left, word selectivity shows the opposite pattern ($F=8.7$, $p<0.005$). Body representation is larger in the right hemisphere but grows modestly in the left. A finer-grained anatomical analysis reveals that responses are not simply scaling with development, but that the distributed activation qualitatively changes across distinct anatomical segments of VLPFC. To quantify this, we divide VLPFC into anatomically-defined portions: inferior, superior, and dorsal PCS, and posterior (pIFS), middle (mIFS), and anterior IFS (aIFS). Face-related development is most pronounced in pIFS and dorsal PCS ($F's > 4.7$, $p's < 0.03$), while the mIFS shows the most body-related growth ($F=4.1$, $p<0.05$). For words, left mIFS and aIFS show the most striking developmental change ($F's > 6.2$, $p's < 0.01$). It is likely that such dramatic functional reorganization requires structural change. To verify this, all subjects also underwent quantitative MRI to acquire maps assessing brain tissue properties. We find strong evidence suggesting the underlying cortical tissue in these regions changes composition with development. For example, in right pIFS, where face responses undergo large functional change, the density of macromolecules grows into adulthood ($p's < 0.001$). Taken together, these findings reveal prefrontal structural-functional changes across development and stress the relevance of the frontal lobe in the maturation of visual processing.

Title: Exploring multiple aspects of the mouse visual cortex functional organization using optogenetic patterned stimulation.

Authors: *V. CHOUINARD[1], M. P. VANNI[2];
[1]Dept. de neurosciences, [2]École d'Optométrie, Univ. de Montréal, Montreal, QC, Canada

Abstract: Multiple studies have shown that mouse higher visual areas are involved in discrimination task through intricate functional properties and complex networks. However, it remains enigmatic how this highly connected network defines specialized perceptual roles in higher visual areas and how these interact in mouse behavior. Here we demonstrate the potential of a novel method to study the connectivity and perceptual roles of these extrastriate areas using patterned optogenetic photostimulation combined with mesoscopic calcium imaging. Compared to galvo-based methods, this approach offers the potential to increase the sensitivity and specificity of the stimulation. (A) Our first goal was to implement an innovative system of photostimulation using a **D**igital **M**icromirror **D**evice (DMD) which uses mirrors to precisely shape a light beam at 475nm (10mW/mm^2) homogeneously into a large surface covering the entirety of the dorsal cortex of the mouse. Validation on Channelrhodopsin-expressing mice showed robust local and long-range activations using the red calcium indicator jrGECO1a. Our methods have also been very robust at evoking complex movement of the forelimb and vibrissae in all tested mice (n = 3). Such innovative technology opens new doors in optogenetics as brain areas often have complex shape and are interconnected with remote areas. Our second goal (B) was to apply this novel method of photostimulation to generate a photo-inactivation paradigm. We hypothesized that the inactivation of one or more extrastriate areas impacts the functional properties of adjacent areas and feedback connections to the primary visual cortex. To perform this experiment, we combined calcium imaging using jrGECO with the chloride channel iC+ expressed in excitatory neurons. We also studied how visual perception was affected during spatially integrated optogenetic inactivation by training mice to perform visual discrimination tasks. Overall, studying visual perception require rigorous knowledge on the function and the organization of visual areas and this research will have the potential to bring new light unto this interaction. Finally, we demonstrate how the simplicity and versatility of experimental methods can be used to study multiple aspects of vision and brain function. Title: Cytoarchitecture scaffolds white matter connectivity of high-level ventral visual areas in children and adults

Authors: *E. KUBOTA[1], M. GROTHEER[2], J. GOMEZ[3], V. NATU[1], D. FINZI[1], A. REZAI[1], H. KULAR[1], M. NORDT[1], K. GRILL-SPECTOR[1];
[2]Dept. of Psychology, [1]Stanford Univ., Stanford, CA; [3]Princeton Univ., Princeton, NJ

Abstract: Classic theories of brain organization suggest that white matter connectivity, cytoarchitecture, and function all define a cortical region. Here, we use ventral temporal cortex (VTC) as a model system for testing the relationship between white matter connectivity, cytoarchitecture, and function. We tested if white matter tracts that connect to category-selective regions in VTC are organized by cytoarchitecture, function, or both using functional MRI (fMRI) and diffusion MRI (dMRI) in 27 children (ages 5-12) and 28 adults (ages 22-29). To test these hypotheses, in each participant we quantify the connectivity profile of white matter tracts that connect to each category-selective region of interest (ROI) in VTC in two ways: (1) the distribution of fibers across known bundles (dMRI models of anatomical fascicles) (2) the distribution of endpoints of white matter connections from each ROI to the rest of the cortical surface. We find that in both children and adults, connectivity profiles are similar between ROIs within the same cytoarchitectonic area, even if they are selective for different domains. Face (mFus-faces) and word (mOTS-words) selective regions in cytoarchitectonic area FG4 have similar connectivity to the posterior arcuate fasciculus (pAF), arcuate fasciculus (AF), and inferior longitudinal fasciculus (ILF). In contrast, we find that connectivity profiles are significantly different between ROIs in different cytoarchitectonic parcellations even if they are selective for the same domain. mOTS-words in FG4 has more connections to the pAF, while pOTS-words in FG2 has more connections to the vertical occipital fasciculus (VOF). Finally, we use an independent classifier to test if connectivity profiles can predict cytoarchitecture, category-selectivity, or ROI. Results show that in both children and adults connectivity profiles predict cytoarchitecture (mean classification accuracy = 0.87; SE = 0.02; chance level = .5) better than category-selectivity (mean classification accuracy = 0.61; SE = 0.03; chance level = .5) or ROI (mean classification accuracy = 0.55; SE = 0.03; chance level = .25). These findings show a tight coupling between white matter connections and cytoarchitecture and challenge the idea that regions selective for different categories have unique white matter connectivity profiles for category-specific processing.

Title: Spontaneous emergence of face-selective units in untrained deep neural networks

Authors: *M. SONG[1,2], S. BAEK[1], J. JANG[1], G. KIM[3], S.-B. PAIK[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., [3]Dept. of Physics, KAIST, Daejeon, Korea, Republic of

Abstract: In the visual cortex of primates, face-selective neurons are observed and considered the basis of facial recognition (Tsao, 2006). The observation of this type of intriguing neuronal tuning in the brain has inspired neuroscientists, raising important questions about its developmental mechanism — whether face-selective neurons can arise innately in the brain or require visual experience, and whether neuronal tuning to faces is a "special" type of function distinctive from tunings to other visual objects. Recently, model studies have used biologically-inspired deep neural networks (DNN) to predict the response of the ventral visual stream and provide insight into the underlying mechanisms of brain functions. Using a DNN model of the ventral visual stream, AlexNet, we showed that face-selective units can arise spontaneously in the complete absence of training. We measured the response of the last convolutional layer to a stimulus set of face and 5 non-face classes. We found face-selective units in the untrained network, where the face-units are defined as a unit that shows a significantly higher response to face images than non-face images. We found that their face-selectivity indices are comparable to those observed with face-selective neurons in the brain. The emergence of face-selectivity is robust across various conditions of initial randomization of the network. Next, to characterize the feature-selective responses of these face-selective units qualitatively, we reconstructed preferred feature images of individual units using a reverse-correlation method and a generative adversarial network algorithm. The obtained preferred feature images show that face-selective units are selective for a face-like configuration, distinct from units with no selectivity. Furthermore, we also tested whether the selective responses of these face units could provide reliable information with which to distinguish between faces and non-face objects. We confirmed that face-selective units enable the network to perform face detection. Intriguingly, we

found that units selective to various non-face objects can also arise innately in untrained neural networks, implying that face-selectivity may not be a special type of visual tuning and that selectivity to various object classes can arise innately in untrained deep neural networks, spontaneously from random feedforward wirings. Overall, our results imply a possible scenario in which the random feedforward connections that develop in early, untrained networks may be sufficient for initializing primitive face-selectivity as well as selectivity to other visual objects in general.

Title: Neuronal basis of dynamic, reliability-dependent cue integration for 3D visual perception

Authors: *T.-Y. CHANG[1], R. DOUDLAH[1], B. KIM[1], A. SUNKARA[2], A. ROSENBERG[1]; [1]Univ. of Wisconsin–Madison, Madison, WI; [2]WiSys Technol. Fndn., Madison, WI

Abstract: The visual system transforms two-dimensional retinal projections into robust (i.e., accurate and precise) three-dimensional (3D) percepts, allowing us to successfully interact with our surroundings. Constructing robust 3D representations requires the integration of distinct sensory signals, including stereoscopic and perspective cues. The reliability of these cues depends on the object's pose (orientation and position). Previous studies have shown that primates perceptually integrate these cues with weights that are dynamically set according to the pose conditions. However, it remains unclear where and how that neural computation is performed. We, therefore, trained macaque monkeys to perform a 3D orientation discrimination task using cue-isolated and combined-cue stimuli at two pose conditions with different relative cue reliabilities. Neuronal responses were then recorded from the caudal intraparietal (CIP) area using laminar probes while the task was performed. At each pose, we found that the number of neurons tuned for a given cue reflected the perceptual sensitivities, such that more neurons were tuned to the cue to which the animals were most sensitive. For neurons tuned to both cues, the cue-specific orientation preferences were highly similar. Consistent with cue integration and decoding models, combined-cue responses were greater in magnitude than cue-isolated responses, and neuronal response magnitude was highly correlated with behavioral sensitivity. To estimate the neuronal cue integration weights, we fit the combined-cue responses using a

linear weighted summation of the cue-isolated responses. The weights changed with the stimulus pose such that greater weight was assigned to the more reliable cue, mirroring the behavioral data. We then used an information-theoretic approach to compute the optimal cue weight ratio that would maximize the Fisher information of the combined-cue responses. The measured weight ratios from the linear fits and the optimal weight ratios were highly correlated, indicating that the information for performing the task was roughly maximized. These findings suggest that CIP neurons encode high-level 3D visual representations through dynamic, reliability-dependent reweighting of stereoscopic and perspective cues in an optimal manner.

Title: Distributed context-dependent choice information in mouse dorsal-parietal cortex

Authors: *J. ORLANDI, M. ABDOLRAHMANI, R. AOKI, D. LYAMZIN, A. BENUCCI; RIKEN Ctr. for Brain Sci., Wakoshi, Japan

Abstract: Choice information appears in the brain as a distributed signal in multi-area networks, mixed with sensory, motor, and cognitive variables. In dorsal-parietal cortical regions—traditionally implicated in decision computations—the presence, strength, and area specificity of choice signals are highly variable, limiting a cohesive understanding of their computational significance.In this study, examining the mesoscale activity in mouse posterior cortex during a complex variant of a two-alternative forced choice visual discrimination task, we found that broadly distributed choice signals defined a decision variable in a low-dimensional embedding space of multi-area activations, particularly along the ventral visual stream. The decision variable was linked to neural trajectories for left and right choices that significantly separated at the onset of the animal's actions with a discrimination strength that ramped up before movement onset ($\Delta d' = 0.2$, $p < 0.001$). The embedding choice subspace obtained using a novel tensor decomposition technique, locaNMF, was near-orthogonal ($\Theta > 80°$, $p < 0.001$) to concurrently represented sensory and motor-related activations. The neural trajectories linked to the decision

variable were modulated by task difficulty and contextually by the animals' attention state, with easier trials during bouts of high sustained attention showing the greatest separation (d'=1.4 ± 0.1) and significantly higher than in low attention bouts (p = 0.003).To mechanistically relate choice representations to decision-making computations, we trained recurrent neural networks (RNN) with the animals' trial-by-trial decisions, including their mistakes, and found an equivalent decision variable whose context-dependent representational dynamics agreed with that of the neural data. The trained RNN reproduced the animals low-dimensional representation as well as their context-dependent modulations. In conclusion, our results demonstrated a decision variable broadly represented in the posterior cortex, controlled by task features and cognitive demands. Its dynamics reflected decision computations, possibly linked to context-dependent feedback signals used in variable animal-environment interactions.

Title: Processing of visual textures in primary and secondary visual cortex of the mouse

Authors: *F. BOLANOS[1,2], J. G. ORLANDI[1], A. V. JAGADEESH[3], J. L. GARDNER[3], A. BENUCCI[1,2];
[1]RIKEN Ctr. for Brain Sci., Wako-shi, Japan; [2]Mathematical Informatics, The Univ. of Tokyo, Tokyo, Japan; [3]Wu Tsai Neurosciences Inst., Stanford Univ., Stanford, CA

Abstract: Textures are a useful class of visual stimuli for studying the circuit-level underpinnings of core object recognition along the visual stream. Textures are sufficiently complex to largely match the statistical properties of natural images, and, unlike natural images, they can be precisely parameterized. Examining the cortical processing of texture stimuli in mouse animal models is useful in light of the abundant tools available for dissecting neural circuits. However, whether the mouse visual system enables a differential encoding of texture

information (as it has been shown in primates) is largely unknown. We addressed this question by presenting mice with two types of stimuli, textures and spectrally matched noise (scrambles) whose low-level features matched those of the textures. While mice passively viewed the stimuli, we performed widefield and two-photon calcium imaging via virally expressed jGCaMP7f. At the widefield level we observed a differential modulation of textures relative to scrambles in the primary and secondary visual cortex (V1, LM); differences in modulation were larger in LM compared to V1 (LM = 21.3 ± 2.8 %, V1 = 13.6 ± 2.5 %, p = 0.013, t-test, n = 6 mice). In the two-photon experiments, we imaged large populations of neurons in areas V1 and LM, and found that the average single cell discriminability (d' measure) between textures and scrambles was significantly larger in LM than in V1 (d' = 0.26 ± 0.05 in V1, d' = 0.60 ± 0.06 in LM; p = 0.009, t-test, n = 5 mice). The difference between LM and V1 suggests a response modulation driven by the higher-order statistical features in texture stimuli. In conclusion, by presenting well-controlled and parameterized stimuli for which the main axis of variation depends on high-order statistical information, we found that the mouse ventral visual stream supports a hierarchical processing of textural information, suggesting that also in this species textures may be relevant for ethological behaviors.

Title: Probabilistic discrimination of relative stimulus features in mice

Authors: *D. LYAMZIN, R. AOKI, M. ABDOLRAHMANI, A. BENUCCI;
RIKEN Ctr. for Brain Sci., Wako-shi, Japan

Abstract: During perceptual decision-making, information about the stimulus and the upcoming decision is encoded in mixed representations within the same brain areas and neuronal populations. Studying decision computations in isolation thus requires tailored experimental design, such as one where decisions depend on a relative property of a stimulus. In this case, the

same amount of decision information can be given by different combinations of physical stimuli, neural representations of which can be factored out during data analysis. Mouse is a recently popular animal model in the research of visual decision-making thanks to the powerful genetic tools available for the dissection of brain circuits. However, whether mice can perform a relative visual discrimination task has not yet been fully established. Here we show that mice (n = 40, 1.3 million trials) can solve a complex version of orientation discrimination task, in which they indicate the more vertical of the two stimuli, and in which the same amount of sensory information can be given by many stimulus combinations as long as the difference in their verticalities is the same. Using this task, we show that mice have a typical orientation discrimination acuity of 9°, reaching 6° for one mouse tested with the smallest angular separation of 3°, which challenges the common belief that mice are poor visual discriminators. To reach these conclusions, we introduced a novel probabilistic choice model that explained behavioral strategies and demonstrated that the circularity of the stimulus space serves as an additional source of choice variability for trials with a fixed difficulty. The model explained additional 9.03% ± 1.48% of deviance fraction in comparison to a classic psychometric curve. Furthermore, the model accounted for history-dependent choice biases (explaining additional 5.07% ± 0.98% fraction of deviance) and demonstrated their dependence on the level of animal's task engagement: whenever an animal was less engaged in the task, as indicated by very short (within 10th percentile) reaction times possibly corresponding to compulsive choices, the decisions were driven by history biases more strongly than on trials with intermediate reaction times. Our results demonstrate that mice can be trained in a relative orientation discrimination tasks to a high discrimination acuity and that they adopt a diverse set of individual strategies that may co-vary with their cognitive state.

Title: Co-speech gestures impact the whole-brain distribution of brain regions involved in the semantic representation of words.

Authors: *B. WANG[1], S. ALIKO[1,2], J. I. SKIPPER[1];
[1]Exptl. Psychology, [2]London Interdisciplinary Biosci. Consortium, Univ. Col. London, London, United Kingdom

Abstract: Some co-speech gestures contribute meaning to spoken words, resulting in better comprehension. Previous studies demonstrate that the processing of these involves 'typical'

language regions, reducing semantic selection and retrieval demands as indexed by processing in the inferior frontal gyrus (IFG). Work on the semantic representations of words demonstrates that they are distributed across the entire brain in a manner that mirrors their sensorimotor properties. Does the semantic content conveyed by gestures interact with that of words only in the IFG or across these more distributed regions? We address this question in a preliminary study, analyzing the fMRI data of six participants from the Naturalistic Neuroimaging Database (3 female; mean age = 22.17 yrs old) who watched the same movie. We analyzed the patterns of brain activity for spoken words and co-speech gestures in the movie using a combination of automated gesture annotation, voxelwise modeling, principal component analysis and clustering. Our cluster analysis revealed three groups of spoken words that were related to actions (e.g., 'think', 'watch', 'listen'), objects (e.g., 'mayor', 'clock') and numbers, and syntax (e.g., 'the', 'for', 'that'). These groups involved a distributed set of brain regions, including the right posterior fusiform gyrus, left central sulcus and inferior precentral and postcentral gyri, and mid-superior parieto-occipital sulcus, respectively. We also identified a number of cortical regions involved in gesture processing that overlap with 'canonical' language regions, including Heschl's gyrus, planum temporale, right STG, and left middle temporal gyrus. They also recruited the left inferior pars triangularis and right inferior temporal gyrus for 67% of participants. In addition, gestures and action words colocated in a further set of distributed regions related to actions in the left anterior angular/parietal cortex. Gestures and object/number words recruited Heschl's gyrus, STG, left planum temporale, and left inferior temporal sulcus. Overall, preliminary results suggest that 'typical' language regions play a crucial role in processing co-speech gestures including the IFG. However, we also show that both words and gestures share a distributed semantic representation in brain regions in and beyond these language hubs. Thus, these results suggest that meanings of co-speech gestures more than impact the selection and retrieval of words but also impact the semantic representation involved in word processing, involving the whole brain.

Title: Exploring the hierarchical organization of the infant visual system with model-based representational similarity

Authors: *C. T. ELLIS[1], T. S. YATES[1], L. J. SKALABAN[1], A. J. BRACHER[2,3], N. B. TURK-BROWNE[1];
[1]Psychology, Yale Univ., New Haven, CT; [2]Intl. Max Planck Res. Sch. on Neurosci. of Communication, Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Dept. of Child and Adolescent Psychiatry, Psychotherapy, and Psychosomatics, Univ. of Leipzig, Leipzig, Germany

Abstract: What is the nature of infant visual experience and how is this content represented in their visual system? In the mature human brain, there is a hierarchy of selectivity across visual areas, from low-level features (e.g., edges, luminance) in V1, to mid-level features (e.g., shapes, parts) in V4, to high-level features (e.g., object identity, category) in lateral occipital cortex. It is unclear how and when during development the visual system acquires this organized selectivity. In adults, prior studies have revealed the hierarchical organization of the visual system by comparing different layers of a convolutional neural network model with patterns of fMRI activity in visual areas. We applied this model-based approach to three cohorts of awake infants watching different movies during fMRI. The first cohort was used to optimize the analysis pipeline and included 15 sessions from infants aged 3-36 months. This pipeline was then applied to a second (38 sessions with infants aged 4-18 months) and third cohort (16 sessions with infants aged 4-32 months). For each cohort, we collected fMRI data from adults as a mature baseline. These data were analyzed by feeding frames of the movies into the VGG-19 computer vision model and calculating a time-by-time similarity matrix using the activation patterns for each layer. Using analogous time-by-time similarity matrices from the patterns of fMRI in different visual areas, we measured representational similarity with the model layers to determine the expression of low-, mid-, and high-level features in each area. In both infants and adults, VGG-19 explained significant amounts of variance in the fMRI data. Different from adults, infants did not show evidence of hierarchical organization: V1 and lateral occipital cortex represented features of all levels of complexity similarly. The lack of a hierarchy of selectivity in the infant visual system indicates that such specialization emerges later in development. This in turn may explain the dramatic changes in visual abilities that occur throughout childhood.

Title: The temporal profile of dynamic facial expression perception as revealed through EEG-based decoding and movie reconstruction

Authors: *T. ROBERTS, G. C. CUPCHIK, J. S. CANT, A. NESTOR;
Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstract: Extensive research has investigated the perception of facial expressions, typically focusing on only a handful of basic and static emotional expressions. However, in our daily experiences we rarely encounter static expressions that perfectly fit these stereotypical expressions. Specifically, this study aims to provide a more complete understanding of the representational nature and temporal signatures underlying dynamic facial expression perception. We address these gaps through EEG-based decoding and movie reconstruction. EEG data were collected from healthy adults who viewed 1-second videos each displaying 1 of 24 dynamic facial expressions from two identities while performing an oddball task (i.e., angry expression recognition). Each stimulus began with a neutral expression and proceeded to a peak expression display over the course of ten 100ms frames. In addition, participants performed a behavioral pairwise similarity rating task with the same 24 expressions. First, we used EEG-based pattern analyses for expression decoding, then conducted a detailed investigation into the temporal dynamics of expression decoding to better profile dynamic expression perception. Lastly, we relied on pattern analysis techniques to conduct movie reconstruction from EEG data to uncover and visualize the structure of neural representations underlying expression recognition. Our investigation shows that the broad representational space of facial expressions derived from behavioral and neural data is generally accounted for by the classical dimensions of valence and arousal. Second, the temporal profile of EEG-based decoding shows a gradual increase in classification accuracy after 350ms reaching a plateau between roughly 600-1200ms following stimulus onset. Further, a frame-by-frame analysis indicates that peak decoding accuracy is reached at an intermediate step (i.e., the 6th frame of the video), prior to the apex expression (i.e., the 10th frame). Third, movie reconstruction is successfully achieved from EEG signals and, consistent with our decoding results, shows that reconstruction accuracy is highest after the midway point of a dynamic stimulus. Our results shed light on the neural and temporal representational structure of dynamic facial expressions. Our results characterize the time course of expression perception and reveal that peak discrimination occurs prior to the availability of a maximally informative peak expression. Of note, our reconstruction results elucidate the pictorial content of a dynamic expression with exceptional detail while also providing evidence for the possibility of EEG-based dynamic stimulus reconstruction.

Title: Exploration path trajectory during self-guided viewing of complex photographs and paintings predicts brain activity patterns in the default network

Authors: *X. LI, E. MUSZ, B. BELLANA, Z. ZUO, J. CHEN;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Studies of scene perception often focus on what can be gleaned from a brief (<1 second) visual presentation, such as the general category or objects within a scene. However, in real life, people may take several seconds, or even minutes, to make sense of a complex scene. As each person takes their own "exploration path" through a visual scene, how does the history of their path influence their understanding of the next moment? How do neural responses reflect the process of making sense of a complex scene over time? In this fMRI study, we tested whether exploration paths during extended perception of complex images could predict neural responses within and across individuals. We recorded brain activity while participants viewed a set of five images and described aloud what they saw (N=17, 6-31 min). For analysis, each of these complex scenes was segmented into constituent people, objects, and environmental landmarks; each participant's utterances and corresponding brain data were labeled according to these segments. We first tested whether each image segment elicited a distinctive multi-voxel activity pattern that was replicable across individuals, regardless of temporal order. In both early visual cortex and in the default network, we observed segment-specific activity patterns—i.e., patterns were more correlated across people during descriptions of matching versus non-matching image segments, irrespective of the order in which the segments were mentioned. Next, we tested whether brain activity was sensitive to this exploration trajectory. For each subject we determined the order in which segments were described, and calculated similarity between all possible pairs of subjects; these correlations showed high similarity across subjects' exploration paths (Spearman's r= .47). Comparing the subject pairwise similarity matrices of these paths, we also found that relationships between subjects were consistent across images (Pearson's r= .70). The path similarity matrix was then used to predict subject-pairwise pattern similarity (inter-subject representational similarity analysis, IS-RSA; Chen et al., 2017; Finn et al., 2018; Nguyen et al. 2019) in selected brain regions (N=12). Results showed that path similarity predicted brain pattern similarity in posterior medial cortex (p=.03) and the entire default network (p=0.05), but not in early visual cortex (p=.16) or early auditory cortex (p=.26). Next, we will test whether subjects with similar exploration paths evince increasingly similar brain activity patterns over time as their comprehension of each scene matures, followed by an analysis of inter-subject similarity during cued recall of the images.

Title: Encoding and decoding models of music perception in the human brain

Authors: *L. BELLIER[1], A. LLORENS[1], D. MARCIANO[1], P. BRUNNER[2], G. SCHALK[3], R. T. KNIGHT[4], B. N. PASLEY[1];
[1]Knight lab, Helen Wills Neurosci. Inst., Berkeley, CA; [2]Nat. Ctr. for Adapt. Neurotechnologies, Albany Med. Col. / Wadsworth Ctr., Albany, NY; [3]Nat. Ctr. for Adapt. Neurotechnologies, Albany, NY; [4]Univ. of California Berkeley, Berkeley, CA

Abstract: Music is core to human experience and multiple brain regions have been reported to be engaged in music perception. However, the temporal dynamics of regional neural activity during music processing (e.g., rhythm) are largely unknown. To better understand the neural code for music, we used predictive modeling tools applied to intracranial EEG data recorded from 2,668 electrodes across 29 neurosurgical patients, who passively listened to a song (Another Brick in the Wall, Part 1; Pink Floyd). We used encoding models to identify electrodes encoding acoustic information about the song and to analyze their tuning patterns. We then performed an ablation analysis by selectively removing sets of music-active electrodes from linear decoding models, to assess how anatomical and functional regions represent information about the song's acoustics. Finally, we explored to what extent we could reconstruct an intelligible song from neural activity and quantified the impact of methodological factors on decoding accuracy.
We focused on high-frequency activity (HFA; 70-150 Hz) which is linked to neural population activity. Using Spectro-Temporal Receptive Fields (STRFs) as encoding models combined with HFA recording, we confirmed previous findings showing a central role of bilateral Superior Temporal Gyri (STG) in music perception. We also highlighted the involvement of bilateral Sensory-Motor Cortices (SMC) and Inferior Frontal Gyri (IFG) and observed a right hemispheric dominance for music perception. Using both a component analysis and temporal modulations, we found these cortical regions to be tuned to specific musical elements (presence of vocals, onsets of lead guitar motifs, sixteenth notes of the rhythm guitar). Within bilateral STG, we observed partially overlapping neural populations also representing these elements.
We performed an ablation analysis which is equivalent to virtually lesioning elements of the

music network. Compared to a baseline model using all 347 significant electrodes, we found that ablating electrodes from left or right hemispheres both deteriorated decoding accuracy, suggesting they each contain important, unique information and documented a right hemispheric dominance for music perception.
By exploring methodological factors impacting the performance of decoding models, we found a logarithmic relationship between decoding accuracy and either the number of electrodes or the dataset duration. Lastly, only non-linear decoding models were able to reconstruct an intelligible song from neural activity.

Title: Measurement of mismatch negativity for changes of melody contour : Effects of contour shape and music training

Authors: *U. NAITO[1], R. SHIBA[2], S. OTSUKA[1,3,4,5], S. NAKAGAWA[1,3,4,5];
[1]Dept. of Med. Engineering, Grad. Sch. of Sci. and Engineering, Chiba Univ., Chiba, Japan; [2]Global Res. Ctr. for Logic and Sensibility, Keio Univ., Tokyo, Japan; [3]Ctr. for Frontier Med. Engineering, Chiba Univ., Chiba, Japan; [4]Med-Tech Link Center, Chiba Univ. Hosp., Chiba, Japan; [5]Grad. Sch. of Medicine, The Univ. of Tokyo, Tokyo, Japan

Abstract: It is well-known that music evokes our emotions. Although such properties of music have been applied to music therapy, the neural basis of music perception and cognition is still unclear. Melody is one of the three main elements of music and includes several factors such as pitch, contour, tonality, and rhythm. The “contour” means a temporal pattern of ascendance and/or descendance of pitch. Humans are thought to perceive melodies as two pieces of temporal information; the contour and the interval (difference of pith between successive two sounds). However, there have been few studies on brain functions related to the perception of the melody contour and the neural mechanisms remain unclear. On the other hand, many studies have reported that musical experiences (trainings of music) affect the perception characteristics and neural responses to sounds, and even the anatomy of the cortex. Therefore, similar changes depending on the musical experiences may be observed also in the melody perception. We measured mismatch negativities (MMNs) for changes of melody contours and pitch in musicians and non-musicians. Five-note tone sequences were used as stimuli. First, four types of standard stimuli with different melody-contour shapes (rising-falling/falling-rising/rising/falling) were

generated by changing the pitch of each note. Second, seven types of deviants were generated by changing the pitch of the third note of each standard stimulus. MMN measurements were conducted 4 times in each subject with different combinations of a standard and seven deviant stimuli. As results, in the musicians, larger MMNs appeared for the change of the melody contour, i.e., a shape of pitch change of the entire sequence, than for the pitch change of the third tone. In term of effects of the melody-contour shape, MMN amplitude were significantly larger for the rising-falling and the falling-rising shape. In addition, the latency of the MMN was shorter in the musician compared to the non-musician. In contrast, in the non-musicians, larger MMNs tended to appear when the pitch change of the third note was maximum . No particular tendency common to all the contour shape was observed.These results indicated that musical experience enhances the ability to perceive sound sequences as a group and consequently improves the discrimination of melody contours, and increases the speed of melody processing. It is also shown that more complicated melody contour elicits larger MMN in the musicians, whereas no significant effects of the melody contour were observed in the non-musicians.

Title: Investigation of effects of the aesthetic preference on the perception of human walking: a preliminary study using event-related potentials

Authors: *S. HAYASHI[1,2], Y. NISHIMURA[3,2], Y. IKEDA[4,2], Y. EGASHIRA[1], M. UKEZONO[1], S. UONO[1], T. OKADA[1], S. HIGUCHI[2];

Abstract: We have an aesthetic preference for daily motion (i.e., walking) as well as artistic activities (i.e., dance performances). This study investigated the effect of the aesthetic preference on visual processing of human walking using event-related potentials (ERPs). Twenty male university students observed point-light movies representing human walking (like a runway model, with good posture, and with bad posture) and their scrambled motion. They were asked to discriminate whether the stimulus is human walking or not. The ERPs at left-/right-occipitofrontal areas (N200 and N300), reflecting the perceptual and attentional processing of visual stimuli, were measured. Participants' evaluation of stimuli showed that they aesthetically

prefer movies especially of model and good posture walking. The analysis of variance with the dot type (biological / scrambled), walking type (model / good posture / bad posture) and laterality (right / left) as within-participant factors for the N200 and N300 revealed significant main effects of dot type, which were qualified by a significant dot type × walking type interaction. The follow-up analysis showed the N200 elicited by the biological motion was larger than that by the scrambled motion for the good and bad posture, but not for the model. The analysis also showed N300 for biological motion were larger than that for scrambled motion regardless of walking types, though the simple effect of walking type was observed for the scrambled motion. The results suggests that the N200 reflect visual processing of biological motion, which is disturbed when the stimuli represent unusual walking (i.e., model walking), while the N300 reflect recognition of integrated human walking regardless the walking type. We also conducted exploratory regression analyses with the aesthetic-preference score of the stimuli as independent variables for the ERPs. The N300 for biological but not for scrambled motion were negatively deflected with increasing the aesthetic-preference scores. There is no significant effect of the aesthetic-preference scores for the N200. The results suggest that the N300 also reflect aesthetic preference when the stimuli represent human motion. In summary, this study suggests that the N200 was involved in processing of familiar biological motion, while the N300 was involved in integration of forms and optic-flow/motion information of biological-human motion as well as extracting the aesthetic information of biological motion even without detailed featural information of the walkers.

Title: Predictive neural representations of sensory input revealed by a novel dynamic RSA approach

Authors: *I. E. J. DE VRIES, M. F. WURM;
Ctr. For Mind/Brain Sci., Rovereto, Italy

Abstract: To successfully navigate dynamic environments, we need to constantly update our inner representations of external dynamic information, such as actions of others. This poses a fundamental problem: how does the brain cope with a stream of constantly changing input? It takes time to transmit and process each retinal image. Consequently, do we represent the world in a lagged manner, or does the brain generate predictions of unfolding dynamics? Our capacity

to react to dynamic stimuli in a timely manner indeed demonstrates that our brain predicts future events. However, the representational nature of such predictions remains largely unexplored. One method that considers neural representations of sensory input is representational similarity analysis (RSA), which typically uses static models to investigate how stimulus features (e.g. color, category) are represented in the brain. We developed a dynamic extension to RSA that uses temporally variable models, i.e. a unique model for each time point, to capture the representational nature of dynamic stimuli (dynamic RSA hereafter). At each time point, the model representation is not only compared to the neural representation at the same time point, but also at all other time points during stimulus presentation, resulting in a model-time by neural-time dynamic RSA. Here we applied this approach to MEG data of 21 healthy human subjects who observed 14 unique 5-sec-long videos showing a sequence of smoothly connected ballet figures (~35 repetitions per video). Dynamic RSA revealed unique insights into the representation of low-level visual, body posture and kinematic features: Both low- and high-level information was represented ~ 110 - 300 msec after the actual visual input, but with low-level information being represented most prominently in occipital areas, and higher-level information in slightly more anterior (parieto-temporal) areas. Strikingly, the motion of the ballet dancer was not only represented in a lagged manner, but also in a second distinct temporal window that preceded the actual input by ~ 140 - 180 msec, indicating that these neural representations predicted future motion. Taken together, dynamic RSA reveals delayed bottom-up and predictive top-down processing in naturalistic dynamic stimuli. As such, it offers a novel approach to investigate how and when our brain represents the dynamics of the world. More generally, it can be used to study interesting concepts such as predictive coding not only in naturalistic visual stimuli, but also across a wide range of other domains such as auditory perception, language or action planning.

Title: Evidence for domain-specific neural adaptation reductions in autism spectrum disorder

Authors: *A. D'MELLO[1], I. R. FROSCH[2], S. L. MEISLER[3], H. GROTZINGER[4], T. K. PERRACHIONE[5], J. D. GABRIELI[1];

[4]UC Santa Barbara, Santa Barbara, CA; [5]Speech, Language, and Hearing Sci., Boston Univ., Boston, MA

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder defined by impairments in social communication and the presence of restricted interests and repetitive behaviors. There is empirical and theoretical evidence that across domains of impairment, individuals with ASD may have a reduced capacity to predict events and use predictions to rapidly adapt to changing situations. It has been hypothesized that many core diagnostic features of ASD, both sensory and cognitive, may be associated with these difficulties in adaptation, and that adaptation may be a mechanism that supports prediction by distinguishing familiar from novel events. Here, we tested the hypothesis that adults with ASD exhibit reduced neural adaptation across a broad range of materials, and that reduced neural adaptation is associated with ASD behaviors.

We assessed neural adaptation with functional magnetic resonance imaging (fMRI) in n=26 neurotypical and n=29 ASD adults. Participants passively attended to repeating and non-repeating stimuli across four domains: faces, spoken words, text, and objects. Neural adaptation was measured by contrasting activation from repeating and non-repeating blocks (non-repeating > repeating). Across all participants, neural adaptation was strongest in stimulus-specific processing cortical regions. Importantly, group differences in neural adaptation were domain specific: individuals with ASD showed reduced neural adaptation to faces in the fusiform face area (FFA) but not for other stimuli such as objects, text, or speech. Reduced neural adaptation in the FFA was associated with greater social and communication difficulties in individuals with ASD. In addition, compared to neurotypical individuals, individuals with ASD showed reduced functional connectivity between the dorsolateral prefrontal cortex and FFA when attending to repeating faces.

These findings suggest that reduced neural adaptation in ASD may be specific to domains that are most relevant to the ASD phenotype (e.g., faces for social processing). Further, differences in neural adaptation in the FFA in ASD may be driven in part by reduced top-down influences from the prefrontal cortex.

Title: Determining the direction of communication between sensory cortex and hippocampus during expectation signalling

Authors: *O. WARRINGTON, N. GRAEDEL, M. F. CALLAGHAN, P. KOK;
Wellcome Ctr. for Human Neuroimaging, UCL Queen Square Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: The hippocampus (HC) holds a central point of interest for many different cognitive functions such as memory, spatial navigation, perception, and mental imagery. Therefore, a principal aim of cognitive neuroscience is to determine the functional role of HC interactions with the cortex. Until recently, these investigations required a trade-off between high spatial resolution with invasive animal techniques or lower resolution in human neuroimaging studies. Now, we can combine advances in ultra-high field MRI of the medial temporal lobe with layer-specific fMRI analyses to answer questions about functional connectivity between the HC subfields and the neocortex. The key to inferring the direction of communication is the entorhinal cortex, as it serves as the primary relay between the HC and cortex. Feedforward connections from the cortex travel to CA3, CA1 & DG via the entorhinal cortex superficial layers, while feedback connections travel from CA1 & subiculum to the deep layers. Therefore, by dissociating the layers of the entorhinal cortex with layer-specific fMRI, we can infer the directionality of functional communication between the HC and sensory cortex. This method could be utilised in studies crossing cognitive boundaries, and here we present a case study asking how the HC communicates with the cortex during the prediction of visual shape. At 7T, we optimised BOLD-sensitive 3D gradient-echo EPI to perform fMRI in the medial temporal lobe, with particular focus on minimising distortion and signal dropout. Participants perform an established shape discrimination paradigm in which auditory cues validly predict the upcoming visual shape on 75% of trials. Crucially, we omit the expected shape entirely on the remaining 25% of trials, allowing isolation of the top-down expectation signal from bottom-up sensory input. This paradigm, in combination with multivoxel shape decoding, allows us to determine which HC subfields and entorhinal cortex layers represent the expected-but-omitted shape. Additionally, functional connectivity analyses using the layers of the entorhinal cortex as seeds enable charting the wider cortical network involved in communication to and from the HC. This cognitive neuroscience paradigm represents a big step forward in studying the communication between hippocampus and neocortex in the human brain, a topic of great relevance to many cognitive domains ranging from memory and navigation to perception and imagery.

Abstract: Sounds play a major role in the comprehension of spoken speech. However, meaningful information provided by visual cues (such as speech content, timing, and speaker identity) facilitates speech perception, perceptually enhancing relevant information for the listener. This information includes the speaker's voice as well as articulatory movements from the speaker's face and lips. While several studies have shown broadband activation of auditory regions in response to visual speech, the information represented by these activations remains poorly understood. Indeed, our recent electrocorticography research demonstrates that visual speech modulates auditory speech processing at multiple temporal, spatial, and spectral scales, indicating multiple discrete influences of vision on speech. As a first step to understand what visual information is encoded within the auditory system, we used functional magnetic resonance imaging (fMRI) to investigate if visual activation of auditory areas reflects linguistic content from visual speech. The present study collected data from a large sample of individuals (n=64, based on a power analysis and pre-registered at osf.io) who were presented with three phoneme exemplars (consonant-vowel pairs such as /fafa/) and three visemes (videos showing articulations for each phoneme) in a randomized event-related design. To understand the extent to which linguistic information is encoded in auditory regions during visual speech, we trained and tested classifiers to discriminate between (1) the three specific phonemes, (2) the three specific visemes, (3) as well as tested phoneme-trained models' ability to classify visemes. Analyses were performed using a whole-brain searchlight classifier as well as ROI-based analyses focusing on auditory regions. Results from the searchlight analyses showed significant above-chance classification accuracy in both the phoneme and viseme conditions in auditory regions, including the posterior superior temporal sulcus (pSTS) and superior temporal gyrus (STG). Results from the ROI analysis showed a similar pattern. These results demonstrate that visual speech crossmodally activates and encodes linguistic information in auditory regions, confirming that auditory activations by visual speech are not merely due to attention or arousal effects.

Title: Deaf people show a weaker flash-lag illusion

Authors: *M. AMADEO, A. TONELLI, C. CAMPUS, M. GORI;
Italian institute of technology, genova, Italy

Abstract: Deaf people show a weaker flash-lag illusion
SUMMARYAccording to the flash-lag illusion (FLI), a brief flash quickly presented with a moving target appears to lag behind the moving stimulus. Over the years, numerous theories have been proposed to explain FLI, discussing whether it is more a spatial or a temporal phenomenon. However, none of them has ever investigated whether and how auditory deprivation interferes with the development of this illusion. Studying how the lack of auditory stimulation influences a visual illusion may give important insights into its underlying mechanisms and the potential role of multisensory processes. Since deafness is a natural model to investigate how neural reorganization following hearing loss influences perception, we tested a group of 13 early deaf and 18 hearing individuals with a visual FLI paradigm. The experiment consisted of two vertically aligned bars moving rightwards or leftwards and a static bar that briefly flashed between them. The static bar could appear in two different portions of the visual field on the horizontal plane: i) within the fovea or ii) in the periphery of the visual field. The instruction was to judge whether the flashed bar spatially appeared to the left or the right with respect to the moving bars. Results showed a reduction of the flash-lag effect following early deafness, independently of the spatial eccentricity of the static bar (i.e., central and peripheral visual field). Moreover, only for deaf individuals, there was a positive correlation between the flash-lag effect in the peripheral and central visual field, suggesting that the mechanisms underlying the effect in the center of the visual field expand to the periphery following deafness. These findings suggest that plastic changes due to early auditory deprivation profoundly impact visual mechanisms underlying the FLI, and multisensory integration processes are involved in developing the illusion.

Title: Effects of presenting first-person camera images in the background of a book on motion sickness when reading with a head-mounted display

Authors: *T. SUWA[1], Y. SATO[2], M. MAKIDA[1], T. WADA[2];
[1]Ritsumeikan Univ., Kusatsu-Shi, Japan; [2]Nara Inst. of Sci. and Technol., Ikoma-Shi, Japan

Abstract: <META NAME="author" CONTENT="諏訪 司(is0414if)">With the development of virtual reality (VR) technology, head-mounted displays (HMDs) are often used to view or read 2D content, such as videos and books, in a vehicle; however, when the 2D content are displayed in a fixed position on the display (head coordinate system), the visual appearance does not change even with head movement, and the body movements cannot be perceived from visual sensation. This cause conflicts with the body-movement information obtained from vestibular sensation. This visual–vestibular conflict may also cause severe motion sickness. However, previous studies have not clarified the means to reduce motion sickness when watching 2D content on HMDs while riding in a vehicle. Therefore, the purpose of this study is to investigate whether the motion sickness in reading with an HMD can be reduced by allowing readers to perceive body movements through visual sensation in situations where the body vibrates, such as riding a vehicle. Participants performed 20-minute reading tasks in which they read a book displayed on a HMD while seated in a device that vibrated randomly in the pitch direction. Because the book was fixed to the head coordinate system of the HMD, the appearance of the book was constant, and the participants could not perceive body movements through visual sensation. Two experimental conditions were explored: the first was the camera background condition in which the user could perceive his or her body movements through peripheral vision via real-time images of the first-person viewpoint obtained from the front camera mounted on the HMD in the background of the book; the second was a white background condition in which the background of the book was completely white (no movement) and the participants could not visually perceive their movements. The misery scale of motion sickness after the reading task was evaluated using a 11-point questionnaire, and the results indicated that motion sickness was significantly lower in the camera background condition than the white background condition. This suggests that when watching 2D content on a HMD in situations where the body is in motion, such as riding a vehicle, the sensory conflict between visual and vestibular sensations can be resolved and motion sickness can be reduced, provided the user perceive his or her motion information in the peripheral vision through the camera image, even if the user gazes at the 2D contents fixed in the head coordinate system in the central vision.

Title: Quick as a flash: Electrocorticographic (ECoG) recordings show that sounds influence visual perception by speeding up visual responses in motion sensitive visual cortex (hMT+)

Authors: *C. FINE[1], W. C. STACEY[2], D. BRANG[1];
[1]Psychology, [2]Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: The natural environment presents imperfect information to each of our sensory systems. To make sense of ambiguous signals, the brain readily integrates information from multiple modalities through crossmodal processes, weighting each sense by its reliability. However, the neural mechanisms through which crossmodal influences are coordinated in humans remain poorly understood, particularly when the senses receive conflicting information. The double-flash illusion (DFI; also known as the sound-induced illusory flash effect) is a powerful example of how sounds can bias perception and change what is seen, even when it results in lower perceptual accuracy. In this illusion, a single visual flash surrounded by two brief sounds evokes the experience of two discrete flashes. Previous research has shown that the predisposition to see an illusory flash is modulated by prestimulus activity, and that the illusion is typically associated with reduced alpha, increased beta, and increased gamma power, localized to early visual areas and the STS. However, non-invasive imaging (EEG, MEG, and fMRI) lack the combined spatial and temporal resolution necessary to definitively identify where and how in the brain sounds modulate visual perception during this illusion. To address this gap, we recorded neural activity during the DFI from two patients who were undergoing clinical evaluation for epilepsy using electrocorticography (ECoG). Intracranial electrodes implanted within visual motion cortex (hMT+) were analyzed across unisensory trials (auditory-alone, visual-alone) and crossmodal trials that included the illusion (one flash + two beeps) and control conditions. Results showed a consistent pattern across the two patients, such that sounds elicited greater alpha suppression, increased high-gamma power (a correlate of population firing rates), and earlier visual response latencies. Moreover, these enhancements were greater on trials in which the illusion was experienced (one flash perceived as two). We hypothesize that these power and latency effects are due to phase-resetting mechanisms in visual cortex, in which incoming sounds increase the excitability of visual neurons before the visual stimulus is processed.

Title: Auditory Cortex Uses Visual Timing Information to Enhance Auditory Speech Perception

Authors: *C. CAO[1], K. GANESAN[1], W. C. STACEY[2], D. BRANG[1];
[1]Psychology, [2]Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Seeing a speaker's face facilitates accurate speech perception. However, how such visual speech facilitation is achieved in the human brain remains poorly understood. Previous studies have shown that visual signals can modulate the excitability of auditory cortex. Indeed, recently our group observed that visual speech has spectrally, temporally, and spatially distinct influences on auditory processing, but the information encoded in the auditory system remains unclear. We hypothesize that several types of auditory information are recovered from visual signals, including categorical linguistic representations, predictive and ongoing timing information, relative pitch information, as well as speaker identity. The present study examines the prediction of auditory timing information (e.g. the onset/offset of phonemes and the general rate of speech) extracted from visual speech signals. Such visual timing information has been shown to be encoded by theta band oscillations in the anterior and posterior superior temporal gyrus (STG), but its influence on speech perception accuracy has remained less clear. To address this more directly, the current study examined the impact of visual speech information on auditory timing precision using intracranial recordings (electrocorticography; ECoG) in a large group of patients with epilepsy (n = 21). Group-level analyses using linear mixed-effect models showed that congruent visual speech elicited theta power increases in the posterior superior temporal gyrus (pSTG) following auditory speech onset compared with auditory speech alone. Separately, we observed increases in inter-trial phase coherence (ITPC) at the anterior STG prior to sound onset in response to visual lip-movements (potentially predicting phoneme onset time). Finally, ITPC was increased for congruent (relative to incongruent) auditory-visual trials and maximal when auditory-visual trials were correctly identified. We interpret these results to mean that visual speech is improving the precision of auditory speech in part through predictive timing information.

Title: Effects of presenting motion prediction information using augmented reality on motion sickness

Authors: *Y. SATO[1], T. ISHIKAWA[2], T. WADA[1];
[1]Nara Inst. of Sci. and Technol., Ikoma-Shi, Japan; [2]Ritsumeikan Univ., Kusatsu-shi, Japan

Abstract: <META NAME="author" CONTENT="佐藤勇起">According to the sensory conflict theory, motion sickness results from a mismatch between sensed and expected motions. Previous studies have demonstrated that motion sickness in a car could be reduced by presenting motion prediction information, for example, in the peripheral visual field using LED lights. However, the effects of presenting predictive information using augmented reality (AR) on motion sickness have not been investigated. AR may be more intuitive since it can superimpose motion prediction information over real space for viewing in the central visual field without large eye movements. Therefore, this study aims to verify how motion prediction information presented in AR using a head-mounted display (HMD) affects motion sickness. A participant wearing a HMD sat on a seat rotated in a range of ±30° in the yaw direction for 10 min at a preset irregular rotational direction and velocity, so that the end of the current or upcoming motion cannot be predicted. This motion prediction information was presented as an arrow in the AR space of the HMD. The rotational direction was indicated by the arrow, and the stop position was indicated by the arrow tip. The arrows were arched and placed around the participant's head to enable viewing the motion prediction information in the central visual field without large eye or head movements. New arrows were presented once the stopped seats began moving again to indicate the next rotational direction and stop position. Two experimental conditions were considered, namely with and without the arrows in AR space. The misery scale (MISC) of motion sickness was evaluated every minute during the rotations using a 11-step questionnaire. The results showed that the average MISC was significantly lower with the arrow information than without ($p = 0.0039$, Wilcoxon signed-rank test). The results of the study suggest that motion sickness could be reduced by presenting motion prediction information using AR.

Title: Rubber hand illusion related EEG oscillation in real and VR environment

Authors: *N. KANAYAMA[1,2], M. HARA[3], K. KIMURA[1];
[1]Natl. Inst. of Advanced Industrial Sci., Tsukuba, Japan; [2]Hiroshima Univ., Hiroshima, Japan; [3]Saitama Univ., Saitama, Japan

Abstract: Virtual reality (VR) enables highly controllable experimental body image and body schema setting. The rubber hand illusion (RHI), which is a typical illusory experience induced by visuo-tactile stimulations, can be realized in VR settings. Also, some phenomena related bodily illusion, such as full-body illusions, require head-mounted display (HMD), which can show the VR environment. However, when we measure scalp EEG during VR experience, HMD must add any noise on the EEG waveforms. To elucidate the difference of RHI related neural oscillation between real and VR environment, we have to control the noise contamination caused by usage of HMD. In this study report, I have introduced the way to control HMD-related noise contamination on the scalp EEG recording. Then under this noise-controlled condition, we have recorded scalp EEG components related to the the multisensory integration process during RHI in VR. Multisensory integration process can be altered in VR compared to real environment, because the visual scene is a not ordinary one when we wear HMD. Especially, the visual stimuli are only presented through the lens located near eyes, implemented in HMD, and the light from the room lighting is fully occluded. The objects seen in the field of view of HMD was created in 3D computer graphics, which mimicked the real things but not fully photorealistic. Although the 3DCG VR environment mimicking the real experimental settings can be subjectively felt very similar to the real one, the information process of visuo-tactile integration in VR is possibly different from real one. One useful investigative approach is measuring brain activities related multisensory integration process during RHI. We compared EEG data obtained in both real and VR environments, in which RHI task using vibration elements and LED as visuo-tactile stimuli. As a result, we observed the gamma and theta band oscillatory activities. Importantly, we found statistically significant differences between congruent (RHI) and incongruent (not RHI) conditions in the real environment, which agrees with previous studies. Only late theta activity, which is increased to incongruent visuotactile stimulation preventing RHI in real condition, has difference between real and VR environment, suggests that we have any alternation of multisensory process. The theta activities can be considered as the cognitive load in the visuotactile integration process based on the previous studies. Thus, we have to consider such a difference when we model the multisensory integration in VR to investigate our bodily self-perception.

Title: A map of muscle coactivation in rat frontoparietal cortex revealed with intracortical microstimulation (ICMS)

Authors: J.-J. PÉREZ-CORDERO, M. HAFEZI, L. A. GROCHOWSKI, B. K. NG, S. R. U, ***D. F. COOKE**;
Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: Muscles and joints rarely operate in isolation. Consistent with this, intracortical microstimulation (ICMS) at single sites in motor and parietal cortex often activates muscles across multiple joints and the activity of single motor cortex neurons is correlated with movement of multiple muscles. Yet many studies focus on the single muscle or joint most strongly linked to a distinct location in cortex, assuming that more widespread ICMS activation of muscles is artifactual. In contrast, we have shown previously that ICMS evokes coordinated combinations of muscle activation closely resembling natural complex behaviors like reaching, feeding, and defensive movements. Moreover, by targeting an ICMS-defined defensive zone with GABAergic drugs, we could selectively up- and down-regulate natural defensive behavioral reactions, demonstrating a functional role in specific multi-joint behaviors. Thus, patterns of muscle coactivation by ICMS reflect localized coding of complex motor behaviors, a finding since replicated by others. With the past focus on a primary muscle or joint, however, little is known, about how multiple muscles are coordinated by motor and parietal cortex. A few studies have examined patterns of arm muscle activity in monkeys during ICMS, and we have previously studied complex ICMS-evoked movements in rats, but without data from individual muscles. Here we describe a systematic study of muscle activity evoked by stimulation at sites across frontoparietal cortex. We applied ICMS in anesthetized rats to evoke muscle movements while recording video and electromyographic (EMG) activity from multiple muscles ranging in size and spanning the face, forelimb, trunk, and hindlimb. ICMS comprised 500-ms trains of biphasic pulses presented at 200 Hz with current amplitude ranging from 5-320 μA. While 500-ms ICMS is “long train”, we also analyzed the initial “short train” 50-ms period of EMG. We optimized stimulation circuitry to minimize ICMS artifact in EMG signals. Stimulation was controlled by a novel closed-loop system that conducts preliminary EMG analysis in real time and pauses ICMS during spontaneous muscle activity. Combined EMG and video data showed

that ICMS of sites over a large proportion of excitable cortex in M1 and S1 evoked coactivation of multiple muscles, which together frequently acted on more than one joint or body part. EMG data provided more precise latency information (and thus relative timing of co-activated muscles). For the first time these muscle-specific data are presented for motor maps spanning the full body representation.

Title: Signals from different layers of posterior parietal cortex area 5b to M1 during simple and vision-guided locomotion

Authors: *I. N. BELOOZEROVA[1], W. U. NILAWEERA[2];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Div. of Neurobio., Ellsworth Community Col., Iowa Falls, IA

Abstract: Area 5 of posterior parietal cortex is a part of the cortical pathway that processes visual information for action conveying it from visual to motor cortex (M1), the "dorsal stream". While a number of studies investigated transmission of information in the beginning of the dorsal stream, the composition of signals that area 5 ultimately conveys to M1 remained unknown. We investigated the activity of area 5b neurons from most rostral aspect of the suprasylvian gyrus that send axons to M1, cortico-cortical neurons (CCs). In cats, we compared their activity between locomotion on the flat surface and horizontal ladder, thereby identifying components of the activity related to visual processing versus limb movement. Activity of 54 CCs with somata in cortical layers II-IV, 21 in layer V, and 10 in layer VI was analyzed. To understand how well CCs reflect activity of the respective layers, we investigated activity of neighboring neurons with non-identified projection of axon (noIDs): 58 in layers II-IV,162 in layer V, and 3 in layer VI. During locomotion on the flat surface, noIDs in layer V at ~13 spikes/s were twice more active than in layers II-IV. More neurons discharged one activity burst per stride than in layers II-IV, and less had two bursts. The activity of layer V groups was stride-related: one-bursters peaked during swing, two-bursters peaked during stance. The activity of layers II-IV groups was barely modulated. Discharge of individual CCs was stride-related showing same one-/two-burst patterns but the rate was only1/5th of noIDs. CC group activity was not stride-related in any layer. Thus,

these CC groups did not transfer any unified stride-related signal to M1, while individual CCs sent various low rate signals. Upon transition to the ladder, noIDs increased discharge, activity of more cells became stride-related. Proportion of two-bursters doubled, most gain occurring in layer V. In layer V, group of one-burst noIDs developed an additional activity peak during swing-to-stance transition, two-bursters formed an additional peak in early stance. Discharge of CCs doubled, proportion of two-bursters also increased and their activity became stride-related with two peaks that preceded peaks of two-burst noIDs by 15% of the stride. The group activity of one-burters remain steady. In layers II-IV, activity of two-burst noIDs became modulated with peaks during stance-to-swing and swing-to-stance transitions, while activity of one-bursters remained stride-unrelated. Activity of CC subgroups was barely modulated. Thus, layers II-IV CC groups did not transfer unified stride-related signal to M1, while layer V two-burst CCs transmitted an early vision-related signal.

Title: Anterior-posterior gradient in the joint processing of reach direction and depth in the macaque posterior parietal cortex

Authors: *K. HADJIDIMITRAKIS[1,2], M. DE VITIS[1], M. FILIPPINI[1], M. GHODRATI[2], P. FATTORI[1];

Abstract: Accurate performance of arm movements depends on the integrity of a network of areas located in the parietal cortex that integrate visual information about the location of objects in space with visual and proprioceptive information about hand position, to guide arm movements. Although every arm movement happens in 3D space, it has become traditional among researchers to make a distinction between the direction of a movement and its depth. Psychophysical studies suggest that the direction and depth of reaching movements are likely to be specified independently, however there is no clear physiological evidence of this segregation. The present work addresses this gap of knowledge and provides with a comprehensive model of how movement-related areas contribute to different phases of complex 3D movements. Neural activity was recorded from 899 neurons in three distinct parietal cortex areas in *Macaca*

fascicularis monkeys while they fixated and reached towards visual targets located at different distances and directions from the body. We used information theory, singular value decomposition and dimensionality reduction methods and compared direction and depth strength and convergence within and across the three parietal areas. We found two major categories of cells: a) neurons that encoded both distance and direction information, and b) cells encoding only one type of signal. We compared direction and depth processing across task progress. While direction information was stronger than depth during early planning, depth signals became dominant towards movement execution. Going from anterior to posterior locations, cells that processed both signals consistently increased. These findings suggest a significant degree of sequential direction and depth processing that supports behavioral evidence. In addition, they reveal a gradient-like organization of joint versus independent control of reach parameters in parietal cortex that could be viewed in light of its role in visuo-motor transformations during actions.

Title: Thalamocortical and corticothalamic connections of functional domains in posterior parietal cortex of galagos

Authors: *Q. WANG, I. STEPNIEWSKA, C.-C. LIAO, J. KAAS;
Vanderbilt Univ., Nashville, TN

Abstract: The posterior parietal cortex (PPC) of prosimian galagos (Otolemur garnetti) is subdivided into several functionally distinct domains from which specific types of complex movements (e.g., reach, climb, grimace) can be evoked by 500 ms long trains of electrical stimulation. Previous studies have shown that each PPC domain has unique corticocortical connection patterns. However, connections of these domains with the thalamus remain unclear. Here, we investigated corticothalamic and thalamocortical connections of movement-specific PPC domains in seven adult galagos. We made eight injections of retrograde and bidirectional tracers, including cholera toxin B subunit (CTB), biotinylated dextran amines (BDA) and fluoro-ruby (FR) in different movement domains (i.e. hindlimb, forelimb and face movements). Thalami were cut in horizontal, coronal and sagittal planes across cases to gain different view of

thalamic nuclei. Sections were divided into series, some of which were processed for Nissl substance, acetylcholinesterase or vesicular glutamate transporter 2 for architecture. Other series were processed either for CTB or BDA, or FR for labeled neurons and axon terminals. Plotting from brain sections revealed that all PPC domains investigated in this study received major inputs from the ventral lateral nucleus (VL), the posterior nucleus (Po) and the anterior pulvinar (APul). Additional labeled neurons were distributed in the ventral anterior (VA) and lateral posterior nuclei (LP). Occasionally, we observed labeled neurons in ventral posterior (VP), intralaminar (IL) and mediodorsal nuclei (MD). PPC domains mainly projected to VA, LP, VL, Po and APul, with the densest projections concentrated in VL and Po/APul. Most of densely labeled neurons and axon terminals were spatially overlapped, suggestive of reciprocal connections between PPC functional domains and these thalamic nuclei. These preliminary results from prosimian galagos appear to be largely consistent with related results from New world and Old world monkeys.

Title: Inter-areal communication in posterior parietal cortex during coordinated eye and arm movements

Authors: *J. KANG[1], E. MOOSHAGIAN[1,2,3], L. H. SNYDER[1];
[1]Neurosci., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Cognitive Sci., Univ. of California San Diego, La Jolla, CA; [3]Systems Neurobio. Labs., The Salk Inst. for Biol. Sci., La Jolla, CA

Abstract: Behavior usually involves coordinated movements to different locations in space, and different parts of the nervous and musculoskeletal systems must communicate to plan and execute coordinated movements. However, the neural mechanisms of information exchange between different brain regions during eye-hand coordination are not fully understood. Posterior parietal cortex (PPC) in the macaque brain has been implicated in spatial processing during eye-hand coordination. A long-standing controversy concerns whether the lateral intraparietal area (LIP) in PPC is a locus for spatial attention or oculomotor control. Attention and eye movements

are confounded by the fact that we usually look at whatever we are attending to. We studied information flow between LIP and the parietal reach region (PRR), a nearby area involved in reaching. We recorded spikes and local field potential (LFP) in LIP and PRR while animals were instructed to make coordinated eye and arm movements. If LIP is an attentional filter for spatial information, then information should flow from LIP to PRR when a target for a reach is being identified. However, if LIP primarily subserves an oculomotor control, then information should flow from PRR to LIP so that animals can look at what they are reaching for: eye-hand coordination. We used two largely independent methods, spectral Granger causality between two LFP signals and spike-LFP coherence analyses in beta band, to assay information flow between the two areas during the movement preparatory period. Both methods suggest that information primarily flows from PRR to LIP rather than vice versa. Our results support the idea that LIP subserves primarily an oculomotor rather than an attentional role during eye-hand coordination.

Title: Predictive coding of tracking and intercepting inferred moving target in posterior parietal cortex

Authors: *R. ZHENG[1,2], H. CUI[1,2];
[1]Lab. of Neural Mechanism of Motor Control, Ctr. for Excellence in Brain Sci. and Intelligence Technol. (Institute of Neuroscience), CAS, Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: Benefit from “the predictive brain” which compensates for inevitable delays in sensory transmission and movement execution, we can survive in a dynamic world. Although the delay compensation has been widely studied, the underlying neural mechanism is still elusive. As an important sensorimotor interface, the posterior parietal cortex (PPC) has been found profoundly involved in sensory-guided movement. To further elucidate whether the PPC estimates current state of external stimulus or predicts consequence of an upcoming movement,

we recorded single-unit activity from the lateral intraparietal area (LIP, n=86) and parietal reach region (PRR, n=65) while a monkey (*Macaca mulatta*) performed the occluded manual interception task. During the task, the monkey initiated a trial by touching a central dot for 400 ms, then a target appeared at a random location of a circle and moved circularly with one of five angular velocities (0, static control; 120°/s or 200°/s clockwise, 120°/s or 200°/s counterclockwise) for 400-800 ms (cue period) and then disappeared. After the occlusion period of 500 ms, the center dot dimmed (GO cue) and the monkey was required to manually intercept the target inferred from the previous target motion during the cue period within 700 ms. The activity of LIP and PRR revealed a gradient from sensory to movement coding in the occlusion period. Most of neurons (~75%) in both areas were tuned to the instantaneous target location when it was visible. Once target disappeared, 45 (69%) PRR neurons and 39 (45%) LIP neurons were tuned to the upcoming reaching direction, whereas 28 (33%) of LIP represented inferred stimulus location, this type of neuron accounts for only 12 (18%) of PRR. In addition, a small proportion of neurons (~8% in each area) exhibited a transition from tracking of moving target to forming movement plan. However, the target tracking coding in above groups of neurons only lasted in the early occlusion period for ~200 ms. Therefore, during planning manual interception of inferred moving targets, most PRR neurons function as reach plan formation instead of instantaneous target estimation, while LIP neurons might subserve extrapolating stimulus state and forming motor plan. During the transformation process, we observed the interaction between sensory and movement modulation, indicating the role of evaluating or converting the sensory information into movement output in PPC. The encoding properties in PPC neurons revealed that it is not only involved in establishing the internal estimation of sensory state, but also forming impending motor plan in predictive sensorimotor control.

Title: Do marmosets reach predictively for moving targets?

Authors: *L. H. SHAW[1], K. H. WANG[2], J. MITCHELL[3];
[1]Neurosci. Grad. Program, [2]Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY; [3]Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY

Abstract: Visual information plays a critical role in the planning and on-line correction of coordinated movements. Primates especially utilize vision in reaching behavior. Studies of reaching in macaques indicate that the dorsal premotor and the medial intraparietal cortices are involved in on-line corrections that guide the hand towards dynamic targets. However, the specific behavioral contributions of circuit connections between these two areas have not been determined, due to technical challenges associated with circuit targeting and behavioral training in macaques. Marmosets provide an accessible experimental model for this research due to their lissencephalic brains that facilitate intraparietal targeting and innate insect hunting behavior that facilitate dynamic reach testing. We set out to generate high fidelity descriptions of marmoset hands as they reach for live crickets and ask whether unrestrained marmosets reach predictively for moving crickets. We developed a novel machine learning approach to achieve marker-less tracking of the hand and the cricket, and determined their spatiotemporal interplay during reaching. We utilized kinematic data and a multivariate linear modeling approach to demonstrate the influence of cricket motion on the future hand motion of reaching marmosets. Our findings suggest that marmosets incorporate cricket motion into their reaches in a predictive fashion. Furthermore, there is a specific time window when cricket motion strongly influences marmoset hand motion. These behavioral characterization and modeling results will provide a foundation for future research using optogenetic tools in marmosets to determine the circuit mechanisms underlying predictive reaching and online corrections.

Title: Configuration of sensory, parietal, and frontal cortices during goal-directed virtual navigation in non-human primates

Authors: *J.-P. NOEL[1], E. BALZANI[2], E. AVILA[2], S. BRUNI[2], P. ALEFANTIS[2], C. SAVIN[2], D. ANGELAKI[3];
[1]New York Univ., New York, NY; [2]New York Univ., NEW YORK, NY; [3]New York Univ., New York City, NY

Abstract: We do not understand how neural nodes operate within the recurrent action-perception loops that characterize our natural environment, nor how brain networks change with different computational demands. Here, we simultaneously record spiking activity from the dorso-medial superior temporal area (MSTd), area 7a in the posterior parietal cortex, and dorsolateral pre-frontal cortex (dlPFC) as monkeys attempt to “catch fireflies” in virtual reality. This task

required animals (1) to integrate optic flow signals into a position estimate over protracted periods of time, (2) to actively sample from a dynamic environment (e.g., via eye movements), and (3) to compute the evolving location of a latent variables - i.e., the angular and radial distance to target and from origin. We leveraged a novel Poisson Generalized Additive Model (P-GAM; Balzani et al., 2020) capable of inferring marginal confidence bounds for the contribution of each feature to neural responses. This technical innovation allowed us to identify a minimal set of task features that each neuron is responsive to while circumventing the need for computationally prohibitive model selection procedures (particularly given the number of variables in this naturalistic task). We observed mixed selectivity, with even MSTd tracking the latent variable. Strikingly, MSTd showed a global encoding profile akin to that of dlPFC and very distinct from 7a. We also observed significant unit-to-unit coupling (i.e., firing rate of one neuron impacting that of another) between MSTd and dlPFC. In contrast, single unit coupling between 7a and either dlPFC or MSTd was less common. Lastly, when sensory evidence was scarce and instead the task heavily relied on pre-established internal models, lateral connectivity within MSTd strengthened but its pattern remained fixed. On the other hand, the shape of the coupling filters within 7a and dlPFC adaptively re-configured when the task relied on internal models as opposed to sensory evidence. Together, these results highlight the distributed nature of naturalistic neural coding and suggest internal models may be housed in the pattern of fine-grain lateral connectivity within parietal and frontal cortices.

Title: Neural correlates of naturalistic decision-making in parietal and frontal cortices

Authors: *X. NIU, E. BALZANI, J.-P. NOEL, B. CAZIOT, E. AVILA, C. SAVIN, D. E. ANGELAKI;
New York Univ., New York, NY

Abstract: Classical decision-making experiments usually involve an artificial stimulus (e.g., random dots), a predefined motor response (e.g., a saccade), extensive training, and thus poorly reflect behavior and neural circuitry in a naturalistic setting. To address these limitations, we modified a "firefly task" (see Noel, Balzani et al., SfN 2021) wherein monkeys actively path integrate to a briefly flashed target in a virtual reality environment. Specifically, after training with a single firefly, during testing we presented monkeys with two identical fireflies

simultaneously, so they now had to make a choice. We recorded single units from area 7a in the posterior parietal cortex, and dorsolateral pre-frontal cortex (dlPFC), which are involved in sensorimotor transformations and working memory. Not only did monkeys adapt to this new paradigm, but they also showed a preference for closer and more straight-ahead targets, a strategy that maximizes reward rate. To study the neural correlates of this decision-making process, we fit a Poisson Generalized Additive Model (P-GAM; Balzani et al., 2020) on smoothed spike counts. Most units exhibited mixed selectivity, with units in area 7a more tuned to sensorimotor variables (velocity, acceleration, target on/off and movement on/off) and LFP, and units in dlPFC more tuned to latent variables (distance traveled, distance to target). More units encoded the chosen target than those for the unchosen target, and this difference was larger when the target pair was far apart. To interrogate time-dependent effects, we trained a linear regression that decoded the distance to target from neural responses at each time point. Throughout the trial, the firing rates were better able to predict distance to the chosen target than the unchosen one, and the decoding performance peaked a short time after targets were extinguished. Interestingly, decoding showed another smaller peak when animals stopped moving, potentially revealing a "replay" or a different distance-coding mechanism when animals are stationary versus moving. Lastly, on a subset of trials monkeys appeared to change their mind, where they first leaned towards one target, then made an abrupt turn to approach the other target instead. Neurally, both targets could be decoded early in the trial, while decoding performance dropped quickly for the unchosen target and continued increasing for the chosen one. These results suggest an ongoing competition between the neural representations of two targets, which on occasions can lead to a behavioral change-of-mind consequence.

Abstract: In arboreal environments, substrate orientation modifies body axis orientation and biomechanical constraints on fore- and hindlimbs, resulting in adjustments of postural and locomotor strategies. To characterize the role of cortical oscillations in integrating these demands, we recorded electrocorticographic activity from left dorsal premotor, primary motor, and supplementary motor cortices of three common marmosets moving on a branch-like small-diameter pole, fixed horizontally or vertically. Power spectrum was calculated in β (16-35 Hz) and γ (75-100 Hz) bands and differences between conditions were statistically assessed by aligned-rank-transform ANOVAs followed by Wilcoxon rank-sum tests. Results showed that animals displayed behavioral adjustments to the task in terms of preferred forelimb posture and gait. The horizontal condition mainly induced quadrupedal walk with pronated/neutral forelimb postures, whereas the vertical condition induced walk and bound gaits with supinated/neutral postures. Examination of cortical activity supports the view that β and γ oscillations fulfill partly different roles during the task. At rest, modulation of β power by substrate orientation (horizontal/vertical) could illustrate sensorimotor processes for postural maintenance, in line with close links between β oscillations and tonic muscle contraction. During locomotion, modulation of γ event-related synchronization by substrate orientation and epoch (preparation/execution) highlights precise tuning to the temporal dynamics of the task. By comparison, modulation of β event-related desynchronization by gait could depict a role in movement sequence and interlimb coordination; we do not exclude a possible similar role of γ frequencies, which could be addressed by future experiments. Overall, these results confirm that arboreal locomotion and postural maintenance in common marmosets rely on specific mechanisms involving adjustments of β and γ oscillatory activity to substrate orientation.

Title: Detrended fluctuation and coherence under emotional burnout formation (Exhaustion stage)

Authors: *S. TUKAIEV[1], D. HARMATIUK[2], A. POPOV[2], M. MAKARCHUK[1];
[1]Inst. of Biol. and Med., Taras Shevchenko Natl. Univ. of Kyiv, Kyiv, Ukraine; [2]Dept. of Electronic Engin., Igor Sikorsky Kyiv Polytechnic Inst., Kyiv, Ukraine

Abstract: The neurophysiological mechanisms of emotional burnout remain insufficiently studied. It was found that EEG changes during burnout differ from biomarkers of depression and chronic fatigue syndrome. To establish the EEG markers of burnout was our aim. 182 volunteers, first-third year students from the Taras Shevchenko National University of Kyiv aged 18 to 24 years participated in this study. The EEGs were recorded during the resting state (3 min, closed eyes condition) monopolarly using EEG 23-channel system Neurocom. To establish EEG correlates of emotional burnout during rest state we used a special software written in Python 3.6 to implement Power Spectral Density calculation, the interhemispheric and intrahemispheric average coherence and Detrended Fluctuation Analysis (DFA). We analyzed separate artifact-free EEG segments in all frequency bands from 0.2 to 45 Hz. Psychological testing was performed before the registration of EEG. To determine the formation of emotional burnout Boyko's "Syndrome of emotional burnout" Inventory was used. The Exhaustion phase of emotional burnout was formed in 13 participants, and it was under development in 47 participants. In background EEG activity during the development of the exhaustion variations in EEG spatial synchronization were observed in low- and high-frequency EEG components. Development of exhaustion includes breaking of parietal-occipital links (alpha2,3-subbands) and formation of interhemispheric prefrontal, anterior frontal, and frontal links (alpha1,2-subbands). There were interruptions of coherence in the beta1 (interhemispheric frontal-frontal and parietal-parietal links) and beta2 subbands (right interhemispheric frontal link). DFA describes the long-term temporal correlations in the cortex, which are involved in different aspects of brain functioning. We detected a high resting state DFA scaling exponent values (up to 0.70-0,95) under exhaustion development in the theta1 (left prefrontal area), theta2 (right frontal area), alpha3 (posterior regions), beta2 (left temporal region). Obtained values of DFA exponent and average coherence suggest the exhaustion formation is accompanied by the changes in visual and verbal processing, emotional processes (discretion and analysis).

Title: Acute changes in default-mode functional connectivity by cognitive fatigue

Authors: *S. IWAKI[1,2], T. FUJIWARA[2,3];
[1]Natl. Inst. Adv Indust Sci. & Tech., Tsukuba, Japan; [2]Univ. of Tsukuba, Tsukuba, Japan; [3]Natl. Inst. Adv Indust Sci. & Tech, Tsukuba, Japan, Tsukuba, Japan

Abstract: Sustained engagement to a monotonous cognitive task causes a decrease of cognitive resources accompanied by subjective feeling of mental exhaustion, which is called “cognitive fatigue (CF)” (Pattyn, 2018). In this study, we aim to elucidate the CF-related changes in brain state by employing functional MRI to evaluate resting-state functional connectivity between brain regions to investigate changes in macroscopic brain networks under CF. Eighteen young adults (22.8±1.8 years of age, all right-handed) participated in the study. The experiment includes two days of lab visits, separated by more than a week. On each visit, the participants conducted two sessions of MRI data acquisition separated by either cognitive task sessions for fatigue loading (CF condition) or passive environmental video viewing sessions as control. The order of CF and control conditions was randomized between participants. The fatigue loading in the CF condition consisted of 4 sessions of 30-minutes continuous simple mental arithmetic task with 5 minutes of interval. MRI scans were conducted before and after the fatigue loading/control sessions, which include T1 structural scans and 12-minutes resting-state fMRI (rsfMRI) scans (TR=2,000 ms, TE=35 ms, FA=90 deg, 31 slices with 3.7 mm thickness) using 3 T scanner (Philips Ingenia 3.0T). CONN software (Whitfield-Gabrieli, 2012) was used to analyze the effective connectivity between brain regions. This study was approved by the internal review board of AIST. Results of the connectivity analysis of the rsfMRI data showed significant increase in effective connectivity between the posterior cingulate cortex (PCC), which is a part of the default mode network (DMN), and the bilateral inferior occipital gyrus (IOG) ($p < 0.05$; FDR corrected). The current results indicate the changes in resting-state brain network after the CF loading which might reflect the difficulty in allocating attentional resources to specific task performance under CF (Esterman, 2013).

Title: Activity variability as a neural marker of fatigue on sustained alertness tasks.

Authors: *I. LIMA DIAS PINTO[1], K. BANSAL[2], J. O. GARCIA[3];
[1]Human Res. and Engin. Directorate, US DEVCOM Army Res. Lab., Aberdeen Proving Grounds, MD; [2]Biomed. Engin., Columbia Univ., New York, NY; [3]U.S. Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: The ability to maintain alertness and attention for a sustained amount of time is essential for a wide range of tasks, and has severe consequences on other aspects of cognition and decision making. Fatigue accumulation during a task has the potential to thwart this alertness and jeopardize performance. The psychomotor vigilance test (PVT) is one of the most used assessments of vigilance and alertness where subjects are asked to make a motor response as soon as they perceive a visual stimulus on the screen, this procedure is repeated for several minutes, and, importantly, inter-trial interval is random. From this task, alertness is often inferred from a score derived from the response time to the briefly presented stimulus. Previous research has shown that the subject's response tends to be slower as time progresses during the task (Basner, M. et al. 2011), suggesting behavioral sensitivity to fatigue accumulation. Recently, researchers have investigated the the ratio of the variability of BOLD activity between brain networks, containing somato-motor and -sensory regions of the brain, and investigated the relationship of this metric to the perception of the speed of time (Northoff, G. et al. 2018). Here we probe the effects of this balance of sensory and somatomotor networks on the performance of the subjects during the PVT in which the response time is essential. We examined the ratio of fMRI BOLD variability for visual and somatomotor networks whilst subjects were engaged in the PVT. Using the Schaeffer parcellation and network demarcation (Schaefer, A. et al. 2018) to determine networks of interest, we observed that the temporal evolution of the visual and somatomotor variability ratio decays over time and is highly correlated to the decay in performance after a rapid but brief transient period. Our results indicate that faster responses are observed when the balance of variation of the BOLD activity is associated with performance in the PVT, suggesting that the emergence of fatigue from time-on-task can alter this balance and affect the performance. This work suggests a new avenue of fMRI BOLD feature extraction that may be highly predictive of performance change in a variety of tasks and suggests the importance of the dynamic network tension in cognition.

Title: Investigating the effect of stress on prospection and intertemporal choice

Authors: *H. E. AHN, A. G. SHIVERS, G. J. NORMAN, A. BAKKOUR;
Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: When we imagine events in our lives that haven't happened yet, we generate and evaluate mental representations of possible futures. What we are able to imagine seems to be constrained by what we have previously experienced, suggesting a close link between memory and prospection. Prior literature points to the deleterious effects of acute stress on memory, but the implied effect of stress on prospection is not well understood. Furthermore, humans tend to discount the value of future rewards over time during intertemporal choice. But having people imagine future events can bias them to make more farsighted, patient choices, thereby reducing delay discounting. However, having to consider tradeoffs between immediate and delayed outcomes might be particularly challenging under acute stress. Studies have shown that some individuals make more impulsive decisions when stressed out, but the question of whether stress affects decision making through its effect on prospection remains unclear.

We sought to investigate how acute stress might affect one's ability to prospect about their future and make future-oriented decisions accordingly. We hypothesized that stress influences decision making through its impact on memory and prospection. In order to test this, we conducted a two-visit online study: participants began one session with an online adaptation of the Trier Social Stress Test, and the other session with a no-stress control condition. In each session, participants were then asked to either imagine themselves spending money in a future event, or describe a picture of a scene. This 2x2 study design yielded four conditions for each participant: Stress-Imagine, Stress-Describe, No Stress-Imagine, No Stress-Describe. Following each Imagine/Describe trial, participants were prompted to make a choice between a larger future reward and a smaller immediate reward.

We predicted that the discounting parameter *k* (obtained from fitting a hyperbolic discounting model to the choice data) would be lower (less discounting of delayed reward) during prospection, but would increase (more discounting) in Stress sessions. Our results show a trend of less impulsivity for immediate rewards when participants prospected about the future under stress. These results weakly conform to our predictions. But the effects of stress on behavior were not clear in an online format, given that physiological measures of the stress response were not captured. As a whole, this study attempts to uncover the ways in which one can begin to view stress, memory, and decision making in tandem by examining how prospection influences future-oriented choice, and how stress might disrupt this relationship.

Title: Early-life stress, depression and acute stress are related to impaired selectivity for important information in a value-directed remembering paradigm.

Authors: *A. L. GORDON, T. K. PATTERSON, H. P. DE GUZMAN, B. J. KNOWLTON; Psychology, UCLA, Los Angeles, CA

Abstract: Early-life stress (ELS) is linked to lifelong increased risk for a broad spectrum of negative health outcomes including substance use disorders, sexually transmitted infections, and early mortality. However, the cognitive and neurological mechanisms producing these elevated risks are poorly understood. We have shown that ELS is associated with increased habits at the expense of goal-directed actions during instrumental avoidance learning. If this association is driven by impaired goal-directedness, we would expect ELS to be associated with other disrupted goal-directed behaviors such as selectivity for remembering important information under capacity constraints. To test whether this is the case participants (n = 100), half of whom underwent Trier social stress test induction, performed a value-directed remembering task in which they were asked to maximize their score by recalling words associated with arbitrary values. Half of the lists were performed under cognitive load. Patterns of recall were analyzed using hierarchical generalized linear modeling. Both ELS and acute stress were associated with diminished selectivity for high value words. Joint significance tests suggest that the effects of ELS are mediated by depressive symptomatology. These results have important implications for understanding how ELS has lifelong consequences for exposed individuals.

Abstract: Mind body techniques-based amelioration of stress and cognition through possible neurogenesis dependent pathway**Kanupriya Sharma*,** Akshay Anand, Sonu Goel, Prashant Verma, Kiran Sharma, Kalyan Maity, Sheetal Jindal**Conflict of Interest**: None**Funding Agency:** DST SATYAM**Abstract**The developing society has increasing severity of stress and anxiety-based disorders due to the current lifestyle and work life balance. Stress and anxiety can lead to cognitive decline and influence adult neurogenesis. Mind body techniques like Yoga have been known to reduce the stress and related complications. In order to understand the molecular mechanism through which Mind Body technique-based yoga protocol helps in amelioration of lifestyle stress-based cognitive decline, 45 women between the age of 20-55 were assessed, who were given 45 minutes of Yoga intervention for 3 months for 5 days a week. They were assessed for stress and anxiety scale through STAI (State Trait Anxiety Inventory) and their cognitive profile was assessed using neuropsychological scales, i.e., Digit Span test, Trail Making Test, Digit Symbol Substitution Test before and after the intervention. In order to understand the molecular aspects associated with cognitive benefits, we assessed the neurogenesis markers in blood through ELISA i.e., BDNF, VEGF and Angiogenin which are known to influence cognitive profile through the neurogenesis mechanism. After 3 month of Yoga practice, reduction in the stress and anxiety with improvement in the cognitive profile was observed. Neurogenesis and Angiogenesis markers also showed alterations after Yoga practice. These results call for comprehensive study to examine whether Yoga based mind body techniques can help in ameliorating lifestyle stress-based cognition through the neurogenesis.

Abstract: Individuals having low immunity and other comorbidities are more vulnerable to COVID-19. Healthcare system plays important role to rescue and provide the primary care to the patients suffering from deadly virus. Thus, COVID positive, recovered patients and healthcare workers have higher levels of distress, anxiety, and depression while dealing with such situations that has mental effects. Mental stress and depression are vulnerable conditions to increase the risk of acute respiratory infections by lowering the immunity. Here, we report that yoga practice may improve neuropsychological parameters. Study subjects were recruited from Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, India from 13th October, 2020 to 7th January 2021. The three groups were 1) COVID-positive group 2) COVID-recovered group 3) Health care workers (HCW) group. Each group was randomly divided into intervention or yoga group and non-intervention or control group (n=12 each). The Yoga intervention was given for 15 days. Neuropsychological parameters included Perceived Stress Score (PSS), Profile of Mood States (POMS). JOY subscale (DPES-Joy), Warwick-Edinburgh Wellbeing Scale (WEMWBS), WHO quality of life (WHOQOL). COVID positive Yoga (CPY) group showed non-significant reduction in PSS and tension whereas, vigor was significantly increased in both CPY ($p=0.01$) and COVID positive control (CPC) group ($p=0.004$) as compared to baseline. Physical, psychological & environmental health were increased in both the groups as compared to the baseline. Whereas, social relationship was significantly reduced in CPY ($p=0.05$) as compared to baseline. After 15 days, physical health improved whereas, social relationship domain of WHOQOL scale reduced in COVID recovered Yoga (CRY) group. In HCW Yoga group tension, anger, fatigue, vigor, and overall wellbeing were non-significantly reduced and overall quality of life increased. Yogic practices can be considered as therapeutic intervention to prevent and manage COVID-19 related stress and improve overall wellbeing.

Title: Examining stress markers during restricted environmental stimulation

Authors: *S. M. KING, K. A. FEIGENSON;
Albright Col., Reading, PA

Abstract: This study examined the impact of restricted environmental stimulation technique (REST) on stress biomarkers, and how effectively it could be used as a form of meditation. We hypothesized that the sensory restriction treatment would lower stress levels but increase anomalous sensory experiences. The methodology used was an alteration to traditional sensory deprivation techniques, where instead of a complete absence of sensory input there were incomprehensible sensory inputs (such as white noise). We assayed stress biomarkers before and after the treatment, focusing on salivary cortisol levels, which were examined using enzyme-linked immunosorbent assay. Randomized treatment participants relaxed on an air mattress for 20 minutes wearing noise cancelling headphones playing white noise and Ganzfeld-like goggles, whose purpose was to obscure light. The control group procedure mimicked the physical sensations of the treatment group, wearing goggles and headphones but without the sensory restriction elements. We quantified participants' sensory experiences as well as the average galvanic skin conductance for 20 minutes. Our experiment used established sensory perception techniques (e.g. Ganzfeld like goggles, headphones playing white noise, salivary cortisol levels) and combined them with measures to validate the reporting of the anomalous sensory events. This was created by having participants press a handheld button when they experienced a percept, and this was compared against a record the experimenter kept if they perceived any added stimuli during that time (e.g. external noise, gust of air, light shining into the room).

Additional variables collected included age, sex, race/ethnicity, in addition to self-reported scores on questionnaires on the Revised Hallucination Scale, the Peters Delusional Inventory, and the Multidimensional Schizotypy Scale. The anticipated results were that the cortisol levels and skin conductivity would be lower with the use of REST techniques compared to the control group. Results instead suggested that there were no significant differences by condition, but there was an across group decrease in cortisol levels from the start of the experiment to the end. Additionally, results show that the more sensory experiences an individual reported, the higher their cortisol levels at the end of the experiment. These findings suggest both REST and short term meditation reduce stress to similar degrees, but these effects are weakened when individuals experience anomalous sensory events.

Abstract: Effects of yoga on memory, cognitive levels, overall quality of life, and lipid profile in Police recruits

Authors: Prashant Verma[1],* Pramod Avati[2], Akshay Anand[3] Gurmeet Singh[4], Krishan Kumar Soni[5], Kalyan Maity[6], Sheetal Jindal[7], Kanupriya Sharma[8] Surinder Kaushal[9], Navneet Kaur[10], Parul Bali[11], Saras Jyoti[12], Sushant Sharma[13],

Abstract

Stress and health issues are common among police professionals and it also affects the mental status of the police and deteriorates the police-public relations due to their job profile which is full of challenges. Hence, there is an urgent need to develop validated mind-body techniques in their daily routine to improve their overall health and improve the compassion and mind-body balance among professionals. A few recent studies suggest that yoga aids in reducing stress and Meditation is functional in reducing stress and anxiety; in addition, it improves memory and attention. This study included additional parameters than past studies. 478 recruits from the

police department, UT Chandigarh, India were recruited for the study. The recruits were divided into two major groups as Group A and Group B. Group A practiced yoga with common yoga AYUSH protocol and their basic exercises for 3 months and Group B did not practice yoga but followed only traditional training exercises i.e. regular physical exercise regimen, Running, etc. during these 3 months. To examine the effects on memory, attention, and their overall health TMT A and TMT B, Digit memory test, WHO-QOL Bref, BMI, lipid profile tests were carried out at baseline and 3 months. In between the groups and within the group comparison were done in between Group A and Group B. Group A and Group B were analyzed according to age and gender after dividing them into 4 groups (comparison between 20-24 age males, 20-24 age females, 25-30 age males, 25-30 age females of Group A and Group B). Group A showed significant improvement in BMI, memory, executive functioning, cognitive processing speed, lipid profile, and overall quality of life, in all age groups and gender. This data supports that Yoga can be helpful in reducing stress during training and future studies may use this study to launch larger studies.

Title: Establishment of mPGES-1 deficient rats lacking LPS-inducible hyperthermia

Authors: *T. MATSUWAKI[1], A. SANDO[2], S. KAKUTA[2], K. YAMANOUCHI[1];
[1]Dept. of Vet. Physiol., [2]Dept. of Biomed. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Prostaglandin E_2 (PGE_2) is a strong pyrogen working in the CNS under infectious conditions. It has been demonstrated that mice lacking the inducible PGE_2 synthase, microsomal prostaglandin E synthase-1 (mPGES-1), show no endotoxin-dependent fever. In addition, we have recently reported that female mPGES-1 deficient (KO) mice showed strong hypothermia in response to injection of lipopolysaccharide (LPS) only when they are on proestrus stage. These results suggested that the endocrine system strongly affects hyperthermic and/or hypothermic response to the immune challenge. In the present study, thus, we produced mPGES-1 KO rats using Cas12a/CRISPR genome editing system for the future investigation of the possible

involvement of the endocrine system in thermoregulation under infectious conditions. The KO animals are lacking the splice acceptor site of intron1 of mPGES-1 locus. Reverse transcription PCR using their hypothalamus showed that they produce a short form of mRNA of mPGES-1 without exon2. First, we implanted a temperature transponder in the abdominal cavity of male rats and started measuring body temperature every minute immediately after implantation. Two weeks later, we injected LPS intraperitoneally to the animals. Subsequently, we treated another group of rats with LPS and obtained their CSF from the cisterna magna 5 hours after injection to measure the concentration of PGE_2. KO rats presented a regular circadian rhythm of body temperature as WT rats, suggesting mPGES-1 plays no role in regulation of body temperature under normal conditions. On the other hand, LPS-inducible hyperthermia was observed only in WT but not in KO rats. Moreover, PGE_2 concentration in the CSF was remarkably enhanced by LPS injection also only in WT rats. We have established a novel line of mPGES-1 KO rats and successfully reproduced the feature of mPGES-1 mice concerning the thermoregulation under infectious conditions. These animals will be of good use for studying the role of PGE_2 in the endocrine system that requires serial samples or samples of large amount.

Abstract: The preoptic area (POA) of the hypothalamus is an interoceptive brain structure able to detect changes in local temperature. It has been proposed that the ion channel TRPM2 is part of the machinery detecting warmth in the POA. However, the mechanism underlying TRPM2-mediated temperature detection in the POA is not fully understood.
Here, we show that TRPM2 facilitates whole-body cooling upon POA warming in mice. At the cellular level, TRPM2 enhances the thermosensitivity of preoptic warm-sensitive neurons (WSN). TRPM2 achieves this by modulating in a temperature-dependent manner the synaptic inputs that arrive at WSN. Altogether, our data suggests that TRPM2 mediates direct warmth detection in the POA. We further provide evidence that preoptic WSN are indeed a neuronal population detecting warmth in the POA and that WSN thermosensitivity can be conferred synaptically by temperature sensors, like TRPM2, acting extrinsically to WSN.

Title: Molecular characterization of preoptic area warm sensitive neurons

Authors: *K. ZUZA, G. B. KAMM, J. E. SIEMENS;
Inst. of Pharmacol., Heidelberg Univ., Heidelberg, Germany

Abstract: Body temperature is a dynamic homeostatic property, tightly regulated by the autonomic nervous system. How the brain coordinates maintenance of the body temperature within a narrow range of 37 °C, a condition which is needed for all enzymatic reactions and cellular processes to function properly, remains unclear. Among the brain regions that have been implicated in thermoregulation is the hypothalamus, more precisely its anterior portion, the preoptic area (POA). Early experimental studies have implemented *in vivo* heating or cooling of the POA which resulted in activation of thermoregulatory effector mechanisms. Additionally, electrophysiological studies have found neurons within the POA to respond to temperature stimuli suggesting that these neurons, known as warm sensitive neurons (WSNs), are the cells which detect deep brain temperature and might integrate temperature information from the periphery. The lack of specific molecular markers to identify preoptic WSNs limits our capacity to study how the POA acts as a body thermostat. Effort has been put in investigating those cells,

with several molecular candidates emerging, such as TRPM2 ion channel found to play a role in POA temperature detection and hypothermia. Therefore, our aim was to characterize WSNs of the POA at the molecular level. To achieve this goal we used primary POA cell culture from 9 days old C57BL/6 N mice (P9) and performed calcium imaging while applying a temperature stimulus of 45 °C in the presence and the absence of the TRPM2 antagonist, 2-Aminoethoxydiphenyl borate (2-APB). We identified and hand-picked temperature responding cells (n=37), cells which had temperature response blocked by 2-APB (n=34) and temperature non-responding cells (n=22) for the single-cell RNA-sequencing (scRNA-seq). Analysis of the scRNA-seq data pointed to the limitations of the P9 cell culture used. Majority of the temperature non-responding cells sequenced expressed glial marker genes together with neuronal markers, a combination not found *in vivo*. We concluded that genetic heterogeneity of the sequenced cells was too large and putative WSNs' molecular markers identified from cultured neurons would be ambiguous. In order to disentangle the neuronal circuits involved in body temperature homeostasis, further effort needs to be invested in search for WSNs' markers. Alternative ways include combining low throughput RNA-seq experiments coupled with physiological characterization of neurons, such as Patch-seq (Cadwell et al., 2016, Fuzik et al., 2016), with large scale scRNA-seq data sets, such as the POA genetic atlas (Moffit et al.,2018).

Title: Preoptic BRS3 neurons increase body temperature and heart rate via multiple pathways

Authors: *R. PIÑOL, A. MOGUL, A. SAHA, C. LI, V. SKOP, H. PROVINCE, S. KULKARNI, C. XIAO, O. GAVRILOVA, M. KRASHES, M. REITMAN;
NIH-NIDDK, Bethesda, MD

Abstract: The preoptic area (POA) is a key brain region controlling whole-body metabolism and body temperature (Tb), dictating thermogenic, cardiovascular, and behavioral responses to

regulate Tb. Ultimately survival depends on proper Tb regulation, making it critical to understand the physiology of this motivational need of the body. Known POA neuronal populations reduce Tb when activated; a population that increases Tb upon activation has not yet been reported. Using mice, we now identify bombesin-like receptor 3 (BRS3)-expressing POA (POA^{BRS3}) neurons as having this missing functionality. BRS3 is an orphan receptor that regulates energy and cardiovascular homeostasis, but the relevant neural circuits are incompletely understood. We demonstrate that POA^{BRS3} neuronal activation increases Tb, heart rate, and blood pressure sympathetically, and stimulation of projections to the paraventricular nucleus of the hypothalamus and dorsomedial hypothalamus does the same. Acute POA^{BRS3} inhibition reduces Tb. Long-term inactivation of POA^{BRS3} neurons increased Tb variability and produced exaggerated Tb changes, overshooting both increases and decreases in Tb set point, with RNA expression profiles suggesting multiple types of POA^{BRS3} neurons. Thus, POA^{BRS3} neuronal populations regulate Tb and heart rate, contribute to cold-defense, and fine-tune feedback control of Tb. These findings advance understanding of homeothermy, a defining feature of mammalian biology

Title: Secretome analysis of hypothalamic neuroendocrine circuits regulating core body temperature in mice

Authors: *C. ARAUJO-SOUSA[1,2], D. COLOMBO[3], G. B. KAMM[1], S. CALDERAZZO[3], J. KRIJGSVELD[3,4], J. SIEMENS[1,2];

Abstract: Surviving environmental challenges requires flexible neural systems. In this context, neuromodulators, including neuropeptides and some peptide hormones, are important players in tuning neural activity. These molecules were shown to regulate several physiological processes, such as sleep, mating, behavior, and energy balance. The core body temperature (T_{core}) in

mammals is maintained by the central thermoregulatory circuitry, which has its center at the preoptic area (POA) of the hypothalamus. Brain injection of peptides and differential expression (DE) analyses suggested a role of neuromodulators in energy balance, especially at the POA. Such studies implicated different peptides in the control of T_{core}, for instance: pituitary adenylate cyclase-activating peptide (PACAP) and leptin. However, these studies have limitations. The injections required previous knowledge about the identity of the peptides, and many did not account for other parameters that influence T_{core}, such as locomotor activity. And none of the DE analyses evaluated the peptides at the protein level. Therefore, the molecular mechanisms that modulate body temperature during thermal challenges remain unclear. Thus, we performed an unbiased screening of peptides released under thermal challenges. The peptides were collected from the POA of freely behaving adult male mice using microperfusion under warm and cold temperature stimulation. The control group was kept at room temperature. The samples were analyzed in an unbiased manner by liquid chromatography and mass spectrometry (LC/MS) and label-free quantification. With this, we aimed to investigate which peptides are released at the level of the POA during these stimuli, and how they help to integrate thermal information and to control T_{core}. We were able to detect, in unstimulated animals, peptides part of 29 proneuropeptides and propeptide hormones. In total, we identified twenty peptides more in comparison to a previous unbiased screening of brain secretome. Also, comparing samples of unstimulated and stimulated animals, we detected peptides from six proneuropeptides that were significantly regulated in warm-exposed animals. With the cold stimulation, we found ten peptides from neuromodulators that were differentially regulated. Further on, we plan to investigate if the identified peptides modulate neural activity and T_{core} by *in vivo* and *in vitro* studies. Hence, the identified peptides could contribute to a better understanding of thermoregulatory mechanisms. And considering the impact that T_{core} has on mammals, this project could have meaningful outcomes for healthy and diseased states.

Title: Electrophysiological characterization of circadian clock neurons entrained to temperature cycles

Authors: *N. SONI, S. YADLAPALLI;
Cell & Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Abstract: Fruit fly *Drosophila melanogaster* offers an excellent model to study the distinct roles of different clock neuron classes in circadian timekeeping and sleep regulation. Flies central circadian clock consists of a network of approximately 150 clock neurons, each of which contains a molecular clock that generates gene expression oscillations with a period of approximately 24 hours. Circadian rhythms are self-sustained in constant conditions, but they must be entrained by external cues such as light and temperature cycles to maintain a precise 24-hour period. While we know a lot of how light entrains the clocks, the neural and molecular mechanisms underlying temperature entrainment are largely unknown. To address these critical gaps, here we employed electrophysiology, behavioral, and other genetic techniques to gain a deeper insight into how clocks are entrained to temperature cycles. Specifically, to understand the nature of change in membrane potential of DN1p in temperature cycle, we employed in vivo whole-cell voltage patch-clamp to measure the resting membrane potential (RMP) from all DN1p clock neurons; and found that RMPs measured in temperature cycle were not aligned to a common pattern usually observed in these neurons in LD cycle (Flourakis *et. al*., Cell 2015). Based on RMP measured in temperature cycle we observe three major clusters of DN1p. A recent finding suggests the presence of molecular heterogenicity within the DN1p population (Ma *et. al*., elife 2021), therefore, to maintain homogeneity in our recordings, we used a very specific subset of DN1 cells tagged with the GFP. We used DN1p cells positive for CnMa peptide. We observe that in LD cycle DN1pCnMA change in RMP follows a similar pattern observed previously (Flourakis *et. al*., Cell 2015). However, we observe that in temperature cycle there is a ~6 hour phase difference in the oscillations of neuronal depolarization of DN1pCnMA cells compared to that of LD cycles. Together, these results provide the first comprehensive measurement of DN1p change in RMP in temperature cycle. This study greatly expands our understanding of change in clock neurons electrophysiological behavior in two naturally occurring circadian changes in LD as well as in temperature and allow researchers to consider that clock neurons are not homogeneous in their electrical rhythm when we consider different entrainment.

Title: Post-inspiratory activity elicits by activation of phox2b-expressing retrotrapezoid nucleus neurons depends on the integrity of the Kolliker-Fuse region

Authors: *K. FLOR[1], L. M. OLIVEIRA[2], A. C. TAKAKURA[2], T. S. MOREIRA[1];
[1]Dept. of Physiol. and Biophysics, [2]Dept. of Pharmacol., Inst. of Biomed. Sci. - USP, São Paulo, Brazil

Abstract: Considering that the retrotrapezoid nucleus (RTN) would be an important center in the central nervous system (CNS) involved in the maintenance and modulation of respiratory activity, we hypothesized that neurons in this nucleus would also be involved in the post-inspiratory phase of the respiratory cycle. Here we performed pharmacogenetic manipulation (AAV-hM3D(Gq)-mCherry or AAV-hM4D(Gi)-mCherry) in VGlut2-cre,Ai6 conscious mice to evaluate breathing parameters through whole body plethysmography. Under baseline conditions, RTN stimulation by intraperitoneal administration of CNO (90 µg/mL - 0.1 mL/animal) produced a long-lasting increase in respiratory frequency (f_R), tidal volume (V_T) and minute ventilation (V_E), as well as reduction in the duration of the post-inspiratory (T_{PI}) phase. The increase in V_T (3.3 ± 0.47 vs. RTN stimulation: 5 ± 0.39 ml/kg) and V_E (1108 ± 201 vs. RTN stimulation: 1595 ± 276 ml/min/kg) were reduced in a condition of pharmacogenetic inhibition of Kolliker-Fuse (KF) glutamatergic neurons. The reduction in TPI (152 ± 42 vs. RTN stimulation: 123 ± 16 ms) was prolonged after inhibition of KF neurons. After the inhibition of KF glutamatergic neurons, RTN stimulation produced a further increase in f_R (416 ± 36 vs. RTN stimulation: 284 ± 23 bpm). The phox2b-expressing RTN neurons seem to be involved in the modulation of respiratory activity and depend on the integrity of the glutamatergic neurons in the KF region.Financial support: FAPESP, CNPq, CAPES-Proex

Title: A Randomized Control Pilot Study of the Efficacy of Qigong vs Exercise-Nutrition Training on Improving Mood and Cardiorespiratory Measures

Authors: *C. S. ZIMMERMAN[1], D. DANIELS[1], C. PENNER[1], S. TEMEREANCA[2], C. E. KERR[3], S. JONES[4];
[1]Neurosci., [2]Dept. of Neurosci., [3]Brown Univ., Providence, RI; [4]Neurosci., Brown Univ., Brown University, RI

Abstract: Cancer-related fatigue is a debilitating, often long-term side effect of cancer treatment typically accompanied by significant mood disturbance. Since the autonomic nervous system governs overall body homeostasis and energy regulation and is intimately related to limbic and affective processing, cardiorespiratory measures of autonomic output such as heart rate variability (HRV) and respiratory sinus arrhythmia (RSA) may also be important for understanding overall mood and fatigue burdens. Exercise has emerged as an important contributor to alleviating fatigue but can be prohibitively intense for someone struggling with fatigue. Qigong is a form of meditative movement deriving from Chinese medical traditions and offers a feasible and gentle alternative to exercise. Additionally, the meditative awareness fostered in Qigong may have added benefit for mood-related symptoms of fatigue. We therefore assessed the effect of exercise vs qigong training on fatigue reduction in a 10-week pilot randomized control trial (n=22). We present secondary outcome measures related to mood changes assessed through multiple self report questionnaires (Profile of Mood States, Perceived Stress Scale, Multidimensional Assessment of Interoceptive Awareness, Difficulties in Emotion Regulation Scale) and alterations in cardio-respiratory measures of HRV and RSA (as assessed through Biopac MP150 3-lead ECG). Analysis of our primary fatigue reduction endpoint indicates that while both exercise and Qigong significantly reduced fatigue levels pre-post intervention, there did not appear to be a significant group x time interaction on ANOVA, suggesting that one may not be superior to the other in terms of fatigue reduction. Improvements in mood related function pre-post intervention were statistically significant in the Qigong but not the exercise group, suggesting that while both groups reduce fatigue, Qigong may additionally address mood-related symptoms. Results will be presented in relation to our ongoing analysis of HRV and RSA. This study suggests Qigong may be an effective therapy for improving mood and cardiorespiratory health, and helps identify changes in these factors in both exercise and qigong training that can influence fatigue reduction in cancer survivors with fatigue.

Title: Effects of mindfulness-based hypertension intervention on resting state functional connectivity

Authors: J. POLCARI[1], R. CALI[3], B. NEPHEW[1], *J. CIROLI[1], F. SAADEH[4], E. LOUCKS[4], J. A. KING[2];

Abstract: Hypertension related illnesses are a leading cause of disability and death in the United States. Due to the high prevalence of adverse effects of pharmacological interventions for hypertension, there is increased interest in the development of nonpharmacological interventions. A mindfulness-based blood pressure reduction program (MB-BP) is effective in attenuating hypertension, but the neural correlates of this intervention are unknown. The objectives of the present study were to identify functional neural correlates of MB-BP using functional resting state magnetic resonance imaging (MRI) and assess potential correlations with key clinical outcomes. In subset of participants from a larger randomized controlled trial, MB-BP participants exhibited increased mindfulness and decreased depression compared to controls. Analyses of functional MRI data revealed significant group differences in several regions in the limbic system and/or associated with hypertension. Specific changes in functional connectivity were significantly associated with clinical measures of blood pressure, depression, anxiety, mindfulness, and emotional regulation. It is concluded that MB-BP has extensive and substantial effects on neural functional connectivity which could mediate beneficial changes in mindfulness, depression and related clinical measures in individuals with hypertension.

Title: Bodily Arousal Fluctuations During Task Performance: evidence from tonic and phasic electrodermal activity

Authors: T. GUIEYSSE[1], A. DOUBLIEZ[1], M. HOUOT[2], F.-X. LEJEUNE[2], S. RAZAFIMAHATRATRA[1], T. MEDANI[3], A. KLARSFELD[4], G. DREYFUS[4], ***K. ANDRADE**[1];
[1]Salpêtrière Hosp., Paris, France; [2]Paris Brain Inst., Sorbonne University, France; [3]Signal & Image Processing Inst., University of Southern California, CA; [4]ESPCI-Paris PSL, Paris, France

Abstract: Background: Our ability to learn from errors and flexibly adapt ongoing behavior is critical for an optimal performance. Fluctuations in physiological arousal, as revealed by both tonic and phasic components of electrodermal activity (EDA), typically accompany changes in attentional and emotional states with impact on task success. Nevertheless, the specific role of each of these EDA components during task performance is still imprecise. Objective and methods: Our main goal was to study whether tonic (activated arousal during the task) and phasic (electrodermal responses, EDR, to the stimuli) EDA components co-vary with each other and how they evolve during task performance. To this end, we recorded and analyzed the fluctuations of these components in nineteen healthy elderly subjects while they performed two consecutive sessions (A and B) of an experimental task composed by modified versions of the Go/No-go and Stroop tests. These tests were characterized by distinct workload conditions within and between sessions: the instructions of the Go/No-go test remained unchanged between sessions, while the instructions of the Stroop test were inversed in session B. Results: We observed a habituation effect related to stimulus repetition as revealed by a significant decrease in the amplitude of activated arousal between sessions (B < A) and within each test (end < beginning) in each session, as well as by a similar decrease in the amplitude of EDR on correct responses (session B < A). However, the amplitude of EDR on errors did not vary between sessions for any of the tests. Accordingly, the significant correlation between activated arousal and EDR amplitude observed on correct responses for each test, separately, disappeared with errors. Last, we observed higher EDR amplitudes in the Go/No-go test than in the Stroop test, as well as higher EDR amplitudes on erroneous (versus correct) responses only in the Go/No-go test, thus suggesting that subjects were less aware of their errors while performing the Stroop test (that is, the test more demanding in terms of mental effort and working memory). Conclusion: Our results suggest that fluctuations in tonic and phasic EDA are differently influenced by stimulus habituation and type of response (correct versus erroneous), which is in line with the role of EDR as a physiological signal of error awareness. Importantly, they further suggest that awareness of having committed an error (as revealed by EDR amplitude) might depend on the level of cognitive load associated with the task.

Title: Examination of sex differences and diurnal variation in hippocampal neurophysiology and spatial memory

Authors: *L. GOODE[1], A. FUSILIER[1], N. REMISZEWSKI[1], K. L. GAMBLE[2];
[1]Univ. of Alabama Birmingham, Birmingham, AL; [2]Psychiatry, UAB Med. Ctr., Birmingham, AL

Abstract: Circadian rhythms are biological processes that cycle across 24-hours and are known to regulate many aspects of neurophysiology, including the processes of learning and storing memories. While there is well-documented evidence of diurnal variation in performance on spatial memory tasks, the effect of sex has not been as thoroughly examined across time of day. Moreover, there is little known regarding the impacts of time of day on hippocampal neuronal physiology. Here, we investigated the effects of both sex and time of day on hippocampal neurophysiology and hippocampal-dependent spatial memory in C57BL/6J mice. We found that performance on a hippocampal-dependent object location memory (OLM) task differs across circadian time of day and across sex. Using whole-cell patch-clamp, we measured spontaneous and mini excitatory and inhibitory postsynaptic currents in CA1 pyramidal cells in acute hippocampal slices from male and female mice during both the day and night. We found that the frequency and amplitude of both excitatory and inhibitory postsynaptic currents differed depending on time of day. We also measured active and passive properties of CA1 pyramidal cells and found differences in pyramidal cell excitability across time of day. Given that many neurological disorders impacting the hippocampus also display circadian disruption (e.g., Alzheimer's disease and epilepsy), understanding how hippocampal physiology and function are impacted by time of day can provide insight into the development of therapeutics targeting circadian disruption and inform the appropriate timing of existing treatments.

Title: The circadian coupling signal pigment-dispersing factor modulates visual sensitivity and locomotor output in the Madeira cockroach Rhyparobia maderae

Authors: *J. A. PLATH[1], **H. ZOLMON**[1], J. GESTRICH[1], P. ROJAS[2], W. ALAKA[1], M. BARTHOLMAI[1], T. VÖLKER[1], R.-M. VON BERLEPSCH[1], M. GARCIA[2], M. STENGL[1]; [1]Animal Physiology, Univ. of Kassel, Kassel, Germany; [2]Theoretical Physics, Univ. of Kassel, Kassel, Germany

Abstract: Circadian clocks are organized as dual morning and evening oscillator circuits of mammals and insects orchestrate sleep-wake rhythms entrained to external light dark cycles. We investigate how the circadian clock in the nocturnal Madeira cockroach gates and modulates sensory inputs and locomotor outputs for orchestration of sleep-wake cycles via timed neuropeptide release. The clock network was identified as multiple-peptide-expressing clock neurons which innervate the accessory medulla (AME) - a small neuropile in the optic lobes. The AME receives indirect visual input from the compound eyes and sends outputs to the midbrain to regulate rhythms of physiology and behavior. A key neuropeptide in insect circadian clock networks is pigment-dispersing factor (PDF), which controls sleep wake cycles via mostly unknown processes. Previous physiological recordings of the cockroach circadian clock suggested that PDF release at dawn activates morning-oscillator cells that promote sleep and inhibits evening oscillators promoting activity, thereby keeping sleep and activity promoting neuronal ensembles in stable antiphase. Here, in electroretinogram recordings from the compound eye we examined whether PDF as clock output controls circadian rhythms in visual sensitivity. Our preliminary results indicate that in the early day, when cockroaches sleep, PDF applications reduced the response to visual stimuli. Furthermore, in running-wheel studies of PDF-precursor/PDF-receptor RNAi double knockdown animals under constant conditions amount and rhythmicity of locomotor behaviour was strongly reduced. Surprisingly, rhythmicity was only moderately compromised in PDF-precursor or PDF-receptor single knockdown animals. We further characterized the activity of the clock network in long-term extracellular recordings of clock cells *in vivo*, which revealed dominant activity peaks at dawn, midday, dusk, and midnight consisting of electrical events at multiple scales. We are currently investigating whether these activity peaks are indicative of circadian clock-dependent release of PDF and other neuropeptides that together gate sleep wake rhythms.

Title: Circadian gene expression of the endocannabinoid system in the mouse suprachiasmatic nucleus

Authors: *T. D. NIEPOKNY[1], I. D. PRATT[2], E. M. MINTZ[3];
[1]Biol. Sci. & Biomed. Sci., [2]Biol. Sci., [3]Col. of Arts & Sci., Kent State Univ., Kent, OH

Abstract: The endocannabinoid and circadian systems regulate a variety of physiological and behavioral processes in mammals; however, there is relatively little known about the interplay between the two. Some components of the endocannabinoid system, such as anandamide and 2-arachidonoylglycerol concentrations, are under rhythmic control in parts of the brain and body. Receptors and enzymes for endocannabinoid synthesis and degradation have recently been elucidated in the rat suprachiasmatic nucleus (SCN). A preliminary study of our own conducted at two timepoints, zeitgeber time (ZT) 4 and ZT16, confirms the presence of mRNA expression of many of the same components in the mouse SCN. We looked for 6 different receptors targeted by cannabinoids, cannabinoid receptor 1 (*Cnr1*), cannabinoid receptor 2 (*Cnr2*), vanilloid receptor 1 (*Trpv1*), and several orphan G-protein coupled receptors: *Gpr18, Gpr55,* and *Gpr119*. Of these, we only detected the presence of *Cnr1*. Gene expression was detected for each of the endocannabinoid synthesis and degradation enzymes we investigated: N-acyl phosphatidylethanolamine phospholipase D (*Nape-pld*), diacylglycerol lipase alpha (*Dagl-a*), diacylglycerol lipase beta (*Dagl-b*), glycerophosphodiester phosphodiesterase 1 (*Gde1*), abhydrolase domain-containing 4 (*Abhd4*), abhydrolase domain-containing 6 (*Abhd6*), abhydrolase domain-containing 12 (*Abhd12*), fatty acid amide hydrolase (*FAAH*), monoglyceride lipase (*Mgll*). The mRNA of some of these components are rhythmic in the rat SCN, and we hypothesize that they are also rhythmic in the mouse SCN. Experiments currently in progress are using laser capture microscopy and quantitative real-time PCR to assess gene expression patterns of the detected endocannabinoid system components in the SCN of male and female mice around the 24-hour cycle. These data will further establish whether necessary cannabinoid system components are rhythmically expressed in the SCN and help determine their role in clock function.

Title: Components of the endocannabinoid system in the mouse dorsal and median raphe nuclei

Authors: I. D. PRATT[1], T. D. NIEPOKNY[2], *E. M. MINTZ[2];
[1]Biol. Sci., [2]Biol. Sci. & Biomed. Sci., Kent State Univ., Kent, OH

Abstract: Activity in the dorsal raphe (DR) and the median raphe (MR) influence circadian rhythms. The MR has a direct serotonergic projection to the suprachiasmatic nucleus (SCN), while the DR innervates the intergeniculate leaflet (IGL) as well as having connections to the MR. The IGL then innervates the SCN. Several molecular components of the endocannabinoid signaling, synthesis, and degradation systems have previously been identified in the SCN, DR, and MR. This experiment aimed to comprehensively identify gene expression of components of the endocannabinoid system in these regions, with a focus on future identification of the role of these components in the regulation of circadian rhythms. Male and female mice housed on a 12:12 light/dark cycle were sacrificed at two time points 12 hours apart (4 hours each after lights on and lights off). Brains were extracted and frozen for analysis. Sections were collected containing the MR and DR. The MR was removed from these sections with the use of a tissue punch and the DR was removed by dissection. Quantitative PCR was used to determine the presence or absence of numerous genes thought to be involved in the endocannabinoid system. B-actin was used as a control gene and tryptophan hydroxylase was used as a positive control for raphe tissue. Significant expression was detected in the DR for *Cnr1*, *Trpv1*, *Napepld*, *Dagl-a*, *Dagl-b*, *Faah*, and *Mgll*, while in the MR *Cnr1*, *Gpr18*, *Gpr119*, *Napepld*, *Dagl-a*, *Dagl-b*, *Faah*, and *Mgll* were detected. Ongoing experiments are evaluating whether any of these genes have a circadian rhythm of expression. The presence of the identified endocannabinoid system components suggests that endogenous cannabinoid signaling may modulate the influence of the raphe nuclei on circadian clock function.

Title: Investigating cell-specific neuronal ER stress after prolonged wakefulness

Authors: *A. CHAKRABARTY[1], S. E. NEWEY[1], L. DENLY[1], M. PROMI[1], J. PRIUS-MENGUAL[1], D. MUNRO[1], L. B. KRONE[1], L. E. MCKILLOP[1], A. HOERDER-SUABEDISSEN[1], Z. MOLNAR[1], S. PEIRSON[1], N. NAIDOO[2], V. V. VYAZOVSKIY[1], C. J. AKERMAN[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The restorative nature of sleep is supported by subjective experience as well as its homeostatic and local regulation in the mammalian cortex. Waking periods are believed to result in challenges to cellular physiology that leads to cellular stresses, and which sleep then serves to restore. For example, periods of extended wakefulness and sleep disruption have been linked with the accumulation of misfolded proteins in the endoplasmic reticulum lumen ("ER stress") in mouse brain tissue (e.g. Naidoo et al., 2006). Yet, it remains to be determined whether neuronal cell populations undergo different degrees of ER stress as a function of their activity and sleep-wake history. To address this question, we developed a quantitative immunohistochemical analysis pipeline to measure ER stress in neuronal subtypes in cortex after a period of prolonged wakefulness. We used cortical tissue from male C57BL/6 mice following a 6h period of sleep deprivation (SD) from light onset or an equivalent period of undisturbed sleep. In the first application of our pipeline, we used anti-NeuN and anti-PV antibodies to identify all neurons and parvalbumin-expressing fast-spiking interneurons, respectively. We stained for the major protein folding chaperone BiP/Grp78, an established marker of ER stress, with an anti-SEKDEL antibody. In frontal cortex, NeuN neurons showed a 15% increase in SEKDEL reactivity following 6h SD, whereas PV neurons did not. PV neurons showed a lower level of SEKDEL reactivity than neighbouring non-PV neurons. NeuN neurons from somatosensory cortex did not show a significant effect with SD. Together, these results indicate that there may be cell type-specific and region-specific differences in ER stress levels following prolonged wakefulness. In order to be able to monitor ER stress dynamically in further defined neuronal populations, we have also developed a novel fluorescent reporter based on the BiP/Grp78 promoter. In NIH3T3 mouse fibroblast cells challenged with low doses of the ER stress inducer, Tunicamycin, the BiP/Grp78 transcriptional reporter showed substantial changes in fluorescence compared to DMSO control. The novel reporter also reflected the temporal dynamics of ER stress following a 2h pulse treatment with Tunicamycin, with the reporter's fluorescence peaking at 12h and returning to baseline by 72h. These properties validate the reporter as a useful tool for monitoring patterns of physiological ER stress, with the potential to genetically target specific cell populations. Such an approach could be used to further investigate the relationship between cell-specific ER stress and sleep-wake history.

Title: Sleep deprivation-induced impairments in hippocampal memory and plasticity might be mediated by somatostatin interneurons

Authors: *F. RAVEN[1], J. DELORME[1], L. WANG[1], F. ROIG KUHN[3], V. K. KODOTH[2], J. MA[4], J. D. MARTINEZ[1], B. A. TOTH[5], V. BALENDRAN[1], A. VEGA MEDINA[1], K. SCHMIDT[6], S. JIANG[1], S. J. ATON[1];

Abstract: Sleep loss is an increasing phenomenon, and can harm both physical and mental health. Even a single night of sleep deprivation (SD) can result in disturbed cognition, and as little as 6h of SD affects the dendritic spine density within the hippocampus, which is crucial for memory storage. Recent work from our lab has demonstrated that activity-dependent phosphorylation of ribosomal protein S6 (pS6) is decreased in dentate gyrus (DG) granule cells, and increased in somatostatin-expressing (SST+) interneurons, after just a few hours of SD. We find that chemogenetically activating SST+ interneurons in the mouse DG disrupts sleep-dependent fear memory consolidation. Conversely, inhibition of this specific cell population during post-learning sleep promoted fear memory consolidation, and increases pS6 labeling of granule cells. More recently, we have tested whether SD also affects SST+ interneurons at the structural level, using quantitative analysis of Cre-dependent Brainbow labeling in DG and other hippocampal structures after a period of *ad lib* sleep or SD. Our data indicate that the negative consequences of SD on hippocampus-dependent memory and hippocampal plasticity might be mediated by local SST+ interneurons. This finding may aid in the development of new therapeutic strategies to fight disorders that are associated with both sleep loss and memory deficits or structural disruption in the hippocampus, such as Alzheimer's disease.

Title: Interactive role of basal forebrain neurons in sleep homeostasis

Authors: *R. BASHEER, C. YANG, H. BOUAOUDA, E. L. HODGES, D. S. UYGUN, J. T. MCKENNA;
VA Boston Healthcare System-Harvard Med. Sch., West Roxbury, MA

Abstract: Previous work by us and others suggested that basal forebrain (BF) cholinergic (ChAT+) neurons are important for the homeostatic sleep response (HSR) and the localized elevation of extracellular levels of the sleep-promoting neuromodulator, adenosine (ADex). Immunohistochemical and *in vitro* electrophysiological studies provide evidence for local interaction of cholinergic neurons with neighboring parvalbumin expressing GABAergic (PV-GABA) and vesicular glutamate transporter 2 expressing glutamatergic neurons (vGluT2+). Furthermore, blocking cholinergic receptors in BF during optogenetic cholinergic stimulations attenuated arousals suggesting that, within the BF, acetylcholine induces arousal indirectly via its action on neighboring non-cholinergic neurons. However, direct tests of the role of cholinergic vs. non-cholinergic systems for eliciting the HSR are lacking. To test the effect of individual neuronal subtype on HSR, we injected AAV-ChR2-EYFP virus into BF of ChAT-Cre, PV-Cre or vGluT2-Cre male and female mice also outfitted with EEG and EMG electrodes and optodialysis probe. Each set of mice were subjected to EEG/EMG recording and in vivo microdialysis from ZT0-ZT9 on (1) baseline day (no stimulation); (2) sleep deprivation (SD) day- SD from ZT3-7; and (3) stimulation day-opto-stimulation from ZT3-7 with or without pharmacological intervention. Levels of ADex were measured during SD or opto-stimulation. NREM sleep time and NREMδ (0.5-4Hz) were measured post-SD or post opto-stimulation from ZT 7-9.Preliminary results (N=3 for all) show both ChAT and vGluT2, but not GABA-PV, similar to SD effects, optogenetic stimulations led to increase in ADex levels (ChAT: 213%; vGluT2: 150%); and in post-stimulation, NREM sleep time and NREMδ (ChAT: 12.2±3% and 22±7% and vGluT2: 18.3±14% and 40±6%, respectively). Reverse microdialysis of a cocktail of cholinergic receptor antagonists during BF-ChAT+ neuronal stimulation did not attenuate ADex increase. On the contrary, administration of a cocktail of glutamate receptor antagonists attenuated ADex increase (62%) during BF-vGluT2+ neuronal stimulation. These preliminary observations suggest that cholinergic neuronal activity leads to increase in ADex, whereas the glutamatergic neurons elicit ADex increase via activation of cholinergic neurons.

Alliance, Univ. of Tsukuba, Tsukuba, Japan; [5]Dept. of Mol. Genet., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Sleep is a fundamental behavior conserved from vertebrates to invertebrates. Although the “two-process model” has been proposed as a conceptual framework of sleep regulation, the molecular mechanism for homeostatic regulation of sleep and the neural substrate of sleep need remain unknown. *Salt-inducible kinase 3* (*Sik3*) is a member of AMP-activated protein kinase family, implicated in sleep need and circadian rhythm regulation. The gain-of-function *Sleepy* mutation in the *Sik3* gene increases sleep need and NREM sleep amounts. Most of systemic *Sik3* null mice die neonatally, but the few survived mice exhibit longer circadian period lengths. It remains unknown as to whether endogenous SIK3 is involved in sleep/wake regulation and, if so, which neuronal groups are responsible for the SIK3-dependent regulation. Here, we examined the sleep/wakefulness of neuronal type-specific SIK3-deficient mice. We established *Sik3-flox* mice, which abolished SIK3 expression in a Cre recombinase-dependent manner. *Sik3-flox* mice were crossed with various type of Cre driver mice to search for the SIK3-dependent sleep-regulating brain regions. We found that SIK3 deficiency in glutamatergic neurons (*Vglut2-cre; Sik3-flox* mice) resulted in reduced NREM sleep amounts. *Vglut2-cre; Sik3-flox* mice exhibited decreased delta power (1-4 Hz) during NREM sleep, which is a marker of sleep need, throughout the day. SIK3 is expressed broadly in brain and *Vglut2* positive cell lineage also covered many brain regions. Through further screening of various Cre lines, we found that *Vglut1-cre; Sik3-*

flox mice, whose SIK3 expression was diminished in glutamatergic neurons mainly in the cerebral cortex, showed reduced NREM sleep time and delta power in NREM sleep. We also confirmed that SIK3 deficiency in GABAergic neurons (*Vgat-cre; Sik3-flox* mice) did not change sleep time or delta power in NREM sleep. Instead, *Vgat-cre; Sik3-flox* mice showed a phase delay in sleep/wake pattern and longer free-running period length in constant dark conditions as previously described in *Sik3* null mice. Our results indicate that SIK3 regulates homeostatic sleep need through glutamatergic neurons in the cerebral cortex, and sleep need regulation was independent from the regulation of circadian rhythms by endogenous SIK3.

Title: Effect of 5HT7R agonist and antagonist on biological markers and pathophysiological mechanisms in neuropathic rats

Authors: *V. GOURA[1], P. JAYARAJAN[1], A. KISHORE[2], R. NIROGI[1];
[1]Suven Life Sci. Ltd., Hyderabad, India; [2]Pharmacol., Manipal Col. of Pharmaceut. Sci., Manipal, India

Abstract: Clinically it is acknowledged that treating neuropathic pain is most difficult due to comorbidities. To treat neuropathic pain, physician must evaluate all aspects of pain comorbidities like depression, anxiety, sleep and cognition of patients. As per literature, biological and neuroimaging data show that common brain areas are involved in the modulation of pain and its comorbidities. Improved understanding of the analgesics, its effect on biological markers of pain, and its comorbidities may offer promising avenues to treat neuropathic pain. We have tried to understand the effect of a newly identified G-protein coupled receptor (GPCR), the serotonin receptor subtype 7 (5-HT7). In this study, LP-211 a 5-HT_7R agonist and SB-269970 a 5-HT_7R antagonist were evaluated to find their role on modulation of monoamines, neuroendocrine markers, neurotrophic markers and immune-modulators in neuropathic rats. Histological studies were performed to evaluate its effects on the sciatic nerve myelin sheath. We also performed *in-vivo*electrophysiology study in spinal dorsal horn neurons to support further pathophysiological mechanisms. In the current study, we tested LP-211, 3mg/kg, *i.p*., LP-211, 3mg/kg, *i.p.* + Gabapentin (GBP) , 10mg/kg, *i.p.*, SB-269970, 3mg/kg, *i.p.* and LP-211, 3mg/kg,

i.p. + SB-269970, 3mg/kg, *i.p.*, on partial sciatic nerve ligation induced neuropathic pain (PSNL) and streptozocin induced diabetic neuropathic pain (DNP) rats. Von Frey filaments were used for evaluating pain, monoamines (serotonin (5-HT), norepinephrine (NE) and dopamine (DA)) were estimated using high performance liquid chromtography (HPLC), neurotrophic markers, immune- modulators using ELISA kits, and neuroendocrine markers using liquid chromtography mass spectrometry (LC-MS/MS). Monoamines were significantly decreased in pain animals when compared to control animals. LP-211 and LP-211 + GBP combination showed significant increase in 5-HT, NE levels were maintained equivalent to control animal values and there is no improvement was observed on levels of DA. LP-211 and LP-211 + GBP combination showed significant increase in neurotrophic markers. Only LP-211 + GBP combination showed decrease in immune modulators and substance P. The decreased myelin sheath density was restored by LP-211 + GBP combination. Dorsal horn neuronal firing induced by mechanical stimulation in PSNL rats was significantly decreased by LP-211 + GBP combination. SB-269970 did not show any significant affect on biological markers in the tested animal models. Thus, LP-211 a 5-HT_7R agonist in combination with GBP would be a promising therapy for treating neuropathic pain and its comorbidities.

Title: Inoculation mouse model of endometriosis creates a lowered abdominal pain threshold and signs of anxiety and depression, secondary to chronic pain, in the home-cage and group housed conditions.

Authors: *P. J. SWEENEY;
Naason Sci. Inc., Osong, Korea, Republic of

Abstract: Endometriosis is a condition that involves the ovaries, fallopian tubes and pelvic tissue. The condition rarely spreads outside of the pelvis and is characterized by pain of varying degrees and can result in debilitation from chronic pain and infertility if left untreated. There are currently treatments available, but these often don’t fully address the condition in women suffering from it. We attempted to model endometriosis in a group (N=20) of Balb/C mice by creating an age- matched donor group that was hormonally primed to induce the onset of menstruation and the subsequent generation of menstrual tissue that, after decidualization, was

extracted, post euthanasia, from the donor mice. This tissue was then introduced to the uterus of the donor mice (N=20) and resulted in endometriosis like tissue changes with a large percentage (80 %) of the animals developing a cystic like response to IP injection of the inoculate. After the inoculation animals were observed in their home cages using a unique home cage monitoring system that allowed for temporal observation of locomotor function and behavior in group housed conditions. RESULTS: Animals who received the inoculate of donor tissue tolerated the IP injections of this donor tissue very well with no mortality in the 72 hours after IP injections. Animals who received the inoculate were seen to have a slower overall motility in the home-cage and a higher degree of thigmotactic behavior than control animals subjected to a suture in the colonic mesentery which would produce pain and a degree of discomfort. Animals in both groups, control and tissue receivers, showed signs that could be considered to be symptomatic of abdominal pain with tactile allodynia measured with abdominal von Frey filament showing a significantly lowered pain thresholds in those mice that had the inoculation procedure performed. This threshold was in the region of 50% lower in gram value - control and sham operated groups did not show this decreased pain threshold. Upon closer inspection of the tissue pathology it was found that the lowered pain threshold persisted in those animals that received the inoculate but was also significantly lower in the groups that went on to develop cysts in the peritoneum that were visible to the naked eye. Conclusions: The presence of an endometriosis-like condition imposed in the Balb/c mouse creates an increased sensitivity to pain as measured by von Frey filament as well as locomotor and suspected psychological symptoms associated with chronic neuropathic pain. Further investigation into the group housed social behavior and chronic pain associated behaviors is warranted.

Title: Alteration of emotional behavior and associated neuroanatomical and immunohistochemical properties in the corticolimbic system of OLETF rats regardless of diabetic stage

Authors: *R. OCHI[1], N. FUJITA[1], N. GOTO[1], H. NISHIJO[2], S. URAKAWA[1];
[1]Musculoskeletal Functional Res. and Regeneration, Hiroshima Univ., Hiroshima, Japan; [2]Syst. Emotional Sci., Univ. of Toyama, Toyama, Japan

Abstract: Metabolic disorder, such as diabetes, can be accompanied with psychiatric disorders. We have reported that 20-week-old Otsuka Long-Evans Tokushima fatty (OLETF) rats, a model of progressive type 2 diabetes with age, exhibit increased anxiety-like behavior with reduced brain area and increased cholecystokinin (CCK)-positive neurons in the corticolimbic system. Parvalbumin (PV)-positive neurons in the corticolimbic system are also reportedly involved in anxiety. However, those alterations in different stages of type 2 diabetes remain unclear. Some of the diabetic animals reportedly show increased neuronal apoptosis and activating transcription factor 4 (ATF4), involving apoptosis accompanied by caspase-3 activation. However, these apoptosis related properties in OLETF rats remain unclear. We aimed to investigate emotional behaviors and its possible mechanisms at different diabetic stages in OLETF rats. Eight- and 30-week-old OLETF rats were used as diabetic animal models at the prediabetic and progressive stages of type 2 diabetes, and age-matched Long Evans Tokushima Otsuka (LETO) rats were served as non-diabetic controls. Glucose levels were higher in OLETF rats than in LETO rats at both ages, and those increased with age in OLETF rats. To examine the emotional states, we performed the open field test. Locomotion in the center zone was less and latency to leave the center zone was longer in OLETF rats than in LETO rats at 8 and 30 weeks old, respectively. To examine possible mechanisms of altered emotional behaviors in OLETF rats, we measured brain regional areas and performed immunohistochemistry. The area of the medial prefrontal cortex was smaller in OLETF rats than in LETO rats at both ages. The densities of CCK-positive neurons of OLETF rats were higher than those of LETO rats in the lateral and basolateral amygdala at only 8 weeks old, and in the anterior cingulate and infralimbic cortices and hippocampal cornu ammonis area 3 at both ages. The densities of PV-positive neurons of OLETF rats were lower than those of LETO rats in the prelimbic and infralimbic cortices at both ages, and in the hippocampal cornu ammonis area 2 at only 8 weeks old. To examine the mechanisms of those area and neuronal reductions, we performed immunohistochemistry for caspase-3 and ATF4. No caspase-3-positive cell was detected in both strains, but the percentage of ATF4 co-expression in CCK- and PV-positive neurons was higher in OLETF rats than in LETO rats at both ages in the anterior cingulate cortex and basolateral amygdala, respectively. These results suggest neurological changes in the corticolimbic system affect in emotional behavior already at prediabetic stage of OLETF rats.

Title: Pain increases inhibitory tone from RMTg onto VTA dopamine neurons to drive anhedonia-like behaviors

Authors: *T. MARKOVIC[1], N. MASSALY[1], Y. VACHEZ[1], C. MURPHY[1], K. ABIRAMAN[1], B. RUYLE[1], H. YOON[1], S. M. CONWAY[1], M. MIKATI[1], R. AL-HASANI[3], M. CREED[2], J. MORON-CONCEPCION[4];
[2]Dept. of Pharmacol., [1]Washington Univ. in St. Louis, Saint Louis, MO; [3]Dept. of Anesthesiol., St. Louis Col. of Pharm. & Washington Uni, Saint Louis, MO; [4]Anesthesiol., Washington Univ. In St Louis, St Louis, MO

Abstract: The persistence of negative affect in pain leads to co-morbid symptoms, such as anhedonia and depression, representing a major health issue in the US. However, the neuronal circuitry and contribution of specific cellular populations underlying these behavioral adaptations remains unknown. A common characteristic of negative affect referred as anhedonia is a decrease in motivation to initiate and complete goal-directed behavior. Here, we found that the resting membrane potential of VTA DA neurons, which are critical mediators of motivational and hedonic states, was decreased in pain animals while the rheobase was significantly higher. We next assessed the contribution of inhibitory inputs to this decrease in excitability, by washing on $GABA_A$ receptor antagonist picrotoxin onto the slice. While the application of picrotoxin had negligible effect on the control group, it depolarized the VTA DA cells from the pain group to levels comparable to control animals.Next, we measured the spontaneous inhibitory postsynaptic currents as a reflection of spontaneous neurotransmitter release. We found that pain increases the frequency of spontaneous events indicating enhanced pre-synaptic release and an increase inhibitory drive onto VTA DA neurons.One of the main sources of inhibitory drive onto the VTA DA neurons is rostromedial tegmental nucleus (RMTg) and inhibition of VTA DA neurons is known to mediate anhedonia-like behaviors. Thus, we hypothesized that pain enhances RMTg GABA input onto VTA DA neurons. Indeed, we show that pain increases release probability of RMTg GABA terminals onto VTA DA neurons. Furthermore, we show that activation of RMTg GABA neurons in naïve animals is sufficient to induce a decrease in consumption of sucrose solution in two-botte choice task similar to pain-induced anhedonia-like states. Lastly, we demonstrate that chemogenetic inhibition of RMTg GABAergic input onto VTA DA neurons is sufficient to prevent anhedonia-like behaviors in animals in pain.Previous findings indicate that pain induces dysfunction of μ opioid receptor (MOR) system within VTA. In addition, RMTg represents the major opioid sensitive inhibitory input onto VTA DA neurons. Thus, the ongoing experiments utilizing pharmacology and in vivo microdyalisis will assess the effects of pain on MOR system function and whether these changes contribute to the increased inhibition from RMTg onto VTA DA neurons in pain. In conclusion, our results provide further understanding of

pain's regulation of the inhibitory input onto VTA DA neurons and its consequences on anhedonia-like behaviors.

Title: Anxiety: ethanol and chlorazepate oral consumption after reward loss

Authors: *L. MANZO[1], E. MAGAÑA[2], A. C. TAFOLLA[2];
[2]Postgrado, [1]Univ. Michoacana De San Nicolas De Hidalgo, Morelia, Mexico

Abstract: Male rats from the Wistar strain received training in an instrumental extinction (reward loss) task in a straight alley after acquisition with continuous reinforcement (CR; 12 pellets per trial) vs. 50% partial reinforcement (PR; 12 or zero pellets per trial in random sequence). Extinction after CR training is known to induce a higher level of emotional activation than extinction after PR. Increased emotional activation is reflected in enhanced behavioral suppression (i.e., faster extinction) during episodes of reward loss after CR than after PR acquisition. We measured the impact of the reward loss experience in a 2-h preference test administered immediately after extinction sessions. increased preference for ethanol after being exposed to sessions of appetitive extinction (Manzo et al., Physiol Behav 2014 123:86-92). Such increased fluid preference did not occur after acquisition (reinforced) sessions or in control groups with postsession access to water, rather than ethanol. Because ethanol has anxiolytic properties in tasks involving reward loss, oral consumption after extinction sessions was interpreted as anti-anxiety self-medication. To test this hypothesis, Wistar rats exposed to a 12-to-zero pellets event in a PR situation were given a two-bottle, 2-h preference test immediately after extintion sessions. One of the two bottles contained 2% ethanol, 1.5 mg/kg chlorazepate, or water for different groups (the second bottle contained water for all groups). Chlorazepate is a potentially addictive benzodiazepine anxiolytic used in the psychiatric treatment of individuals suffering from anxiety disorders. Three additional groups received the same postsession preference tests, but were always exposed to 12 pellets during CR. Rats showed during extinction session effect, suppressing behavior after the downshift relative to unshifted controls. This effect was accompanied by a selective increase in both ethanol and chlorazepate oral intake

during the initial downshift sessions. Downshifted animals with access to water or unshifted controls with access to the anxiolytics failed to exhibit any changes in preference during the postsession test. This study shows for the first time that a prescription anxiolytic supports enhanced voluntary consumption during periods of emotional distress triggered by reward loss. These results support the hypothesis that anti-anxiety self-medication may provide insights into the early stages of addictive behavior.

Title: Effects of forebrain NMDA receptor chimeric GluN2 subunit expression on anxiety behavior

Authors: *J. I. ESCOBAR[1], T. C. DUMAS[2];
[2]Psychology, [1]George Mason Univ., Fairfax, VA

Abstract: Title: Effects of forebrain NMDA receptor chimeric GluN2 subunit expression on anxiety behavior **Authors:** J. I. Escobar; Perdomo, Fares, Wild, Mastracchio, Keith, T. C. Dumas **Theme & Topic**:Theme G: Motivation and EmotionSubsection 4: EmotionsSub-subsection C: Emotion – Fear, anxiety, and painTheme B: Neural Excitability, Synapses and GliaSubsection 2: Ligand-gated ion channelsSub-subsection C: Ionotropic glutamate receptors **Grant Support:** 1R15 AG060461-(01)**Key Words (3):** NMDA Receptors, Transgenic Mice, Anxiety**Date of Submission:** July 15th, 2021**Abstract (Maximum 2300 Characters – Not including spaces):** Open channel blockers of N-methyl-D-aspartate receptors at excitatory glutamatergic synapses have been shown to ameliorate the symptoms of depression and anxiety in animal models and human beings. The current presumption is that drugs like ketamine antagonize extra synaptic NMDARs while causing a burst of release of glutamate, which returns depressed synapses to normal synaptic strength and completes circuits required for optimal mood regulation. An alternative explanation is that ketamine causes an increase in nonionotropic NMDAR signaling that permits subsequent activity-dependent synaptic strengthening. The latter notion has not been tested. However, nonionotropic NMDAR signaling influences on anxiety can be tested in mice with modified NMDAR subunits. GluN2 subunits are proposed to mediate nonionotropic signaling via their intracellular carboxy termini (CTD). By switching the CTDs of GluN2A and GluN2B it is possible to gain some insight into the distinct signals produced by

each CTD. Our “ABc” chimeric mice express the GluN2A amino terminal domain and transmembrane domain with the GluN2B CTD driven in the forebrain through the alpha calcium-calmodulin kinase II (CaMKII) minimal promoter. Conversely, our “BAc” chimeric mice express GluN2B amino terminal domain and transmembrane domain with the GluN2A CTD. Using the Open Field Maze (OFM) and Elevated Plus Maze (EPM), anxiety levels assessed in part through measures of latency to enter and dwell time in open regions of the mazes. Tests on young adult chimeric and wildtype mice on the EPM and OFM revealed no differences in anxiety levels across genotypes, which suggests that that GluN2 CTD signaling alone is likely not responsible for mediation of anxiety behaviors. Developmental experiments are underway to better understand how alterations in NMDAR signaling impact development of anxiety regulating systems. Results from these studies may reveal novel targets for the treatment of human anxiety disorders.**Current Character Count**: 1698

Title: Contribution of Neuropeptide Y (NPY) Y5 receptors in the basolateral amygdala to social interaction in male and female rats.

Abstract: Neuropeptide Y (NPY) is associated with resilience in humans and behavioral resistance in animal models of stress. Within the basolateral amygdala (BLA) both acute and repeated activation of NPY receptors increases social interaction (SI) and buffers against the deleterious effects of stress (Sajdyk et al., 2008). One of the striking effects of repeated NPY injections includes the induction of neuroplasticity of BLA neurons that is associated with persistent increases in SI and stress resistance as well as decreased freezing during fear extinction in male rats. Of the multiple NPY receptors expressed within the BLA, activation of either Y1R or Y5R increases SI acutely, and activation of Y5R, not Y1R, underlies the

generation of the persistent effects of NPY thereby supporting a novel role for the Y5R subtype (Michaelson et al., 2020). These findings provided an interesting dichotomy to the functions of Y1 and Y5 receptors in the BLA and put a new focus on the importance of the relatively understudied Y5R. This study was designed to examine the contribution of Y5R to the enhancement of SI and alterations in stress and BLA-related behaviors. Adult male and female rats received injections of shRNA-Y5R (lentiviral vector; Addgene) into the BLA and SI behavior was monitored weekly at 2-4 weeks post-injection. Behavior on the elevated plus maze (EPM) was also assessed at 4 wks. At the end of the experiment, brain tissue was collected to verify injection placements and degree of Y5R knockdown using Western analysis and immunohistochemistry. Using Western blot analysis, we observed decreases (40-60%) in Y5R protein after shRNA-Y5R treatment when compared with uninjected control BLA tissue. SI was decreased in both male and female rats 2 weeks post injection and decreased further at 3 wks ($p<0.05$, ANOVA) compared to their baseline SI (prior to virus injection). There were no significant changes in open arm time in the EPM, although a more complete analysis is being finalized. These data indicate that the Y5R plays an important role in regulating SI behavior in male and female rats and support the development of future studies to further characterize the circuitry involved in these NPY-mediated responses.

Title: Investigating the effect of differential striatal dopamine projections on reversal learning and immediate early gene (IEGs) expression

Authors: *R. K. VAN DER MERWE, M. GHANEM, J. A. NADEL, D. COPES-FINKE, S. PAWELKO, J. S. SCOTT, M. FOX, C. MOREHOUSE, R. MCLAUGHLIN, C. MADDOX, G. MALAKI, C. D. HOWARD;

Abstract: Behavioral flexibility is key to survival in a dynamic environment. One form of flexibility is reversal learning, or the ability to switch between opposing actions following a change in outcome. Key to this process is the striatum, a subcortical structure tasked with action selection and the learning of novel motor behaviors. Early development of motor behaviors is

dependent on the dorsomedial striatum, which later becomes dependent on lateral striatum as behaviors become inflexible. Similarly, dopamine release in striatum mirrors this medial-to-lateral transition, suggesting that lateral dopamine release may be a key mechanism in establishing inflexible behaviors late in learning, though this has not been directly tested. To investigate this, we bred DATcre x Ai32 mice to allow selective optogenetic activation of dopamine terminals within medial, lateral, and ventral striatum. These mice performed an intracranial self-stimulation reversal task in which they received optogenetic stimulation to medial (n=7), lateral (n=7), or ventral (n=8) dopamine inputs when they pressed one of two levers, before the active lever was switched. Consistent with presumed ventromedial/lateral striatal function, we found that mice self-stimulating ventral or medial striatal dopamine were flexible following reversal, while activation of lateral striatal dopamine impaired reversal. This effect was associated with no difference in place preference or locomotion in an open field across groups. In addition, pilot studies suggest optogenetic activation of medial and lateral dopamine modifies reversal for food rewards, and this manipulation may be associated with striatal immediate early gene (IEG) expression, which support synaptic plasticity and learning. This work contributes to our general understanding of how dopamine modifies subcircuits within the striatum to switch between different behavioral strategies, and may provide insight into how drugs of abuse promote inflexible, habitual behaviors in drug addiction.

Title: Variation of the inter-trial interval during associative conditioning produces sex differences in sign-and goal-tracking behavior

Authors: *F. CZESAK[1], J. MORROW[2];
[1]Univ. of Michigan, Wappingers Falls, NY; [2]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Variation of the inter-trial interval during associative conditioning produces sex differences in sign-and goal-tracking behaviorWhen associating a neutral stimulus (CS) with a reward (US), individual differences can be revealed in the propensity to attribute incentive salience to the CS. When the presentation of a lever (CS) is paired with a food reward (US), some rats will travel immediately to the food magazine to obtain the reward. This is called goal-tracking behavior, and these animals seem to interpret the CS simply as a predictor for the US. Other rats, upon associating the lever with the food reward, will interact with the lever itself, thus exhibiting sign-tracking behavior and suggesting an attribution of incentive salience to the CS. The behavior a rat will express has been found to differ depending on the length of the interval between associations of the CS and US. Here we asked how altering this inter-trial interval (ITI) between associations affects the attribution of incentive salience to reward cues in both males and females. Rats were trained using the PCA paradigm in experimental groups with different ITI ranges – 20-30s, 30-60s, or 30-260s. The results showed that increasing the ITI during PCA training causes increased sign-tracking behavior in all animals, and thus a greater likelihood of attributing incentive salience to the cue. Most importantly, females were significantly more likely to increase sign-tracking behavior with an increased ITI than males. These data suggest that males and females differ in their propensity to attribute incentive salience to cues, and highlight the importance of considering ITI length when studying Pavlovian conditioning in both sexes.

Title: Delayed reward presentation among well-trained mice with lever preferences: Examining sign- and goal-tracking behaviors

Authors: *T. SATO[1], T. YAMAKUNI[2];
[1]Social Welfare, Nagano Univ., Ueda, Japan; [2]New Industry Creation Hatchery Ctr. (NICHe), Tohoku Univ., Sendai, Japan

Abstract: When the presentation of an anticipated reward is delayed in an instrumental learning situation, despite the correct behavioral response for reward acquisition, various behaviors occur that do not directly contribute to the appetitive results. In experimental sessions with delayed reward presentation, some of these behavior patterns might facilitate or hinder reward acquisition. Thus, in this study, we examined a small sample of well-trained mice in a Skinner box. We focused on their preference between the right or left lever and measured both their lever-pressing and nose-poke responses to a pellet under five different time-lengths from lever-pressing to the delayed food pellet presentation (in seconds): 0 (no delay), 10, 20, 30, and 40. For this purpose, we measured the number of lever-pressing and nose-poke responses, of seven well-trained C57BL/6N mice, to acquire a pellet. Animals could press the levers in the predefined delay duration, but this action did not result in acquiring a food pellet. Response latency to the lever-presentation after predetermined delay was also measured for each trial. Moreover, the differences observed in the number of responses between the trials at 10 and 20 seconds, 20 and 30 seconds, and 30 and 40 seconds, were used to estimate the frequency of lever-pressing and nose-poke responses at the second, third, and fourth 10-second intervals, respectively, within the five reward delay trials. The animals were divided into two groups based on their lever preference: 1) the high preference group pressed either of the two levers at a rate of 70% or more and 2) the low preference group pressed both the levers at a rate of less than 70%. An exact probability test indicated that the high preference group tended to acquire more reward pellets in the overall sessions. In addition, the high preference group showed more correct responses, thereby acquiring more food pellets, than the low preference group within a test session. The high preference group also produced a relatively higher frequency of lever-pressing that did not contribute to appetitive results at the first 10-second reward delay interval, but not at any other intervals. Furthermore, the response latency from the lever presentation to pressing it was shorter in the high preference group. However, there were no significant group differences in the frequency of nose-poke responses during the delay intervals. The high preference group seemed to acquire more food pellets due to short latency to lever press, and to display a higher frequency of sign-tracking behavior immediately after the reward delay commencement.

Title: Homeostatically regulated reinforcement learning accounts for sodium balance-restoring behavior and state-dependent taste-specific dopamine signaling.

Authors: A. DURIEZ[1], T. HSU[2], M. F. ROITMAN[3], ***B. GUTKIN**[1,4];
[1]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France; [2]Univ. of Illinois At Chicago, Chicago, IL; [3]Psychology, Univ. of Illinois at Chicago Dept. of Psychology, Chicago, IL; [4]Inst. for Cogntiive Neuroscience, Ctr. for Cognition and Decision Making, NRU Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Seeking nutritive outcomes in anticipation of homeostatic need is crucial for survival. Stimuli predictive of nutritive outcomes invigorate approach towards obtaining the nutritive outcomes with behaviour driven by learned hedonic values even in absence of need. The taste of nutritive stimuli acquires value that appears to depend on the internal state of the organism. Sodium appetite is an excellent demonstration of this, where only sodium-depleted animals seek out and consume hypertonic sodium solutions and not other salts (e.g. potassium chloride). Experiments showed that dopamine signals triggered by sodium stimuli depend both on the internal state and taste. How such modulations of dopamine signalling may generate sodium-motivated behaviour, in an interplay of innate and learned processes, has been an open question. Classical reinforcement learning (RL) models have not been able to account for appetite dependent changes in responding, nor for how internal needs modulate dopaminergic signals. A recent homeostatically regulated reinforcement learning theory (HRRL) has proposed a solution to this problem by defining the origins of rewards in a homeostatic manner: as outcomes that tend to re-establish homeostatic stability. Hedonic values are then learned for nutritive outcomes and assigned to stimuli that predict them. The theory also shows how responding is modulated by internal states and predicts that dopaminergic activity that signals the reward-prediction errors (among other things) is modulated as a function of the internal state. Last but not least, the theory suggests that sensory properties of the consumed goods can be a predictor of their impact on the internal state. We apply HRRL to sodium-seeking behavior, showing that it can fully account for the experimental data. We show that our simulated sodium-depleted HRRL agents replicate conditioned responding for sodium and stimuli predictive of sodium delivery, but not to potassium. We further show that this responding vanishes as the agent is satiated. The models explain how the experimentally observed modulation of dopamine signalling may reflect the state-dependence of the reward-prediction errors at consumption and predictive hedonic values at salient stimulus presentation. Finally we suggest that orosensory-based predictions of postingestive impact drive the state-dependent dopamine signals within the Nucleus accumbens. In sum, we suggest that sodium appetite is a paradigmatic example of homeostatically motivated

learned pre-emptive behaviour. Furthermore, we propose that taste is at least partially learned to act as an unbiased predictor of the state-dependent hedonic value.

Title: Chemogenetic activation of Prelimbic to Dorsomedial Striatum Pathway during acquisition attenuates goal-directed control

Authors: *M. L. SHIPMAN, J. A. EMTAGE, L. H. CORBIT;
Univ. of Toronto, TORONTO, ON, Canada

Abstract: The dorsomedial striatum (DMS) has been well established as a mediator of goal-directed behaviour, since lesion or inactivation before training or testing result in an insensitivity to reinforcer devaluation. Increased spontaneous activity in the same region following cocaine leads to a similar behavioural deficit suggesting that dysfunction, whether due to decreased or increased activity in the region, result in the same reduction in goal-directed control. We therefore aimed to evaluate whether tonically activating specific inputs to the DMS would produce deficits in goal-directed control. The prelimbic cortex (PL) sends robust glutamatergic afferents to the DMS and is also important in goal-directed responding. Because of this, it is a likely candidate for the increased glutamatergic input that impairs goal-directed control with drug and diet manipulations. We therefore utilized a dual-vector chemogenetic approach to activate the PL-DMS pathway while rats were trained on two levers with unique outcomes. We hypothesized that tonic activation of this pathway during training would interfere with the acquisition of specific response-outcome associations resulting in impairments in subsequent devaluation tests. Subjects were 8 male and 8 female Long Evans rats. Half of the rats received an active cre-dependent DREADD vector (AAV-hSyn-DIO-hM3D(Gq)-mCherry) while the other half received a control vector (AAV-hSyn-DIO-mCherry) in the PL in addition to all receiving a retrograde Cre vector (AAV-hSyn-HI-eGFP-Cre) in the DMS. Training began with two levers present, both associated with a common outcome. Once initial responding was acquired, training progressed where each lever now resulted in a specific outcome. Rats were injected with Clozapine dihydrochloride peripherally 30 min prior to each specific outcome acquisition session (6 sessions; 3 RR5 and 3 RR10). Choice extinction tests were then conducted following devaluation of one outcome by specific satiety. Histology and c-fos staining was

utilized to confirm activation of striatal MSNs following clozapine application and rats without expression or evidence of activation were removed from analysis (final N=5 for DREADDs and N=5 for controls). We found that responding was reduced for both the devalued and nondevalued reinforcers in the group trained under DREADDs activation suggesting reduced goal-directed control. These results suggest that DREADDs-mediated release of glutamate within the DMS during instrumental learning interfere with normal encoding instrumental associations. Ongoing studies are increasing sample size to examine potential sex differences.

Title: Mesostriatal dopamine is sensitive to Pavlovian information loss

Authors: *E. GARR[1], Y. CHENG[1], S. BROOKE[2], P. H. JANAK[1];
[1]Psychological and Brain Sci., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Decades of research suggest that temporal contiguity between events—how close they occur in time—is not sufficient to explain Pavlovian learning. Even when the interval between cue and reward is held constant, the rate of learning is nevertheless stunted by free rewards in the absence of the cue and shortened inter-trial intervals (ITIs). This has been taken as evidence that Pavlovian learning is a function of the mutual information between cue and reward—the degree to which a cue signals a change in reward rate relative to the overall rate. Despite the importance of information in learning, investigations of mesostriatal dopamine function continue to emphasize a role in learning based on value, which is orthogonal to information. We therefore sought to find out whether mesostriatal dopamine dynamics are sensitive to Pavlovian information loss. We used fiber photometry to record calcium transients in dopamine neurons in the ventral tegmental area (VTA) during magazine approach conditioning followed by selective contingency degradation in TH-Cre+ rats (n = 8). Anticipatory magazine approaches increased during conditioning and decreased during contingency degradation. We also tested whether behavior was similarly attenuated during ITI shortening in a separate cohort (n = 8), but could not find supporting evidence. Calcium transients showed dynamics consistent with reward prediction error signaling during conditioning, and during contingency degradation the dopamine response to cue and reward during degraded trials was overall lower than during non-degraded trials. Dopamine response to reward on degraded trials did not significantly differ when the same

reward was delivered non-contingently during the ITI. In a separate experiment, we asked whether degrading the contingency between an audiovisual cue and optogenetic VTA dopamine neuron stimulation would attenuate conditioned locomotion. During conditioning, conditioned locomotion increased over time in TH-Cre+ rats (n = 15), but not in TH-Cre- rats (n = 8). During contingency degradation—when stimulation was delivered randomly during the ITI but conditioning trials remained unchanged—conditioned locomotion in TH-Cre+ rats was attenuated compared to a group of TH-Cre- rats and a group of TH-Cre+ rats that did not experience contingency degradation. These results suggest that VTA dopamine neuron activity within and outside conditioning trials can support sensitivity to contingency degradation.

Title: Chemogenetic suppression of the perirhinal and postrhinal cortex impairs value inference in appetitive sensory preconditioning

Authors: *X. PENG, D. L. POETA, M. SLUSAREWICZ, R. D. BURWELL;
Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Complex goal-directed behavior is often supported by internalized models representing associative relationships in the environment. Building such models often requires integrating memories from separate events. Recent evidence suggests that the hippocampus plays an important role in model-building across multiple episodes. However, it is unclear whether other medial temporal lobe (MTL) structures also contribute to this process. This study employed the Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) technique to investigate the involvement of two parahippocampal structures, the perirhinal and postrhinal cortices, in memory integration and value inference. Adult male rats received either sham surgery or bilateral viral injections into the perirhinal or postrhinal cortex. Then they were trained and tested in a three-phase appetitive sensory preconditioning procedure. In phase one, rats received presentation of two pairs of auditory stimuli, each containing one preconditioned stimulus and one conditioned stimulus (CS). In phase two, one auditory stimulus (CS+) in one pair was paired with pellet delivery, whereas one stimulus (CS-) in the other pair was presented alone. Finally in phase three, the preconditioned stimulus from each pair was presented to the

rats, and their responding was recorded as the dependent measure. All rats received intraperitoneal injections of clozapine N-oxide before behavioral sessions. This led to temporary suppression of neural activity in the perirhinal or postrhinal cortex for the experimental groups but not the control group. Preliminary results show that the experimental group had lower levels of responding to the preconditioned stimulus than the control group, indicating that suppressing either the perirhinal or postrhinal cortex impairs the ability to infer stimulus value based on its associative relationships. These findings update our existing knowledge of how various MTL structures contribute to goal-directed behavior and point to possible cooperation between them and other cortical areas.

Title: Instrumental conditioning of video-playback of maternal behavior

Authors: *K. QUIÑONES-LARACUENTE[1], N. LÓPEZ CARABALLO[2], A. T. SEIDENBERG[2], O. M. MAVRIDIS[2], R. C. FROEMKE[3];
[1]Dept. of Psychiatry, [3]Skirball Institute, Neurosci. Institute, and Departments of Otolaryngology and Neurosci. and P, [2]NYU Langone Sch. of Med., NY, NY

Abstract: Certain aspects of mammalian parental behavior may be innate, while other behaviors can be learned by experience (Dulac et al. Science 2014). One form of maternal care in mice involves retrieval of isolated pups, in which experienced care-takers respond to ultrasonic distress calls and other sensory cues to move pups back to the nest. Non-biological adults can become alloparents after experience, and begin retrieving pups after co-housing (Marlin et al. Nature 2015). Recently, we found that alloparenting behaviors can be learned by virgin female mice visually observing experienced mothers retrieving pups. Visual input from the superior colliculus likely provides a visual signal to hypothalamic oxytocin neurons, promoting onset of alloparenting in virgin female mice (Carcea et al. Nature 2021). Here we have begun to determine the specific sensory cues and features that enable learned alloparenting, asking which aspects of maternal behaviors virgins might be observing. These studies build on ongoing work from our lab showing that pup retrieval onset is accelerated in head-fixed virgin female mice passively observing video-playback of dams and pups (López Caraballo et al. SfN Abstracts

2021). We presented head-fixed virgin females with the option to trigger the playback of a pup retrieval video with the press of a lever. This design allows us to ask about decision-making processes and the 'effort' animals are willing to expend to view or not view specific videos. Head-fixed mice were trained to press a lever for a 10 s video-playback of a dam retrieving a stray pup back into the nest. By the third day, mice were pressing the lever on their own (1.0 ± 0.06 presses/min, N=8 virgin female mice). The number of presses after a video started decreased over days (day three: 5.2, and day four: 2.9 average presses after video-playback started) The same animals were then presented with video playback that was controlled to match the color palette and luminescence levels of the pup retrieval video (abstract video), but with scrambled visual features. After four days, these mice were instead pressing at a much lower rate for these scrambled videos (0.2 ± 0.06 presses/min). A separate cohort of mice were trained with bar presses solely for the scrambled video. Lever presses were lower than in the group that could press for maternal retrieval videos (day three: 0.3 ± 0.06 presses/min, day four: 0.2 ± 0.06 presses/min, N=4). These data suggest that mice can exert effort to watch videos of conspecifics, and that video playback of certain behaviors might be rewarding.

Title: The effect of temporal expectation on motion direction representation of an occluded object

Authors: *S. SON[1,3], J. MOON[1], J. LEE[1,3,2];
[1]Dept. of Biomed. Engin., [2]Dept. of Intelligent Precision Healthcare Convergence, Sungkyunkwan Univ., Suwon-Si, Gyeonggi-Do, Korea, Republic of; [3]Ctr. for Neurosci. Imaging Res., Suwon-Si, Gyeonggi-Do, Korea, Republic of

Abstract: When a moving object briefly disappears, people track the occluded object with the inner eye and predict when and where the object will reappear. Previous studies showed that the timing of the occluded object's reappearance was represented in the suppression of the brain wave's alpha oscillation (Rohenkohl and Nobre, 2011; Samaha et al., 2015). Other studies also suggested that the temporal expectation enhances certain features of the occluded object, such as contrast sensitivity (Rohenkohl et al., 2012) or resistance over distractors (Bonnefond and

Jensen, 2012; van Ede et al., 2018). However, little is known about how the temporal expectation dynamically interacts with the motion information of the temporarily disappeared object. In this study, we estimated the motion information of the occluded moving object from the spatially distributed pattern of electroencephalography (EEG) recordings. The participants were asked to pay attention to a Gabor stimulus moving from the periphery towards the center of the screen while maintaining fixation at the central fixation point. A moving Gabor was turned on briefly then disappeared for a fixed amount of time or a randomized duration. When it reappeared at the center of the screen, the participants were instructed to smoothly track the moving stimulus with their eyes until it stopped moving. To estimate the motion direction information while the stimulus was occluded, we used an inverted encoding model (Brouwer and Heeger, 2009). The result showed that the neural representation of motion direction expectation was highest at the expected timing of the occluded stimulus's reappearance but barely existed for the rest of the time. Also, the strength of the neural estimate of the direction information was predictive of the behavioral biases induced by the direction expectation. Further analysis showed that the motion direction information of the occluded stimulus was most evident in EEG data recorded at the anterior channels. At the same time, the attenuation of alpha oscillation by temporal expectation mainly occurred at the posterior channels. Significant modulation of motion direction representation by the temporal expectation was only observed from EEG recordings in the vertex region. Taken together, the neural representation of temporal expectation was spatially distinct from the representation of motion direction expectation, and the integration of the two appeared to occur at the brain regions close to the vertex channels.

Title: Using SSVEP to evaluate attentional modulation in Action Video Game Players during facial emotion discrimination

Authors: A. CIOBANU[1], K. SHIBATA[1], L. ALI[2], K. RIOJA[1], S. K. ANDERSEN[3], D. BAVELIER[4], ***B. BEDIOU**[1];
[1]Univ. of Geneva, Geneva, Switzerland; [2]Univ. De Geneve, Geneva, Switzerland; [3]Sch. of Psychology, Univ. of Aberdeen, Aberdeen, United Kingdom; [4]UNIGE - FPSE, Geneva, Switzerland

Abstract: Attentional mechanisms have been posited to mediate benefits in decision making. We investigated whether increased attentional modulation is associated with enhanced discrimination of facial emotions. We compared behavioural and neural correlates of attention to emotion in Action video game players (AVGP) known to have enhanced attentional processing, with non-video game players (NVGP) (ages 18-35). AVGP (n=36) and NVGP (n=32) underwent an emotion discrimination task which required detecting target emotions in one of two laterally presented streams of faces flickering at different frequencies (2Hz/2.5Hz). Steady-state visual evoked potentials (SSVEP) were used to quantify the neural activity corresponding to the processing of attended and unattended emotional streams. AVGP outperformed NVGP at detecting target emotions in the attended stream regardless of emotion valence (Hedge's g = 0.51, p = 0.04). As expected, SSVEP amplitudes extracted from parieto-occipital electrodes revealed group differences in attention (Group x Attention interaction: $F(1, 1054) = 7.949$, p = 0.005, $\eta^2 = 0.007$), driven by non-significant trends for both greater attentional enhancement and greater attentional suppression in AVGP. Importantly, the amplitude difference between attended and unattended SSVEP amplitudes correlated with behavioral performance (r = 0.35, p=0.0031), indicating an association between neural and behavioral measures of attention. In sum, we find enhanced attentional modulation in AVGP to be associated with enhanced discrimination of facial emotions. Additional unregistered exploratory analyses revealed the expected classical ERP components associated with target detection (larger P3 to targets vs. non-targets, p<.0001) and error processing (larger Error Related Negativity to false alarms vs hits, p<.0001). Neither of these effects interacted with group (all p's > 0.28), although AVGP displayed overall larger amplitudes than NVGP to both targets and non-targets in the P3 range. In conclusion, this study provides evidence for enhanced attentional processing in AVGP that extend to the processing of emotional stimuli.

Title: Primary rewards and aversive outcomes have comparable effects on attentional bias

Authors: *H. KIM, B. ANDERSON;
Texas A&M Univ., College Station, TX

Abstract: Reward learning imbues initially neutral stimuli with value, such that they come to predict reward and capture attention even when non-salient and task-irrelevant. The same is true for aversive conditioning; stimuli that signal threat also bias attention, suggesting that motivational salience guides attention. Most research that supports this conclusion has manipulated monetary gain, a secondary reinforcer, for reward learning and electric shocks, a primary punisher, for aversive conditioning, making it difficult to directly compare their influence on attention. Therefore, we matched for reinforcer dimensions by using primary taste as reinforcers/punishers and assessed their influence on attention.
Participants first completed a decision-making task to determine their point of subjective equality. On each trial, a certain amount of sweet juice and salt water each ranging from 0.1 ml to 1 ml were indicated. Participants had to decide whether to place a bet. One of the two solutions, in the amount indicated, was delivered following a decision to place a bet (each equally-likely); no solution was delivered if participants chose not to place a bet. We fit a regression and determined the amount of each solution to be used in a training phase on the next day.
In the training phase, participants had to make a saccade to a peripherally-presented square target, which could appear in one of three colours. One colour was associated with sweet juice (reward) and another with salt water (aversive) on 80% of trials, in the amounts determined in the decision-making task. A third color was never followed by liquid (neutral). In a test phase, a square (distractor) and a circle (target) were presented simultaneously; the same colours were used as during training, fully crossed and counterbalanced with respect to target and distractor status. Participants had to make a saccade to the circle.
We analysed response times (RTs) and error rates from the test phase. Error rates were defined as the proportion of trials containing an initial saccade to the distractor. RTs slowed down marginally when an aversive distractor was presented with a neutral target than when an aversive target was presented with a neutral distractor. Error rates were higher when there was a reward distractor than when there was a reward target. Importantly, a direct comparison of reward and aversive stimuli revealed no significant differences in RT or error rate. These results suggest that when matched for reinforcer dimensions, reward and aversive stimuli both bias attention in a similar manner and that their effects are comparable, providing further evidence in support of the motivational salience account.

Title: Direct recordings of sustained attention dynamics in the human brain

Authors: *M. T. DEBETTENCOURT[1], N. HAKIM[2], T. XIE[1], M. PADMANABAN[1], E. AWH[3], E. K. VOGEL[1], P. C. WARNKE[1];

Abstract: In our daily life, attention inevitably fluctuates over time, encompassing highly attentive moments to potentially catastrophic lapses of attention. These attention dynamics have been characterized using sustained attention to response tasks, in which behavioral responses predict forthcoming attention lapses. Studies have implicated particular subcortical areas, including the basal ganglia and thalamus, as important for successfully performing these tasks. In this study, we examined neural signatures of attentional dynamics by directly recording from the human brain. We collected data from 9 patients who were awake and performing a sustained attention task while undergoing surgery for deep brain stimulator implantation. The task required patients to click a button to frequently presented circle stimuli (80% of trials) and withhold a response to infrequent square stimuli (20% of trials). We found that this task elicited canonical behavioral signatures of sustained attention performance. Patients demonstrated attention lapses (29% lapse rate), operationalized as failures to inhibit the prepotent response to the infrequent (i.e., square) trials. Furthermore, when responding more quickly, patients were more likely to lapse to an upcoming square trial that required deviating from the prepotent response (mean RT=50 ms faster prior to lapses). Next, we examined whether these behavioral signatures were reflected in electrode recordings from the subthalamic nucleus (STN) of the basal ganglia and ventral intermediate (VIM) nucleus of the thalamus. Indeed, using cluster-based permutation tests, we observed that total power in low-frequency power bands (e.g., alpha, 8-12 Hz) was significantly higher during frequent than infrequent trials. We also demonstrated that worse attentional states, as indexed by RT, correlated with lower beta power (12-20 Hz). Furthermore, we used multivariate pattern analyses to classify high vs. low attentional states. We reliably decoded attentional state from time-frequency decompositions of macroelectrode recordings ($p<0.05$). Finally, we used microelectrode recordings to identify single units with different responses during sustained attentional states. Overall, these results provide comprehensive insight into how moment-to-moment fluctuations of sustained attention are reflected in the brain.

Title: Impacts of cognitive fatigue on attentional control and evoked neural activity

Authors: *D. MCHAIL, K. PETTIJOHN, K. J. BLACKER, S. SHERWOOD;
Naval Med. Res. Unit - Dayton, Wright-Patterson AFB, OH

Abstract: The warfighter must often exercise attention and inhibitory control for prolonged periods to achieve mission success. However, performance in cognitive domains, including attention, is known to degrade with increased time on task. It is therefore critical to understand how brain regions underlying attentional control (i.e., the prefrontal cortex, or PFC) respond to cognitive fatigue. In this study, we leverage validated attentional control tasks to assess the impacts of cognitive fatigue on task performance and associated changes in PFC activity. Twenty-six participants age 18-40 were recruited for the study, which utilized a counterbalanced, within-subjects design. On two separate days, participants performed computerized versions of two tasks that assessed attention and cognitive control through inhibition. One variant required a response to rare stimuli based on the preceding stimulus, and the other required frequent responses to common stimuli while withholding responses to rare stimuli. Prior to task performance, participants in the experimental fatigue condition completed the Psychomotor Vigilance Task (PVT) for 10 min. Participants in the non-fatigue control condition watched a short video in lieu of the PVT. PFC blood-oxygenation was measured with functional near-infrared spectroscopy (fNIRS) during task performance. Analyses compared the effects of the fatigue and non-fatigue conditions on task performance (i.e., accuracy, response time) and PFC blood oxygenation (deoxygenated and oxygenated hemoglobin changes). The results suggest that overall task performance did not differ between fatigue and non-fatigue conditions. However, a non-statistically significant trend for greater PFC activation (relative oxygenated hemoglobin) was apparent in the fatigue compared to the non-fatigue condition during the inhibitory control task. In contrast, PFC activation was marginally lower in the fatigue compared to non-fatigue condition during the vigilance task. This suggests that the PFC may increase activity to maintain performance in fatigued individuals for tasks that require attentional control through inhibition. Results from this study help clarify the impact of cognitive fatigue on attentional control and how the brain responds to maintain performance. Follow-on efforts will focus on individual differences in susceptibility to cognitive fatigue and its effect on other cognitive abilities (e.g. task switching). Ultimately, these efforts will help develop real-time cognitive fatigue alerting systems and countermeasures to maximize warfighter performance during sustained attention tasks.

Title: Rhythmic phase modulation on divided attention sampling

Authors: *J. CHUNG, D.-J. YI;
Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of

Abstract: Recent studies have demonstrated that sustained attention has rhythmic temporal structures. When participants allocate attention to a spatial location or salient stimulus, target detection fluctuates at around 8 Hz. Interestingly, this sampling frequency decreases when multiple locations or stimuli are attended. Here, we explored the phase relationship between divided attention samplings by a sequential presentation of two stimuli with distinct visual features. We hypothesized that the prior temporal status of sampling determines the subsequent phase relationship between multiple samplings. In two experiments, participants detected color saturation of moving dots. In Experiment 1 (N = 31), the fluctuation of target detection was first explored when a single stimulus was attended (1-Cloud task). Target onsets were varied across 250 to 750 ms with a 34-ms gap. We found a near 8-Hz fluctuation of hit rates along with the target onsets. We fitted it with a sinusoidal function individually to extract three time points (two at the minimum and one at the maximum peaks). A 2-Cloud task was then performed, which sequentially presented two stimuli, with the second stimuli onsets corresponding to the three time points. Target onsets were the same in the 1-Cloud task. Fluctuation frequencies were consistent across the different onsets (around 3 Hz for the first and 5 Hz for the second stimulus). However, the phase difference between the first and second stimulus fluctuations was different across the onsets. The phase differences of the minimum-peak-onset conditions showed anti-phase relations (180°) but not in the maximum-peak-onset condition. In Experiment 2 (N = 25), a 2-Cloud task was performed with varied second stimulus onsets across 250 to 750 ms with a 34-ms gap. We found that hit rate differences between the first and second stimulus along the second stimulus onsets show rhythmic fluctuations (4 Hz). The findings indicate that the second stimulus onset affects the phase relationship between divided attention samplings. The phase modulation was rhythmic depending on the pre-division sampling. This study suggests that the temporal structure of divided attention would differ depending on the prior attention state.

Title: Human population motor fields and population motor attention fields as they relate to saccadic eye movement accuracy

Authors: *W. E. HUDDLESTON[1], A. E. CATTERSON[1], M. J. PENNING[1], O. L. SWANSON[1], A. S. GREENBERG[2], E. A. DEYOE[3];
[1]Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [2]Biomed. Engin., [3]Dept. of Radiology, Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Attentional selection of task-relevant information is fundamental to our ability to interact with our complex natural environment. This process operates through modulation of multiple topographically organized brain maps. We hypothesize that the attentional control computations demonstrated in the visual system may be generalizable to information selection in other modalities (e.g., motor domain), suggesting these modulations may apply widely throughout the brain. In Experiment 1, we assessed saccade crowding limits and found wide variation among participants (between 3-12°) in their ability to plan separate saccades to two possible targets with variable spacing. In Experiment 2, we tested a second group of participants performing two separate tasks while undergoing fMRI. In the first task, participants made saccades between two diametrically opposed targets slowly rotating clockwise around fixation. From this saccade localizer task, we calculated population motor fields in maps across cortex. In a second task, participants completed a delayed saccade task while we concurrently collected eye movement data to determine saccade accuracy. Participants selectively attended to a centrally presented RSVP stream surrounded by 24 static peripheral targets (radius 8°). Every 4 s, an 'N" appeared in the central RSVP stream to cue the participant to prepare a saccade to the next target in the clockwise direction thereby creating a focus of motor attention (i.e., saccade intention) drifting through associated cortical saccade-target maps. However, participants delayed saccade execution until a rarely presented 'X' appeared in the RSVP stream (approx. 5 times per run). Two times per cycle, a number (12 or 6) in the central RSVP provided a cue indicating the correct 'clock' location to be attended at that moment to ensure accurate shifting of motor attention. fMRI data from the Attentional Drift Design task just described were then used to constrain a computational model of the size and shape of the focus of motor attention, the voxel's population motor attention field. Consistent with the variation of saccade crowding limits seen in Experiment 1, population motor attention fields not only varied among participants, but were uniquely selective for spatial locations within individual participants, indicating promise as a neural substrate of eye movement behavior. Establishing a direct link between brain activity

and behavior is a crucial first step on the development of treatment interventions for patients with attentional deficits.

Title: Interpreting the neuromodulation of 1/f aperiodic activity through the arousal-related switch of adaptation currents

Authors: *V. MEDEL[1], M. IRANI[1], B. MUNN[2], J. VALDÉS[1], F. GONZÁLEZ[1], B. FOLLET[1], G. WAINSTEIN[2], G. BONCOMPTE[1], J. M. SHINE[2], N. CROSSLEY[1], T. OSSANDÓN[1]; [1]Pontificia Univ. Católica de Chile, Santiago, Chile; [2]Univ. of Sydney, Sydney, Australia

Abstract: To actively engage in ever-changing environmental demands, animals dynamically switch between a variety of behavioral states that differentially affect neural responsiveness and the ability to optimally process information. Computational approaches have shown that the range of these activity patterns can be achieved by simulating a network of neurons with balanced excitatory and inhibitory synaptic activity modulated by activity-dependent adaptation on excitatory cells which dynamically close K+ channels, From this perspective, in order to shape the cortical activity and transition the cerebral cortex to an optimal state, the brain depends on global variables, such as relative levels of excitation and inhibition and the level of activity-dependent adaptation on excitatory populations. Interestingly, there is strong evidence showing that extracellular application of arousal-related neuromodulators, such as noradrenaline, eliminates the activity-dependent adaptation. This suggests that diminishing adaptation through neuromodulation could facilitate E/I balance and suggests a mechanistic role of ascending arousal system in regulating E/I balance and cortical state. Here we directly test this hypothesis by using a validated measure of E/I balance -the power spectral 1/f slope- and, with both a computational modelling and a human and non-human primate experimental approach, demonstrate a close relationship between activity-dependent adaptation and the 1/f slope of electrophysiological signals. Finally, we will show that fluctuations of arousal-related

neuromodulation (as measures by pupil diameter) track time-resolved changes of 1/f slope, suggesting a dynamic neuromodulatory mechanism shaping E/I balance and aperiodic activity in the cerebral cortex.

Title: Closed-loop EEG-TMS modulation of frontal-occipital communication enhances visual perception

Authors: *S. KLORFELD-AUSLENDER[1], C. ZRENNER[3], S. YUVAL-GREENBERG[1,2], U. ZIEMANN[4], N. CENSOR[1,2];
[1]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel-Aviv, Israel; [2]Sch. of Psychological Sci., Tel Aviv Univ., Tel Aviv, Israel; [3]Ctr. for Neurol., Univ. Hosp. Tübingen, Tuebingen, Germany; [4]Eberhard Karls Univ., Tübingen, Germany

Abstract: Visual perception is constantly shaped by top-down mechanisms, such as attention. Indeed, it was shown that engagement of frontal and parietal regions that coactivate with the visual system, successfully prioritize processing of visual information. Previous studies suggested that these co-activations are expressed by lateralized alpha oscillations, measured at occipital electrode sites contralateral to an attended location, reflecting frontal-occipital communication. The goal of the current study was to causally reveal how communication patterns between frontal and occipital brain regions can facilitate visual performance. To address this question, we used a combination of electroencephalography (EEG) and non-invasive transcranial magnetic stimulation (TMS), in a closed-loop EEG-TMS procedure (Zrenner et al., 2018). TMS was delivered over the right frontal eye field (FEF) according to the phase of occipital alpha oscillations, measured in real-time with scalp EEG. This rationale was based on the notion that phase-locked oscillatory activity enables interregional synchronization and thus effective communication between anatomically distinct regions (Fries, 2005). Accordingly, we reasoned that enhanced frontal-occipital co-activation with closed-loop EEG-TMS would facilitate visual perception and its corresponding electrophysiological signatures. Subjects underwent a classical visual detection-attention task, known to require the engagement of frontal and occipital regions, before and after the closed-loop procedure. In the task, subjects were required to detect a peripheral low contrast target that appeared after the onset of either a valid or neutral cue. To assure there are no test-retest improvements that may be attributed to other factors, participants in a pilot no-stimulation condition completed the same task, without the stimulation procedure. Preliminary results show that frontal-occipital closed-loop EEG-TMS enhanced visual sensitivity in the neutral condition relative to performance improvements without stimulation. Consistently, the closed-loop stimulation to the right FEF induced greater right occipital alpha power suppression at the post-cue interval during the neutral, but not the valid, cue condition. If validated, these results suggest that real-time modulation of frontal-occipital communication can enhance visual perception.

Title: Disentangling the impact of top-down spatial attention and bottom-up stimulus drive on estimates of spatial selectivity in human cortex

Authors: *T. C. SPRAGUE, K. VU-CHEUNG, D. D. THAYER;
Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Visual attention enables the selection of relevant information in the environment for further processing. In single neurons, attention to a location of the visual field results in a warping of spatial receptive fields (RFs) measured from extrastriate visual cortex (e.g., Womelsdorf et al, 2006; Anton-Erxleben et al, 2009; Anton-Erxleben & Carrasco, 2013). Similarly, functional MRI experiments have identified changes in the spatial tuning of populations of neurons within voxels in retinotopic cortex whereby the location and/or size of voxel RFs (vRFs; Dumoulin & Wandell, 2008; Mackey et al, 2017) change as the locus of attention is manipulated between scanner runs (Klein et al, 2014; Sprague & Serences, 2013; Vo et al, 2017; van Es et al, 2018; Sheremata & Silver, 2015; Kay et al, 2015). In many of these studies, attention was directed either to the vRF mapping stimulus or the fixation point, which typically results in an increase in measured vRF size in extrastriate cortex when attending the mapping stimulus (Sprague & Serences, 2013; Kay et al, 2015; Sheremata & Silver, 2015; van Es et al, 2018). In other studies, attention was directed to a fixed location while vRFs are measured with an ignored mapping stimulus, which typically results in a shift in the vRF position with a change in the locus of spatial attention (Klein et al, 2014; Vo et al, 2017). However, in all these studies, the entire mapping stimulus was either attended or ignored. Thus, it remains unknown how vRFs depend on the locus of attention to a subpart of the mapping stimulus. Here, we acquired fMRI data while participants viewed a traversing bar vRF mapping stimulus broken into 3 segments. Each segment contained black and white dots moving in one of two directions. Across scanning runs, we manipulated which segment(s) of the bar participants attended using a central cue, and participants reported the direction of dot motion in the attended bar segment. Importantly, the stimulus sequence was fixed across scanning runs, so any changes in observed signals necessarily result from a change in the locus of attention. Direct comparison of activation timeseries revealed similar spatial selectivity, but a dynamic reweighting of activation levels at each voxel's preferred position as a function of which bar segment was attended. This reweighting was more pronounced in extrastriate visual cortex as compared to V1, consistent with previous reports that attentional modulation of vRF properties is smallest in V1. In ongoing work, we are fitting a variety of nonlinear vRF models (Kay et al, 2013; Mackey et al, 2017) incorporating the stimulus drive, attentional locus, and a combination of these factors.

Title: Divide and Conquer: Own-Name detection during ecological concurrent speech processing

Authors: *D. PINTO, M. KAUFMAN, E. ZION-GOLUMBIC;
The Gonda Ctr. for Multidisciplinary Brain Research, Bar Ilan Univ., Ramat Gan, Israel

Abstract: A well-known phenomenon is the experience of noticing one's own name spoken by unattended speaker. This "Cocktail Party Effect" has fueled debates regarding the extent to which so-called "unattended" speech is processed. However, it is difficult to reliably gauge the prevalence of this effect since most studies use selective attention tasks, where detection of unattended words is assessed indirectly. For example, using subject-report measures, only ~33% of participants report noticing their name. This limits the ability to draw theoretical inferences regarding the depth of processing of concurrent speech. We address this from a different perspective by employing a Divided attention task. We ask two questions: What is the capacity for detecting individual words from background speech, while primarily engaging in processing a natural speech narrative? And does detecting one's own name enjoy a unique status? Participants were presented with two concurrent speech streams: A **Narrative** stream, which was a natural recording of continuous speech, and a **Starbucks** stream, that simulated a barista calling out orders, including names and food items. Participants were told to listen to the Narrative and answer comprehension questions. In addition, they were also required to monitor the Starbucks stream and detect a specific target-name, which could be their own name or a different name. Neural activity was measured using EEG during the task, as well as changes in skin-conductance (GSR). Accuracy in both tasks was high, with target detection rates near ceiling (>90%). Also, there were no apparent behavioral tradeoffs between performance on the two tasks. This suggests that individuals have a relatively good capacity for monitoring background speech and detecting specific words, without compromising comprehension of a main narrative. When comparing detection rates of the two targets, performance was better for detecting one's own name vs. a control name. This was accompanied by increased neural responses (in a time-window corresponding to the P600 component) as well as heightened GSR responses to one's name. These results provide new perspectives about the capacity for processing concurrent speech and indicate that it is possible to monitor background speech for specific information while also processing continuous speech. This is in line with 'late-selection' models and invites fine-tuning of theoretical accounts of 'bottlenecks' for processing concurrent speech. In addition, the advantage for detecting one's own name is in line with previous findings, indicating an advantage for processing personally meaningful information in noisy, multi-speaker contexts.

Title: The enhancement effects of background knowledge on selective auditory attention: an analysis of cortical responses in the cocktail party problem

Authors: *T. SÁNCHEZ-COSTA, A. CARBONI, F. CERVANTES CONSTANTINO; Facultad de Psicología, Univ. de la República, Uruguay, Montevideo, Uruguay

Abstract: When chats overlap, listeners will ignore so they get to hear the more interesting story. To solve this 'cocktail-party' problem, gain mechanisms by selective attention operate on the neural representations of individual speech objects. Foreground enhancement by attention has been observed to peak around 125 ms during online processing of speech in auditory cortex. In sensory cortex, it has been suggested that attentional and predictive processes interact to boost even further a foreground when it is predictable. Priming studies, by contrast, indicate that familiarity with a stimulus may produce lower neural responses than when it is novel. In a cocktail party, does prior experience of a foreground boost or revert foreground enhancement? Would background foreknowledge help reduce its representation during a subsequent selection? To address these questions, 27 participants attended individual speakers from brief (7-9 s) acoustic mixtures of two while undergoing electroencephalography (EEG). Each mixture was presented once and immediately preceded by a solo speech segment which could be identical to the foreground (attended known 'AK') or the background (unattended known, 'UK'), or to an unrelated stimulus (no prior, 'NP'). Every unique mixture was built anew from a diverse database of over 250 natural speech segments, per participant. Subjects identified aspects such as topic, keywords, and sex and age groups of the attended speaker.
Temporal response function (TRF) estimates of the auditory response were used to assess single-trial cortical encoding of speech across conditions. Attentional enhancement of the neural representation of foreground speech, observable around 140 ms (N1 component), improved in UK over AK conditions. Background knowledge boosted differential encoding more effectively than foreground knowledge did, even as UK trials appeared to be more difficult than AK behaviorally. The UK lead at this stage was associated to a significantly delayed, but also increased, P1 peak corresponding to the known unattended stream. Such changes also resulted in observable neural segregation effects by attention as early as 60 ms for UK conditions only.

The results indicate that while neural stream segregation normally occurs at the N1 stage without any prior knowledge, knowledge of the background is incorporated into segregation mechanisms much earlier. By contrast, foreground knowledge appears to reduce the problem of active segregation, at either the P1 or N1 stage, as listeners only verify a narration already heard. It is suggested that prediction is adaptively involved in the cocktail party problem via gain magnitude and delay mechanisms.

Abstract: The ability to deal with conflict from processing incompatible sensory information is fundamental to adaptive behaviors in humans and other primate species. It is generally known that conflict reduces the speed and efficiency of sensory information and decision-making processes. One prominent theory posits that such behavioral interference is due to an additional step required for individuals to focus their attention on task-relevant sensory inputs while filtering out task-irrelevant distractors. Recent studies have directly tested this hypothesis using a variety of conflict tasks but many of them failed to provide positive evidence. Here, we examined changes in the spatial scopes of attention in human subjects performing a variant of the Eriksen flanker tasks where they discriminated the shape of the cued target surrounded by congruent or incongruent distractors. The spatial scopes of attention in the congruent and incongruent conditions were indexed by the spatial reconstructions based on the modeling of spatially specific alpha band activity (EEG oscillations at 8-12Hz), which have been shown to track the precise location of covert attention. We found that the scopes of the alpha-based spatial reconstructions were smaller in the incongruent conditions compared to the congruent conditions and these conflict-induced modulations occurred ~100-250 ms after stimulus onset. Moreover, we found that the degree of the reduction in the spatial scope of attention predicted the degree of behavioral interference. These results provide neural evidence implicating the important role of early attentional selection in conflict resolution at least in the context of our experimental design.

Title: Cross-frequency phase-amplitude coupling as a mechanism for temporal expectation: a human intracranial recording study

Authors: *N. TAL-PERRY[1], D. MARCIANO[3], L. BELLIER[3], J. J. LIN[5], P. BRUNNER[6,8,7], R. T. KNIGHT[3,4], S. YUVAL-GREENBERG[1,2];

Ctr. for Adaptive Neurotechnologies, [7]Dept. of Neurol., Albany Med. Col., Albany, NY; [8]Dept. of Neurosurg., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Expectations allow our perceptual system to guide itself through the everyday information deluge. One form of expectation is temporal expectation, based on predictions about the timing of relevant events. Despite abundant evidence on the behavioral benefits of temporal expectation, little is known about its underlying neural mechanisms. Scalp-EEG studies provided evidence for anticipatory oscillatory activity accompanying temporal expectation and correlated with target predictability and behavioral performance. Based on these findings we hypothesized that temporal expectation is driven by cross-frequency coupling (CFC) between the phase of a low-frequency oscillation and the amplitude of high-frequency activity: cycles of low frequencies oscillations are required for timing interval durations, whereas their coupled high-frequency bursts are involved in performing the local computations required for motor preparation for the upcoming event.
Here, we examined this hypothesis using invasive electrocorticography (ECoG) and stereoencephalography (sEEG) in epileptic neurosurgical patients (n=5). We analyzed 66 electrodes implanted in pre-motor area (in 5/5 patients), supplementary motor area (SMA; in 2/5 patients), and primary motor area (M1; in 2/5 patients). In each trial, participants heard an auditory cue (4 kHz pure tone for 50 ms) followed by a vocalization target ("goo" or "ga" presented for 100 ms). The interval between cue and target (the foreperiod) was manipulated between blocks, as either 2 s throughout a block (fixed condition), enabling anticipation of target onset, or changing randomly between 1, 2, or 3 s between trials (random condition), making prediction more difficult. Participants were asked to indicate which of the two syllables was presented via a speeded button press. CFC between low-frequency (1-6 Hz) phase and high-frequency (40-150 Hz) amplitude was computed during the foreperiod (+300 ms relative to the cue and -50 ms relative to the target).
Results showed evidence for enhanced cross-frequency phase-amplitude coupling in the fixed relative to the random condition in the premotor area, SMA, and M1 (all p < .05). Specifically, we found coupling between (i) delta phase (1-3.5 Hz) and low-gamma (40-70 Hz) amplitude in 12 channels (3 patients) of the premotor area; (ii) delta phase and high-gamma (120-140 Hz) amplitude in 7 channels (2 patients) of the SMA; and (iii) delta phase and broadband gamma (40-120 Hz) amplitude in 8 channels (2 patients) of M1. These findings provide the first human intracranial evidence that the construction of temporal expectation is driven by delta-gamma CFC in the motor cortices.

Title: Differential neural mechanisms underlie top-down attentional modulation mediated by cortical alpha-band oscillations

Authors: *X. YANG[1,2], I. C. FIEBELKORN[1,3], J. PARVIZI[4], O. JENSEN[5], R. T. KNIGHT[6], S. KASTNER[1,2];
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ; [3]Dept. of Neurosci. & Del Monte Inst. for Neurosci., Univ. of Rochester, Rochester, NY; [4]Dept. of Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA; [5]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [6]Helen Wills Neurosci. Inst. & Dept. of Psychology, Univ. of California Berkeley, Berkeley, CA

Abstract: Selective attention relies on neural mechanisms that facilitate processing of behaviorally relevant sensory information and suppress processing of irrelevant information. M/EEG studies in humans have repeatedly linked increases in alpha-band oscillations in the visual attention network to the suppression of potentially distracting information, thus facilitating the processing of target stimuli. However, M/EEG data provide a limited window into the spatial selectivity and network-level dynamics of such alpha-related attentional modulation. We therefore analyzed cortical alpha-band activity from intracranial electrodes implanted in 8 epilepsy patients who performed a spatial attention task. Following a spatial cue and a variable delay, subjects differentiated between two shapes at the cued location in an array of distracters. We observed a cortical dissociation between attention-modulated alpha desynchronization and synchronization in preparation for an upcoming, spatially predictable target, with dorsal cortical areas primarily demonstrating attention-related alpha desynchronization (at attended locations) and ventral cortical areas primarily demonstrating attention-related alpha synchronization (at unattended locations). We next probed the relationship of cortical alpha-band activity and high-frequency broadband (HFB) activity (a proxy for population neuronal spiking) by measuring within-region cross-frequency coupling (CFC) and directionality (CFD) between alpha phase and HFB amplitude. We found that areas along the intraparietal sulcus (IPS) exhibited significant group-level increases of within-region alpha-HFB coupling relative to baseline at attended and unattended locations. Our findings of negative mean CFD further suggest that population spiking modulates the phase of alpha-band activity during attentional deployment. Finally, we investigated whether IPS alpha activity mediates top-down attentional modulation across the visual system by measuring between-region CFC/CFD and found that IPS alpha phase modulates

cortical excitability of the visual cortex in directing attention-related enhancement to facilitate the processing of upcoming target. Results of Granger causality analysis further suggest that IPS areas influence visual cortex through the alpha-band channel in directing attention-related suppression to attenuate the processing of distracting information. Our findings uncover the differential neural mechanisms underlying target enhancement and distractor suppression in directing top-down attentional modulation to prepare the sensory system for upcoming target detection.

Title: Balanced scaling of horizontal excitation and inhibition in primary visual cortex as a plausible mechanism for fine visual resolution modulation by exogenous attention

Authors: *A. FRANCI[1], Y. ZHANG[2], M. POLETTI[3];
[1]Dep. Matematicas, Facultad De Ciencias, UNAM, Coyoacán, Mexico; [2]Active Perception Lab., [3]Dept. of Neurosci., Univ. of Rochester, Rochester, NY

Abstract: Recent experiments have revealed how exogenous attention modulates in time and space fine spatial vision across the central fovea. At short delays, visual resolution is locally enhanced at the cued location and decreased at un-cued locations. At long delays, the pattern is reversed. The first contribution of our work is to explain mechanistically how vision of detail can be controlled in this highly localized fashion. We show that a balanced scaling of horizontal excitation and inhibition in V1 can focus (enhance the resolution of) or defocus (decrease the resolution of) the feedforward visual kernel originating in the upstream visual pathway. We illustrate our theory on a neural field model of V1. The second contribution is to show that the existence of an attention traveling wave, originating at the cued location and coordinating the E/I-balanced scaling of V1 horizontal connections, explains and reproduces the spatiotemporal dynamics of visual-resolution control. Lateral inhibition around the bump of the attention traveling wave explains the early resolution decrease at un-cued locations. The after-hyperpolarization period of the attention traveling wave explains the late resolution decrease at the cued location. Our modeling results constitute a novel mechanistic account of covert-

attention-related resolution changes in the visual pathway and reveal an overlooked connection between visual resolution control and the scaling of balanced horizontal excitation and inhibition in V1. Besides explaining a number of recent experimental observations, they allow us to formulate novel predictions about the mechanisms of fine visual resolution modulation by exogenous attention.

Title: Brain signatures of active visual search in a free-viewing task

Authors: *J. E. KAMIENKOWSKI[1], M. DA FONSECA[1], D. CARE[1], B. BIANCHI[1], M. J. ISON[2];
[1]Lab. de Inteligencia Artificial Aplicada, Inst. de Ciencias de la Computación, Univ. de Buenos Aires - Consejo Nacional de Investigaciones en Ciencia y Técnica, Ciudad Autónoma de Buenos Aires, Argentina; [2]Sch. of Psychology, Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Visual search involves a series of mental processes that guide the eye movements through the visual scene. Early access to categorical visual information plays an important role during free-viewing in real-world behaviour. In fixed-gaze, there are well-established electrophysiological signatures of categorical processing. In particular, a hallmark of face processing emerges around 170 ms after stimulus onset with an increased EEG amplitude to faces. Previous evidence suggests the higher involvement of low-frequency oscillations in integrative brain processes, such as decision-making or top-down attention, in comparison to local processing of the stimuli.Here, we aimed to study how the sensitivity to category information extends to a free viewing paradigm by studying fixation-related potentials and brain oscillations. We co-registered brain activity and eye-tracking to investigate fixation-related potentials to pictures of different categories during visual search and exploration. Participants were asked to “observe” / “search for one target from” an array of faces and objects embedded in random noise. We hypothesized a larger evoked response to face fixations in comparison to objects. Moreover, we proposed that there are specific oscillatory brain signatures underlying active search for a target that is not present during exploration.Firstly, we show a stronger

activation for fixations to faces than to objects in both types of tasks. Secondly, exploiting a deconvolution approach of the electrophysiological signal, we observed significant early differences (100-200 ms after fixation) between the components elicited by fixations before the target was found in visual search and fixations during exploration. Moreover, differences between visual search and exploration also impacted low-frequency oscillations in a broader interval after fixation onset. These results generalize the characterization of early visual face processing to a wider range of experiments and show specific components potentially associated with eye movement guidance in active search.

Title: Self-control and its association with global/local attentional processing

Authors: *E. LÓPEZ-GONZÁLEZ[1], C. GUILLERMO-FLORES[1], A. LAZARO-FIGEROA[1], C. SANCHEZ-GACHUZ[1], T. ROMAN-LOPEZ[1], M. MENDEZ DIAZ[2], O. PROSPERO-GARCIA[3], A. E. RUIZ-CONTRERAS[4];

Abstract: Attention guides hierarchical (global/local) information processing and contributes to decision making and self-control processes. The later two processes are key to achieve long-term goals and resist short-term temptations. Individual differences in global/local processing may be associated with the primacy of self-control or its counterpart, impulsivity. The main goal of this study was to assess personality traits on the self-control/impulsivity continuum and their association with global/local information processing efficiency. Seventy-four young participants (38 women) responded to the five-factor model of personality, the UPPS-P: negative or positive Urgency (tendency to act hastily under negative or positive emotions), lack of Premeditation (tendency to act without considering the consequences), lack of Perseverance (difficulty for staying focused on a task), and Sensation seeking (tendency to seek new and exciting

experiences); and the Navon task (NT) which assesses global/local processing. In reaction times (RT) and percentage of correct responses (%CR), the effects previously reported in the NT were observed, with no differences identified as a function of the high or low self-control group. However, the inverse efficiency (IE) index (a relative measure which relates RT and %CR), revealed that low self-control was associated with higher efficiency solving the attention task, regardless of global/local processing, than those with medium or high self-control. These results suggest that being a low level self-control subject might be adaptively functional in some settings, since it guides attentional behaviors to generate quick responses to cope with sudden environment demands.

Title: Common and unique inhibitory control signatures of action-stopping and attentional capture suggest that actions are stopped in two stages

Authors: *C. SOH, J. R. TATZ, J. R. WESSEL;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: The ability to stop an already initiated action is paramount to adaptive behavior. Much scientific debate in the field of human action-stopping currently focuses on two interrelated questions. First: Which cognitive and neural processes uniquely underpin the implementation of inhibitory control when actions are stopped after explicit stop-signals, and which processes are instead commonly evoked by all salient signals, even those that do not require stopping? Second: Why do purported (neuro)physiological signatures of inhibition occur at two different latencies after stop-signals? Here, we address both questions via two pre-registered experiments that combined measurements of cortico-spinal excitability (CSE), electromyography (EMG), and whole-scalp electroencephalography (EEG). Adult human subjects performed a stop-signal task that also contained 'ignore' signals - equally salient signals that did not require stopping but rather completion of the Go response. We found that both stop- and ignore-signals produced equal amounts of early-latency inhibition of CSE and EMG, which took place ~150ms following

both signals. Multi-variate pattern analysis of the whole-scalp EEG data further corroborated that this early processing stage was shared between stop- and ignore-signals, as neural activity following the two signals could not be decoded from each other until a later time period. In this later period, unique activity related to stop-signals emerged at fronto-central scalp sites, reflecting an increased stop-signal P3. These findings suggest a two-step model of action-stopping, according to which an initial, universal inhibitory response to the saliency of the stop-signal is followed by a slower process that is unique to outright stopping.
Figure1. Left Panel: Cortico-spinal excitability (CSE) recorded from the task-irrelevant hand; Middle Panel: Decoding results using the signals recorded from the whole scalp EEG electrodes; Right Panel: Trial-averaged continuous electromyography (EMG) traces for Go, Ignore, Successful (SS) and Failed Stop (FS) trials.

Title: A common factor for inter-subject correlation of brains, hearts, and eyes

Authors: *J. MADSEN, L. C. PARRA;
Biomed. Engin., City Col. of New York, New York, NY

Abstract: A wide range of neural, physiological and behavioral signals correlate between human subjects in a variety of settings. A great number of hypotheses have been proposed to explain this inter-subject correlation, however there is no clarity under which conditions or

circumstances it arises, for which signals, or whether there is a common underlying mechanism. In this work we hypothesized that similar cognitive processing of a shared stimulus is the source of inter-subject correlation. To test this we presented informative videos to participants in an attentive and distracted condition and subsequently measured recall memory. Inter-subject correlation was observed for electro-encephalography, gaze position, pupil size and heart rate, but not respiration and head movements. The strength of correlation was co-modulated in the different signals, changed with attentional state, and predicted subsequent recall of information presented in the videos. There was robust within-subject coupling between brain, heart and eyes, but not respiration or head movements. The theory that emerges is that inter-subject correlation is the result of cognitive processing of a shared stimulus, but can be observed only for those signals that exhibit a robust brain-body connection. While physiological and behavioral fluctuations may be driven by multiple features of the stimulus, correlation with other individuals is co-modulated by the level of attentional engagement with the stimulus.

Title: The Neural Bases of Simulation in the Primate Brain

Authors: *A. AHUJA, T. M. DESROCHERS, D. L. SHEINBERG;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: To engage with the world, we must regularly make predictions about the outcomes of scenarios. How do we make these predictions? Recent evidence points to simulation - the idea that we can internally manipulate rich, mental models of the world - as one possible explanation for how such predictions are accomplished. While theories based on simulation are supported by computational models, neuroscientific evidence for simulation is lacking and many important questions remain. For instance, do simulations simply entail a series of abstract computations? Or are they supported by sensory representations of the objects that comprise the scene being simulated? We posit the latter and suggest that the process of simulating a sequence of events is

likely to evoke imagery of those events. Using functional magnetic resonance imaging (fMRI), we demonstrate that when human participants predict how a ball will fall through an obstacle-filled display, motion-sensitive brain regions (such as area MT) are activated. This activity, which occurs even though no motion is being sensed, resembles activity patterns that arise while participants actually perceive the ball's motion. We also demonstrate that when a nonhuman primate (NHP) performs the same task in an fMRI scanner, motion-sensitive brain regions are similarly activated as he attempts to predict the ball's path. Together, these findings suggest that the process of simulating the ball's movement is accompanied by a sensory representation of this movement in human and nonhuman primates. Thus, these data may show that mental simulations can recreate sensory depictions of how a scene is likely to unfold.

Title: Unrestricted eye movements strengthen causal connectivity from the medial temporal lobes to oculomotor regions during scene construction

Authors: *N. LADYKA-WOJCIK[1], Z.-X. LIU[2], J. D. RYAN[3,1];
[1]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Univ. of Michigan-Dearborn, Dearborn, MI; [3]Rotman Res. Inst., Baycrest, North York, ON, Canada

Abstract: There is an intimate relationship between the memory system of medial temporal lobes (MTL) and the oculomotor system. This relationship is not only reflected in the functional and anatomical connections between these systems, but also in eye movement behaviours. Visual exploration during perceptual and mnemonic viewing tasks has previously been shown to be associated with constructive processes in the MTL, including the hippocampus and parahippocampal place area. However, the directionality of connections between memory and oculomotor control regions, and how it relates to visual exploration, has not been studied directly in human neuroimaging. In the current study, we used dynamic causal modeling (DCM) for functional magnetic resonance imaging (fMRI) to investigate this relationship at a mechanistic level using a scene construction task in which participants' eye movements were either restricted or unrestricted. By omitting external visual input in our task design, we were able to determine the directionality of neural connectivity while participants mentally constructed scene representations. As opposed to when eye movements are restricted, allowing free eye movements during construction of novel scenes strengthens top-down connections from the MTL, to oculomotor regions, and to lower-level cortical visual processing regions. Meanwhile, our results

also demonstrated that bottom-up connections along the visual stream are suppressed. Taken together, these findings provide novel, non-invasive evidence for the causal architecture between the MTL memory system and oculomotor system associated with constructing vivid mental representations of scenes.

Title: The neural basis of visual-orthographic processing in perception and mental imagery

Authors: *S. LING[1], A. C. LEE[1,2], B. C. ARMSTRONG[1,3], A. NESTOR[1];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res. Inst., Toronto, ON, Canada; [3]Basque Ctr. on Cognition, Brain, and Language (BCBL), Donostia-San Sebastian, Spain

Abstract: Clarifying the neural and representational basis of mental imagery has elicited significant interest in the cognitive neuroscience of visual recognition. Recent work has suggested that visual perception and mental imagery are supported by overlapping regions of high-level and early visual cortex (EVC) and by similar patterns of activation at the level of these regions as captured by functional magnetic resonance imaging (fMRI) data. Here, we investigated the neural correlates of perception and imagery underlying visual-orthographic processing with the aid of fMRI.
To this aim, we collected data from 13 participants while they viewed or mentally imagined the appearance of four-letter nouns exhibiting the same CVCC (consonant-vowel-consonant-consonant) structure. Multivariate searchlight mapping revealed, consistent with previous findings, extensive and overlapping areas of the ventral stream capable of supporting pairwise word discrimination for perception and imagery. Yet, perception and imagery diverged in exhibiting more widespread reliance on occipitotemporal areas, for the former, and frontal areas, for the latter. Region-of-interest (ROI) analyses revealed significant levels of decoding for the visual word form area (vWFA) with higher accuracy for imagery than perception and the opposite pattern of results for early visual cortex (EVC). Notably though, decoding accuracy, as characterized by multivariate mapping, peaked in the vicinity of the vWFA at adjacent locations for perception and imagery. Further, we identified separate cortical networks accounting for visual-orthographic, phonological and sematic similarity across words in the two conditions.
In sum, the current study supports the idea of distinct but overlapping mechanisms for perception

and imagery of orthographic information, it points to the similar role of the vWFA in mediating these processes, and, more broadly, it sheds light on the neural architecture underlying these two types of visual processing.

Title: Auditory-frontal and -motor networks during distinct neural subprocesses of auditory imagery

Authors: *S. SAKAMOTO, K. MATSUSHITA, A. KOBAYASHI, R. SHIMIZU, A. AOYAMA;
Keio Univ., Fujisawa, Japan

Abstract: Neuroimaging studies in auditory imagery have reported regions associated with multiple neural subprocesses, including auditory information processing, memory retrieval, and mental manipulation. However, the distinct neural oscillations related to these subprocesses are less known; our objective was to investigate the oscillations associated with the memory retrieval and mental manipulation subprocesses during auditory imagery.
In the experiment, we first presented a reference sound at 880 or 220 Hz for 2 s and then a visual stimulus of either upward or downward arrow for the context of imagery. After an upward arrow, the participant imaged a sound octave higher than the reference sound (1760 or 440 Hz), and after a downward arrow, they imaged a sound octave lower than the reference sound (440 or 110 Hz). We analyzed 64-channel electroencephalogram data during imagery with two types of contrasts: the context contrast, which shared the imaged frequency of 440 Hz but had different contexts, and the content contrast, which shared the context of imagery but had different imaged frequencies. The context and content contrasts enable us to extract the mental manipulation and memory retrieval processes, respectively. All participants had music training experience (mean=10.8 years).
During imagery of sound, we found significant differences in the right frontal and temporal gamma power for the context contrast and right fronto-temporal delta phase coupling, left fronto-temporal delta-gamma phase-amplitude coupling (PAC), and right frontal-central delta-beta PAC for the content contrast.
Our finding of delta-gamma fronto-temporal PAC is convincing as frontal gamma and temporal delta power reflect memory load, suggesting that these oscillations also reflect the memory content during auditory imagery. Frontal and temporla gamma power in the context contrast

implies the importance of top-down manipulative process during imagery, as the same oscillation is involved during visual object rotation as well as the top-down process from frontal to temporal regions during auditory recall. Moreover, the distinction of two contrasts sheds light on the dual-pathway model of auditory cortical processing; anterior stream process spectral content while the dorsal stream process spectral motion and calculation. While more analysis is needed using methods with higher spatial resolution, our result in the auditory-frontal network possibly reflects the distinct oscillations of the two streams. Additionally, the delta-beta coupling in the content contrast plays a role in auditory-motor integration, implying possible relation of memory functions and motor functions.

Title: Behavioral and neural differences in imagery between a pair of aphantasic and non-aphantasic identical twins: a case study

Authors: *D. PRASAD, W. A. BAINBRIDGE;
Univ. of Chicago, Chicago, IL

Abstract: Aphantasia is a recently defined term characterizing people who lack voluntary visual imagery, despite otherwise normal performance in other cognitive abilities like perception and visual recognition (Zeman et al., 2015). Instead of experiencing perception-like imagery during visual recall, they often report semantic representations of their memories (Bainbridge et al., 2021). This atypical experience offers us a unique insight into the neural underpinnings of visual recall and what kinds of information these representations contain. Although the prevailing thought behind visual recall is that of sensory reinstatement, recent research has challenged this idea that brain regions activated during perception are similarly activated during recall, showing an anterior shift and representational transformation during recall versus perception (Bainbridge et al., 2020; Favila et al., 2020; Steel et al., 2021). Studying aphantasics could inform us on the nature of these newly defined recall regions - whether this anterior shift reflects representation of more abstract, conceptual information. Here, we present a case study with a pair of monozygotic, handedness discordant twins (Female, Age=31 years) where one twin reports having typical visual imagery (VVIQ=47, OSIQ Spatial=38, OSIQ Object=56) but the other twin reports lacking visual imagery (VVIQ=24, OSIQ Spatial=49, OSIQ Object=22). Using a paradigm adapted from Bainbridge et al. (2020), we examined whether there were differences in the

content of their visual recall. Participants studied naturalistic scene images, then drew them from memory and, later, from perception. Despite their drawings from perception having a similar amount of visual information, drawings from recall were starkly different between the aphantasic and non-aphantasic, with the aphantasic twin drawing fewer objects and using less color. To further examine this difference in recall ability, we conducted an fMRI study using two visual imagery tasks: imagery for novel object and scene images (Bainbridge et al., 2020), and imagery for familiar people and places (Steel et al., 2021). We also used a resting state scan to examine functional connectivity and a language localizer task to account for potential differences in lateralization (Fedorenko et al., 2010). Importantly, both twins experienced identical experiments, with identical familiar stimuli, allowing us to examine the ability to cross-decode stimulus representations between the two twins. We observe interesting differences between the aphantasic and non-aphantasic imagery representations, despite perceiving and recalling the same inputs across tasks.

Title: Intuitive physical inference: misconceptions, biases and neural bases.

Authors: *G. ZBÄREN[1], S. MEISSNER[1], V. GASHAJ[2], M. KAPUR[2], N. WENDEROTH[1,3]; [1]Neural Control of Movement Lab., Dept. of Hlth. Sci. and Technology, ETH Zurich, Zurich, Switzerland; [2]Inst. for Learning Sci. and Higher Educ., Dept. of Humanities, Social and Political Sciences, ETH Zurich, Zurich, Switzerland; [3]Future Hlth. Technologies, Singapore-ETH Centre, Campus for Res. Excellence And Technological Enterprise (CREATE), Singapore, Singapore

Abstract: *Introduction* Despite our ability to successfully interact every day with the physics of the world, our physical inferences are prone to errors. This can be seen in common misconceptions that arise when solving seemingly simple physics problems. A well-known example is the “straight-down misconception”, the erroneous belief that an object falling from a moving body falls straight-down.
We investigated (i) how common the straight-down misconception is when participants are exposed to a dynamical scene (ii) whether people who do *not* have a straight-down misconception still exhibit biases not in line with the laws of physics and (iii) what neural substrates support physical inference.

Methods 79 healthy volunteers (42 females; age = 24.13 +/- 4.17) took part in our study for which we created a computer-based, dynamical 3D physics world. In this 3D world, a horizontally moving object with a ball attached is displayed. The moving object comes either from the left or the right side of the screen, and its height and velocity vary across trials. At a certain point, the ball drops and participants are asked to indicate via button presses when and where they think the ball lands. Crucially, once the ball drops, the screen gets occluded such that the trajectory of neither the ball nor the moving object can be seen. In a next step, first pilot participants underwent a training session during which they performed the same physics task while receiving corrective feedback on their performance. This training was followed by a 3T fMRI experiment using the same task to measure BOLD responses during physical inference. *Results and Conclusion* Similar to previous studies using paper-pencil tests to assess the straight-down misconception, we found that 53.16% of the participants exhibited this misconception. Participants who correctly estimated the ball trajectory, tended to overestimate the falling time and mistakenly predict that the ball falls faster at higher velocities of the object. Thus, even when people do not exhibit a misconception, their inferences are prone to biases. Preliminary training and fMRI data suggest that errors greatly diminish when participants receive feedback. Neural activity underpinning physical inference of falling objects activates motion-responsive visual (MT/V5), motor and parietal regions when compared to a control task matched for visual input but not requiring physical inference. By applying multivariate pattern analysis to our fMRI data, we could successfully decode essential task parameters from visual and parietal regions. This suggests that participants use mental simulation to solve the task, which is line with current views on intuitive physics.

Title: Can we modulate locus coeruleus activity via pupil-based neurofeedback?

Authors: *S. N. MEISSNER[1], M. BAECHINGER[1], A. TAUBNER[2], N. WENDEROTH[1]; [1]Hlth. Sci. and Technol., [2]Computer Sci., Swiss Federal Inst. of Technol. Zurich, Zurich, Switzerland

Abstract: ***Introduction*** The locus coeruleus (LC) in the brainstem contains noradrenaline (NA)-releasing neurons and sends widespread projections to most of the brain. The LC-NA system is suggested to be involved in the control of various behaviors. Recently, there is growing evidence for a link between LC activity and non-luminance dependent changes in pupil size. Building on this knowledge, we aimed to investigate whether changes in pupil size (i) can be *volitionally* induced by humans via pupil-based neurofeedback (pupil-NF) training, and (ii) are linked to changes in LC activity as measured with fMRI.
Method To investigate whether healthy volunteers can learn to volitionally modulate (i.e., *increase* or *decrease*) their own pupil size, 43 participants (pupil-NF group; 28 females; 24 +/- 3.60 years) received three pupil-NF sessions on three consecutive days. 27 control participants (11 females; 24 +/- 5.45 years) received the same amount of training but no veridical pupil-NF. Prior to training, all participants were familiarized with potential mental strategies to modulate pupil size. Pupil size was measured by means of an eye tracker and fed back to the participants during training. To further explore the link between pupil size changes and LC activity, first participants (n = 11) underwent follow-up sessions combining pupil-NF with 3T fMRI to measure BOLD responses in the LC. First-level analyses involved the construction of a general linear model (conventional block design: *pupil increase vs. decrease)*. To further extract responses from our region of interest, we delineated the LC for each participant by means of turbo spin echo (TSE) structural MRI scans (in-plane resolution: 0.7 x 0.88 mm).
Results Healthy volunteers were able to modulate (i.e., *increase* and *decrease*) their pupil size relative to baseline measurements (mixed-effects model main effect *session*; $p < .001$). Importantly, this self-modulation was clearly reduced in control participants who did not receive veridical pupil-NF (main effect *group*; $p < .001$). Our preliminary fMRI analysis further showed that volitional pupil modulation may be linked to activity changes in the LC and connected areas including the amygdala and thalamus: we found higher BOLD responses in these areas during volitional *increase* than *decrease* of pupil size.
Conclusions Our findings suggest that healthy volunteers can learn to modulate their own pupil size via pupil-NF. Furthermore, we provide new insights into the link between pupil dynamics and LC activity by offering first preliminary evidence that volitional pupil modulation may indeed be linked to activity changes in the LC and interconnected areas.

Title: Alpha-band ERD in unimanual and bimanual motor imagery

Authors: *K. UMENO[1], Y. ITAGUCHI[2];
[1]Tokoha Univ., Shizuoka-shi, Japan; [2]Keio Univ., Tokyo, Japan

Abstract: <META NAME="author" CONTENT="梅野 和也">Bimanual movements have been reported to be effective for rehabilitation of stroke patients. However, few studies have examined the effects of bimanual motor imagery on brain activity and motor learning. This study investigated how the motor imagery of bimanual movements differs from that of unimanual movements in the effects on brain activity, by calculating ERD (Event-related desynchronization) recorded from motor-related areas. When one mentally simulates a physical action, called motor imagery, the amplitude of the α wave band in the motor-related areas decreases, which is called ERD and considered to reflect the quality of the motor imagery.In the experiment, twelve right-handed healthy students participated. The participants mentally simulated the action of rotating two balls (45 mm in diameter) on their palm without physical movements (ball rotation imagery task). They alternately performed the imagery task unimanually (left or right hand) or bimanually. One trial consisted of a rest period (physical activity was not allowed; 6 s), a preparation period (2 s), an imagery period (7 s), and a break period (5 s). Participants watched visual cues displayed on the computer screen during the task. The experiment consisted of 4 blocks, and 1 block consisted of 5 trials each of right-hand imagery, left hand imagery, and bimanual imagery (accordingly, 15 trials × 4 blocks in total). The participants took a two-minute break between blocks.OpenBCI Ultracortex Mark IV was used for the measurement of EEG. Eight channels of EEG data were recorded with the OpenBCI system. The EEGs recorded from the electrodes of C3 and C4 were analyzed. The reference and ground were placed at A1 and A2, respectively. EEG signals were filtered with a bandpass filter of 8 - 13 Hz to measure the amplitude of the α wave band. ERD was calculated by dividing the difference in the amplitude of the α wave band between the imagery and rest periods by the amplitude in the rest periods.The results showed that the amplitude of bimanual ERDs were higher than those of the unimanual ERDs. There was not a large difference in the amplitude of ERD between the left and right hand imageries. The amplitude of ERDs did not increase as practice proceeded. In addition, some participants did not show reliable ERDs through the experiments. The stronger ERDs observed in bimanual motor imagery compared to unimanual motor imagery may indicate that bimanual motor imagery helps neurofeedback beginners to efficiently evoke ERDs in the motor-related areas, which might also lead to the development of effective training for stroke patients.

Title: The neural basis for visual effects induced by inhaled psychedelics:DMT leads to activation of extrastriate cortex concomitantly with behavioural effects

Authors: M. TEIXEIRA*[1], C. SOARES*[1], M. PAIS*[1], G. LIMA[1], S. MACHADO[2], ***M. CASTELO-BRANCO**[1];
[1]ICNAS, CIBIT Univ. of Coimbra, Coimbra, Portugal; [2]Univ. of Northampton, Northampton, United Kingdom

Abstract: Introduction: DMT is an indole alkaloid widely found in nature, best known by its presence in ayahuasca. It is a psychedelic tryptamine associated with intense visual phenomena, perception changes and profound spiritual experiences. Induced visual percepts are driven by environment but characterized by an increased mismatch between the physical objects and their internal representations. In this study we aimed to explore the neural correlates of these altered brain states and the role of the visual system, during the experience produced by inhaled DMT using fMRI and periodic visual stimuli. **Methods:** A within-subject design study with control and active treatment conditions is being conducted at CIBIT, in 2 sessions (different days): Control (no treatment) or Active treatment (DMT). 6 healthy volunteers (mean ages= 35YO, SD= 13; 4 Males; 2 Females) have been tested. The study was conducted in accordance with the tenets of the Declaration of Helsinki and all participants signed a written informed consent. History of neuropsychiatric or organic disorders was excluded. For the active condition, smoked DMT was self-administered by participants (~50mg), obtained by extraction from the root bark of Mimosa Hostilis in freebase form. In both sessions, pre and post measures of subjective experience were collected with the Spiritual Well Being Questionnaire(SWBQ), the Vividness of Visual Imagery Questionnaire(VVIQ-RV), the Mystical Experience Questionnaire(MEQ30) and the Hallucinogen Rating Scale(HRS). fMRI task consisted of a block design with a visual hallucination inducer paradigm, with visual stimuli containing parts with empty-field flicker. Data were pre-processed and analysed in BrainVoyager 21.4. **Results and Conclusion:** Multivariate ANOVA results with HRS, MEQ and Condition (active and control group as within fixed factors) suggest overall higher scores for all the items of both scales in the active condition with significant differences between conditions for HRS Total [marginally sig: F= 6,347 (1,4), p=0,65] and Intensity [F =25,6 (1,4), p< 0.05) factors, and Positive Mood factor of MEQ[F=

12,774 (1,4), p<0.05]. No differences were found for repeated measures ANOVA Pre and Post VVIQ and SWBQ. Exploratory analysis of brain activity measured with fMRI contrasting DMT vs Control conditions under visual stimulation, show increased BOLD activity in non-primary visual areas BA 18, 19 and Precuneus for active condition. These results suggest a neural basis for the visual effects evoked by Ayahuasca which occur concomitantly with significant behavioral effects. *equal contribution **Funding:** FCT/UID4950, ICNAS Produção and Bial Foundation 252/18

Title: Mindfulness-induced white matter changes in breast cancer survivors with cognitive complaints: A preliminary longitudinal fixel-based analysis

Authors: *M. MELIS, J. BLOMMAERT, A. SMEETS, G. SCHROYEN, C. SLEURS, K. VAN DER GUCHT, S. SUNAERT, S. DEPREZ;
Catholic Univ. of Leuven, Leuven, Belgium

Abstract: Cancer-related cognitive impairment affects 17-78% of cancer survivors and has been associated with white matter abnormalities. It might impact the quality of life, but unfortunately, there is currently no treatment available. Previous research showed that standardised mindfulness-based interventions (MBI) might have an impact on cognition and white matter structure. Therefore, we investigated the potential of MBI to reduce cognitive complaints and reverse chemotherapy-induced white matter changes. Thirty-three adult breast cancer survivors with cognitive complaints after chemotherapy (mean age (SD) = 45.2 (6.19)) were randomly allocated to a mindfulness (MBI; N=18) or waitlist control condition (WL; N=15). Twenty-three participants (N=12 MBI; N=11 WL) completed multi-shell diffusion-weighted imaging (DWI) before the start of the intervention, immediately after, and 3 months post-intervention. White matter micro- and macrostructure was assessed using a whole-brain longitudinal fixel-based analysis (FBA). In this analysis, significant changes in fibre density (FD), fibre cross-section (FC) and a combined measure of fibre density and cross-section (FDC) were evaluated using connectivity-based fixel enhancement (p_{FWE}<0.05). Spearman correlations (r_s) were calculated to

investigate the relationship between significant changes in FBA-outcomes and cognitive/emotional complaints. We found a significant group-by-time interaction effect; a bigger reduction in log FC in fixels (N=5) located in the right superior longitudinal fasciculus in the mindfulness compared to the control group immediately post-intervention. Within-group analyses showed that immediately after the intervention, MBI participants had a lower FC in a group of fixels (N=122) in the right superior longitudinal fasciculus and a higher FC in fixels (N=63) located in the optic radiation compared to baseline. The decrease in FC correlated with a reduction in cognitive complaints (r_s=.42). The participants in the waitlist group had a lower FDC in a group of fixels (N=19) in the genu of the corpus callosum at three-month follow-up versus baseline. This reduction correlated with an increase in emotional complaints (r_s=-.52). In conclusion, these results provide preliminary evidence for white matter micro- and macrostructural changes following MBI, which might aid in recovery from cancer-related cognitive impairment. Research with bigger sample sizes is necessary to evaluate the potential of MBI in targeting cognitive impairment after cancer treatment.

Title: Hippocampal replay reflects specific past experiences rather than a plan for subsequent choice

Authors: *A. K. GILLESPIE[1], D. A. ASTUDILLO MAYA[1], E. L. DENOVELLIS[1,2], D. F. LIU[1], D. B. KASTNER[1], M. E. COULTER[1], D. K. ROUMIS[1], U. T. EDEN[3], L. M. FRANK[1,2]; [1]UCSF, San Francisco, CA; [2]HHMI, San Francisco, CA; [3]Boston Univ., Boston, MA

Abstract: Executing memory-guided behavior requires both the storage of information about experience and the later recall of that information to inform choices. Awake hippocampal replay, when hippocampal neural ensembles briefly reactivate a representation related to prior experience, has been proposed to critically contribute to these memory-related processes. However, it remains unclear whether awake replay contributes to memory function by promoting

the storage of past experiences, by facilitating planning based on an evaluation of those experiences, or both. We designed a dynamic spatial task which promotes replay before a memory-based choice and assessed how the content of replay related to past and future behavior. We found that replay content was decoupled from subsequent choice and instead was enriched for representations of previously rewarded locations and places that had not been recently visited, indicating a role in memory storage rather than in directly guiding subsequent behavior.

Title: Hippocampal replay of experience at real-world speeds

Authors: *E. L. DENOVELLIS[1], A. K. GILLESPIE[1], M. E. COULTER[1], M. SOSA[2], J. CHUNG[1], U. T. EDEN[3], L. M. FRANK[1];
[1]UCSF, San Francisco, CA; [2]Stanford Univ., Stanford, CA; [3]Mathematics and Statistics, Boston Univ., Boston, MA

Abstract: Representations related to past experiences play a critical role in memory and decision-making processes. The rat hippocampus expresses these types of representations during sharp-wave ripple (SWR) events, and previous work identified a minority of SWRs that contain “replay” of spatial trajectories at ~20x the movement speed of the animal. Efforts to understand replay typically make multiple assumptions about which events to examine and what sorts of representations constitute replay. We therefore lack a clear understanding of both the prevalence and the range of representational dynamics associated with replay. Here we develop a state space model that uses a combination of movement dynamics of different speeds to capture the spatial content and time evolution of replay during SWRs. Using this model, we find that the large majority of replay events contain spatially coherent, interpretable content. Furthermore, many events progress at real-world, rather than accelerated, movement speeds, consistent with actual experiences.

Title: Latent learning drives sleep-dependent plasticity in distinct CA1 subpopulations

Authors: *W. GUO, J. J. ZHANG, J. P. NEWMAN, M. A. WILSON;
The Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Latent learning allows the brain the transform experiences into cognitive maps, a form of implicit memory, without reinforced training. Its mechanism is unclear. We tracked the internal states of the hippocampal neural ensembles and discovered that during latent learning of a spatial map, the state space evolved into a low-dimensional manifold that topologically resembled the physical environment. This process requires repeated experiences and sleep in-between. Further investigations revealed that a subset of hippocampal neurons, instead of rapidly forming place fields in a novel environment, remained weakly tuned but gradually developed correlated activity with other neurons. These ‘weakly spatial’ neurons bond activity of neurons with stronger spatial tuning, linking discrete place fields into a map that supports flexible navigation.

Title: Selective disruption of hippocampal sharp-wave ripples leads to impaired object-place recognition memory

Authors: *S. DUTTA, J. ZHANG, C. KEMERE;
Rice Univ., Houston, TX

Abstract: Animals exhibit an innate curiosity towards novelty. Whether in the form of contexts or objects, the resultant behavior is quantified by them spending more time with novel or displaced objects or even novel locations as opposed to familiar ones. Extensive lesion studies have demonstrated this novelty preference to be hippocampally-dependent via a variety of object recognition test (ORT) paradigms. More recent work has correlated hippocampal CA1 LFP signatures, such as fast-gamma and beta-band oscillations, as potential neural substrates for object-place recognition memories and has demonstrated modulations in other transient hippocampal events, sharp-wave ripples (SWRs). Specifically, SWRs have been shown to increase after encoding of novel or displaced objects and general novelty in the testing paradigm; however, the concomitant spiking activity has not been correlated to preferentially code object-place pairings prompting the question of the role of these events in this curiosity driven task. To illuminate the role of SWRs in potentially driving the curiosity towards novelty, we selectively modulate SWR activity using our previously engineered open-source, closed-loop SWR detection system during a displaced ORT paradigm. Although behaviorally similar with regards to various exploration environment metrics, our results show statistically significant deficits in exploration of familiar objects in novel locations of SWR disrupted rats compared to control animals (post-SWR stimulation or non-implanted wild type rats). We look to further investigate the role of SWRs along with its co-occurring neural activity and potential causal changes that SWRs transiently cause within the hippocampal circuit that may lead to such a deficit in this novelty recognition memory through exploration of LFP metrics such as cross-frequency coupling, phase-amplitude comodulation, SWR rates, etc. Altogether, our preliminary findings suggest SWRs play a crucial role in curiosity driven memory tasks as opposed to just spatial memory recall tasks.

Title: Using auditory and multisensory virtual reality to understand how spatial acoustic cues contribute to hippocampal place map formation

Authors: *S. GAO[1,2], Z. CHEN[2], M. J. MCGINLEY[3], C. KEMERE[2];
[1]Electrical And Computer Engin., Rice Neuroengineering Initiative, Houston, TX; [2]Rice Univ., Houston, TX; [3]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: For decades, many neuroscientists have actively been uncovering how our brain recognizes the environment around us during spatial navigation. Traditionally, spatial navigation in animal models in virtual reality (VR) settings has been studied primarily using visual cues. There has recently been interest in exploring other sensory cues such as odor and sound. However, few studies have investigated VR navigation in environments promoting interactions between the auditory system and hippocampus. Here we present a novel virtual reality system defined exclusively by acoustic landmarks that are amplitude modulated based on the animal's position. We used modified UCLA Miniscope to chronically image the CA1 area of head-fixed mice performing an operant navigation task collecting water reward for up to two months. We report behavioral evidence that mice can learn to navigate in our auditory VR task. Namely, we observed anticipatory licking and slowing preceding the reward region. Furthermore, we introduced a signal-to-noise ratio (SNR) manipulation on well trained animals in order to study how precision of sensory stimulation is integrated with idiothetic cues. We observed population wise hit rate performance increase as the SNR increases. In addition, the distance between the reward location and the lick location increases as SNR decreases. Our results suggest that animals were able to form a cognitive map with only auditory landmarks but rely heavily on the ability to detect onset of target sound within a noisy sound background. Intriguingly, the number of highly spatially selected stable neurons observed were low, and we asked whether visual cues are necessary to engage a large population of stable place cells during navigation. To investigate further, we have developed a visual VR system that is synchronized with our previous auditory VR, and we are aiming to understand whether the inclusion of visual motion cues facilitate the formation of stable place cells defined by acoustic landmarks. We envision that combining our behavior paradigm with our novel sound and visual VR system has the potential to provide new insight on how multiple neural systems interact with each other and respond to stimuli using spatial aspects of sound in an environment.

Title: Associative learning dynamics across the dorsal/ventral axis of the hippocampus

Authors: *J. BIANE[1], M. LADOW[1], F. STEFANINI[2], S. BODDU[1], A. FAN[1], S. HASSAN[1], N. DUNDAR[1], D. APODACA[1], K. LITKE[1], N. WOODS[1], M. KHEIRBEK[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Univ. of Columbia, New York, NY

Abstract: The dorsal hippocampus generates internal representations of cue-outcome relationships, while the ventral hippocampus has been implicated in orchestrating responses to emotionally salient cues. Thus, the hippocampus may be responsible not just for binding cue-outcome associations, but also for attaching and modifying the emotional significance of cues, and may do so differentially across its dorsal/ventral (d/v) axis. Using 2-photon imaging in mice we examined the evolution of stimulus encoding across the d/v axis of the hippocampus as mice learned to associate odor stimuli with different outcomes (reward or nothing). We found robust coding of odor identity in populations of dCA1 neurons across all phases of odor-reward learning (baseline, learning, extinction and reaquisition), indicating that odors are robustly encoded by dCA1, regardless of their value. In contrast, neuronal signals in vCA1 tracked the value of odorants assigned during learning. Analysis of the 2 sec trace period between odor offset and reward delivery found that responsivity to this period was virtually absent at the onset of training, but increased considerably with learning in both dCA1 and vCA1. This signal faded following extinction of the odor-reward contingency, but was rapidly restored when the contingency was reinstated. Moreover, in well-trained animals this reward anticipation signal was conserved across days, suggesting a stable representation for reward expectation exists across d/v regions of the hippocampus. We additionally examined the within-trial stability of population activity and found that, following learning, distinct ensembles of dCA1 neurons represented each component of the trial (odor, trace, reward). In contrast, in vCA1 we found overlapping representations to these components, which persisted for seconds after the trial concluded. This suggests that dCA1 neuronal ensembles represent the distinct elements of a trial while vCA1 can generalize across elements to generate a broad representation of trial identity. Collectively, these data further clarify how the hippocampus is recruited for reward seeking, showing both CA1 regions strongly encode reward expectation, but display a shift from externally based (stimulus ID) to internally based (value) encoding of environmental variables along the d/v axis. Further, the specific (dCA1) vs general (vCA1) encoding of task elements suggests the hippocampus may employ different levels of granularity to facilitate information coding and recall.

Title: Place fields can be formed by individual visual landmarks in CA1, but not in CA3, in the hippocampus in a VR environment

Authors: *H.-W. LEE[1], I. LEE, PhD[2];
[2]Brain and Cognitive Sci., [1]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: We investigated the effects of visual landmarks on the formation the place field in the CA1 and CA3 subfields of the hippocampus. For this purpose, we recorded single units simultaneously from the CA1 and CA3 while rats (n = 4) experienced visual landmarks in a virtual reality (VR) environment. The rat was head-fixed and trained to run on a treadmill to obtain water rewards in random locations in the virtual track. Once the rat reached the end of the linear virtual track (3m in length), the rat was unknowingly teleported to the start of the track so that the animal could travel indefinitely along the track. Five different environments were used in the study, depending on the number of visual landmarks presented in the virtual environment: (a) no landmark (NL) - a black screen was presented along the sides of the track; (b) single landmark (SL) - one visual landmark was shown on one side of the track; (c) dual landmarks (DL) - one more visual landmark was added to the SL condition; (d) triple landmarks (TL) - the third visual landmark was added to the DL condition; (e) ensemble landmarks (EL) - the empty spaces among the three visual landmarks of the TL condition were filled with many visual landmarks to produce a scene-like stimulus. On the first day of recording, rats ran in the NL and EL conditions. On the next day, rats ran in the SL, DL, TL, and EL conditions in that sequence (30 trials/condition). Finally, rats experienced the same conditions in the reverse order (EL to SL). Place cells were recorded from the CA1 (n = 312) and CA3 (n = 175) while rats ran in those virtual environments. In the NL, place cells were hardly found in both the CA1 and CA3. However, adding a visual landmark produced a dramatic increase in the number of place cells. Specifically, in the CA1, the proportion of place cells was positively correlated with the number of landmarks (SL: 15.4%, DL: 28.5%, TL: 42.6%, EL: 47.1%). Surprisingly, place cells in the CA3 rarely responded when individual landmarks were added, but they dramatically increased their activities as the scene-like ensemble landmarks were presented in the EL condition (SL:

7.4%, DL: 7.4%, TL: 7.3%, EL: 20.6%). The difference in the proportion of place cells between the CA1 and CA3 was statistically significant ($p < 0.001$, logistic regression). Very similar trends were also found in other measures (e.g., spatial information, sparsity, etc.) to describe the behavior of the place cells, and no sequence effect was found between the SL-to-EL and EL-to-SL sessions. Our findings suggest that the CA1 represents individual landmarks, whereas the CA3 represents a complex visual scene more readily than the individual landmarks.

Title: Theta phase-based multiple place fields of single-units in the subiculum represent multiplex information in a visual scene memory task

Authors: *S.-M. LEE[1], J.-M. SEOL[1], I. LEE, PhD[2];
[2]Brain and Cognitive Sci., [1]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The subiculum is located at the critical juncture to interface the hippocampus with the various cortical and subcortical areas. However, the exact roles of the subiculum in the hippocampal-dependent memory tasks remain largely unknown. One of the major obstacles to making analytical comparisons of neural firing patterns between the subiculum and the hippocampus is the broad and continuous firing fields of subicular neurons. To address this issue, we used spiking-phase relationships to parse the broad firing fields of a subicular neuron into multiple subfields to find the unique functional contribution of the subiculum in a hippocampal-dependent visual scene memory task. Specifically, rats were trained to choose either the left or right arm in a T-maze according to the visual scene stimulus presented on LCD monitors. Once the rat reached the performance criterion, the single-unit spiking activities and local field potential were recorded simultaneously in the dorsal subiculum and CA1 by an implanted multi-electrode drive equipped with 24 tetrodes. We found that some of the broad firing fields of the subicular neurons were successfully divided into multiple subfields by using the theta-phase precession cycle. The resulting phase-based fields in the subiculum were similar to those in CA1 in terms of the field size and phase-precession strength. Furthermore, this new field identification

method using phase code significantly improved the detection of task-relevant information (e.g., visual scene or choice response) in subicular cells without affecting the information content represented by CA1 cells. Notably, multiple fields of a single subicular neuron could carry heterogeneous task-related information such as visual scene and choice, which was rarely observed in the CA1. Our findings suggest that the subicular cells represent multiplex information and integrate them by using theta rhythm to associate an environmental context with action.

Title: A modeling framework for studying dynamic memory representations in the hippocampus

Authors: *M. NATRAJAN, J. E. FITZGERALD;
Howard Hughes Med. Inst. Janelia Res. Campus, Ashburn, VA

Abstract: A central question in neuroscience is how learning and memory are manifested by changes in the brain. In the hippocampus, a key center for learning and memory, connections from CA3 to CA1 region have been found to be highly dynamic, with spines continually appearing and disappearing (Attardo et al., 2015). Dynamics have also been seen at the representational level, as different assemblies of CA1 place cells are activated on different days, even when the animal is not learning or forgetting a task (Ziv et al., 2012). Some neurons lose selectivity for a place while others become selective, leaving many statistics of representation intact. This leads to our general question. How can spatial memory in the hippocampus be retained, or even improved, by circuit remodeling and representational drift? Since there is redundancy when a low-dimensional task is represented in high-dimensional neural activity, representational changes don't lead to memory changes if representational dynamics are limited to the null space (Rule et al., 2020). A Learning scheme from Kappel et al. (2015, 2018) provides a neural network framework for exploring multiple high-performance regions of the synaptic parameter space.
Here we built a hippocampus model with 3 layers: (i) CA3 with stable place representation; (ii) CA1; and (iii) abstract spatial decoding neurons. CA3-CA1 connections were dynamic, while connections from CA1 to decoding neurons were fixed. By adapting the Kappel et al. plasticity rules to CA3-CA1 connections, CA1 learned to inherit spatial information from CA3, and the system could maintain its representation despite ongoing changes in connectivity and CA1 representation. We analytically characterized the representational solution space in a general

case, as well as for a simpler toy model where the solutions could be visualized and intuitively understood. Using these analytical results, we developed a numerical method of diffusion with constraints to explore CA1 representations that generate exact position decoding. This simple model recapitulated the phenomena of fading in and out of the representation, with changes in cellular membership as observed experimentally. Though all CA3-CA1 connections were unstable, when a CA1 neuron dropped out and then dropped back in, it responded to the same angle that it used to respond to previously. Thus, simulations reproduce patterns seen experimentally and help us understand how long-term memory can exist without a stable representation. We are currently applying this framework to study potential benefits of representational drift including encoding uncertainty, timestamping, robustness, and learning multiple environments.

Title: Differential neural correlates of place cells between the CA1 and CA3 subfields of the hippocampus in response to visual novelty in a VR environment

Authors: *J. SHIN[1], S.-W. JIN[2], I. LEE, PhD[2];
[2]Brain and Cognitive Sci., [1]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Although it has been demonstrated that the dentate gyrus and CA3 subfields of the hippocampus process environmental novelty through pattern separation and completion, the roles of the CA1 remain largely unknown. To investigate the differential roles of the CA1 and CA3 in processing a modified environment in a more controlled setting, we recorded single units simultaneously from both subfields in a virtual reality (VR) system. Single units were also recorded simultaneously from the visual cortex (V2L) as the head-fixed rat navigated in different VR track environments by running on a cylindrical treadmill. In each environment, rats (n = 8) were trained to move forward along a linear track to obtain water rewards on the two random sites per trial (20 μL/site). Once the rat reached the criterion, data acquisition started. Robust place fields were found in our VR system (CA1: 27.72%; n = 168/606, CA3: 20.51%; n =

129/629). After experiencing the original environments for ~7 days, different conditions of fog trials (controlled by modifying the density of fog; e.g., 15% and 30% of fog) were introduced. When different densities of visual fog were pseudo-randomly introduced to the familiar environment after the rat finished the standard trials as a baseline, 37.0% (n = 80/216) of CA1 place cells showed global remapping instantly. In contrast, 88.3% (n = 98/111) of CA3 place cells retained their original firing fields. Place cells in CA1 exhibited significant global remapping than those in CA3 and V2L ($p < 0.0001$, Kruskal-Wallis test). In addition, when in-field firing rates were compared across the fog conditions, the subpopulation of CA1 cells that showed global remapping exhibited a significant increase in the firing rate across the fog conditions ($p < 0.0001$). Our findings suggest that most place cells in the CA3 preserve their memory representation of the original environment where there is a subtle visual mismatch between past and present VR environments. However, some place cells in the CA1 rapidly form new spatial representations and increase their firing rates over time, presumably to stabilize the neural firing patterns. Our prelimianary data suggest that the CA1 network is more biased to form a new spatial representation in response to visual novelty than the CA3 network. In contrast, the CA3 is more biased to maintain the neural representation for the original environment despite the novel visual changes in the VR environment.

Title: Temporal recalibration occurs without awareness across motor and perceptual judgment tasks

Authors: *M. BUBNA[1], M. LAM[2], E. CRESSMAN[1];
[1]Sch. of Human Kinetics, Univ. of Ottawa, Ottawa, ON, Canada; [2]Dept. of Human Kinetics, St. Francis Xavier Univ., Antigonish, NS, Canada

Abstract: Sensory stimuli occurring immediately after a voluntary action are typically interpreted as consequences of the action (e.g., one presumes a letter appearing on the screen arises due to the fact that they pressed a key on the keyboard). After exposure to a short, constant delay between voluntary movement and sensory stimuli, temporal recalibration (TR) occurs to realign asynchronous events such that they once again appear consistent with previous expectations. The current experiment looked to establish if awareness of the temporal lag between a motor response (i.e., a keypress) and a sensory event (i.e., a visual flash) is necessary for TR to occur. We further investigated whether the influence of awareness on TR is modulated

based on the motor and perceptual judgment task requirements. Two groups of 24 participants (Group 1: Aware and Group 2: Unaware) completed 8 blocks of trials, in which the motor tasks (e.g., a single or repetitive tap), perceptual judgment tasks (e.g., judging the temporal order of the keypress in relation to the visual flash or judging whether the two events were simultaneous or not), and fixed temporal lag between keypress and visual flash (e.g., a 0 ms or 100 ms lag) varied. The Aware group was told of the temporal lag between their keypress and visual flash at the beginning of each block, whereas the Unaware group was not. TR was determined by comparing judgments between corresponding blocks of trials with the same motor and perceptual judgment task requirements when the temporal lag was 0 ms and 100 ms. Results revealed that both the Aware and Unaware groups demonstrated a similar magnitude of TR across all motor and perceptual judgment tasks. However, accuracy of responses differed between the two judgment tasks, such that simultaneity of the flash and keypress was perceived to occur *before* true simultaneity in the temporal order judgment task, but *after* true simultaneity when judging whether the events were simultaneous or not. We propose that each judgment task engaged different cognitive processes that resulted in their respective response patterns. Together, these results suggest that awareness of a temporal lag does not influence the magnitude of TR achieved and that motor and perceptual judgment task demands do not modulate the influence of awareness on TR.

Title: Testing the crossed-hands effect on motor-effector specificity for learning of multiple prior distributions in human coincidence timing

Authors: *Y. MATSUMURA[1], N. SHIMADA[2], R. SATO[1], J. HERON[3], N. ROACH[4], M. MIYAZAKI[2,1];
[1]Grad. Sch. of Integrated Sci. and Technol., [2]Dept. of Computer Science, Fac. of Informatics, Shizuoka Univ., Hamamatsu, Japan; [3]Sch. of Optometry and Vision Sci., Univ. of Bradford, Bradford, United Kingdom; [4]Sch. of Psychology, Univ. of Nottingham, Nottingham, United Kingdom

Abstract: The brain can acquire a prior distribution of sensory inputs and use them to optimize performance on sensorimotor tasks. Recently, we found that in a coincidence timing task, participants can simultaneously acquire two different prior distributions when they are assigned to two different motor effectors such as the right and left hands (motor-effector specificity). In the present study we use the crossed-hands method (Yamamoto & Kitazawa. 2001, Shore et al. 2002) to investigate whether effector specific priors are organized according to intrinsic (anatomical) or extrinsic (extrapersonal) spatial coordinates. In our experiments, three sequential visual stimuli (S1→S2→S3) were presented on the right or left side of the fixation point. Participants pressed a key such that its onset coincided with the onset of S3 based on the time intervals between S1 and S2 (target intervals). Each participant performed 640 trials (40 trials/set × 16 sets) of the task. Target intervals were sampled from short-time (424-988 ms) or long-time (1129-1694 ms) prior distributions. Each of the two priors (short/long) was assigned to one of the two stimulus locations (right/left). In Experiment 1, participants performed the task while crossing their hands in all sets. For example, when stimuli appeared on the left side, participants pressed the left key using their right hand. Under these conditions, participants' temporal estimates were biased in a manner consistent with acquisition of both the long-time (sets 1-4 onwards) and short-time priors (sets 5-8 onwards). In Experiment 2, participants crossed their hands during the first half of testing (sets 1-8), then uncrossed them for remaining trials (sets 9-16). While similar results to Experiment 1 were found during the initial, crossed-hands trials, the influence of the short-time prior disappeared when the hands were uncrossed. These results suggest that multiple priors are acquired based on the mapping between stimuli and intrinsic, body-centered co-ordinates.

Title: Human's heterogeneous perception of time

Authors: M. POURRAHIMI[1], ***N. MIRHAKIMI**[1], N. ESHRAGHI[2], S. AGAHI[2], M.-R. A.DEHAQANI[1];
[1]Cognitive Systems Laboratory, Sch. of Electrical and Computer Engineering, Col. of Engineering, Univ. of Tehran, Tehran, Iran, Islamic Republic of; [2]Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: A great deal of research has been conducted to reveal the underlying mechanisms of time perception in humans, yet these mechanisms remain still in debate. One of the main observable characteristics of human timing behavior is the way time perception varies with variations in the time interval to be perceived (i.e. target time). Gaining an understanding of the pattern of dependency of time perception on the target time is proved to be a great facilitator in the development and assessment of time perception models as is greatly exploited in the investigation of the conformity of the Scalar Expectancy Theorem (SET) to human timing behavior. Although some research has been conducted to address this dependency through examining the validity of mean accuracy property (the mean of perceived times equals target time) and scalar property of time variance (the standard deviations of perceived times grow linearly with the increase in target time) presumed by the SET, the pattern of this dependency remains poorly understood. Moreover, there is mixed evidence about the validity of SET as a major theorem for human time perception. Therefore, we designed a sub-second fine resolution time production task to investigate the dependency of time perception, measured by participants' produced time (i.e. perceived time), on the length of target time and further study the ability of SET in explaining human timing behavior. Time perception was evaluated regarding three different aspects, namely, temporal accuracy, temporal variability, and temporal learning. The observations reveal heterogeneous dependence of human timing behavior on the target time, regarding all three aspects. These patterns are proved to be consistent for all participants through sessions of the experiment. Results pose a new challenge on the SET, opposing its assumption of scalar property, shedding light on our understanding of underlying time representations in the brain.

Title: Human hippocampal surface micro-grid recordings reveal spatiotemporal timecourses of normal and abnormal neurophysiology

Authors: *J. KLEEN[1], K. K. SELLERS[2], J. ZHOU[3], M. TRIPLETT[3], K. LEE[3], A. TOOKER[3], R. HAQUE[4], E. F. CHANG[5];

Labs., Livermore, CA; [4]Ctr. for Bioengineering, Lawrence Livermore Natl. Lab., Livermore, CA; [5]Neurosurg., UCSF Med. Ctr., San Francisco, CA

Abstract: Intracranial recordings in patients with drug-resistant epilepsy provide a novel approach to studying hippocampal neurophysiology in vivo. This includes how oscillations and other transient phenomena propagate within this structure. We recently described the existence of bidirectional traveling waves moving up and down the hippocampal structure using novel thin-film micro-grid arrays conformed over this structure's ventricular surface. Here, we extend our examination to the spatiotemporal properties of transient bursts of activity including both normal and abnormal (epileptiform) phenomena. Six participants undergoing epilepsy surgery (five with medically-refractory seizures and one with a circumscribed lateral temporal lobe glioma) underwent limited excision of the antero-lateral temporal lobe for clinical purposes (four under anesthesia and R-sided, two awake and L-sided). A 32-channel micro-grid array (4 x 8 layout, 2mm spacing, 1.22mm diameter platinum/iridium contacts) was carefully placed and conformed onto the lateral hippocampal surface over the CA1 region. Activity was recorded at 24 kHz from all 32 contacts for approximately 8-22 minutes for each participant. Using two-dimensional regression modeling, we found that traveling low-frequency (1-15 Hz) oscillations occurred in transient bouts, with medians ranging from approximately 1.2 to 3.0 seconds, and maximums from 3.4 to 9.3 seconds. There was no correlation between maximum bout duration and oscillation frequency ($p=0.141$, Spearman's rho). Normal physiological hippocampal ripples were also observed, though less frequently in participants with more severe hippocampal disease. Interictal epileptiform discharges (IEDs) were observed in five participants (2.13 to 15.71 per minute, median 5.97). Preliminary results using a template matching algorithm suggested IEDs were generated from one or occasionally two consistent spatial sources that were distinct for each participant. In summary, low-frequency traveling oscillations occur in short (seconds-long) bouts, translating to several or dozens of continuous cycles flowing toward either the septal or temporal hippocampal pole. These transient timescales may support information processing (online and offline) by facilitating frequent diverse exchanges between the hippocampus and cortical structures interconnected along its axis. The two-dimensional spatial perspective also suggested that IEDs are generated from intrahippocampal sources that show little spatial variation (within millimeters) suggesting relatively concrete pathophysiological circuitry.

Title: A fMRI-EEG investigation of feedback-driven improvements in visual time reproduction

Authors: *F. BADER[1], M. ALQURAISHI[2], M. WIENER[3];
[1]Dept. of Psychology and Interdisciplinary Program in Neurosci., George Mason Univ., Fairfax, VA; [2]Psychology, George Mason Univ., FAIRFAX, VA; [3]Dept. of Psychology, George Mason Univ., George Mason Univ., Fairfax, VA

Abstract: Time perception is critical for everyday behaviors and cognitive functions ranging from speech to motor control. Errors may occur when learning to time durations; therefore, recognizing and correcting the temporal errors is essential for timing self-awareness. Electrophysiology and behavioral studies have revealed that humans possess a certain self-awareness of their individual timing ability; however, there are conflicting reports over whether humans can discern the direction of the timing error (earliness or lateness). Testing the impact of feedback on time perception is a way to understand the level of self-awareness of temporal errors. Recently, we performed a behavioral study using a visual temporal reproduction task and showed that temporal estimates were more accurate and precise when post-trial non-directional feedback on the estimates was provided. Even in the absence of feedback, subjects improved the accuracy of temporal estimates but were not more precise. Here, in the present study, we examined the neural underpinnings of our these behavioral findings by conducting a simultaneous fMRI-EEG study of eleven healthy adults while they performed a visual temporal reproduction task. Participants viewed a blue square for a set amount of time and then re-created the time the square was on-screen using a keypress and received adaptive non-directional feedback for their performance. Crucially, participants could repeat each trial following feedback, essentially allowing a “re-do” to learn from the successes or errors in the first trial. We observed two event-related potentials while participants underwent fMRI-EEG: the contingent negative variation (CNV), a timing-related signature that indexes time durations and is associated with temporal expectation and encoding; and the reward positivity (RewP), a feedback component reflective of outcomes in probabilistic trial-and-error learning tasks. During the reproduction phase of the task, significant EEG-informed fMRI activity was observed in the supplementary motor area (SMA), pre-motor cortex, and thalamus. With positive feedback, the EEG-informed fMRI activity due to the CNV from the SMA elicited a large RewP and was observed in the basal ganglia and thalamus. Conversely, negative feedback due to inaccurate responses led to greater activity within the SMA. The results demonstrate the importance of feedback valence in modulating region-specific responses to temporal judgements and in influencing the future processing of temporal information.

Title: Inner-speech specificity for the acquisition of multiple prior distributions in human coincidence timing

Authors: *S. NATSUME[1], C. YAMADA[3], Y. MATSUMURA[1], R. SATO[1], M. MIYAZAKI[1,2]; [1]Grad. Sch. of Integrated Sci. and Technol., [2]Fac. of Informatics, Shizuoka Univ., Hamamatsu, Japan; [3]Advanced Res. Ctr. for Human Sci., Waseda Univ., Tokorozawa, Japan

Abstract: The brain can maximize precision in a sensorimotor task by optimally utilizing a prior distribution of the task. To deal with various events in daily life, we should acquire multiple priors in the real environment. Our group recently reported that if two priors are assigned to two different motor effectors (left hand/right hand), participants acquire the priors separately ("motor-effector specificity"). However, in daily tasks (e.g., baseball), we cannot always use different motor effectors according to differences in targets (e.g., fastball/slowball). Here, we focused on "inner speech." During timing in sports, we often chant "1, 2, 3" internally. We expect that if we assign different inner speeches to different priors, we may acquire the priors separately ("inner-speech specificity"). In our experiments, three sequential visual stimuli (S1, S2, S3) were presented on the left or right side of a fixation point. Based on the S1-S2 interval, participants anticipated the onset of S3 and pressed a key to temporally coincide with the onset of S3. The S1-S2 (= S2-S3) interval was randomly sampled from the short-time (424-988 ms) or long-time (1129-1694 ms) prior distribution. These priors were assigned to the left or right visual stimuli. The participants performed the task using only the dominant index finger. Each participant completed 640 trials (40 trials/set × 16 sets) of the task. In Experiment 1, participants (n = 12) had no instructions regarding inner speech. As a result, the participants only acquired the long-time prior but not the short-time prior. In Experiment 2, participants (n = 12) were instructed to perform the task with inner timing as "A, A, A" or "B, B, B" according to the stimulus positions. In the first-half (1-320) trials, the participants acquired the long-time prior but not the short-time prior. However, in the second-half (321-640) trials, they also acquired the short-time prior. These results suggest that we can acquire multiple prior distributions by assigning different inner speeches to the priors. Meanwhile, individual variation was also observed, although the results were statistically significant. Four of twelve participants did not acquire the short-time prior in the second-half trials, in which two participants acquired the short-time prior in the first-half trials, but this disappeared in the second-half trials. This may reflect that some participants could not continue the inner speeches with sufficient intensity over

a large number of trials. We should also investigate whether participants acquire multiple priors more robustly if they are assigned different explicit speeches to the priors.

Abstract: Language tone is a suprasegmental speech unit and functionally serves word meaning distinction. Understanding how tone processing proceeds in the brain is essential because it can help resolve a paradox between linguistic pitch processing (i.e., tone) and non-linguistic pitch in the brain and link to research about how the brain develops to acquire a language. In this study, by taking advantage of the high spatiotemporal resolution of intracranial EEG data, i.e., the stereo-EEG (SEEG), we were allowed to profile the neural mechanism of language tone processing with precision higher than other neuroimaging tools, for example, fMRI. Specifically, we expect that linguistic (tone) knowledge would modulate brain activation of the frontal and temporal language areas, i.e., earlier and larger activation for language tone judgment (linguistic pitch) than for voice gender discrimination (non-linguistic pitch).
Twelve refractory epilepsy patients, who received depth-electrode implantation to monitor their epileptiform activities for surgery purposes, gave written informed consent for participation before joining the experiment. Each electrode (5-mm spacing between contacts) had 6 or 8 contacts. SEEG was sampled at 2,048 Hz. T1 MRI before and after electrode implantation was collected for localizing intracranial contacts. Two tasks were designed by using the same set of speech sounds. Participants performed tone judgment in one task and gender judgment in another one. Noise-normalized distributed source modeling of SEEG data was calculated at each time

point using the minimum-norm estimates.
The results for language tones indicated the estimated neural current starts at the left primary auditory cortex (A1) at 24 ms after the tone sound display and starts later with smaller amplitudes at the right A1 (34 ms). Then, the neural current spreads to the associated auditory cortex (A2) and medial temporal cortex at around 44 ms after the sound onset and subsequently to frontal and inferior temporal regions. For voice gender processing, the start of neural current occurs at about 63 ms of the sound onset. It spreads through bilateral A2 and medial temporal areas to the ventromedial prefrontal cortex and frontal pole. The activity for voice gender judgment is smaller and relatively dispersed than that for language tone discrimination.
In sum, our SEEG results indicated the brain networks recruited for process language tone (linguistic pitch) and voice gender (non-linguistic pitch). Neural activation for the former took place in temporal and frontal language networks with an earlier onset and a larger amplitude than that for the latter.

Title: Lateralization during development as a predictor of language outcomes in ASD

Authors: *G. BLANCO-GOMEZ[1], C. O'REILLY[2], M. ELSABBAGH[2];
[1]Integrated Program in Neurosci., [2]McGill Univ., Montreal, QC, Canada

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by impaired social and communication skills also involving language impairments in 50% of the cases. It is also associated with reduced brain lateralization, but more research is needed to understand how a lack of lateralized dominance during language tasks in ASD contributes to language impairments. We hypothesize that abnormal lateralization in language areas will predict language outcomes. We used the EEG-IP cohort; a multi-site ASD sibling cohort (London: 7, 14 months; Seattle: 6, 12, 18 months) including 195 infants. We excluded 12 subjects after artifact rejection/correction (92 at familial risk; 91 controls; 88 males; 95 females). We estimated EEG cortical sources and computed brain lateralization based on spectral power

(SP) using (Left SP− Right SP)/(Left SP+ Right SP). Mullen Scales of Early Learning (MSEL) scores were also collected at 24 months. We used cluster-permutation to identify regions showing significant between-group differences in lateralization, in both sites independently. For this set of regions, we confirmed these associations by using a linear mixed-effect model with age and site as within-subject covariates. Controls showed leftward lateralization for all 3 selected regions (superior parietal gyrus: p=0.03, z=-1.91; middle temporal gyrus: p=0.04, z=-2.05; pericalcarine area: p=0.03, z=-2.21; n=164). Infants at risk showed reduced lateralization. To investigate interactions between lateralization and MSEL Expressive and Receptive Language scores, we supplemented this set of regions with 6 language-associated regions based on the literature. Using linear regression, lateralization was correlated with 24-month expressive language across EEG time points for the at-risk group for the inferior parietal region (Pearson's ρ= 0.62, 95% CI [0.57, 0.74], p=10−12). Other regions showed inconsistent patterns across diagnostic groups and time points. No significant correlations were found for receptive language. The inferior parietal region has been previously associated with syntax processing, sensorimotor integration and the perception of emotion, suggesting that disruption of these networks during infancy can contribute to expressive language impairments.

Title: Neural mechanisms of sensorimotor control in the auditory dorsal stream of the macaque

Authors: J. JACOBS, **P. WIKMAN**, P. KUSMIEREK, *J. P. RAUSCHECKER; Neurosci., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Ventral and dorsal streams analogous to those in visual cortex have been established in the auditory cortex (AC) of humans and nonhuman primates using neuroimaging and electrophysiology (Rauschecker and Tian, 2000; Rauschecker and Scott, 2009). The auditory dorsal stream is known for its role in the processing of auditory space and motion, action understanding, and speech processing. What these seemingly heterogeneous functions have in common is the implementation of internal models, relating motor commands to their sensory outcomes. Using functional MRI, our lab has shown that motor regions along the dorsal stream and in the putamen are activated, when macaques are listening to auditory-motor sequences they had previously learned to produce by pressing levers with their hands ('monkey piano')

(Archakov et al, 2020). Specifically, the hand/arm regions of premotor cortex (PMC) displayed increased activity when the monkeys listened to self-produced sound sequences as opposed to sound sequences they could not produce. To characterize the role of dorsal-stream areas in auditory-motor control at the single-unit level, we are now performing electrophysiological recordings from auditory and motor regions in awake behaving monkeys. Animals are trained to produce an 8-note tone sequence on the monkey piano. During unit recordings, the animals are either listening to learned auditory sequences, or are engaged in the production of auditory-motor sequences. The results suggest that a predictive forward model alters sensory responses in AC and PMC based on task conditions. Auditory responses of single neurons in AC were suppressed during sequence-production compared to passive listening of the same learned sounds. Furthermore, when the piano produced incorrect notes, i.e. the sounds did not align with the animal's expectation, AC neurons responded to the sound more robustly, indicative of an error signal being generated. Similar error signals were also observed in PMC. Our findings support the notion that an internal model of expected auditory consequences of motor behavior is generated in PMC. This prediction signal is sent to AC, where it is compared to the actual auditory input. Prediction errors generate a signal in the AC, which is sent to motor regions. To confirm the directionality of these signals, we are planning simultaneous recordings in AC and PMC. Together, the results provide evidence for the existence of internal models in the auditory dorsal stream of old-world monkeys. Internal models are a prerequisite for speech. The fact that monkeys don't speak suggests that internal models have evolved to support their hand movements but not their vocalizations.

Title: Bidirectional Connectivity Between Broca and Wernicke's Areas During Interactive Listening

Authors: *Y. ONO[1], X. ZHANG[2], J. A. NOAH[2], S. DRAVIDA[3], J. HIRSCH[2,4,5,6];
[1]Meiji Univ., Kanagawa, Japan; [2]Dept. of Psychiatry, [3]Interdepartmental Neurosci. Program, [4]Neurosci., [5]Comparative Med., Yale Sch. of Med., New Haven, CT; [6]Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom

Abstract: We investigated a directional connectivity network in canonical language areas of two brains during interactive and non-interactive verbal communication. The underlying hypothesis is that functional connectivity between canonical speech areas in the human brain will be modulated by social interaction. Thirty-three pairs of healthy adult participants alternately talked and listened to each other while performing an object naming and description task that was either interactive or not during hyperscanning with functional near-infrared spectroscopy (fNIRS)[1]. In the non-interactive condition, the speaker named and described a picture-object without reference to the partner's description. In the interactive condition, the speaker performed the same task but included an interactive response about the preceding comments of the partner. Directional connectivity networks of hemodynamic responses from Broca's and Wernicke's Areas were determined by comparing Granger causality measures between real, surrogate, and shuffled trials within dyads. We found valid directional connectivity within the speaker's and the listener's brains, while no statistically significant across-brains directional connectivity was found[2]. The interactive communication was characterized by bidirectional connectivity between Wernicke's and Broca's Areas of the listener's brain. Whereas, this connectivity was unidirectional in the speaker's brain. In the case of the non-interactive condition, both speaker's and listener's brains showed unidirectional top-down (Broca's Area to Wernicke's Area) connectivity. The directional connectivity analysis revealed bidirectional flow of neuronal information during dynamic two-person verbal interaction for processes that are active during listening (reception) and not during talking (production). Findings are consistent with prior cortical activity measures showing neural modulation of the receptive language system associated with Wernicke's Area during two-person live interaction.

Title: Differential brain activity on mnemonic predictions during natural reading: an EEG and eye tracking co-registration study

Authors: *B. BIANCHI[1], R. LOREDO[2], J. CARDEN[2], V. JAICHENCO[2], T. VON DER MALSBURG[4], D. E. SHALOM[3], J. E. KAMIENKOWSKI[5];

Inst., CONICET, Buenos Aires, Argentina

Abstract: During reading our brain is continuously generating predictions on upcoming words. These predictions, if correct, could speed up the processing of the word when it is finally read. Also, they are a reflection of the ongoing integration of the text. It has been amply shown that Predictability (i.e. the estimated probability of guessing the next word) have an impact on how we move our eyes across the text: eye tracking (ET) experiments showed that more predictable words are fixated for shorter periods of time than less predictable words. Additionally, EEG experiments showed that the amplitude of the N400 potential, a hallmark of semantic processing, is modulated by the Predictability: the more predictable words are, the less amplitude the N400 has. Typically, EEG experiments were performed avoiding eye-movements, because the muscular contraction interferes with the brain electrical signal. But, during the last years, co-registration of EEG and ET have become a powerful technique for understanding our brain in more natural contexts, allowing eye movements during the task.
Previous ET studies have shown that mnemonic predictions increase the skip probability and decrease the gaze duration on words. Meanwhile, previous EEG studies during Serial Visual Presentations of words have shown that the N400 potential is only present for predictions performed based only on linguistic context. In the present work, we analyzed brain potentials and eye movements during natural reading of Common and Memory-Encoded sentences (like proverbs), with the goal of understanding how different sources of predictions are used during natural reading.
Firstly, we replicated the results from both experiments under the co-registration paradigm. Secondly, our results showed that during memory-encoded sentence reading there is also a decrease in regression and refixation probabilities. And thirdly, fixation-related potentials analysis using a novel Linear Mixed Models (LMM-CBP) approach showed that the classical N400 component is only present for common-sentence reading and for words previous from the point in which the Memory-Encoded sentences are recognized. These results indicate that the

N400 potential could be associated only with predictions performed based only on linguistic context.

Title: The critical role of the mid fusiform cortex in semantic word retrieval

Authors: *K. SNYDER[1], C. DONOS[2], K. FORSETH[3], P. ROLLO[4], J. BREIER[5], S. FISCHER-BAUM[6], N. TANDON[7];

Sch. at Houston, Houston, TX

Abstract: Temporal lobe resections often result in significant confrontation naming decline, which can prevent patients from returning to independent functioning. While exact substrates responsible are unknown, it was previously assumed that injury to the superior temporal gyrus or resection size predicted these declines. A clear understanding of critical constituents might influence surgical strategies to minimize language declines. We used multivariate voxel based lesion symptom mapping (VLSM) to relate changes in language function using the Boston Naming Test (BNT) to dominant temporal lobe resections.
Data were obtained from 95 patients who underwent surgery in the dominant left temporal lobe for epilepsy. Patients underwent neuropsychological testing and MRI prior to and 6 months after surgery. Lesion masks were traced on postoperative MRIs and aligned to a normative space. The effects of preoperative scores were removed from postoperative scores via linear regression. VLSM using multivariate support vector regression was used to assess postoperative test scores. Beta maps were converted to p values and corrected using a permutation-based cluster level correction. In a subset of subjects with ECoG recordings, a surface-based mixed-effects multilevel analysis was used to estimate broadband gamma activity during picture naming, and the resulting maps were integrated with VLSM results. Additionally, DCM results were mapped to the cortical surface as percent of stimulations causing functional disruption, and regions associated with language disruption were compared with those found in VLSM. Lastly, fMRI

(picture naming) was used to assess SNR in significant regions.
VLSM results revealed that loss of basal temporal regions, primarily mid fusiform gyrus (mFus) and inferior temporal gyrus, was associated with a prominent decline on BNT ($p<0.005$). ECoG analysis showed a significant increase in activity in mFus during picture naming immediately preceding articulation. CSM of mFus caused disruption of visual naming without disrupting repetition. Many of these voxels were spatially correlated with the susceptibility artifact on fMRI perhaps explaining why this region has been underappreciated as the locus responsible for postoperative deficits.
The importance of the ventral temporal cortex in lexical access is shown using multivariate VLSM and further supported by both ECoG and CSM. While it has previously been assumed that mFus lesions do not cause pervasive impairment, our data and recent work (FATES study) support the role of mFus as a critical semantic access hub. As such, surgical approaches in temporal lobe epilepsy should strive to preserve mFus.

Title: Reading is fundamental: connectivity at rest between visual word form area and left inferior frontal gyrus predicts global language skills throughout childhood and adolescence

Authors: *N. DEOM, O. KHALIL, L. J. AYOUB, M. MCANDREWS;
Univ. of Toronto, Toronto, ON, Canada

Abstract: The language network includes a vast system of interconnected brain regions, involving most of the temporal lobe as well as frontal and parietal regions. Characterization of the individual role of key regions in the network is well advanced, but assessment of the importance of connectivity between regions in the network is still incomplete, especially in children and young adults. We used resting-state functional MRI (rsfMRI) to investigate the connectivity between regions of interest in Broca's area, Wernicke's area, and the visual word form area (VWFA) and the rest of the language network and assessed their relationship to performance on language tests. Analyses were conducted on publicly available data from the Child Mind Institute's Healthy Brain Network initiative. From the available dataset, 175 subjects (81 males), ranging from age 6 to 21 (mean 12.2, SD 3.6), with complete 10 minutes resting-

state scans were included. From the rsfMRI scans, resting-state connectivity was calculated ROI-to-ROI between BOLD timeseries extracted from all regions of the language network. Language ability was evaluated using the listening comprehension subtest of the Wechsler Individual Achievement Test (WIAT-III) and the Clinical Evaluation of Language Fundamentals (CELF-5) Screening Test which assesses a broad range of language functions including grammar, semantics, verbal comprehension, and auditory memory. We found a significant positive correlation between connectivity between the VWFA and the left inferior frontal gyrus (l-IFG) and performance on the CELF ($r(173) = .30$, $p < .05$ FDR-corrected for multiple comparisons). We also found a positive correlation only as a trend between the connectivity between the VWFA and the left supramarginal gyrus and the WIAT ($r(155) = .29$, $p < .10$ FDR-corrected). Thus, a stronger connectivity at rest between the VWFA and the l-IFG predicted a better global language performance. In addition, none of these connectivity measures significantly correlated with participants' age. Our findings suggest that greater network connectivity of a brain region primarily associated with visual word decoding has a broader influence on language ability than had been previously recognized.

Title: Narrative Event Segmentation in the Cortical Reservoir

Authors: *P. F. DOMINEY;
INSERM U1093-CAPS, UBFC, Dijon, France

Abstract: During perception of movies or stories, humans cortical activity reveals hierarchical segmentation of event structure. Sensory areas display high frequency segmentation related to the stimulus, while semantic areas display a lower frequency segmentation related to transitions between events (Baldassano et al. 2017). These hierarchical levels of segmentation are associated with different time constants for processing. Chien and Honey (2020) observed that when two groups of participants heard the same sentence in a narrative, preceded by different contexts, neural responses for the groups were initially different and then gradually aligned. The time constant for alignment followed the segmentation hierarchy: sensory cortices aligned most quickly, followed by mid-level regions, while some higher-order cortical regions took more than 10 seconds to align. These hierarchical segmentation phenomena can be considered in the

context of processing related to comprehension. Uchida et al. (2021) recently described a model of discourse comprehension where word meanings are modeled by a language model pre-trained on a billion word corpus (Yamada et al 2020). During discourse comprehension, word meanings are continuously integrated in a recurrent cortical network. The model demonstrates two fundamental characteristics: real-world event semantics are represented in the word embeddings, and these are integrated in a reservoir network which has an inherent gradient of functional time constants due to the recurrent connections.
Here we demonstrate how this model displays hierarchical narrative event segmentation properties beyond the embeddings alone, or their linear integration. The reservoir produces activation patterns that are segmented by the hidden Markov model (HMM) of Baldassano et al (2017) in a manner that is comparable to that of humans. Context construction displays a continuum of time constants across reservoir neuron subsets, while context forgetting has a fixed time constant across these subsets. Virtual areas formed by subgroups of reservoir neurons with faster time constants segmented with shorter events, while those with longer time constants preferred longer events. This neurocomputational recurrent neural network simulates narrative event processing as revealed by the fMRI event segmentation algorithm of Baldassano et al (2017), and provides a novel explanation of the asymmetry in narrative forgetting and construction observed by Chien and Honey (2020).

Title: Distinct nodal responses for verbs in the production network

Authors: *N. MAEREAN[1], K. FORSETH[2], E. MURPHY[3], N. TANDON[4];
[1]UT Hlth., Houston, TX; [2]UT Hlth. Sci. Ctr. In Houston, Houston, TX; [3]Univ. Col. London, London, United Kingdom; [4]Neurolog. Surgery, Univ. of Texas Med. Sch. at Houston, Houston, TX

Abstract: Aphasia often presents with selective impairments in the ability to produce specific word classes, namely nouns and verbs, suggesting that the retrieval and production of distinct word classes engage unique network components. However, the spatiotemporal dynamics that separate these two processes are not yet fully understood. We used electrocorticographic recordings in a large cohort during visually-cued object and action naming tasks (n = 10730, 93 pts) to characterize the cortical network dynamics during noun and verb production. A surface-based mixed-effects multilevel analysis (SB-MEMA) of broadband gamma activity (BGA)

yielded population maps of focal activity changes. We further explored effects of semantic complexity by performing an SB-MEMA of complex versus simple verb stimuli. A broad cortical network was recruited for both verb and noun naming; immediately following picture presentation, cortical activity propagated along dorsal and ventral streams to intraparietal sulcus (IPS) and mid-fusiform gyrus (mFus), respectively. Next, cortical activity was observed concurrently in posterior middle temporal gyrus (pMTG), angular gyrus (AG), and a constellation of frontal regions: pars Triangularis (pTr) and opercularis, superior frontal sulcus, and supplementary motor areas. Pre-articulatory activity was uniquely observed in pMTG and AG during verb naming ($p<10^{-3}$); post-articulatory pMTG activity was matched in both tasks. pTr exhibited similar temporal dynamics in both noun and verb production, but this activity was significantly enhanced during verb production ($p<10^{-3}$). Peaks in cortical activity were observed in mouth sensorimotor and auditory cortex after onset of articulation. With respect to semantic complexity, a gradient of increasing BGA from nouns, to simple verbs, to complex verbs was observed in pTr and mFus ($p<10^{-3}$), suggesting that engagement of these broader language areas is influenced by complexity demands. Finally, we found that posterior AG is sensitive exclusively to verb complexity, whereas more anterior portions were exclusively sensitive to word class. This points to a functional dissociation in AG with respect to both grammatical (anterior) and semantic (posterior) representations, providing a more fine-grained computational description of this region than previous neuroimaging research. Our results demonstrate that object and action naming networks are overlapping but differentially activated. This comprehensive view of category specific production networks may contribute to rehabilitative interventions for aphasia.

Title: Schizophrenia-associated MAP2 phosphorylation affects interactions with microtubules and actin

Authors: *R. DEGIOSIO[1], P. G. NEEDHAM[2], O. A. ANDREWS[3], M. J. GRUBISHA[1], J. L. BRODSKY[2], R. A. SWEET[1];
[1]Psychiatry, [2]Biol. Sci., [3]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Microtubule-associated protein 2 (MAP2) is the predominant dendritic cytoskeletal regulator, influencing dendritic arbor and spine morphology, which are altered in schizophrenia (SZ). MAP2 is regulated by multiple mechanisms, most prominently phosphorylation (MAP2-P). We have previously demonstrated that MAP2-P state is altered in SZ, with multiple phosphopeptides being upregulated in disorder. Moreover, a subset of identified phosphopeptides were negatively correlated with dendritic spine density in primary auditory cortex, suggesting that SZ-associated MAP2-P has consequences for protein function, in turn compromising neuronal morphology/function. Here, we set out to characterize the consequences of SZ-associated MAP2-P events on protein function by assessing the 1) tubulin polymerization, 2) microtubule-binding, and 3) actin-binding abilities of purified phosphomimetic MAP2c constructs. Phosphomimicry at multiple residues in the proline-rich and C-terminal domains- including T293, T300, S426, S439 and S443- were sufficient to delay microtubule nucleation. S426 additionally slowed polymerization rate. T293, T300, S426 and S439 inhibited actin-binding, while only S426 and S439 inhibited microtubule-binding. Other tested sites, including T249, S252, Y253, S297 and S446, showed no effects. These data indicate that SZ is characterized by both regulatory MAP2-P events and events which are irrelevant to its interactions with cytoskeletal filaments. We put forward MAP2-P-mediated changes to microtubule nucleation kinetics and microtubule/actin crosslinking as potential mechanisms for dendritic dysmorphogenesis in SZ.

Title: Executive dysfunction and its relationship with psychosis risk in the schizophrenia-associated 3q29 deletion syndrome

Authors: *E. SEFIK[1], K. ABERIZK[2], R. ESPANA[2], R. GUEST[2], K. GOINES[2], D. NOVACEK[2], M. MURPHY[1], E. WALKER[2], J. MULLE[1];
[1]Dept. of Human Genet., [2]Dept. of Psychology, Emory Univ., Atlanta, GA

Abstract: The 3q29 deletion syndrome (DS) is caused by the recurrent hemizygous deletion of a 1.6Mb genomic interval spanning 21 protein-coding genes. 3q29DS is a major risk factor for

psychosis, as it confers a ~40-fold increased risk for developing schizophrenia. Recent findings by the Emory 3q29 Project indicate that executive function (EF) deficits, which affect higher-order cognitive processes required to control and coordinate behavior, also constitute a significant burden in this population. However, the extent of these EF deficits and their potential clinical correlates remain unknown. In the present study, we conducted the first in-depth investigation of EF in 3q29DS by direct and systematic evaluation of $N = 32$ patients with the deletion (mean age = 14.50 years, SD = 8.26; 63% male). We used the BRIEF as a standardized and ecologically valid measure of EF. Given previous evidence of EF deficits in idiopathic psychoses, we further tested the hypothesis that EF deficits in 3q29DS are associated with severity of florid and attenuated psychotic symptoms, rated by the gold-standard SIPS interview. Our results indicate that the mean *global executive composite* (GEC) score and the means of all BRIEF subdomain scores were elevated in 3q29DS subjects compared to the general population (T scores > 60). 81% of the subjects had clinically significant scores in at least one subdomain of EF (T Scores ≥ 70), with the *shift* subdomain having the highest mean score (T score = 68) compared to other subdomains. Multiple linear regression analyses indicated a significant and positive relationship between GEC scores and symptom severity in the positive and disorganization symptom dimensions of the SIPS ($p's < 0.05$), while covarying for age, sex and full-scale IQ. Overall, our findings confirm that executive dysfunction is a significant feature of 3q29DS that warrants attention. Our findings also indicate that while there is a global EF deficit in 3q29DS, this profile is especially marked by a relative weakness in the ability to shift flexibly between mental sets, tasks, or strategies to generate adaptive behavioral responses. Finally, our results reveal that higher levels of executive dysfunction indexed by the BRIEF is a significant predictor of florid and attenuated psychotic symptoms, beyond the variation explained by psychometric intelligence. EF deficits may represent a previously unknown intermediate cognitive endophenotype in 3q29DS that can help deconstruct the link between the 3q29 deletion and psychosis. Future work will employ performance-based measures of EF and investigate the neurobiological underpinnings of executive dysfunction via neuroimaging in this population.

Title: An imbalance of IgG receptors may contribute to the increased neuroinflammation seen in the midbrain of a sub-group of schizophrenia patients

Authors: *A. PETTY[1], C. S. WEICKERT[2], L. J. GLASS[3], T. PURVES-TYSON[2], D. ROTHMOND[2];
[1]NeuRA, Sydney, Australia; [2]Neurosci. Res. Australia, Sydney, Australia; [3]Schizophrenia Res. Lab., Neurosci. Res. Australia, Randwick, Australia

Abstract: There is growing evidence that neuroinflammation may contribute to schizophrenia pathology. Elevated proinflammatory cytokines are evident in the midbrain of schizophrenia subjects, and these findings are driven by a sub-group of patients, characterised as a "high inflammation" biotype. Cytokines trigger the release of antibodies, of which immunoglobulin G (IgG) is the most common. Testing whether IgG contributes to the neuroinflammatory abnormalities in this sub-group of schizophrenia patients may help direct novel treatment targets. Therefore, we measured IgG protein, IgG receptor transcripts, and IgG transporter levels in midbrain tissue from schizophrenia patients (including both high- and low-inflammation biotypes) and healthy control subjects. Fresh frozen midbrain samples were either homogenised for protein and mRNA analysis, or 14um sections were taken for immunofluorescent staining. IgG protein abundance (relative to β-actin) assessed by western blot was unchanged between groups, however preliminary immunofluorescence analysis indicated a significant difference in levels of parenchymal IgG in the substantia nigra between diagnostic/inflammatory groups, suggesting that differences may exist within brain tissue (p=0.03). In addition, mRNA levels of the pro-inflammatory IgG receptor, FcGR3A (also known as CD16) were increased in the high inflammation biotype schizophrenia subjects (p<0.0001) in comparison to low inflammation schizophrenia subjects, and healthy controls. In contrast, mRNA levels of the anti-inflammatory IgG receptor, FcGR2B (also known as CD32b) were unchanged between all diagnostic and inflammatory groups. Finally, while protein levels of the IgG transporter FcGRT were comparable between groups, mRNA levels of the transporter were elevated in the high inflammation schizophrenia subjects (p=0.02), suggesting that there may be changes in transporter turnover. Future work will quantify whether the anatomical distribution (as well as abundance) of IgG in the midbrain is altered between diagnostic and/or inflammatory groups. However, even if levels of IgG are comparable between groups, the imbalance between the pro-inflammatory FcGR3A and anti-inflammatory FcGR2B receptors suggests that "high inflammation biotype" schizophrenia patients may have an exaggerated response to IgGs. Future work will determine whether this elevation in FcGR3A is specific to a certain cell-type, thereby providing critical information regarding the nature of this neuroinflammatory abnormality in a sub-group of schizophrenia patients.

Title: Markers of inflammation define subgroups of individuals with schizophrenia and bipolar disorder in midbrain

Authors: *Y. ZHU[1], S. J. OWENS[2], K. AJULU[1], D. A. ROTHMOND[2], T. D. PURVES-TYSON[2,3], M. J. WEBSTER[4], C. S. WEICKERT[1,3,2];
[1]SUNY Upstate Med. Univ., Syracuse, NY; [2]Neurosci. Res. Australia, Randwick, Australia; [3]Sch. of Psychiatry, Fac. of Medicine, Univ. of New South Wales, Sydney, Australia; [4]Stanley Med. Res. Inst., Rockville, MD

Abstract: Neuroinflammation is evident in the blood of ~40% of people living with schizophrenia and in postmortem samples from prefrontal cortex, striatum, and midbrain of ~40-50% of schizophrenia cases. Our recent study indicated that inflammation in the midbrain may play a role in dopamine dysregulation since we found 46% of schizophrenia cases in the Tissue Resource Center (TRC) cohort had elevated levels of pro-inflammatory cytokines in the midbrain. In this study, we aimed to replicate these findings in the larger Stanley Medical Research Institute (SMRI) cohort and to define a high inflammation subgroup in bipolar disorder. We investigated mRNA levels of 7 cytokine and immune transcripts in postmortem midbrain tissue (N=105, n=35 per diagnostic group) and performed two-step recursive clustering analysis to define inflammation subgroups. The final cluster predictors were TNFα, IL1β, IL6, and SERPINA3 (predictor importance >0.5). We identified 6% (2/35) as high inflammation controls (HI-CON), 46% (16/35) as high inflammation schizophrenia (HI-SCZ), and 29% (10/35) as high inflammation bipolar disorder (HI-BPD)($X^2 = 14.42$, $p<0.001$). SERPINA3 mRNA was elevated in schizophrenia compared to controls (>200%, $p<0.0001$) and bipolar disorder (>150%, $p<0.05$). However, IL6, IL1β, and TNFα mRNAs were unchanged across diagnostic groups ($p>0.2$). When stratified by inflammation subgroups, all 4 mRNAs used to identify the clusters were increased in HI-SCZ and HI-BPD compared to low inflammation controls (LI-CON) (SERPINA3 $p<0.01$; TNF $p<0.0001$; IL6 $p<0.05$; IL1B $p<0.001$). Protein levels of IL6 and IL1β were elevated in HI-SCZ compared to all low inflammation subgroups, and elevated in HI-BPD compared to LI-SCZ and LI-BPD (all $p<0.05$). In contrast to our expectations, TNFα protein was significantly decreased in HI-BPD compared to LI-CON and HI-SCZ ($p<0.05$). In conclusion, we replicated our previous findings and found the percentage of HI-SCZ in the SMRI cohort was consistent with the TRC cohort. In addition, we found the BPD cases have an intermediate level of high inflammation cases. Most inflammation mRNAs and proteins that we examined were significantly changed when stratified by inflammation subgroups. However, further studies are needed to determine why TNFα mRNA and TNFα protein are differentially expressed. These changes in cytokine levels proximal to dopamine cell bodies may contribute to the dopamine abnormalities that are found in schizophrenia.

Title: Bdnf and trkb splice variants are altered in post-mortem midbrain in schizophrenia and exacerbated by inflammation

Authors: *J. CHANDRA[1], T. D. PURVES-TYSON[1], S. J. OWENS[2], D. A. ROTHMOND[1], C. S. WEICKERT[3];
[2]Schizophrenia Res. Lab., [1]Neurosci. Res. Australia, Randwick, Australia; [3]Neurosci. Res. Australia, Sydney, Australia

Abstract: Background: Psychotic symptoms of schizophrenia likely stem from subcortical hyperdopaminergia in the nigrostriatal pathway. Elevated pro-inflammatory markers (SERPINA3, IL6, IL1β, TNFα) found in the midbrain of ~45% of schizophrenia cases may damage already hyperactive dopamine neurons. Dopamine neurons are not considered to be lost in schizophrenia, suggesting trophic factors such as Brain-Derived Neurotrophic Factor (BDNF), signaling via the full-length Tropomyosin kinase B receptor ($TrkB^{TK+}$), may promote dopamine neuron survival. However, BDNF binding to the truncated receptor ($TrkB^{TK-}$) on glial cells diverts trophic support away from neurons. BDNF transcription is regulated by nuclear receptor related-1 protein (NURR1) and its trophic effects are counteracted by its precursor form, proBDNF, binding to the apoptotic p75 receptor. We hypothesised that molecular measures of BDNF trophic support would be altered in the schizophrenia midbrain and be exacerbated in inflammatory states, reflecting the degraded health of dopamine neurons.
Methods: BDNF (exon IV), $TrkB^{TK+}$, $TrkB^{TK-}$, NURR1 and p75 mRNA levels were quantified by qPCR in post-mortem midbrain tissue (28 control/28 schizophrenia from the NSW Brain Tissue Resource Centre). Gene expression was analysed by diagnosis and by previously assigned high/low inflammation biotypes. $TrkB^{TK+}$ mRNA was visualized using *in situ* hybridization (20 control/10 schizophrenia from the Clinical Brain Disorders Branch).
Results: Gene expression of BDNF IV (31%), $TrkB^{TK+}$ (19%) and NURR1 (21.4%) was significantly reduced, while $TrkB^{TK-}$ (29%) and p75 (8.8%) mRNA levels were increased in the midbrain of schizophrenia cases compared to controls ($p<0.05$). Schizophrenia cases with a high inflammation biotype displayed the greatest degree of alterations in BDNF IV, $TrkB^{TK+}$, $TrkB^{TK-}$, NURR1 and p75 mRNA levels compared to low inflammatory controls ($p<0.05$). $TrkB^{TK+}$

mRNA was localised in midbrain neuromelanin-positive neurons in both schizophrenia and control cases. Males and females were included for both cohorts and no sex differences were observed.
Conclusion: We provide the first evidence for altered gene expression of NURR1, BDNF and its respective TrkB and p75 receptors in the schizophrenia midbrain, the magnitude of which is intensified in the presence of elevated inflammatory markers. These alterations do not reflect the hypothesized elevated trophic support to overcome damage by neuroinflammation. Instead, the lack of trophic support resulting from depleted $TrkB^{TK+}$ mRNA in midbrain dopamine neurons, may further diminish the health of these neurons, known to be dysregulated in schizophrenia.

Abstract: BACKGROUND: Schizophrenia (SCZ) and Bipolar Disorder (BP) have long been associated with dysregulation in the frontal cortex. The gene expression underlying this dysregulation has been explored in detail using transcriptional profiling studies (microarray, RNA-Seq) in the dorsolateral prefrontal cortex, but the larger frontal pole region (Brodmann Area 10, BA10) has received less attention. Our study explored the association between SCZ and BP and the frontal pole using methods that provide a sensitive snapshot of neurotransmission-related gene expression. METHODS: To ensure a high concentration of neuron-derived transcripts, post-mortem dissections focused on grey matter. Only samples with agonal factor=0, pH>6.5, and RNA integrity>6.0 were included to exclude brains with prolonged hypoxia before death. Gene expression was measured using two sets of TaqMan microfluidic qPCR cards targeting transcripts related to signaling via 1) GABA and glutamate ("GABAGLU" experiment), 2) dopamine and serotonin ("DA5HT" experiment). In each experiment, the subject samples were run on at least two separate cards. After quality control (QC), the sample size was 69 subjects (control (CTRL): n=26, SCZ: n=22, BP: n=21) and included measurements from 111 targeted gene transcripts (GABAGLU: 82, DA5HT: 29). We normalized measurements using a panel of reference gene transcripts (GABAGLU: 11 genes, DA5HT: 17 genes). Differential expression (DE) was assessed via a multi-level model that included biological (gender, age, pH, post-mortem interval [PMI]) and technical (RNA concentration, integrity, card) co-variates. The results from the top DE genes (false discovery rate <0.10) were explored in relation to symptom profiles, medication, and drug and alcohol exposure. These results were compared to the results from two publicly available microarray datasets examining the influence of psychiatric diagnosis on gene expression in BA10 (GSE12654; GSE17612). We re-analyzed both datasets using a custom chip definition file with updated annotation. Our DE models controlled for large sources of noise as determined by relationships with top principal components of variation (pH, age, RNA degradation, PMI, rate of death). After QC, the sample size for GSE12654 was 50 subjects (CTRL: n=15, SCZ: n=13, BP: n=11, Depression: n=11); and for GSE17612 the sample size was 51 subjects (CTRL: n=23, SCZ: n=28). RESULTS AND CONCLUSION: Collectively, our results showed a similar pattern of DE gene expression in the frontal pole in both disorders, including genes directly involved in major neurotransmitter functions affecting the serotonergic, dopaminergic and GABAergic systems.

Inst. of Mental Hlth., Bethesda, MD

Abstract: Schizophrenia (SCZ) is a complex, polygenic disorder with marked clinical heterogeneity and no clear pathological mechanism or cellular pathology. The advent of human induced pluripotent stem cell (iPSC) technology has enabled the capture of the polygenic nature of SCZ *in vitro*. Several previous studies using iPSC to model SCZ have identified interesting phenotypes, but their relevance to the clinical illness in adults remains unclear. Here, we describe results of our investigation into the relationships between the electrophysiological properties of iPSC-derived cortical neurons and the individual's clinical status, severity of symptoms, and cognitive performance. Importantly, we look beyond case-control differences, and identify within-case patterns of association that could serve to illuminate dimensions of illness and subgroups of patients that may be suitable for targeted treatments. We studied cortical neurons from 13 SCZ patients with high polygenic risk scores (PRS) and 15 neurotypical individuals with low PRS with a battery of assays to identify cellular phenotypes, done in a double-blind manner. We correlated electrophysiology measures to the individual's rating on the Positive and Negative Syndrome Scale (PANSS), six cognitive domains (Verbal Memory, Nback, Visual Memory, Processing Speed, Card Sorting, and Digit Span), estimated IQ, and general cognitive ability composite ("g"). We observed five electrophysiological measures related to Na^+ channel function associated with diagnosis. Lines derived from SCZ donors showed an increase in membrane resistance, an increased number of Na^+ current peaks in response to a voltage ramp protocol, a decrease in the activation threshold of the second Na^+ peak, a significantly hyperpolarized shift in Na^+ channel activation and V1/2 activation voltage, and a significant hyperpolarized shift in the voltage dependence of inactivation and V1/2 inactivation voltage. In SCZ, the number of Na^+ peaks showed a directionally-consistent, positive association with some positive symptom ratings ($R=0.77$, $p=0.0033$), whereas there were no correlations with negative symptom ratings or cognitive measures. In striking contrast, sEPSC amplitude showed no correlation with positive symptoms, but showed a negative correlation ($R=-0.93$, $p=2.94E-05$)

with Wisconsin Card Sort Test performance. Our results demonstrate for the first time that common genetic variants associated with SCZ converge on electrophysiological mechanisms that relate to clinically relevant features of SCZ, and therefore underscore the potential of this approach for biomarker identification and perhaps downstream drug development.

Title: Modeling the loss-of-function mutation of OTUD7A within the schizophrenia-associated 15q13.3 microdeletion in human neurons

Authors: *A. KOZLOVA[1], S. ZHANG[1], A. KOTLAR[2], J. MCDAID[1], M. FORREST[3], H. ZHANG[1], B. JAMISON[1], D. CUTLER[2], M. ZWICK[2], Z. PANG[4], A. SANDERS[1], S. WARREN[2], P. GEJMAN[1], J. MULLE[2], J. DUAN[1];
[1]Northshore Univ. Healthsystem, Evanson, IL; [2]Emory Univ. Sch. of Med., Atlanta, GA; [3]Northwestern Univ., Chicago, IL; [4]Rutgers Univ., New Jersey, NJ

Abstract: A number of large and rare copy number variants (CNVs) are found to confer strong risk to schizophrenia (SZ) and other neurodevelopmental disorders. However, identifying the causative gene(s) within a CNV is challenging since most CNVs encompass many genes. *Otud7a* heterozygous and homozygous knockout mice have been shown to recapitulate some phenotypes associated with the 15q13.3 microdeletion syndrome, leading to the hypothesis that *OTUD7A* is the driver of neuropsychiatric phenotypes. Here, by sequencing 1779 SZ cases and 1418 controls for SZ-associated protein-coding variants in genes encompassed by SZ-associated CNVs, we identified three different loss-of-function (LoF) mutations in the exon 5 of *OTUD7A in* 3 cases, but none in controls. We thus aimed to model the LoF of *OTUD7A* in human induced pluripotent stem cell (hiPSC)-derived induced excitatory neurons (iNs). We performed CRISPR/Cas9

editing to introduce the risk allele of a LoF mutation rs757148409 onto two control donor iPSC lines, each with three different clones, resulting in a heterozygous G to A change leading to a stop-gain mutation. By examining the isogenic iNs, we found that the introduced premature stop-gain mutation did not cause nonsense-mediated mRNA decay of *OTUD7A*, but instead resulted in ~50% decrease in protein expression. Consistent with the reduced *OTUD7A* expression, iNs carrying the heterozygous LoF mutation exhibited ~50% reduction in dendritic complexity and ~30% decrease in total dendrite length. Synaptic puncta analysis further showed a marked decrease in the puncta density and area of AMPA receptor subunit GluA1 and postsynaptic scaffold PSD-95 in iNs carrying the LoF mutation. Congruent with the observed phenotypic alterations associated with the *OTUD7A* LoF mutation, our transcriptomic analysis of the CRISPR-edited isogenic iNs showed that genes downregulated, but not upregulated, in the *OTUD7A* LoF iNs were significantly enriched for gene ontology (GO) terms relating to the synapse, synaptic vesicle cycle, and neurotransmitter release. In addition, microelectrode array analysis showed reduced neuron firing rate and network activity in iNs carrying LoF of *OTUD7A*. Taken together, these results suggest that the rs757148409 LoF mutation in *OTUD7A* impaired neurodevelopment, causing decreased dendritic complexity, synapse number, and expression of synaptic genes. Our study provides mechanistic insight into the possible role of *OTUD7A* in driving phenotypes associated with SZ and other neurodevelopmental disorders associated with the 15q13.3 microdeletion.

Title: Progressive Brain Abnormalities in Schizophrenia Across Different Illness Duration: A Structural and Functional MRI Study

Authors: *C.-L. SHEN[1,2], A. C. YANG[2];
[1]Tsao-Tun Psychiatric Ctr., Tsao-Tun, Taiwan; [2]Inst. of Brain Sci., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan

Abstract: Schizophrenia has been regarded as a chronic and deteriorating brain disorder since it was named originally as dementia precox by Kraepelin in 1900s. However, when and how brain abnormalities occur and evolve in schizophrenia remain undetermined. The present study aimed

to explore progression of brain abnormalities on structural and functional MRI in patients with schizophrenia throughout the illness course by using the four analysis methods of voxel-based morphometry (VBM), fractional anisotropy (FA), global functional connectivity density (gFCD) and sample entropy (SampEn). We recruited 336 Han Chinese participants and stratified them into three age and sex-matched groups. The 5-year group (illness duration below 5 years) had 40 individuals with schizophrenia and 80 healthy controls, the 15-year group (illness duration between 12 and 18 years) had 33 individuals with schizophrenia and 66 healthy controls, and the 25-year group (illness duration over 25 years) had 39 individuals with schizophrenia and 78 healthy controls. All participants underwent resting-state scanning using a 3T MRI. T1-weighted images were preprocessed with the DARTEL algorithm for VBM analysis. FA values were calculated by fitting a tensor model to the data at each voxel obtained from diffusion tensor imaging. gFCD was defined as the number of Pearson's correlation r between BOLD signals at that voxel and those in the remaining gray matter voxels, which surpassed an arbitrary threshold ($r>0.6$). SampEn of the BOLD signal was computed for all gray matter voxels to create a whole-brain parametric map. We used T-test, Chi-square test, ANOVA and General Linear Model (GLM) to do statistical analysis. We found functional abnormalities occurs firstly in single brain areas in early course of schizophrenia, functional connectivity abnormalities and gray matter abnormalities ensue in middle course, and structural connectivity abnormalities manifesting with white matter tracts disintegration emerge at last. Our findings represent a novel approach to study progression course of brain abnormalities in schizophrenia. In conclusion, using structural and functional brain MRI analysis, we showed brain abnormalities occur in limited areas in early course of schizophrenia and progress into much widespread areas in later course.

Abstract: Dopamine (DA) is a crucial monoamine neurotransmitter involved in many physiological and pathological processes, and the ability to directly monitor DA dynamics is essential for understanding its physiological function. Here by tapping into different species and dopamine receptor subtypes, we further developed a series of green fluorescent $GRAB_{DA}$ sensors (DA3m and DA3h), for improved signal-to-noise (SNR), sensitivity, selectivity and as well as diverse pharmacology properties in cultured cells. The improved $GRAB_{DA}$ sensors also exhibited superior properties in mouse acute brain slice, *in vivo* in flies and mice by using transgenic or virus-mediated expression. Specifically, the improved DA3m could stably report DA dynamics during sleep-wake cycles and selectively monitor DA changes under anesthesia condition induced by 1.5% isoflurane in the mice medial prefrontal cortex (mPFC). Apart from green DA sensors, we further optimized spectrum-compatible red dopamine sensors ($rGRAB_{DA}$) with higher brightness and larger fluorescent increase in DA detection after iterative engineering in fluorescent module and molecular scaffold based on the prototype, and also generated red DA sensors with different affinity range and pharmacology profile by introducing diverse GPCR backbone. In sum, by enabling multicolor imaging of DA and other signaling components, these $GRAB_{DA}$ sensors serve as powerful tools to study comprehensive neurochemical modulation in dopamine system.

Title: Improved norepinephrine sensors shine lights on in vivo noradrenergic activities

Authors: *J. FENG[1], **R. CAI**[1], J. LISCHINSKY[2], J. ZHOU[3], H. DONG[1], H. WANG[1], F. DENG[1], H. XIE[4], Q. DAI[4], G. CUI[3], D. LIN[2], Y. LI[1,5,6];

Abstract: Norepinephrine (NE) is a key biogenic monoamine neurotransmitter involved in a wide range of physiological processes. However, its precise dynamics and regulation remain poorly characterized. With the structural similarity and promiscuous patterns inside our brain for norepinephrine and dopamine, it is indispensable to tease apart these two monoamines during behaviors in vivo. Previously, we have developed prototype GPCR activation-based NE ($GRAB_{NE}$) sensors with either high sensitivity or high selectivity to NE. Here, we further optimized and characterized improved $GRAB_{NE}$ sensors (NE2m and NE2h) with higher responses. They exhibited both higher sensitivity and selectivity to NE compared with prototypes. Viral-expression of improved $GRAB_{NE}$ sensors was able to detect optogenetically and behaviorally triggered NE release in the locus coeruleus (LC) and hypothalamus of freely moving mice. Specifically, dual color fiber photometry recording of a transgenic mouse expressed both $GRAB_{NE2m}$ and jRGECO1a reveals NE and calcium dynamics during sleep and wake. Moreover, dual color 2-photon and large-scale imaging of $GRAB_{NE2m}$ and jRGECO1a reveals spatiotemporally dynamics of noradrenergic and calcium activity in awake mice. Additionally, we further optimized NE sensors by introducing backbone GPCR from Arabian Camel and screened a candidate with up to 10-fold ΔF/F0 and over 1000-fold selectivity to NE vs. DA in cultured cells. We also expanded the spectrum of the sensor by generating a prototype red NE sensor that shows 2-3 folds ΔF/F0 in cultured cells with good sensitivity and specificity, which offers the potential for further simultaneously multicolor imaging of NE with other biosensors. In sum, the improved $GRAB_{NE}$ family provides robust tools for spatiotemporally monitoring in vivo NE dynamics with high sensitivity and specificity in both physiological and pathological processes.

Title: Local 5-HT signaling bi-directionally modulates the coincidence time window of associative learning

Authors: *X. LI[1,2], J. ZENG[1,2,3], Z. ZHANGREN[1,2], Y. LI[1,2,3];
[1]State Key Lab. of Membrane Biology, Peking Univ. Sch. of Life Sci., Beijing City, China; [2]PKU-IDG/McGovern Inst. for Brain Res., Beijing, China; [3]Peking-Tsinghua Ctr. for Life Sciences, Acad. for Advanced Interdisciplinary Studies, Peking Univ., Beijing, China

Abstract: In Pavlovian associative learning, the temporal coincidence between a conditioned stimulus (CS) and an unconditioned stimulus (US) is an essential component for memory formation. The coincident time window of associative learning has been observed in a variety of behavioral paradigms in a wide range of species, including the eye-blinking task in humans, the gill-withdraw reflex in Aplysia, and the olfactory learning in Drosophila. Despite the importance of this component, it remains unclear how does the coincidence time window is regulated in a molecular or circuit-based way. To address this question, we explored the role of the serotonergic dorsal paired (DPM) neuron by a sensitive 5-HT sensor, $GRAB_{5\text{-}HT1.0}$. We found the DPM neuron releases 5-HT at the mushroom body (MB) in a compartmentalized pattern in response to both an odorant (the CS) and electric shock (the US). This 5-HT signal is induced by local acetylcholine (ACh) release from MB intrinsic Kenyon cells (KCs) via nicotinic ACh receptors. Relatively, the KCs receive feedback inhibition from DPM via the inhibitory 5-HT1a receptor. By manipulating the 5-HT signals or the DPM activity with genetic or pharmacological methods, we found suppressing or promoting 5-HT release from DPM neuron shortens or prolongs the coincidence time window of the odor-shock pairing–induced change in synaptic plasticity and the resulting olfactory learning behavior. These results revealed the serotonergic feedback circuit in MB regulates the length of coincident time window, which provides a model for studying how an organism times the temporal continuity of environmental events and learns the underlying causal relationship.

Title: A series of genetically encoded GRAB sensors for detecting serotonin dynamics in vitro and in vivo

Authors: *F. DENG[1,2], J. WAN[1,2], G. LI[1,2], H. DONG[1,2], X. XIA[1,2,3], T. QIAN[1,2], Y. LI[1,2,3]; [1]Sch. of Life Sci., [2]PKU-IDG/McGovern Inst. for Brain Res., [3]Peking-Tsinghua Ctr. for Life Sciences, Acad. for Advanced Interdisciplinary Studies, Peking Univ., Beijing, China

Abstract: Serotonin (5-HT), a phylogenetically conserved monoamine neurotransmitter, is associated with a plethora of important physiological functions, such as sleep-wake cycles, appetite control, mood regulation, as well as learning and memory. Malfunction of the serotonergic system also involves in addiction, anxiety, depression and other neurological diseases. In order to understand the physiological and pathological roles of the serotonergic system under different conditions, it is essential to decipher the precise dynamics of 5-HT with high sensitivity, high spatiotemporal resolution and good cell specificity. Based on the GPCR Activation Based (GRAB) strategy, we systematically developed a series of genetically-encoded 5-HT sensors named GRAB$_{5\text{-HT}}$, including novel red 5-HT sensors and improved green 5-HT sensors, by inserting cpmApple or cpEGFP into the third intracellular loop (ICL3) of different 5-HT receptors. The HTR4 based sensors showed the largest response to 5-HT and were further improved by semi-rational engineering of GPCRs and cpmApple or cpEGFP. After characterization of the performance of these newly developed sensors in cultured cells and acute brain slices, we further demonstrated that these sensors could reliably detect the extracellular 5-HT *in vivo* in different organisms, including *Drosophila* and mice. Thus, these newly developed 5-HT sensors will facilitate our understanding of the serotonergic system both in health and in diseases.

Title: A DNA-based nano MRI contrast agent for detecting acetylcholine

Authors: *H. SEO[1], **K. MA**[1], E. FRIEDENTHAL[1], C. A. FLASK[2], H. A. CLARK[1]; [1]Northeastern Univ., Boston, MA; [2]Case Western Reserve Univ., Cleveland, OH

Abstract: Acetylcholine is a neurotransmitter that plays a key role in motivation, arousal, attention, learning, and memory in the brain. Since its discovery, numerous efforts have been poured into understanding the regulatory mechanism of acetylcholine towards brain function and how dysregulation can lead to brain disorders such as Alzheimer's disease, Parkinson's disease, and schizophrenia. However, elucidating the exact mechanism and function of acetylcholine-mediated signaling processes remains challenging. The solution to understanding acetylcholine could be solved with non-invasive tools with high spatial and temporal resolution for use *in vivo*.

Magnetic Resonance Imaging (MRI) is a radiation-free, non-invasive imaging modality that offers good spatial and temporal resolution, making this modality popular in neuroscience research and clinical work. For example, fMRI has been widely used to study brain activity in humans in real-time. Direct visualization of the molecular target in the brain, however, is limited on MRI without having a target-specific contrast agent. Gadolinium-based contrast agents (GBCA) have been used around 30% of clinical scans to improve the accuracy of diagnosis by enhancing the contrast at the accumulated area. To give the GBCA a target-specificity, developing bioresponsive contrast agents have gained much attention to enable modulation of MR contrast in the presence of molecular targets on MRI. In our previous study, we reported nanoparticle-based MRI contrast agents for *in vivo* detection of acetylcholine in rat brain. Immobilized acetylcholinesterase selectively converts acetylcholine to choline and acetic acid, decreasing the local pH and thus modulating the signal of co-immobilized pH-sensitive GBCAs. To further improve the homogeneity in size and functionalization of the nano-sized contrast agent, here we report a DNA nanostructure-based MRI contrast agent for monitoring acetylcholine. DNA nanostructure was programmed to have a dendrimer shape with ten peripheral functional sites. We conjugated pH-responsive contrast agents and acetylcholinesterase on the DNA scaffold and characterized the functionalization and structure by MALDI-TOF and gel electrophoresis. The synthesized DNA-based contrast agent induced brighter contrast on the T_1-weighted image in the presence of acetylcholine. The application will be further demonstrated in *in vivo* animal experiments. This research would benefit developing new tools to visualize acetylcholine to better understand acetylcholine-related signaling processes in the brain.

Berkeley Dept. of Mol. and Cell Biol., Berkeley, CA; [5]PKU-IDG/McGovern Inst. for Brain Res., Beijing, China; [6]PKU-THU Ctr. for Life Sciences, Acad. for Advanced Interdisciplinary Studies, Peking Univ., Beijing, China

Abstract: Neuropeptides are key signaling molecules in endocrine and nervous system, regulating virtually all physiological processes, ranging from food ingestion, sleep & circadian rhythm, to pain sensation and social behaviors. To understand their important functions in vivo, it is critical to be able to monitor neuropeptide dynamics with selectivity, sensitivity and good spatiotemporal resolution. One major hindrance to the above goal is the lack of direct, sensitive and non-invasive probes to report these bioactive peptides *in vivo.* Here, by tapping into GPCRs for neuropeptides, we developed a toolbox of GRAB (GPCR activation based) sensors for neuropeptide Y (NPY), somatostatin (SST), corticotrophin releasing factor (CRF), neurotensin (NT), cholecystokinin (CCK), vasoactive intestinal peptide (VIP), substance P, vasopressin (AVP) and oxytocin (OXT). These fluorescent sensors utilize native GPCR ligand binding pockets as neuropeptide sensing modules and circular-permutated GFPs as optical reporters. We have developed sensors with ultra-good selectivity for neuropeptides, with nano molecular affinity, up-to 1500% dF/F fluorescence increase upon cognate ligand application. In addition, these GRAB sensors have minimal downstream G protein coupling, or arrestin coupling, compared to their original GPCR scaffolds. The neuropeptide GRAB sensors are able to reveal endogenous CRF and oxytocin release in acute brain slices and capture the CCK, OXT and AVP dynamics in behaving mice. These sensors are capable of detecting the relevant peptides with microendoscopic imaging across sleep wake cycles with good temporal resolution. Further development of these sensors and their deployment will likely significantly enhance our understanding of neuropeptide release mechanisms, neuropeptide functions and regulation in physiological and pathophysiological conditions.

Title: A Fluorescent Sensor for Real-Time Measurement of Extracellular Oxytocin Dynamics in the Brain

Authors: *D. INO, H. HIBINO;
Osaka Univ., Suita, Japan

Abstract: Oxytocin (OT), a neuropeptide initially discovered as an uterus-contracting hormone in the early 20th century, has been attracted a lot of attentions as a key regulator of many animal behaviors. In addition to the well-characterized roles as a peripheral hormone to promote childbirth and lactation, OT released as a neuromodulator within the brain participates in the regulation of diverse physiological functions from sensory processing, feeding control, social cognition, and emotion. To exert such central effects, OT primarily supplied from neurons in paraventricular nucleus and supraoptic nucleus of hypothalamus acts on the target brain regions such as limbic regions, sensory cortex, and brainstem, where a G-protein coupled receptor (GPCR) named as OT receptor (OTR) is highly expressed. OT release in the brain is evoked by external inputs such as sensory cues, food intake, and social rewards, and can also be controlled in an autoregulatory manner potentially by the signaling associated with biological clocks. Reportedly, the impairment of OT signaling in the brain may underlie the cognitive and emotional dysfunctions associated with psychiatric disorders (e.g. autism, schizophrenia) and brain aging. Despite its importance in health and disease, the relation between the animal behaviors and the spatio-temporal distribution of OT in the brain still remains largely elusive. Here, we describe MTRIA$_{OT}$, a GPCR-based green-fluorescent sensor that enables us to conduct real-time measurement of brain OT dynamics in living animals. MTRIA$_{OT}$ exhibit a large dynamic range, an optimal affinity, ligand specificity to OT orthologues, minimal effects on the downstream signaling, and long-term fluorescence stability in vitro. By combining viral gene delivery and fiber photometry-mediated fluorescence measurement, we demonstrate the utilities of MTRIA$_{OT}$ to track the OT level in the living brain. Moreover, we also demonstrate the potential of the fluorescent module of MTRIA$_{OT}$ for development of a variety of GPCR-based fluorescent sensors. MTRIA$_{OT}$ will be a powerful new tool to understand the OT functions in the brain.

Title: A highly sensitive mu-opioid peptide sensor engineered with a massively parallel GPCR optogenetic tool building platform.

Authors: *M. RAPPLEYE, S. J. WAIT, J. C. SIEBART, J. D. LEE, A. A. NGUYEN, N. SMITH, D. C. CASTRO, A. SUKO, J. D. DEEM, M. R. BRUCHAS, A. BERNDT;
Univ. of Washington, Seattle, WA

Abstract: The mu opioid receptor (MOR) plays a critical role for regulating neuronal networks involved in analgesia, addiction, reward behavior, and more. However, we currently lack a tool capable to investigate MOR activation with high spatio-temporal precision in vivo. Here, we present a protein-based mu opioid sensor engineered from a high throughput, optogenetic engineering platform. We constructed a genetic library with >1 million potential variants by randomizing DNA codons in key structural elements of the sensor. We express the library in a genetically engineered HEK 293T cell line that ensures each cell expresses a single sensor variant. In the next critical step, we then isolated the cells on our customized polydimethylsiloxane microwell array for subsequent sensor stimulation by the synthetic opioid peptide DAMGO and signal detection by fluorescent microscopy. Our transfection, expression, and screening techniques are streamlined and highly efficient, enabling us to screen hundreds of variants in parallel in a single field of view and tens of thousands of cells/sensor variants per day. Immediately upon signal detection on PDMS arrays, we quantify and rank each construct's performance with a custom, real-time analysis. Specifically, for the development of the mu-opioid sensor, we have screened >40,000 cells/variants, by far exceeding current throughput in sensor development. After recovering the gene, we validated the sensor's signal, biophysical characteristics (retaining MOR specificity, agonist, and antagonist ligand profiles) within mammalian cell culture populations. Importantly, we confirmed that the sensor does not internalize upon stimulation and does not induce intracellular signaling cascades. Furthermore, we confirmed that the sensor maintains the MOR's native hierarchy of affinities towards endogenous peptides (measured using epifluorescence microscopy in triplicate experiments for each replicate). After several rounds of unbiased high-throughput optimization, our platform produced an MOR-based sensor, able to detect endogenous neuropeptides in the nM range. Additionally, we confirmed these sensor features are maintained in cultured primary rat neurons. In summary, we demonstrated the ability to rapidly engineer and optimize neuropeptide sensors, showcasing our platforms abilities to develop highly specific and sensitive sensors through the directed evolution of a mu opioid sensor. Our ability to screen and identify variants specialized to detect low levels of agonist opens the field to the rapid creation of effective sensors for low concentration neuropeptide ligands.

Title: Monomeric green fluorescent probe gCarvi is optimal in cyclic adenosine monophosphate imaging of live neuron

Authors: S. KAWATA, *N. SAITOH;
Doshisha Univ. Fac. of Life and Med. Sc, Kyotanabe, Japan

Abstract: The second messenger cyclic adenosine monophosphate (cAMP) plays regulatory roles in various neuronal functions. Although molecular mechanisms underlying cAMP-mediated signaling pathways are well clarified, spatio-temporal dynamics of intracellular cAMP remain largely unknown. To address this issue, we have developed a new monomeric green fluorescent cAMP indicator named “gCarvi”. gCarvi is composed of cAMP binding domain of E coli cAMP receptor protein, conjugated with circular permutated GFP. This probe detects cAMP within 0.2-20 μM with a Kd of 2 μM and has a 2.5-fold dynamic range. This probe rapidly detects cAMP with a Kon of $1.13 \pm 0.19 \times 10^6$ mol^{-1} s^{-1} and Koff of 2.19 ± 0.16 s^{-1}. Unlike previous cAMP probes, this cAMP probe has more than 100-fold specificity in cAMP detection over cGMP or other nucleotides. Since presynaptic cAMP is thought to be involved in synaptic plasticity at cerebellar granule cell - Purkinje synapses, we asked whether presynaptic elevation of cAMP might affect the efficacy of vesicle cycling. rAAV-gCarvi expressed granule cells (ICR mice, 15 DIV) were stimulated by depolarization with a high K^+ solution in the presence (load) of FM 4-64 dye, and were simultaneously applied with 10 μM forskolin and 50 μM ibudilast to stimulate cAMP production and inhibit cAMP degradation, respectively. The presynaptic cAMP elevation of the granule cell boutons showed a positive correlation to the magnitude of FM 4-46 changes ($r = 0.84$, $P < 0.001$). These results suggest that intra-bouton cAMP elevation can increase the recycling synaptic vesicle size in individual boutons. Next, gCarvi and jRCaMP1b (a red fluorescent Ca^{2+} probe) were co-expressed in hippocampal neuron (ICR mice, 17 DIV). After confirming fluorescent cAMP and Ca^{2+} signals in hippocampal neurons, we bath-applied 10 μM forskolin and 100 μM IBMX (a phosphodiesterase inhibitor), which caused a gradual increase in the somatic gCarvi fluorescence and reached a plateau within 2 min. Dual imaging of cAMP and Ca^{2+} revealed that forskolin-induced cAMP increase caused increases in Ca^{2+} signals in hippocampal neurons. We utilized this probe to measure basal [cAMP]i in hippocampal culture neurons. The mCherry fused ratiometric gCarvi expressed neurons were permeabilized using 30 μM escin and exposed to cAMP at various concentrations (1-100 μM). The basal [cAMP]i estimated from the titration curve was 1.25 ± 0.20 μM. This concentration is slightly below the level required for PKA activation. The Kd of gCarvi for cAMP is just above the basal concentration, indicating its suitably for imaging dynamic changes of neuronal [cAMP]i.

Title: Massively parallel, high-throughput engineering of optogenetic biosensors for neuronal signaling.

Authors: M. RAPPLEYE, J. LEE, S. WAIT, J. SIEBART, A. NGUYEN, D. CASTRO, N. A. RICHARDSON, N. SMITH, P. P. GUNDAPANENI, A. SUKO, C. CHAVKIN, J. D. DEEM, M. BRUCHAS, ***A. BERNDT**;
Univ. of Washington, Seattle, WA

Abstract: The use of genetically encoded sensors, combined with in vivo microscopy and fiber photometry, has revolutionized the access to and dissection of neuronal circuits that control every aspect of information processing in the brain. The complexity and the sheer number of biochemical signaling pathways in the brain calls for an equally precise array of sensor technology. However, the development of novel sensor proteins is significantly slowed down by the low throughput of current validation methods that test engineered optogenetic sensors sequentially and one-by-one. Consequently, only a few hundred new variants can be tested within reasonable timeframes risking to miss superior sensors that match the sensitivity and specificity necessary to detect neuronal signals in vivo optically. Therefore, we developed a novel high-throughput engineering platform that significantly accelerates the screening process. We can generate sensor libraries with up to several million variants and functionally test a large number of them (>40,000) in a novel parallel approach. Here, individual sensor variants are expressed in individual mammalian host cells (HEK293), and hundreds of them are simultaneously stimulated on Polydimethylsiloxane (PDMS) arrays. The resulting change in signal (dF/F_0) is tracked using fluorescent microscopy and analyzed in real-time. Furthermore, our unbiased approach provides a high degree of freedom as we can screen the protein libraries at low ligand concentrations and use varying ligands, which is especially useful for neuropeptide sensors that are activated by several different agonists. As a result, more extensive sensor protein libraries can be screened in shorter timescales under relevant physiological conditions. Importantly, we confirmed the high accuracy and reproducibility of our platform. For example, the coefficient of variation of the fluorescent output during the screen is below 10% of the total signal (dF/F_0). Furthermore, the selected sensor variants produce equivalent signals in

mammalian cell culture populations. We will showcase the development of improved sensors for monoamine neurotransmitters, neuropeptides, and intracellular signaling pathways. The sensor ligand sensitivities and specificities have been validated in mammalian cell populations in replicates of at least three independent double-blinded experiments, each totaling >100 individual cells. In summary, our novel engineering platform can significantly accelerate sensor development at a lower cost which enables us to adopt them from the whiteboard to neuroscience applications quickly.

Abstract: Nanomedicine have emerged as a promising and innovative approach for targeted drug delivery and treatment of numerous diseases including CNS related diseases. Among them DNA nanotechnology assembles versatile, biocompatible, and programmable structures enabling selective accumulation of drug molecules in targeted sites. However, despite the importance of the investment in the development of these technologies, most are on hold at the *in vivo* evaluation stage. Lack of tools enabling the investigation of cellular level biodistribution hinders the fine tracking of these structures in the whole body. Recent developments in tissue clearing and light sheet microscopy have made it possible to investigate large volumes at cellular resolution. Here, we took advantage of our newly designed whole-mouse body clearing and

imaging technologies (vDISCO) to investigate the cellular level distribution of DNA origami. Towards this goal, we generated DNA origami rods (8nmx80nm) carrying fluorescent dyes. The production efficiency and stability were assessed *in vitro* prior *in vivo* evaluation of the immune compatibility, half-life, targeting efficiency and bio-distribution. DNA origami administered intravenously (iv) or per gavage inCD1 mice (n=5). The DNA origami treatment did not alter immune cell counts up to 7 days post-injection demonstrating the immune safety of the treatment. Brain surface imaging using intravital 2-photon microscopy enabled to show clearance of the DNA origami from the meningeal blood circulation less than 20 min after injection. We did not see leakage of DNA origami into the brain parenchyma. In the periphery, the DNA Origami was gradually cleared from the liver until 24h post-injection. We then compared the biodistribution and targeting potential of iv injected DNA origami coupled with antibodies. After 20 minutes circulation, the intact whole mouse bodies were subjected to vDISCO clearing and imaged using light sheet microscopy. DNA origami coupled with CX3CR1 antibody, specific to immune cells was detected in lymph nodes, spleen as well as in kupffer cells in liver. We also coupled the DNA origami with human carbonic anhydrase (CA) XII-specific antibody (6A10), a cancer therapy antibody. We analyzed the targeting efficiency in mice that injected with MDA-MB-231metastatic cancer cells. While the DNA origami coupled with CX3CR1 preferentially targeted immune organs the 6A10 coupling directed the DNA origami to the lung were it co-localized with metastases. So far, our approach enables the assessment of biodistribution in the intact body with sensitivity down to the single-cell level, revealing DNA origami's feasibility for drug targeting.

Abstract: Drug delivery to the brain tissue is key for the treatment of multiple central nervous diseases. However, drug therapies for central nervous diseases has the lower success rates compared to other therapeutic fields due to the poor transport across the blood-brain barrier (BBB). Therefore, one of primary needs for brain drug delivery is overcoming the BBB, which prevents entry into the brain of most drugs. Intranasal route has emerged for brain drug delivery with a benefit of circumventing the BBB, via neural pathways in the olfactory region. However, when drugs administrated intranasally, extremely low amount of drugs can reach the olfactory region, because it located the upper and posterior region of the nose. Hence, strategies to improve intranasal drug delivery are critically needed. In this study, we proposed a new delivery approach based on the hypothesis that magnetic nanoparticles (MNPs) can be guide in a desired direction such as olfactory region by applying a proper magnetic field. We demonstrated the feasibility of our concept using the *in vivo* experiments via rat models. To deliver intranasally administrated MNPs to brain, we designed the magnetic field device that can generate strong static magnetic fields (<175 mT) in the superior direction. During injecting fluorescence MNPs, the rat's head was fixed inside our designed device and exposed to superior magnetic field. After the magnetic exposure, the brain was extracted and fluorescently imaged to identify brain delivery (n= 3~5). For finding appropriate delivery conditions, we tested various magnetic field exposure times (90~150 min). Our results showed that our proposed strategy enhance the delivery efficiency of MNPs from nose to brain by the magnetic force. Although there were slight differences in the results depending on the magnetic exposure time, brain delivery was markedly increased compared to the sham control. From these results, we confirmed the feasibility of our proposed magnetic induced drug delivery concept. In the next phase of the study, we intend to conduct a parameter study to establish the conditions for drug delivery by the intranasal pathway using drugs containing MNPs.

Title: Feedback control on the pituitary-thyroid hormone axis by thyroid hormone agonists correlates with peripheral exposure as opposed to central exposure and on-target activity

Authors: D. A. MACKENNA[1], J. M. BACCEI[1], *M. B. WOERNER[1], A. ALAVI[1], M. W. AKHTAR[1], T. S. SCANLAN[2], B. A. STEARNS[1], J. R. HARRIS[1];
[1]Autobahn Therapeut., SAN DIEGO, CA; [2]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Thyromimetic small molecule agonists are known to perturb the thyroid hormone axis (THA) at pharmacologically relevant doses. Established biology suggests that this may occur centrally in the hypothalamus, through thyrotropin releasing hormone in the periventricular nucleus, or peripherally in the pituitary, through thyroid stimulating hormone, or both centrally and peripherally to varying degrees.
We are developing brain-directed thyromimetic prodrugs that are activated by fatty acid amide hydrolase (FAAH). FAAH is ubiquitously expressed but is enhanced in the CNS and gastrointestinal tissues. The objective of these studies was to utilize our novel delivery technology to elucidate mechanisms by which thyromimetics disrupt the THA. Is it possible to separate on-target activity in the brain from that on the THA? Studies were performed using recombinant FAAH, tissue-derived S9 fractions, in vivo tissue distribution (TD), gene expression in brain and liver and effects on T4 in mice as a marker of THA disruption.
ABX prodrugs enhance delivery of active metabolite to the brain by >30x with brain-to-plasma ratios >1. T3-regulated gene expression in the brain increased at doses 30-fold lower than that of the metabolite with little difference in potency in liver and heart. Both prodrug and active metabolite reduce T4 levels after 7 days of treatment. Effects on THA and liver gene expression parallel plasma distribution more closely than exposures in the CNS suggesting this may be primarily a pituitary-driven effect.
We characterized both centrally-penetrant and peripherally-restricted FAAH inhibitors (CFI & PFI, respectively). PFIs have a >30-fold dose window in mice for inhibiting FAAH peripherally vs. centrally, while CFIs inhibit FAAH globally. Using the CFI, potency shifted by ~35x for all endpoints including TD, gene expression in brain and liver and THA. In contrast, PFI administration reduced potency of prodrugs on activation of T3-regulated genes in the liver and heart by >10x, without affecting activity or exposure in the brain. PFIs also decreased potency on the THA, consistent with negative feedback based on circulating peripheral metabolite rather than brain exposure. Thus, use of a PFI allowed separation of on-target brain effects from those on THA.
Negative regulation of T4 by thyromimetics does not appear to be predominantly centrally-mediated because the effects on THA and liver gene expression parallel plasma distribution more closely than exposure or activity in the CNS. As such, the combination of a thyromimetic prodrug and a PFI may further enhance delivery of our thyromimetics to the brain and maximize centrally-targeted distribution.

Title: Microglia Depletion using Unformulated PLX5622 in Rodent Diet

Authors: *B. L. WEST[1,2], A. MARIMUTHU[2], S. YEUNG[3], M. PELLIZZON[3], K. N. GREEN[4]; [1]CIMA, Newark, CA; [2]Cytoscient, Newark, CA; [3]Res. Diets, Inc, New Brunswick, NJ; [4]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Microglia survival in the adult mouse depends on signaling through the CSF-1 receptor (CSF-1R). Pharmacological inhibition of the CSF-1R causes microglial death, and this method can be used to investigate microglial functions in both health and disease. PLX5622 is a potent and selective inhibitor of the CSF-1R that can be used to lower microglial number. The extent of microglial depletion depends on the concentration of PLX5622 reached in the test animal. Like most drugs with very low solubility, specialized formulation strategies are required for PLX5622 to reach sufficient concentrations in circulation. Mixing of high concentrations of PLX5622 into the AIN-76A diet has successfully yielded microglial depletion at >90% levels. To date, most or all of the successful examples use the PLX5622 drug product which was professionally pre-formulated before incorporation into the AIN-76A diet, raising the question of the necessity of the pre-formulation, and whether a more streamlined production

method is possible.
In the current studies, neat PLX5622 purchased from a chemical vendor and without any pre-formulation was incorporated into the AIN-76A purified rodent diet at a 1200 ppm drug load. This diet was fed ad libitum for 14 days to a cohort of 3 male C57Bl/6N 8-week old mice, as was a drug-free AIN-76A diet fed to 3 control mice. On the morning of day 15, Na2-EDTA plasma samples were taken, diets removed, mice sacrificed, and brains removed for fixation in 4% paraformaldehyde. After 48 hrs fixation brains were transferred to 30% sucrose for histology. Brain sections were imaged for microglia using anti-Iba1 immunostaining, and microglia quantified in whole brain slices via the spots module in Bitplane Imaris 9. In PLX5622-treated mice, microglia were reduced by 68% (2002+/-615 spots drug diet vs 6303+/-306 spots control, difference 4301 +/- 1171). As a correlate, the concentration of PLX5622 extracted from the plasma in 75% acetonitrile was quantified using LC-ms/ms by comparison with a PLX5622 standard curve prepared in control mouse plasma. The mean calculated PLX5622 plasma concentration was 1619+/-26 ng/mL.
Although the reduction of microglia did reach 68%, this level is inadequate for studies aiming to infer a role for microglia in their absence. Even while using the strategy of ad libitum feeding of drug-loaded diet, some additional formulation is required. New methods easily accessible to life science investigators at low cost are now being investigated.

Title: Supersaturable lipid based nanoformulation of atazanavir: a strategy towards eradication of viral sanctuaries in the Brain.

Authors: *S. SETHI[1], V. RANA[2];
[1]Pharmaceut. Sci. & Drug Res., Punjabi Univ., Patiala, India; [2]Pharmaceut. Sci. & Drug Res.,

DEPARTMENT OF PHARMACEUTICAL SCIENCES & DRUG RESEARCH,PUNJABI UNIVERSITY, PATIALA, PUNJAB, Patiala, India

Abstract: Central nervous system (CNS) serves as an immunological privileged sanctuary site for HIV-1 virus that is capable of reactivating the infection.The injury resulting from HIV infection to the brain may leads to milder form of cognitive impairment and dementia in severe cases. Commercially available anti-HIV drugs, although effective in minimizing the viral load, cannot eradicate the virus significantly from the body. The failure of many highly active antiretroviral therapy (HAART) agents to block the accumulation of viral reservoirs is due to the low penetration across the blood-brain barrier (BBB). Therefore, formulating a novel approach foraugmenting the delivery of anti-HIV drugs are required for the treatment of neuro-AIDS. The current investigation entails the systematic development of Atazanavir Sulfate (ATZ) loaded supersaturable lipid formulation prepared with long chain triglycerides for enhanced oral bioavailability and CNS targeting. For this purpose, the optimized supersaturable lipidic formulation (F1) consists of Corn Oil: Oleic acid (1:1) (10% w/w), Propylene Glycol (40% w/w) and Tween 80 (50% w/w) was formulated by employing D-optimal mixture design. Two different radiolabeled formulations (F1 formulation and ATZ suspension) each containing 7 mg/Kg atazanavir were administered by an oral route to adult Wistar rats of either sex (n=6). The *in-vivo* biodistribution studies show significantly higher concentration ($P < 0.05$) of atazanavir in brain administered with F1 formulation, which was also evident by confocal laser scanning microscopy with respect to suspension group. Collectively, these findings suggest that lipid-based nanoformulation may enhance brain delivery of the potent and frequently used antiretroviral drug atazanavir.

Title: Vaporized Methamphetamine: A Novel Noninvasive Approach to Study Methamphetamine Abuse

Authors: *T. C. NAPIER[1], P. CZYZEWSKI[2], A. L. PERSONS[3];
[1]Psychiatry and Behavioral Sci., [2]Rush Univ. Med. Ctr., Chicago, IL; [3]Physician Assistant Studies, Rush Univ. Col. of Hlth. Sci., Chicago, IL

Abstract: Prevalence of nonmedical methamphetamine (meth) use is increasing in many countries. Personal vaporizers (electronic delivery devices, e-cigarettes), are a popular intrapulmonary delivery method for nicotine products, and these have been adapted to deliver illicit drugs, including meth. Powdered meth mixed into vape liquid provides bioavailability that is similar to nicotine (Peace et al; Office of Justice Programs' National Criminal Justice Reference Service, Doc #252921, May 2019). Though clearly important, the consequences of vaporized meth have received little scientific attention. To fill this knowledge gap and provide a model for future studies, we characterized vaporized meth HCl in young adult male Sprague-Dawley rats using off-the-shelf atomizer/tank cartridges secured in sealed e-Vape^{TM} chambers (La Jolla Alcohol Research, Inc). We tested concentrations of meth ranging from 50-200mg per 1mL of various combinations of a propylene glycol (PG)/vegetable glycerin (VG) vehicle. We also tested non-contingent schedules ranging from 3-5s vapor delivery every 2-5min for 45-60min sessions, for total meth delivery time of 60–150s. We determined that 100mg meth per 1mL of 30%/70% PG/VG vehicle delivered in 3s pulses/2min for 60min was optimal. Using this protocol, we tested vaporized meth and vaporized PG/VG vehicle (4 rats/treatment). After 60min, rats were removed from the e-Vape chamber, and motor activity was quantified in automated activity boxes for 60min. The vape protocol was repeated with vehicle only in a second cohort, and these rats were administered an intraperitoneal (ip) injection of meth (1.25mg/kg) or saline (1mL/kg) 30min before collecting locomotor data (4 rats/treatment). Both vaporized and ip meth robustly elevated motor function (e.g., locomotion and stereotypy increased 3-fold) and the hypermotility was sustained for the entire session (two-way ANOVA; $p<0.05$). A Bonferroni's multiple comparisons *post hoc* test revealed an effect of meth but no difference between the meth groups. To determine absorption of vaporized and ip meth, the experiment was repeated, and serum was collected 40-45min after vapor termination or 30min after ip injection. Blinded serum samples were analyzed by mass spectrometry, verified to a meth internal control. Serum concentrations were similar for vaporized and ip meth (68±17 and 50±6ng/mL, respectively; $p>0.05$). These results reveal that vaporized meth (1) is a feasible noninvasive means to deliver meth in rats, (2) is absorbed and detected in the bloodstream, and (3) alters motor function comparable to that of moderate meth doses injected ip.

Title: Biodistribution of Spherical Nucleic Acids in the Mouse CNS Following ICV, ICM and IT Delivery

Authors: *L. MOORE, L. P. KELLY, M. SCHROFF, B. R. ANDERSON, G. T. CORBETT; Exicure, CHICAGO, IL

Abstract: Spherical nucleic acids (SNA^{TM}) are nanostructures comprised of densely packed oligonucleotides radially arranged around a nanoparticle core. Compared to their linear counterparts, SNA show increased cellular uptake and persistence in the central nervous system (CNS). In this study, we sought to assess the biodistribution and cell-type specific uptake of fluorescently labelled SNA in the mouse CNS following three routes of administration (RoA). We synthesized bi-fluorescent SNA harboring BODIPY-labeled DOPC cores and Cy5-labeled oligonucleotides (SNA-BODIPY-Cy5). Single injections of SNA-BODIPY-Cy5 were delivered to eight-week-old male NMRI mice via: i) intracerebroventricular (ICV), (ii) intra-cisterna magna (ICM), or (iii) intrathecal (IT) RoA. Two hours or 14 days after dosing, brains and spinal cords were processed for bone decalcification and tissue clearing prior to 3-dimensional light sheet microscopy. Strong BODIPY signals were observed in the CNS at 2 hours post-injection that were essentially absent at 14 days post-injection, while Cy5 levels were prominent throughout the CNS at both time points. These results suggest: i) rapid distribution of the SNA structure throughout the brain and spinal cord after delivery to cerebrospinal fluid and ii) SNA components are differentially metabolized. Fourteen days post-injection, strongest brain and spinal cord Cy5 levels were observed after ICV and IT delivery, respectively, in accordance with their points of injection. Particularly in ICV and IT injected animals, prominent Cy5 signals could be detected throughout all cortical and subcortical regions of the brain, including brainstem nuclei, cerebellum, thalamic and hypothalamic nuclei, hippocampus, and striated cortical layers. High Cy5 signals were detected throughout all sections of the spinal cord in IT-injected animals, including prominent distribution into dorsal root ganglia. Co-labeling of CNS tissues with cell-type specific markers revealed SNA uptake by all prominent CNS cell subtypes, including neurons, astrocytes and microglia. In conclusion, SNA distribute widely throughout the CNS following local administration to CSF and are taken up by all major CNS cell subtypes. These findings support the continued development of SNA therapeutics for neurological disorders of the brain and spinal cord.

Title: Quantitative detection of the effect on neuronal responses in tri-synapses with the acute application of bisphenol-A-related substances on hippocampal slices with voltage-sensitive dye (VSD)

Authors: Y. TOMINAGA[1], M. TAKETOSHI[1], K. TANEMURA[3], ***T. TOMINAGA**[1,2];
[1]Inst. of Neurosci., [2]Kagawa Sch. of Pharmaceut. Sci., Tokushima Bunri Univ., Sanuki, Japan;
[3]Lab. of Animal Reproduction and Development, Grad. Sch. of Agr. Sci., Tohoku Univ., Sendai, Japan

Abstract: Environmental chemical exposure and drug administration can cause central nervous system (CNS) toxicity. Especially, vulnerability to exposure during early developmental stages is concerned to raise the risk for various neuropsychiatric disorders, including Asperger spectrum syndrome. The neural circuit-level assay is important to fill in a gap between the cellular assay using primary or cell lines and in vivo assay. However, effects on neural circuit activity are challenging to detect with conventional electrophysiological methods. We developed a voltage-sensitive dye (VSD; Di-4-ANEPPS) imaging system to detect subtle neural activity modification in the neural circuits quantitatively on a large scale. Here, we used the hippocampal slice preparation as a representative neural circuit and tested acute effects of the environmental chemical bisphenol-A (BPA) and its related substances BBMTBP and MBMTBP (5 ppm in perfusate). We tested the hippocampal tri-synaptic responses by applying electrical stimulation to Schaffer collateral to CA1, mossy fiber to CA3, and perforant path to DG.The three different regions' responses in the hippocampus were accumulated across five to eight different slices. We assessed effects on excitatory and inhibitory networks using a GABA-A receptor blocker (SR95331) to the system (+Gz). Firstly, we tested with adult mice (eight weeks old). We evaluated the VSD signals with the amplitude of early response (ER, peak values within 40 ms from the stimulation), which corresponds to excitatory post-synaptic potential (EPSP) and action potentials (AP). We used selective ROI to evaluate the response corresponds to CA1, CA3, and DG regions. BBM and MBM reduced CA1-ER in the normal solution (-Gz) and CA3-EPSP components in +Gz. We also evaluated the late phase (40-500 ms) of the response as an integral of the response (LR). In LR, CA1 and CA3 were reduced by BBM in -Gz and -Gz. We also used young (two-week-old) mice to assess the vulnerability of circuit activity. To our surprise, the young group was more-or-less resistant to those chemicals, while still BBM and MBM showed significant suppression of CA3-EPSP components +Gz. In LR, CA1 responses were affected by BBM and MBM. The overall result indicates higher risks with BBMTBP and MBMTBP than with BPA.

Abstract: Advances in Gene Therapy: Convection enhanced delivery for Parenchymal Brain Administration guided by real time MRI Erik A. Larson[1], Jerneja Stare[1], Karen Wong[1], M. Said Maghezzi[1], Clotilde Lecrux-Leblond[1], Michael V. Accardi[1], Simon Authier[1, 21]Charles River Laboratories, Laval, QC, Canada[2]Faculty of Veterinary Medicine, University of Montreal, QC, CanadaConvection-enhanced delivery (CED) has emerged to become a broadly used methodology for targeted delivery of cell and gene therapies directly into various brain regions. To ensure the highest translational value, the same methods are used in non-clinical models to assess safety and efficacy of cell and gene therapies in development. Considering this, we recently implemented real-time intraoperative magnetic resonance imaging (MRI) and a stereotactic navigation system to deliver novel neurological therapeutics in a non-human primate (NHP) model. A gadolinium-containing solution, infused into the targeted brain structure at rates of 1-5 µL/min, was used as a contrast agent which allowed for real-time MRI scanning confirmation of dose site accuracy and dose diffusion monitoring. Real-time MRI scanning was used to assess distribution relative to the targeted brain structures. Further post-hoc analysis using custom bilateral masks outlining target subcortical structures was used to calculate the estimated coverage of the structures. A sequential dosing paradigm was used in the preclinical model to cover structures bilaterally given anatomical constraints. During recovery from surgery, animals typically presented mild and expected procedure-related clinical signs (e.g. mild tremors) which generally resolved within four days. Histopathological assessments also identified the expected neuropathological changes indicative that surgical procedures were well tolerated. Since the use of NHP models is particularly important for testing the delivery of cell and gene therapies, this approach provides a clinically relevant preclinical methodology for targeted brain CED with high structural accuracy.

Abstract: Background: Gold nanoparticles (GNPs) have unique physical and chemical properties that allow them to function as a drug-delivery system for several tissues: skin, eye, liver, and others. However, information about the biological response of brain tissue against GNPs is limited. Astrocytes and microglia cells are the first line of defense against brain insults and proper indicators of the level of brain damage. Objective: To evaluate the astrocytic and microglia response after an intracerebral injection (striatum) of polyethylene-glycol-coupled GNPs (PEGylated GNPs). Methods: Male CD1 mice (P60) were divided in three groups: Gold nanoparticles (GNPs), control-vehicle and control-sham. The GNPs received 100 nl of PEGylated GNPs (85×10^6 nanoparticles/nl). The control-vehicle group received 100 nl of 0.9% NaCl solution whereas control-sham group were submitted to craniotomy without meningeal disruption. All animals were sacrificed by transcardial perfusion at 3, 7, 14, 30 and 90 after administration. We evaluated the cellular response of astrocytes and microglia at all time-points after intracerebral injection by cell counting and morphologic changes in a stereological grid. Results: Astrocytic response shows an increase in their populations and changes in their cytoplasmic transformation at day 3 and decrease at day 90. Microglia response are less prominent and significant changes were found only at day 7 and 14. Conclusion: Our findings indicated that the glial response was transient and mainly circumscribed to the injection site.

Title: A Whole Brain Synchronicity Neural Computing Model -Part 1

Authors: *T. MAEDA[1,2], N. NISHIO[1];
[1]Osaka Univ., Suita-Shi, Japan; [2]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Suita-shi, Japan

Abstract: We propose a computational model of the brain that achieves identity of consciousness across the brain. In order for the brain to retain information as memory, it is believed that synapses must record temporally continuous signals in a temporally and spatially invariant state. In this paper, we propose a computational model of the brain that enables the brain to store information in a temporally and spatially invariant state. Just as synchronous circuits are necessary for large-scale electronic circuits, synchronization of the entire brain is necessary to ensure memory identity. We propose an Eigenfunction Synchronicity Model that utilizes standing waves as a physical phenomenon to achieve this synchronization. In this model, the neural field is regarded as an oscillatory field, as shown in the model of Wilson-Cowen et al. The nodes of the standing wave are the smallest units of memory. The formation of standing waves is defined as the recall of the whole memory and the formation of consciousness. The nodes of a standing wave are the roots of the eigenfunction that serves as its envelope waveform. This root can form a memory that satisfies the identity as nominal scale of 1DOF constraint in the orthogonal complementary space representation. What is the advantage of describing memory with standing waves if organisms use the same principle? This model embraces the principle of the generation of representations in the brain. Representations in the human brain are mappings that are associated with external events, and are information that can be recognized and stored as time-invariant relationships. The mechanism of this model, in which memories are traced in the brain through the "time-invariant and spatially-invariant" phenomenon of standing wave nodes, suggests that the principle of wave transmission is employed in brain information processing. In the wave transfer field, the boundary value of the closed domain and the internal and external states can be treated as mirror images via the Kirchhoff-Helmholtz integral equation. This means that the internal and external states are mapped to each other across the boundary surface, and if the closed domain corresponds to a human being, the boundary value corresponds to sensory-motor signals, the external state corresponds to external phenomena, and the internal state corresponds to representations in the brain. We can define a representation here as a map that extracts the time-invariance of external events. In the formation of these

representations in the brain, it is an essential mechanism that the mapping can be acquired as unsupervised learning only on the condition that the nodes constitute a time-invariant zero point.

Title: Two Types of Nerve Fields Realize Recall of Associative Memory on the Whole Brain-A Whole Brain Synchronicity Neural Computing Model Part 2-

Authors: *N. NISHIO[1], T. MAEDA[3,2];
[1]Osaka Univ., Takatsuki, Japan; [2]Grad. Sch. of Information Sci. and Technol., Osaka Univ., Suita, Japan; [3]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Suita-shi, Japan

Abstract: In the first report, we showed that synchronization of the entire brain is necessary to ensure the memory identity on the whole brain. The synchronization of the entire brain is ensured by the eigenfunctions of the spatial direction of standing waves that are established synchronously on the whole brain. In the second paper, we first argue that the gray matter and white matter of the cerebral cortex works as wave fields in which standing waves of different frequencies are established. Based on the nerve field model proposed by Wilson-Cowan et al. VanRullen et al. suggested that the white matter works as a wave field. On the other hand, the gray matter also works as a wave field, as in the Wilson-Cowan model. In other words, these wave fields support the formation of standing waves throughout the brain across cortical regions. Neurons in the gray matter have no plasticity and can reproduce the same standing waves when given the same boundary conditions. This allows for a reproducible mapping of states of external phenomena to internal states of the brain. On the other hand, the axons of excitatory neurons passing through the white matter are plastic and learnable, and thus play a role in learning the relationship between internal states of the brain. Associative memory, as a fundamental property of human memory, requires whole memories to be recalled from partial memories. How can this associative memory be realized in a uniform wave field? The eigenfunctions in the spatial direction of the standing wave that satisfy the boundary condition are established in the section between the two edges set as the boundary condition. Any node of the standing wave can be set as a new boundary condition. Therefore, a new standing wave will also be established simultaneously in the subsection sandwiched between any two nodes of the standing wave. This

corresponds to partial memory for whole memory. This is also the basic principle that expresses the associative recall of partial memory from whole memory. In addition, it supports the possibility that when partial memories are recalled, whole memories which are associated with them can also be recalled. In the first paper, I argued that sensory-motor signals are the boundary values that map external phenomena to human beings as the closed domain. In the second paper, we will focus on the eigenfunctions of the spatial direction of standing waves established in the closed region as wave field. The eigenfunction has spatial orientation. This makes it possible to distinguish between signal propagations from each modality, although multiple modalities are propagating signals to the association areas of the cerebral cortex.

Title: Weak inhibition synchronizes neuronal populations with spontaneous firing by disengaging from sodium currents

Authors: *T. SHINOZAKI;
NICT CiNet, Suita, Japan

Abstract: Inhibitory inputs are considered to facilitate synchronization of neuronal populations (Hasenstaub et al., 2005; Sohal et al., 2009), and the mechanism of this synchronization is understood to be caused by anchoring the membrane potential to the reversal potential of the inhibitory synapse. On the other hand, neuronal populations in vivo are usually in a spontaneous firing state, and hyperpolarization to the reversal potential of inhibitory synapses requires enormously strong inhibition, which may be unnatural also in terms of efficiency. In this study, we report a synchronization phenomenon caused by weak inhibitory inputs in a neural population with spontaneous firing. Although this phenomenon has been confirmed in our previous computational neuroscience studies (Shinozaki et al., 2007, 2010), in this report, we have clarified the detailed mechanism by analysis using the Fokker Planck equation. In a neural population that does not cause spontaneous firing, the membrane potential forms a certain distribution by balancing the external noise with the leak current. On the other hand, at the membrane potential near the firing threshold, where spontaneous firing occurs, the depolarizing sodium current partially cancels out the leak current, and attenuates the force that suppresses the diffusion of the membrane potential, resulting in a desynchronized state. Thus, under conditions

of spontaneous firing, the membrane potential distribution becomes relatively desynchronized, and hyperpolarization induced by weak inhibitory input causes a disengagement from the desynchronized state, resulting in synchronization. These results were analyzed in models using exponential integrate-and-fire (EIF) (Fourcaud-Trocmé et al., 2003) neurons and validated by numerical simulations. Furthermore, it was confirmed that models using leaky integrate-and-fire (LIF) neurons, which do not have dynamics corresponding to sodium channels, does not exhibit such synchronization phenomena. Since inhibitory inputs are thought to be closely related to the mechanisms of attention in the brain (Mitchell et al., 2007; Synder et al., 2016), our results may contribute to the understanding of the neural mechanisms of attention and oscillation in the brain and to the realization of more energy-efficient neuromorphic information processing.

Title: Inhibitory network model captures asymmetry in the transient dynamics of hippocampal ripple oscillations

Authors: *N. SCHIEFERSTEIN[1,2], T. SCHWALGER[3,2], B. LINDNER[1,2], R. KEMPTER[1,2,4]; [1]Humboldt-Universität zu Berlin, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany; [3]Technische Univ. Berlin, Berlin, Germany; [4]Einstein Ctr. for Neurosciences, Berlin, Germany

Abstract: Hippocampal ripple oscillations have been implicated in important cognitive functions such as memory consolidation (Buzsáki, 1989). Yet ripple generation remains obscure, and several mechanisms were proposed, relying on excitation and/or inhibition as the main pacemaker(s). Inhibition-first models can be subdivided into perturbation-based (Malerba et al., 2016) and bifurcation-based models (Donoso et al., 2018, Brunel, Wang, 2003). While all ripple models produce oscillations in the ripple-band (140-220 Hz), only the bifurcation-based inhibitory model reproduces intra-ripple frequency accommodation (IFA) — an asymmetry in the instantaneous network frequency in CA1 in response to transient, symmetric, sharp wave-like stimulation (Donoso et al., 2018, Ponomarenko et al., 2004).
Here we mechanistically explain IFA in bifurcation-based inhibitory ripple models, using numerical simulations and a theoretical mean-field approach.
We use a spiking network of leaky-integrate-and-fire units that are fully connected via delayed inhibitory pulse-coupling. All units receive independent white noise and the same excitatory drive, mimicking the CA3 Schaffer collateral input to CA1. For increasing excitatory drive this

network undergoes a bifurcation from a stationary to an oscillatory regime (Brunel, Hakim, 1999). To quantify IFA, we a) approximate the highly non-linear oscillation dynamics for constant drive beyond the bifurcation and b) show how the response to transient drive relates to those cyclo-stationary dynamics. Thus, we take the frozen-noise limit and approximate the density of membrane potentials in the mean-field (i.e. the solution of the associated Fokker-Planck equation) as a Gaussian with time-dependent mean. In this framework we can analytically approximate the frequency and amplitude of the network oscillation as a function of excitatory drive. We show that for a wide parameter regime this ansatz provides a good approximation of the cyclo-stationary dynamics beyond the bifurcation.
We demonstrate that IFA is an inherent feature of this model class that results from a speed-dependent hysteresis effect in the amplitude of the oscillatory mean membrane potential, given transient, sharp wave-like drive. We predict that ripples triggered by optogenetic stimulation of CA1 PV^+ basket cells in vitro show *less* IFA if the stimulus ramps up/down more *slowly*.
The present work thus provides new insights into the transient dynamics of oscillations in inhibitory networks that can contribute to model selection and the unravelling of the true generating mechanism of hippocampal ripples.

Title: Generation of sharp wave ripples in the CA1 Hippocampus: a role for chandelier interneurons

Authors: *G. GLICKERT[1], *B. LATIMER[1], M. BHAGAVATHI PERUMAL[2], P. SAH[3], S. S. NAIR[4];
[1]Univ. of Missouri, Columbia, MO; [2]Queensland Brain Insititute, Brisbane, Australia; [3]Queensland Brain Inst., St Lucia, Australia; [4]Electrical & Computer Engin., Univ. of Missouri Columbia, Columbia, MO

Abstract: Sharp wave ripples (SWRs) are the most synchronous large-scale oscillatory activity in neural circuits. Predominantly investigated in the CA1 hippocampus, several circuit models have been proposed for their generation: 1) feedback inhibition 2) reciprocal inhibition 3) feedback and reciprocal inhibition and 4) axo-axonic coupling between pyramidal cells. The first

three models require extrinsic inputs from CA3. However, CA3 population bursts often do not correlate with ripples in the CA1 of the hippocampus. Secondly, isolated CA1 slices have also been shown to generate SWRs, indicating CA1 contains local circuit motifs to generate ripples. In the 4th model, electrical coupling between PN axons and stochastic discharge are proposed to generate SWRs. But intracellular events and pharmacological properties of SWRs suggest neuronal discharge in SWRs are controlled by synaptic inputs. PN discharge in CA1 SWRs are preceded by GABAergic inputs and enhanced by axonal $GABA_A$ receptors. Recently, GABAergic axo-axonic chandelier interneurons (INs) have been reported to initiate SWRs in the amygdala. Using a large-scale CA1 network model, we present a conceptual microcircuit organization that includes chandelier INs to pace local feedback and feedforward circuits to generate SWRs. This model provides an intrinsic circuit and synaptic mechanisms for SWRs generation in the CA1 and reconciles discrepancies in previous models. This model predicts distinctive role for axo-axonic and axo-somatic GABAergic neurons in the generation of SWRs.

Title: Spatially heterogeneous cholinergic release generates theta-gamma coupling

Authors: *Y. YANG[1], H. GRITTON[2], M. SARTER[3], S. J. ATON[4], V. BOOTH[5], M. R. ZOCHOWSKI[6];

Abstract: Theta and gamma rhythms and their cross-frequency coupling contribute to attention and learning. While forebrain acetylcholine (ACh) signaling has been linked to theta-gamma coupling, an underlying mechanism has not been identified. Recent studies indicate that

cholinergic signaling is both temporally and spatially constrained, in contrast to the traditional notion of slow, spatially homogeneous, and diffuse neuromodulation. We show that spatially constrained cholinergic neuromodulation can generate theta-modulated gamma rhythms. Using biophysically-based excitatory-inhibitory (E-I) neural network models, the effects of ACh on neural excitability are simulated by varying the conductance of a muscarinic receptor-regulated K+ current. In E-I networks with local excitatory connectivity and global inhibitory connectivity, theta-gamma-coupled firing patterns emerge when ACh modulated network regions are spatially heterogeneous. Stable gamma activity occurs within regions of high ACh signaling, while theta or mixed theta-gamma activity occurs at the peripheries. Robust theta-gamma coupled activity occurs due to alternation at theta frequency of gamma activity between different high-ACh regions. These results are the first to indicate a causal role for spatially heterogenous ACh signaling in the generation of localized theta-gamma rhythmicity. Additional results provide novel insights into mechanisms by which ACh signaling supports attentional processing of sensory information.

Title: When, not if: Oscillations and active dendrites support fast spiking computations

Authors: *T. S. J. BURGER, M. E. RULE, T. O'LEARY;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Oscillations are found throughout the brain (Buszaki et al., 2004).On a cellular level, they control the spike timing of neurons (Jacobs et al., 2007), and on the behavioural scale they appear to define windows of perceptual awareness (Chakravarthi & VanRullen, 2012).Do oscillations merely correlate with these important variables, or are they used for functional purposes?We present a biophysically motivated model network that can implement a computation very quickly and reliably with a low number of spikes because the computation is orchestrated by oscillations.Endogenous oscillations synchronise spiking activity in the network, which is crucial for the quick integration of related inputs.With this synchrony in place the network can use the all-or-nothing nature of spikes to compute quickly.To make computations flexible the phase of oscillation should be separated from the decision of a neuron to spike.We

demonstrate that this can be achieved with an excitable dendrite.An excitable dendrite equips the neuron with a short memory for integrating inputs, and a dendritic threshold supports binary computations.Meanwhile the soma, influenced by the oscillation, decides when (not if) to spike.In doing so the oscillation defines time windows for the integration of inputs.This decouples the integration from the oscillation; the oscillation orchestrates, but does not change, the computation.We show that by separating the integration from the mechanism controlling the firing time of the soma, a network with these neurons can display synchrony and reliably perform a binary computation at the same time: it acts as a clocked binary circuit.The advantages are efficiency (a low number of neurons and spikes is required), speed, and robustness (to noise and parameter uncertainty).

Title: Network model provides insights into entorhinal cortex mechanisms of theta generation

Authors: *I. GUERREIRO[1], Z. GU[2], J. L. YAKEL[2], B. S. GUTKIN[1,3];
[1]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France; [2]Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC; [3]Ctr. for Cognition and Decision Making, Inst. for Cognitive Neuroscience, NRU SE, Moscow, Russian Federation

Abstract: Hippocampal theta oscillations are prominent 4-12 Hz rhythmic activities in the hippocampal field potential of all mammals studied to date. They have been linked to spatial and episodic memory formation. After decades of research, the origins of the hippocampal theta rhythm remain elusive. In particular, it is not clear how theta oscillations are generated as a result of the interactions among the three essential brain subregions - the septum, hippocampus and entorhinal cortex (EC).
Our recent experimental studies indicate that the EC may be the generator of theta rhythm in a septo-entorhinal-hippocampal brain slice coculture preparation. Not only does the EC leads the hippocampus in the timing of theta rhythm activities, but all hippocampal sub-regions are

synchronized, suggesting that they respond to a common rhythmic input from the EC. However, it is important to note that the EC itself requires hippocampal feedback to maintain the theta rhythm (Zhenglin and Yakel, 2017). In this work, we propose a circuit model of the EC to study the intrinsic properties of the EC that allow for external excitatory inputs to drive the system into an oscillatory regime. We use Izhikevich's two-dimensional QIF neuron model (Izhikevich, 2003) to describe the three major classes of neurons observed in the EC: stellate cells (S), pyramidal cells (E), and fast-spiking interneurons (I). We then take advantage of recently developed exact reduction methods to get a simplified, exact description of the three neural populations. Next, to study the contributions of the neural populations in the generation of the theta, we use a machine learning approach (Gonçalves et al., 2020) to infer the space of connectivity parameters that give rise to theta rhythmic activity in the EC network model. We find that while a subnetwork of S and E-cells is capable to robustly generate synchronized theta oscillations, the I-cells facilitate the generation of low-frequency theta rhythm. The I and E coupling effectively modulates the oscillatory frequency while the S and E intercoupling controls the magnitude of the oscillations. Thereby our modeling results point out complementary roles of the excitatory and inhibitory entorhinal subcircuits in theta rhythmic generation.

Title: Inhibitory neuron participation in simulated M1 neuronal avalanches

Authors: *D. DOHERTY, S. DURA-BERNAL, W. LYTTON;
SUNY Downstate Hlth. Sci. Univ., Brooklyn, NY

Abstract: Accumulating experimental evidence is consistent with the hypothesis that signal processing in the cerebral cortex is maintained near criticality. Proper balance must be maintained between excitation and inhibition to achieve synchronized activity among cortical neurons spanning a broad range of population sizes and durations. As previously presented, our data-driven detailed simulated mouse primary motor cortex (M1), when stimulated by a brief small unstructured current, produced self-organized and self-sustained neural dynamics with spikes clustered by size and duration distributed in log-log plot slopes around -1.5 and -2.0.We

analyzed avalanche durations and identified 4 population spiking patterns that combined to make up each individual avalanche: irregular pattern (exclusively in IT5B and IT6) and patterns with dominant frequencies -- delta (~1 Hz), beta (~22 Hz), and gamma (~40 Hz). We then clustered avalanches containing distinct combinations of these spiking patterns which gave us 4 main avalanche types: Irregular, Fragment, Beta, and Delta+ (note capital letters). Irregular avalanches are composed of only the irregular spiking pattern. Fragment avalanches are brief pieces of frequency-dominated avalanches. Beta, Delta+ contained the respective spiking patterns; the '+' indicating that many Delta+ included nested gamma, beta, irregular spiking patterns.Most Fragment avalanches included inhibitory neuron activity (95.0%+/-0.02%) compared to Irregular 0%; Beta: 100%; Delta+ 100%. The most active Fragment avalanche inhibitory neurons were somatostatin, neurons particularly in layer 2/3, included in 69.9% (SOM2/3) of the Fragment avalanches. Layers 5B and 6 somatostatin neurons were also active with 32.6% (SOM5B) and 35.4% (SOM6) respectively. Layer 5A somatostatin neurons were least active with 15.0% (SOM5A) included in Fragment avalanches. In contrast, a small number of parvalbumin neurons were active in Fragment avalanches, and only in layer 5, with 11.6% (PV5B) active in layer 5B, 6.4% in layer 5A, and 0.0% in the other layers (PV2/3 and PV6).

Abstract: Adult neural stem cells (NSC) were first isolated and characterized using cell culture about 30 years ago. However, recent advances in lineage tracing have elucidated that NSC

properties in vitro do not mimic their native behavior *in vivo*. We have developed a simple culture approach to recapitulate endogenous NSC fate choices. We determined that traditionally used growth factor concentrations promote NSC symmetric divisions while suppressing neuronal fate, and amplify glial-committed progenitors. Additionally, we have shown that high growth factor conditions increase the percentage of transit amplifying cells *in vitro*, a trend which is also replicated with mice treated with similar growth factor conditions *in vivo*. Instead, low growth factor application during an 'expansion phase' balances NSC symmetric, neurogenic, and astrogenic fate choices akin to multipotential NSC behavior *in vivo*. Our study provides an updated system to rapidly study new cell generation, neural circuit formation, and underlying mechanistic regulation.

Title: Blood vessel formation in a 3D scaffold is promoted by human neural stem cell-secreted material

Authors: *B. GUTIERREZ[1], L. A. FLANAGAN[2];
[1]UCI Anat. & Neurobio., Irvine, CA; [2]UCI Neurol., Irvine, CA

Abstract: Human neural stem/progenitor cells (hNSPCs) have the potential to widen the currently narrow therapeutic time window for stroke as hNSPC transplantation several days post-stroke improves functional recovery in rodent stroke models. Transplanted hNSPCs increase angiogenesis and neovascularization in the peri-infarct region and this is linked to functional recovery. However, the mechanisms by which hNSPCs stimulate an increase in vessel formation after transplantation are not fully understood. Our lab modeled the hNSPC-induced increase in

vessel formation *in vitro* by seeding hNSPCs and human endothelial progenitor cells (hEPCs) in a 3D scaffold composed of salmon fibrinogen, laminin, and hyaluronic acid that mimics brain tissue properties. Using our *in vitro* neurovascular model, we tested our hypothesis that hNSPC-secreted material plays a role in the stimulation of vessel formation. Our previous RNA-Seq data showed that hNSPCs express high levels of angiogenic growth factors, such as VEGF, PDGF, and TGF-B1, that could be secreted by hNSPCs to increase vessel formation. In order to determine the effect of hNSPC-secreted material on vessel formation, hEPCs were seeded in 3D scaffolds alone, with hNSPCs, or with hNSPC-conditioned media (CM). We found hNSPC-CM is sufficient to induce an increase in vessel length, area, and branch points, showing that hNSPC secreted material and not contact stimulates vessel formation. CM contains soluble factors and extracellular vesicles (EVs) secreted by hNSPCs. Inhibiting hNSPC exosome production and secretion diminished the effect of hNSPC-CM on vessel formation. In conclusion, material secreted by hNSPCs can recapitulate the increase in vessel formation induced by hNSPCs and secreted EVs, such as exosomes, may play a role in promoting vessel formation. HNSPC secreted material could be beneficial therapeutically since it could be used to treat stroke several days after the initial insult and avoids limitations of cell therapy.

Title: Homeobox Identity of Neural Stem Cells is Maintained Outside of a Developmental Context

Authors: *W. MCINTYRE[1,2], M. KHAZAEI[2], M. G. FEHLINGS[1,2];
[1]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [2]Krembil Res. Inst., Toronto, ON, Canada

Abstract: ***Background***: Neural Stem Cell (NSC) therapy is a promising regenerative strategy to treat central nervous system (CNS) injury because NSCs replace the diverse cell niche that reflects a pre-injured state. However, an NSCs ability to integrate with spared tissue in a transplant environment has been suboptimal, which has halted NSC therapies from advancing into the clinic. The discordant identity of NSC grafts to their respective region of the CNS is perhaps responsible for their limited regenerative success. Supporting this, spinal-derived NSC grafts transplanted into the injured spinal cord promotes the greatest extent of regeneration when compared with brain-derived NSC grafts. Interestingly, an unexplored explanation for this may be conferred through the expression of regional-identifying transcription factors: Homeobox

(*Hox*) genes. During development, region-specific *Hox* promotes the localization of cells in the brain & spinal cord, and ensures appropriate neuronal connectivity to promote motor and sensory functions. Thus, if *Hox* genes are maintained in NSCs cultured for transplantation, this may suggest their developmental role is recapitulated during optimal regenerative attempts. ***Hypothesis***: We hypothesize that (b) brain and (s) spinal cord-derived NSCs will retain region-specific *Hox* expression following isolation, expansion, and differentiation *in vitro*. ***Methods:*** bNSCs and sNSCs (N=9), with distinct *Hox* expression *in vivo*, were dissected from the subventricular zone of the brain and central canal of the spinal cord, respectively. Subsequently, NSC colonies were expanded for several passages and differentiated *in vitro*. Gene and protein *Hox* expression was evaluated using RT-qPCR and Western blot, respectively. Each NSC's differentiation profile were assessed using immunocytochemistry. ***Results:*** Following both expansion and differentiation *in vitro*, both bNSCs and sNSCs retained region specific *Hox* expression. bNSCs maintained a greater proportion of brain-specific markers compared to sNSCs (*Otx2*, *FoxG1*, *Emx2*), whereas bNSCs did not express any spinal cord-specific markers (*Hox4-9*). Notably, each NSC line exhibited tripotency by producing neurons, oligodendrocytes, and astrocytes, a hallmark of NSC colonies. ***Conclusions:*** NSCs derived from developmental *in vivo* niches retain their developmental characteristics *in vitro*. This suggests that successful NPC transplants in experimental therapies may be due to the maintenance of *Hox* expression. Future work will involve evaluating the maintenance of NSC *Hox* identity in experimental CNS injury.

Title: Stat3 induces hypoxic preconditioning against oxidative stress in neural stem cells

Authors: *H. KINOUCHI, **N. FUKUDA**, T. WAKAI, T. TATEOKA, H. YOSHIOKA; Univ. of Yamanashi, Fac of Med., Chuo, Japan

Abstract: Transplantation of neural stem cells (NSCs) has been proposed as a promising therapeutic strategy in stroke; however, oxidative stress in ischemic host brains remarkably reduces the number of surviving transplanted cells. Hypoxic preconditioning (HP) is one of the approaches to improve the ability of NSCs to survive in harsh environments, but the mechanisms of such phenomenon are obscure. Activation of signal transducer and activator of transcription 3 (STAT3) via Janus kinase 2 (JAK2) induces cell differentiation and regulates proliferation in

NSCs, and also plays a pivotal role in hypoxia/ischemia-induced preconditioning in various type of cells. Accordingly, STAT3 may contribute to the beneficial effects of HP in NSCs, however, its role is not well elucidated. In this study, we investigated the role of STAT3 and the representative downstream signals such as vascular endothelial growth factor (VEGF) and cyclin D1 in hypoxic preconditioned NSCs. For the induction of HP, NSCs isolated from neonatal C57BL/6 mice were exposed to 5% hypoxia for 24 hours. HP significantly decreased cell injury of NSCs, and enhanced the viability against H_2O_2-mediated lethal oxidative stress. Western blot analysis revealed that the phosphorylation of JAK2 and STAT3, the activated forms of these proteins, was significantly increased after HP. Moreover, HP increased the concentration of VEGF in the culture media and the expression of Cyclin D1 in the cells. The administration of STAT3 inhibitor significantly suppressed the activation of STAT3 and the upregulation of the downstream signals, resulting in the diminishment of the efficacy of HP in oxidative injury. Our results suggest that the activation of STAT3 could induce HP in NSCs against oxidative stress, which might be due to protective function of autocrine/paracrine VEGF and cell proliferative effects of cyclin D1. Activation of this pathway could be a treatment strategy to improve the efficacy of cell therapy in stroke.

Title: Development of a microfluidic ‘brain-on-chip’ device as an in vitro platform for 3D neural system development and analysis

Authors: *C. FONDER[1], R. YANG[2], T. SYLVESTER[1], S. PENG[1], L. QUE[2], D. SAKAGUCHI[1];

Abstract: In recent years, organ-on-chip models have become increasingly valuable due to their ability to provide a microenvironment platform for three-dimensional (3D) tissue development, which can mimic the interactions of in vivo cells and tissues. Brain-on-Chip models allow for

mimicking neural tissue that is not possible using conventional two-dimensional cell culture techniques which can facilitate study of various neurological disorders, such as Alzheimer's disease, or be used as a tool for drug screening. In our exploratory in vitro study, rat adult hippocampal progenitor cells (AHPCs) were cultured as dissociated cells and non-adherent neurospheres within a novel microfluidic device to determine if these devices allowed for the 3D culturing of the progenitor neural stem cells. The polydimethylsiloxane (PDMS) microfluidic device was fabricated by soft-lithography. Each 2 x 2 cm chip consisted of three independent "S"-shaped microarrays containing 15 microwells for cell culture. The AHPCs were cultured within the microfluidic devices for up to 12 days in vitro (DIV) in either conditioned culture media and/or differentiation media. The formation of neurospheres and their growth was analyzed by evaluating neurosphere size over the 12-day growth period by quantifying the average neurosphere diameter and perimeter distance of neurospheres within the microfluidic devices from 0 to 12 DIV. At 3, 7, and 11 DIV, the AHPCs were fixed and stained with propidium iodide (PI) to evaluate cell viability within the microfluidic devices, with results showing high cell viability at all timepoints for each media condition. At 7, 10, and 12 DIV, AHPCs were fixed and immunolabeled to evaluate proliferation (Ki-67) and cell differentiation looking at cell-type specific markers for neurons (TuJ1 and MAP2ab), oligodendrocytes (RIP), and astrocytes (GFAP) within the microfluidic devices for each timepoint. These results showed that AHPC neurospheres can be successfully generated and propagated within these novel microfluidic devices with continuing cell proliferation (Ki-67 expression) and neurosphere growth overtime for both media conditions. Immunolabeling with the cell-type specific markers indicated differentiation of multiple neural cell types within the growing neurospheres. Fabrication of microfluidic devices can be used to develop preliminary Brain-on-Chip models which may be useful to evaluate neurological disorders and act as drug screening platforms.

Abstract: Two-dimensional (2D) materials have the potential to become the functional elements of future bio-neuro-electronic interfaces. So far, studies directed towards understanding their biocompatibility have mostly utilized exfoliated flakes and suspensions resulting in large uncertainty and discrepancies in their cytotoxicity measures. In this work, as a first step before incorporating them in interface devices, we have performed a comprehensive experimental study of *in vitro* cell-viability of large-scale sheets of electronics-grade 2D materials that include platinum diselenide ($PtSe_2$), platinum ditelluride ($PtTe_2$), molybdenum disulfide (MoS_2), and graphene. These materials were selected because of their superior electronic and mechanical properties, and their atomically thin layered structure which facilitates efficient surface chemical functionalization. We cultured embryonic stem cells (ESCs) and ESC-derived motor neurons (MNs) on the surface of these large-area 2D sheets and quantified cell-viability using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay and the Lactate Dehydrogenase (LDH) assay. Live-dead fluorescence imaging was performed to qualitatively understand the trends in cellular growth and proliferation. The results suggest that $PtSe_2$ displays cell-viability values on par with those of the controls, graphene, and MoS_2. Contrarily, $PtTe_2$ displays the lowest cell-viability value amongst all the 2D materials when observed through the lens of the MTT assay but displays cell-viability similar to that of the controls when observed through the lens of the LDH assay. We provide additional confirmatory tests to validate $PtTe_2$'s anomalous and area-dependent biocompatibility behavior. We believe the results from these *in vitro* biocompatibility experiments can help large-area 2D materials become an alternative for future cell-culture scaffolds and bio-neuro-electronic implants.

Title: Emergence of structured neural activity in human brain organoids with maturation

Authors: *K. G. MENSAH-BROWN[1], J. T. LIM[1], C. D. ADAM[1], D. JGAMADZE[1], G.-L. MING[2], H. SONG[2], J. A. WOLF[1], H.-C. I. CHEN[1];
[1]Neurosurg., [2]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Background: Brain organoids are 3D, stem cell-derived neural tissues that recapitulate neurodevelopment. Recently, they have been used to model Zika virus-induced microcephaly and GBM. Additional clinical applications could include modeling other relevant brain disorders or as structured substrate to repair brain circuitry. However, before we can levy their full translational potential, a deeper understanding of their intrinsic neural activity at the single cell and network level is essential. Here, we present our preliminary analysis of this activity in human forebrain organoids.
Methods: Organoids were generated from hiPSC lines derived from healthy volunteers. Linear microelectrode probes were employed to record extracellular activity from DIV77, 100, and 130 organoids. Extracellular recordings were collected at baseline and following the addition of MK-801 and NBQX. The recordings were processed with offline spike sorting followed by spatiotemporal analysis to characterize baseline unit and network characteristics across age groups.
Results: Nine organoids were recorded successfully (n=3 per time point). A significant difference in unit number was seen ($p < 0.05$). Post hoc comparisons using the Tukey HSD test showed significantly more units at DIV130 (51.67±14.15) than DIV100 (17.67±7.57) and 77 (16.33±14.98). A significant difference in baseline firing rate was observed ($p < 0.05$) with a higher baseline firing rate at DIV130 (0.83Hz ± 0.17) and DIV100 (0.86±0.40) than DIV77 (0.31Hz±0.06). A significant difference in fold response of firing rates to MK-801 and NBQX was seen ($p < 0.05$) with greater fold decreases in firing rate at DIV130 (-24.17%) and DIV100 (-36.81%) compared to DIV77(+1.2%). Global synchrony did not differ among age groups. However, there was a significant difference in the size of statistically significant synchronous unit clusters with larger clusters occurring at DIV100 than DIV77 and 130. Preliminary network analysis through spike time tiling coefficients (STTC) showed the emergence of functional connectivity across age groups. However, at these early time points, network topology showed no modularity or small-world features.
Conclusion: Consistent with findings from 2D cortical cultures, our data reflects increasing excitatory network activity with maturation. Furthermore, the reduction in the average size of clusters alongside the emergence of network connectivity could corroborate evidence of smaller, more efficient cell assemblies and increasingly complex neural activity. Additional work in this area will confer a better sense of how to rationally utilize brain organoids for translational purposes.

Title: Cell extract from adipose tissue-derived stem cells promotes peripheral nerve regeneration

Authors: *Y. KOYAMA[1], N. KISHIMOTO[1], Y. IMAI[1], J. TANUMA[2], K. TAKEUCHI[4], T. MAEDA[3], K. SEO[1];
[1]Div. of Dent. Anesthesiol., [2]Div. of Oral Pathology, [3]Ctr. for Advanced Oral Sci., Niigata Univ. Grad Sch. Med. Dent., Niigata, Japan; [4]Dept.of Med. Biology, Sch. of Med., Aichi Med. Univ., Aichi, Japan

Abstract: Background: Peripheral nerves are well known to regenerate after injury, but this can induce neuroma, which results in intractable pain. The healing process receives enhancing or inhibitory signals from Brain-derived neurotrophic factor, VEGF, and semaphorin 3A. These factors mediate Schwann cells (SCs), vascular tissue, and neurons, which suggests that regeneration of injured nerves requires the contribution of these factors. However, it is difficult to control these factors simultaneously during the regenerative process. Adipose tissue-derived stem cells (ADSCs) have the potential to regenerate several tissues. A cell extract (CE) from ADSCs (CE-ADSCs) promotes functional recovery of salivary glands. Thus, CE-ADSCs may be applied to the treatment of injured peripheral nerves. In this study we examined the effect of CE-ADSCs on SCs and neurons in vitro and immunohistologically investigated the effects on axonal regeneration and localization of SCs in vivo.Animals/Methods: Adipose tissue was obtained from male C57B6/J mice and treated with collagenase. The stromal vascular fraction was cultured to establish ADSCs. CE was prepared by repeated freezing and thawing of ADSCs and centrifugation. CE-ADSCs was applied to SCs or PC12D cells, and the SC proliferation ability and protrusion elongation of PC12D cells were examined.Immunohistochemistry: Male SD rats (6 weeks old) were divided into three groups: nerve exposure surgery only (sham group), saline administration (control group; CG), and CE-ADSC administration (CE group; CEG). The inferior alveolar nerve (IAN) in the rat was transected. Seven days after the transection, fixation was performed by perfusion. The IAN was cut into a sagittal section. Fluorescence immunohistochemical staining was performed using primary antibodies against Protein gene product 9.5, Pan-neurofilament (pNF), and Myelin protein zero (MPZ), and secondary antibodies (Alexa Fluor® 488 and 594).Results: CE-ADSCs increased the number of SCs and PC12D cells with protrusion elongation. Immunohistology showed nerve fibers sprouting in the radiating direction and randomly extending in the distal site from the proximal stump in the control group, whereas regeneration of nerve fibers was observed in the CEG. Double staining for pNF and MPZ showed that fusiform myelin accompanied the axon at the proximal site, but that there was a lack of the axon that accompanied myelin at the distal site.Conclusion: CE-ADSCs might promote peripheral nerve regeneration by inducing proliferation of SCs and enhancing axon regeneration.

Title: Using single-cell transcriptomics to explore the transcriptomic variance underlying the different axon regeneration ability between sensory neuron subtypes

Authors: *X.-W. WANG[1], M.-W. HU[2], C. ZHANG[1,3], Y. ZHANG[1], J. QIAN[2], F.-Q. ZHOU[1,4]; [1]Orthopaedic Surgery, [2]Ophthalmology, [3]Anesthesiol. and Critical Care Med., [4]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Dorsal root ganglion (DRG) neurons are pseudo-bipolar neurons with two axonal branches, a peripheral branch innervating their target organ, and a central branch relaying somatosensory information into the central nervous system. The peripheral branch can readily regenerate upon peripheral axotomy, largely due to the activation of regenerative transcription programs. Thus, sensory neurons in the DRG provide a perfect model system to study the mechanisms underlying axon regeneration at the transcription level, and many studies have been built on this basis. However, as a highly heterogeneous neuronal population, sensory neurons in the DRG are comprised of many anatomically and functionally different subtypes that are likely to respond differently to peripheral axotomy. In addition, it has been previously reported that various subtypes possess different axon regeneration ability. Thus, to understand the transcriptomic difference underlying the different axon regeneration ability between various subtypes, we performed single-cell RNA-seq on DRG sensory neurons from mice receiving sham or sciatic nerve transection, by combining a sensory neuron specific GFP reporter mouse line, and the single-cell gene expression technique (10x genomics). After removal of low-quality cells and doublets, we identified 13 neuronal clusters from a total of 17,690 DRG neurons that can be categorized into non-peptidergic nociceptors (NP), peptidergic nociceptors (PEP), neurofilaments (NF), and C-fiber low-threshold mechanoreceptors (cLTMR). No significant

change of identified clusters or novel clusters were observed within 24 hours after injury. Using 297 genes known to be upregulated in the DRG by peripheral axotomy, we calculated a regeneration score for each neuron to evaluate the axon regeneration potential of the 13 identified neuronal clusters. The analysis revealed that one of the NP clusters had the lowest average regeneration score, suggesting that it may have the least ability in axon regeneration compared with other clusters. In addition, some clusters from NP, NF and cLTMR showed bimodal in the distribution of the score, indicating neurons of the same subtype may also have rather different axon regeneration ability.

Title: Caldendrin is a negative regulator of neurite growth in dorsal root ganglion neurons

Authors: *J. A. LOPEZ[1], A. YAMAMOTO[1], J. VECCHI[1], J. HAGEN[1], K. LEE[2], M. SONKA[2], A. LEE[3];
[1]Mol. Physiol. and Biophysics, [2]Iowa Inst. for Biomed. Imaging, Electrical and Computer Engin., Univ. of Iowa, Iowa City, IA; [3]Otolaryngology Head-Neck Surgery, and Neurology; Dept. of Neuroscience,, Univ. of Texas-Austin, Austin, TX

Abstract: Caldendrin is a calmodulin-like Ca^{2+} binding protein that is expressed primarily in neurons and regulates multiple effectors including Ca_v1 L-type Ca^{2+} channels. Here, we tested the hypothesis that caldendrin regulates Ca_v1-dependent pathways that repress neurite growth in dorsal root ganglion neurons (DRGNs). By immunofluorescence, caldendrin was localized in medium- and large- diameter DRGNs. Consistent with an inhibitory effect of caldendrin on neurite growth, neurite initiation was enhanced, and the rate of neurite growth was faster, in dissociated DRGNs and DRGN explants, respectively, from caldendrin knockout (cald-KO) mice compared to those from wild type (WT) mice. In an *in vitro* axotomy assay, cald-KO DRGNs grew longer neurites via a mechanism that was more sensitive to inhibitors of transcription as compared to WT DRGNs. Strong depolarization, which normally represses neurite growth through activation of Ca_v1 channels, had no effect on neurite growth in DRGN

cultures from female cald-KO mice. Remarkably, DRGNs from cald-KO males were no different from those of WT males in terms of depolarization-dependent neurite growth repression. We conclude that caldendrin opposes neurite regeneration and growth, and this involves coupling of Ca_v1 channels to growth-inhibitory pathways in DRGNs of females but not males. Our findings suggest that cald-KO mice represent an ideal model in which to interrogate the transcriptional pathways controlling neurite regeneration and the mechanisms that distinguish these pathways in males and females.

Title: Loss of the axon initial segment inhibits axon regeneration

Authors: *L. H. TELISKA, M. N. RASBAND;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Peripheral nervous system (PNS) injury can be caused by a variety of traumas and has symptoms ranging from temporary numbness and mild pain to complete loss of feeling and motor control. Therapeutic targets for these injuries will require a comprehensive understanding of the mechanisms of regeneration. In neurons, the axon initial segment (AIS) is essential to generate the action potential and to maintain neuronal polarity. AnkyrinG (AnkG) is the master organizer of the AIS and functions to cluster voltage-gated sodium and potassium channels, as well as cell adhesion molecules. When AnkG is lost, the AIS is dismantled, leading to protein mistrafficking between somatodendritic and axonal domains. There are many examples of AIS disruption in injury and disease. However, the role of the AIS in axon regeneration is not well understood. We tested if the AIS is necessary for axon regeneration. We compared axon regeneration in control and AIS-deficient mice. AIS-deficient mice were generated by removing AnkG from motor neurons using *ChAT-Cre; AnkG$^{F/F}$* mice. We induced PNS injury at postnatal day 21 using a sciatic nerve crush model, then evaluated axon innervation of the lumbrical muscles in the foot. We used immunofluorescence microscopy and recorded compound muscle action potentials to determine if structural and functional recovery occurred after injury. Our data show that axon regeneration is significantly inhibited in the *ChAT-Cre; AnkG$^{F/F}$* mice compared to control mice. At 14 days post crush (DPC) there was 66% and 3% reinnervation of the NMJ in

control and *ChAT-Cre; AnkG$^{F/F}$* mice, respectively. Synapse function fully recovered by 21 DPC in control mice, but synapse function never completely recovered even by 35 DPC in *ChAT-Cre; AnkG$^{F/F}$* mice. Future work will focus on determining why loss of the AIS inhibits axon regeneration. Since the AIS has been shown to maintain polarity in neurons, we will combine mRNA and proteomic approaches to determine if trafficking is disrupted in regenerating axons that lack an AIS. These data will enable us to better understand the role of the AIS in PNS axon regeneration.

Abstract: Complete motor functional recovery is virtually non-existent in patients with proximal peripheral nerve injury (PNI), largely due to the slow rate of axon regeneration leading to chronic target denervation after PNI. In central nervous system (CNS), most of the injured axons failed to regenerate due to the poor intrinsic regenerative capacity of adult neurons. The presence of growth-inhibitory molecules at the lesion site further limited the extent of axonal regrowth after CNS injuries. This remained the major challenge for scientists to identify effective drugs to enhance the intrinsic regenerative capacity and facilitate considerable axon regeneration after nerve injuries. Our pilot study demonstrated that *Lycium barbarum* polysaccharides (LBP), the major bioactive constituent in wolfberry, markedly enhanced the intrinsic growth capacity of axotomized peripheral neurons and accelerated *in vivo* sensory and motor functional recovery after severe PNI. To delineate the molecular mechanisms underlying the growth-promoting effects of LBP, we performed weighted gene co-expression network analysis (WGCNA) on the

microarrays of DRGs from LBP-treated mice. Our WGCNA indicated that LBP treatment induced up-regulation of key regeneration-associated genes and inhibited the expression of growth-inhibitory molecules. Subsequent *in silico* screening using LBP-induced key gene signatures identified two FDA-approved bioactive small molecules that recapitulated the growth-promoting effects of LBP. These two small molecules not only accelerated *in vivo* axonal regrowth after PNI, but also induced sustained axon regeneration after optic nerve crush (ONC) injury. Some of the injured axons can regenerate the entire length of optic nerve and reached optic chiasm 4 weeks after injury. To test if such extent of axonal regrowth was sufficient to elicit neural activity after ONC, we performed local field potential (LFP) recordings at superior colliculus (SC) upon optogenetic activation of injured retinal ganglion cells 6 weeks after ONC. While we failed to detect eye-evoked LFPs in vehicle-treated mice, mice treated with one of these two small molecules could elicit reliable eye-evoked LFP responses at SC 6 weeks after ONC. More remarkably, mice treated with this small molecule could partially restore the pupillary light reflex to constrict the pupil upon light stimulation to the injured eye. Taken together, our study highlighted the therapeutic potential of LBP and these two FDA-approved small molecules for functional recovery in patients with nervous system injuries. Further studies are required to optimize the dosage regimen for maximal clinical outcomes.

Title: Cspg sulfation prevents sympathetic nerve regeneration following myocardial infarction

Authors: *M. R. BLAKE[1], S. SUEDA[2], B. A. HABECKER[1];
[1]Chem. Physiol. & Biochem., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Portland State Univ., Portland, OR

Abstract: Sympathetic denervation of the heart following Myocardial Infarction (MI), which is sustained by chondroitin sulfate proteoglycans (CSPGs) in the cardiac scar, predicts risk of sudden cardiac death. Previous work demonstrated that blocking CSPG signaling restored

sympathetic axon outgrowth into the cardiac scar, decreasing arrhythmia susceptibility. Growth inhibition by CSPGs is thought to depend on the sulfation status of the glycosaminoglycans (GAGs) attached to the core protein. In the central nervous system, tandem sulfation of CSPGs at the 4th (4S) and 6th (6S) positions of n-acetyl-galactosamine is thought to be a primary inhibitor of axon outgrowth. It is not known if CSPG sulfation prevents sympathetic nerve regeneration. Our data suggest that CSPG sulfation prevents sympathetic axon outgrowth just as it alters regeneration in the CNS. Sympathetic neurite outgrowth across purified CSPGs is restored *in vitro* by removing 4S-CSPGs with the enzyme Arylsulfatase-B (ARSB). Neurite outgrowth across CSPGs was reduced to 69% of control levels while pre-treatment of CSPGs with increasing amounts of ARSB restored outgrowth to control levels in a dose dependent manner. Additionally, we co-cultured cardiac scar tissue with sympathetic ganglia *ex vivo* and found that removing 4S-CSPGs with ARSB restored axon outgrowth to control levels. Axon outgrowth towards infarcted myocardium was reduced to 66% of control (healthy myocardium) levels while treatment of infarcted myocardium with ARSB restored axon outgrowth to 97% of control levels. We examined levels of the enzymes responsible for adding and removing sulfation to CSPG-GAGs by western blot to determine if they were altered in the left ventricle after MI. We found that CHST11 (4-sulfotransferase) was downregulated, CHST15 (4S dependent 6-sulfotransferase) was upregulated, and ARSB (4-sulfatase) was downregulated after MI. This change was preceded by increased expression of Galectin 3, a key regulator of the inflammatory fibrotic response after ischemic injury. Increased CHST15 combined with decreased ARSB suggest a mechanism for production and maintenance of sulfated CSPGs in the cardiac scar.

Title: Transcriptomic changes toward brain remodeling in response to silk-based wearable bioreactor induced hindlimb regeneration in a non-regenerative animal model system

Authors: *N. MURUGAN[1], M. SPERRY[2], K. MILLER[3], *Q. PHAN[3], N. ROULEAU[1], D. KAPLAN[4], M. LEVIN[5];

[1]Algoma Univ., Sault Sainte Marie, ON, Canada; [2]Wyss Inst. at Harvard, Boston, MA; [3]Allen Discovery Ctr., Medford, MA; [4]Biomed. Engin., Tufts Univ., Medford, MA; [5]Tufts Univ., Medford, MA, Canada

Abstract: Advances in regenerative medicine and biomedical engineering are yielding tools with which the limbs of non-regenerative models can be regrown and repatterned following experimental amputations. The prospect of restoring form and function by initiating autopoietic tissue programs without genetic micromanagement is becoming a realistic possibility with significant clinical implications. However, as technologies rapidly develop, one significant set of challenges that must be addressed are the short- and long-term neuroplastic responses to injury and regeneration including neuropathic pain and the phantom limb phenomenon. Our silk-based wearable bioreactor - the Biodome - can successfully deliver time-released, multi-drug treatments to regrow and repattern limbs in *X. laevis* with new skin, muscle, bone, vasculature, and notable regrowth of peripheral nerve fibers and restoration of efferent neuromuscular connections. Indeed, sensorimotor responses in regenerated limbs were indistinguishable from non-amputated wild types, indicating complete regain of function. These results also include an evaluation of brain reorganization. Here, we present next generation sequencing (NGS) data from the brains of animals extracted 11hr, 24hr, and 7d post-amputation, comparing frogs treated with a Biodome intervention to animals receiving amputation only. We identified significant enrichment of genes associated with the reorganization of the brain's extracellular matrix (ECM), cell-cell interactions, porphyrin metabolism, and heme biosynthesis - particularly after 24hrs and 7d. These changes within the central nervous system reflect similar changes that we originally identified within the regenerating blastema proximal to the amputation site. A parallel immune signaling pathway revealed by transcriptomic analysis may represent a mechanism linking peripheral tissue repatterning and central nervous system plasticity. Together, these findings suggest the long-range transfer of information from local events in the distal hindlimb to the brain. In addition to revealing the systemic propagation of regenerative state information through the body, our data suggest the hypothesis that induced brain remodeling soon after intervention may functionally support long-term limb regeneration in non-regenerative systems.

Title: Effects of cell extract from adipose-derived stem cells on peripheral nerve regeneration

Authors: *Y. IMAI[1], N. KISHIMOTO[1], Y. KOYAMA[1], J. TANUMA[2], K. TAKEUCHI[4], T. MAEDA[3], K. SEO[1];
[1]Div. of Dent. Anesthesiol., [2]Div. of Oral Pathology, [3]Ctr. for Advanced Oral Sci., Niigata Univ. Grad Sch. Med. Dent., Niigata, Japan; [4]Dept.of Med. Biology, Sch. of Med., Aichi Med. Univ., Aichi, Japan

Abstract: *BACKGROUND*: Adipose-derived stem cells (ADSCs) have the potential to trans differentiate into other tissue types, such as nervous system or myocardial tissue. Cell extract produced from ADSCs (CE-ADSC) promotes functional recovery of the salivary gland, suggesting that some factors in CE-ADSC can induce tissue regeneration. This study aimed to investigate whether CE-ADSC has a regenerative effect on peripheral nerve tissue using incubated nerve cells. *METHODS*: ADSCs were isolated from adipose tissue from 8- to 15-week-old C57BL/6J mice, and CE-ADSC was then extracted by the repeated freezing and thawing of ADSCs. To evaluate the regenerative effects of CE-ADSC on nerve tissue, two experiments were performed. First, changes in proliferative capacity (using the MTT assay) and glial fibrillary acidic protein (GFAP) expression levels (using enzyme-linked immunosorbent assay) were compared before and after CE-ADSC application in immortalized rat Schwann cells (Cosmo Bio Ltd, Tokyo). In addition, the effects of CE-ADSC on rat dorsal root ganglion (DRG) neurons were evaluated by calculating the number of neurite-bearing cells (neurons with neurites that were longer than the cell body diameter) and by measuring the lengths of the neurites. Second; CE-ADSC that had been heated to 95℃ or treated with proteinase K was applied to the Schwann cells and DRG neurons, and the same changes in proliferative capacity and the number of neurite-bearing cells were measured. Statistical analysis was performed using *t*-tests or non-repeated measures analysis of variance (ANOVA), and the $p < 0.05$ was considered significant. *RESULTS*: (1) CE-ADSC increased proliferation (non-repeated measures ANOVA, $p < 0.01$) and GFAP expression (*t*-test, $p < 0.01$) in Schwann cells. (2) CE-ADSC increased the number of neurite-bearing cells (non-repeated measures ANOVA, $p < 0.01$) and the lengths of neurites (*t*-test, $p < 0.05$) in DRG neurons. (3) Heat or proteinase K treatment decreased the total amount of protein in CE-ADSCs; this inhibited both the proliferation of Schwann cells and the number of neurite-bearing cells (non-repeated measures ANOVA, $p < 0.05$). *CONCLSIONS*: Some proteins in CE-ADSC might have a regenerative effect on peripheral nervous cells. (This study was supported by JSPS 19H03850, 19K10261)

Title: Strategies to Optimize Functional Recovery in Distal Nerve Transfers

Authors: *J.-L. B. SENGER[1], K. N. RABEY[2], L. ACTON[2], S. LIN[2], K. CHAN[2], C. A. WEBBER[3];

Abstract: Strategies to optimize functional recovery in distal nerve transfers
Background: Distal nerve transfers (DNTs) are a popular reconstructive technique for peripheral nerve injuries. In this surgery, the distal motor targets of an injured nerve are reinnervated by a redundant branch of a nearby functioning nerve. As DNTs require the donor nerve to innervate new targets, synaptic plasticity is integral to success. Exercise therapy improves plasticity and enhances regeneration following a nerve injury, but its effects have never been evaluated in DNTs. We have recently shown that conditioning electrical stimulation (CES) significantly improves recovery following DNT. In this study we compare the effects of preoperative CES and postoperative exercise therapy on regeneration, reinnervation, and recovery following a lower limb DNT.**Methods**: Sprague-Dawley rats were divided into four cohorts i) CES, ii) exercise training, iii) CES and exercise training (CES-ExT), and iv) DNT. The common fibular nerve of all animals was crushed. Seven days later, CES was delivered to the tibial nerve. Fourteen days post-injury, a DNT was performed by coapting a tibial nerve branch to the common fibular nerve. Post-operatively, animals were run daily on a treadmill for either four ('short-term') or thirteen ('long-term') weeks. Outcomes included axonal extension, gait analysis, and skilled locomotion testing.**Results**: Animals treated with CES-ExT had significantly greater regeneration and functional recovery. The length of axon extension in CES-ExT nerves was significantly longer than other cohorts ($p<0.05$). These animals had significantly improvements on the horizontal ladder test and earlier recovery of dorsiflexion when compared to other cohorts. Restoration of a symmetrical gait was significantly improved ($p<0.01$) among CES-ExT treated animals, with increased weight-bearing and increased contact-time of the affected limb compared to the other groups ($p<0.01$). No significant difference was identified between short- and long-term exercise training.**Conclusions**: The combination of CES-ExT enhances regeneration and functional recovery following DNT. Both electrical stimulation and exercise training are clinically feasible, therefore, this perioperative regimen may be a strategy to significantly improve functional recovery for patients undergoing a DNT.

Title: Injury to the peripheral axon of dorsal root ganglia neurons alters the centrally projecting axonal transcriptome

Authors: *T. SMITH[1], J. MARRYAT[1], Q. WANG[2], R. KAWAGUCHI[2], J. TWISS[1];
[1]Dept. of Biol. Sci., Univ. of South Carolina, Columbia, SC; [2]Dept. of Psychiatry and Neurol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: The sensory neurons in dorsal root ganglia (DRG) are pseudounipolar, projecting one axon into the periphery and another into the spinal cord. Injury to the peripheral axon results in a robust regeneration response, whereas injury to the central axon does not. It is well established that initiation of an intrinsic growth program following injury to the peripheral nerve contributes to regeneration of the peripheral axon. Our lab has shown that mRNAs encoding growth-associated proteins, like growth-associated protein 43 (GAP-43), increase in the peripheral axons after injury, and the local translation of these mRNAs in the axon supports nerve regeneration. The possibility that peripheral nerve injury might also alter mRNA transport into centrally projecting sensory axons has not been tested. Alterations in transport and translation of mRNAs in centrally projecting sensory axons could alter their plasticity or function in the CNS, possibly contributing to pain signaling. We initially screened central dorsal roots for candidate mRNAs known to be increased in peripheral axons after axotomy. By RTddPCR using extruded axoplasm and FISH/IF, we found that *Gap-43* and *galanin* mRNAs are significantly increased in dorsal root axoplasm 7 days after sciatic nerve crush. Surprisingly, the increase in *galanin* mRNA is more substantial in the dorsal root than it is in the sciatic nerve. This initial screen raised the possibility that mRNA transport into centrally projecting DRG axons can be regulated differently than transport into the peripherally projecting axons. To systematically test this possibility, we performed RNA-Seq analyses of dorsal root axoplasm, sciatic nerve axoplasm, and DRG under naïve conditions and after sciatic nerve crush. We found 34 differentially expressed genes in the central axons and 1,223 in the peripheral axons after crush injury. 8 were seen in both the central and peripheral axons, while 16 were unique to the central axon and 1,087 unique to the peripheral axon. These results indicate that the transcriptome of the centrally projecting DRG axons is indeed altered by peripheral nerve injury, and mRNAs can be differentially directed to the periphery or to the central nervous system.

Title: Pura drives axonal localization of Calreticulin mRNA through conserved UTR motifs

Authors: *M. ZDRADZINSKI[1], S. J. LEE[1], J. OSES-PRIETO[2], A. BURLINGAME[2], J. TWISS[1];
[1]Univ. of South Carolina, Columbia, SC; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Neurons are highly polarized cells with widely separated and specialized subcellular domains that are essential for function of the nervous system. Axons provide long-range connections in the nervous system and axons can extend from a few millimeters to a few meters depending on size of the organism. Axons locally synthesize proteins autonomous from their cell body that support growth, survival, and function of axons. Localization of mRNAs into axons is determined by proteins binding to sequence elements within the mRNA, and these are often present in the untranslated regions (UTRs) of the RNAs. Local translation of Calreticulin mRNA (Calr) in injured axons was reported to support initiation of regeneration. We have previously shown that Calr utilizes conserved regions in its 3' UTR to localize to axons. The 5' UTR of Calr is necessary for local translational regulation within axon but this regulation requires presence of a 3'UTR localization motif raising the possibility for common protein mediators binding to both UTRs, but the RNA binding proteins (RBPs) that mediate this post-transcriptional regulation of neuronal Calr mRNA are not known. We performed RNA affinity mass spectrometry (RAMS) analyses using the conserved Calr 5' and 3'UTR regions as baits to identify axonal proteins interacting with these motifs. 42 proteins were identified as high specificity interactors for Calr's 5' and/or 3'UTR motifs. Of these, only PurA and Ncl bound to both the functional 5' and 3'UTR Calr motifs. Using biotinylated RNA, PurA validated as precipitating with both the 5' and 3' UTR Calr motifs. RIP analyses for PurA protein immunoprecipitants, showed that endogenous Calr binds to these RBPs in sciatic nerve axoplasm. By high resolution single molecule FISH/IF, PurA colocalizes with Calr mRNA in axons of cultured rat DRG neurons. Depletion of PurA from these cultures decreased axonal Calr mRNA levels. Together, these data indicate that PurA is needed for the axonal localization and translation of the mRNA encoding the axon injury response protein Calreticulin.

Title: Loss of the lipid phosphatase Fig4 results in decreased axonal mRNA transport and mitochondrial dysfunction

Authors: *I. DALLA COSTA[1], J. MONEY[1], H. R. CHILLURA[1], A. N. KAR[1], J. OSES-PRIETO[2], R. KAWAGUCHI[3], A. BURLINGAME[2], R. J. GIGER[4], P. K. SAHOO[1], J. L. TWISS[1];

Abstract: FIG4 mutations are causative for the neuropathic condition Charcot-Marie-Tooth Disease 4J [CMT4J]. Fig4 (also called Sac3) is a 5'-phosphoinositide phosphatase in the PI(3,5)P2 regulatory complex/PAS complex that plays an important role in endosome-to-lysosome maturation and vesicle trafficking. Considering the roles of endosomes/lysosomes in axonal transport, we performed proteomics on PNS axoplasm from $Fig4^{fl/fl}$ [WT] vs. $Fig4^{fl/fl}$ x Syn1-Cre [$Fig4^{-/-}$] mice deficient for Fig4 in neurons. These data show significant increase and decrease of proteins in $Fig4^{-/-}$ axons. Pathways disrupted by Ingenuity Pathway Analysis [IPA] included Ca^{2+} homeostasis and mitochondrial electron transport chain complex. IPA from transcriptomics data obtained from primary DRG neurons similarly pointed to disrupted oxidative phosphorylation following Fig4 depletion. Consistent with these findings, there is a marked loss in mitochondrial membrane potential in the axons of $Fig4^{-/-}$ neurons, with an exacerbated mitochondrial depolarization upon treatment with 2-deoxy-glucose to attenuate glycolysis. Recent reports show co-transport of axonal RNAs with endosomes/lysosomes. Axons from $Fig4^{-/-}$ neurons show a significant reduction of several nuclear-encoded mitochondrial mRNAs, both in culture and sciatic nerve in vivo. Taken together, these data point to a previously undetected disruption in axonal mRNA transport with the CMT4J-associated loss of Fig4. A decline in axonal mRNA levels of nuclear encoded mitochondrial proteins likely disrupting mitochondrial function. Given the importance of mitochondria in axonal health and survival through ATP production and Ca^{2+}-buffering, this raises the possibility that disruptions in endosome/lysosome-linked axonal mRNA transport contribute to CMT4J pathogenesis.

Title: The local translatome within central axons of dorsal root ganglia neurons

Authors: *E. SILAGI, M. PAZYRA-MURPHY, O. TASDEMIR-YILMAZ, R. SEGAL; Dana Faber Cancer Inst., Boston, MA

Abstract: Dorsal root ganglia (DRG) neurons are first-order neurons in the somatosensory pathway that communicate noxious and innocuous stimuli from the periphery to the central nervous system. DRG neurons are pseudo-unipolar, with one axonal branch that innervates peripheral tissues and another that synapses in the spinal cord and brainstem. Thus, DRG neurons provide an ideal system for understanding how spatially regulated mRNA localization and translation enable distinct subcellular protein compositions and functions in peripheral and central axons. We investigated local mRNA translation in the soma and axons of DRG sensory neurons from P0-P3 aged mice. In these mice, Nav1.8-Cre drives selective expression of a GFP-tagged ribosomal subunit, L10a-GFP, in many DRG sensory neuronal subtypes. Tagged ribosomes can be visualized in the DRG cell soma, in central axons in the spinal cord, and in peripheral nerves. Using these animals, we carried out Translating Ribosomal Affinity Purification (TRAP) followed by RNA sequencing of central axon and DRG cell bodies. Specifically, GFP-tagged ribosomes were purified from the lysates using anti-GFP antibody and the ribosomal-associated RNAs from DRG soma and central axon were isolated for sequencing (n=4; ~20 mice/set). Negative controls were prepared from L10a-GFP mice without Cre expression. Principal component analysis of GFP+ samples confirmed that central axon and DRG samples clustered separately yet have little variance within sample groups. The dataset identified 265 genes in the translatome of central axons and 1630 in the DRG; importantly, the soma and central axon included genes characteristic of multiple distinct DRG subtypes. In the central axon, significantly enriched Gene Ontology Biological Processes related to sensory perception and pain; meanwhile a significantly enriched Kegg Pathway was Neuroactive-ligand Receptor Interaction, containing genes associated with post-synaptic serotonin receptors. In contrast, the enriched biological processes in the DRG soma are related to microtubule transport,

RNA processing, and DNA damage. These data suggest that the DRG central axons may constitute a critical location for modulation of pain and somatosensory input by the serotonergic system. Further studies are ongoing to explore the role of local translation and the serotonergic pathway for modulating pain sensation.

Title: Direct connections between the spine apparatus and the synapse are characteristic of large spine and are more frequent after associative learning

Authors: *E. PARRISH-MULLIKEN[1], L. OSTROFF[2];
[1]Univ. of Connecticut, Storrs, CT; [2]Physiol. and Neurobio., Univ. of Connecticut, Storrs Mansfield, CT

Abstract: The spine apparatus is a specialization of the smooth endoplasmic reticulum that is found in approximately 20% of all dendritic spines and is particularly associated with large, mature spines. The spine apparatus structure consists of membranous cisterns stacked between dense actin plates and it is involved in activity-dependent cytoskeletal changes of spine actin. These structural changes may be responsible for the undefined role the spine apparatus plays in synaptic plasticity and its association with calcium storage and synaptopodin. Additionally, the spine apparatus has been shown to form an actin-based physical connection to the post-synaptic density. However, detailed studies of its structural variability and distribution in the spine population are lacking, and whether every spine apparatus contacts the synapse is unknown. Synaptic plasticity in the lateral amygdala (LA) mediates aversive Pavlovian conditioning, and the spine apparatus is found more frequently in LA spines after this type of learning. Here, we investigated the structure of the spine apparatus and its physical connection to the synapse during the long-term memory phase of Pavlovian conditioning. Using serial section transmission electron microscopy, we examined reconstructions of the spine apparatus in 544 spines in the rat LA, and found that overall, the spine apparatus contacted the synapse only 18.9% of the time. The number of plates in the spine apparatus ranged from two to eight, and a connection to the synapse was associated with both more plates and a larger synapse. The spine apparatus was more likely to contact the synapse in the conditioned group, particularly if polyribosomes were

also present in the spine. Our results demonstrate that the connection between the spine apparatus and the synapse does not occur randomly, but instead is associated with synapse size and spine apparatus structure. These findings give further evidence that the spine apparatus is involved in synaptic plasticity and structurally plays a role through direct contact with the post-synaptic density.

Title: Nanoscale rules governing the organization of glutamate receptors in spine synapses are subunit specific

Authors: *R. CAIN[1], M. HRUSKA[2], M. B. DALVA[3];
[1]Thomas Jefferson Univ. Grad. Neurosci. Program, Philadelphia, PA; [2]West Virginia Univ., Morgantown, WV; [3]Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Dendritic spines are important sites for synaptic transmission and plasticity, and changes in their size and shape are thought to be structural correlates for learning and memory. Within the spine, the post synaptic density (PSD) is home to many proteins including MAGUK PSD-95 and glutamate receptors α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) and N-methyl-D-aspartate receptor (NMDAR). PSD-95 is organized in nanoscale puncta that scale in number, but not size as spine size increases. However, whether other postsynaptic proteins such as AMPAR and NMDARs share a similar organization is not known. Heterotetrameric glutamate receptors are essential for the development, function, and plasticity of spine synapses but how they are organized to achieve this is not known. Here we show that the nanoscale organization of glutamate receptors containing specific subunits define distinct subsynaptic features. Glutamate receptors containing GluA2 or GluN1 subunits establish nanomodular elements precisely positioned relative to Synaptogamin-1 positive presynaptic release sites that scale with spine size. Glutamate receptors containing GluA1 or GluN2B specify features that exhibit flexibility: GluA1-subunit containing AMPARs are found in larger spines,

while GluN2B-subunit containing NMDARs are enriched in the smallest spines with neither following a strict modular organization. Given that the precise positioning of distinct classes of glutamate receptors is linked to diverse events including cell death and synaptic plasticity, this unexpectedly robust synaptic nanoarchitecture provides a resilient system, where nanopositioned glutamate receptor heterotetramers define specific subsynaptic regions of individual spine synapses.

Abstract: Dendritic spines are components of neuronal synapses receiving and transforming synaptic inputs into a succession of biochemical events regulated by calcium signaling. The spine apparatus (SA), an extension of smooth endoplasmic reticulum participates in slow and fast calcium transients inside spines.We previously showed that the fastest calcium ions arriving at ryanodine receptors (RyRs) present mostly at the base of the spines trigger calcium-induced calcium release events that deplete the SA calcium ion reservoir rapidly. However, the next signaling cycle requires refilling of these calcium stores, and how spines achieve such refilling without triggering calcium release remains unclear. In the present study, we employ a

combination of computational modeling & simulations along with calcium imaging and STED super-resolution microscopy to address this enigma. Our main goal is to determine the conditions under which SA-store refilling without triggering depletion through RyRs is possible via the store-operated calcium entry pathway involving ORAI1 channels. First, diffusion modeling revealed that a small amplitude and a slow timescale for the calcium ion influx is required not to trigger RyRs. We confirmed this prediction through calcium imaging of cultured hippocampal neurons (prepared as Korkotian & Segal 2000) under channel blockages letting only the ORAI1 calcium influxes into spines. We measured slow calcium transients with timescales in the order of 2s, contrasting with fast NMDA & AMPA currents that last only a few tens of milliseconds. Second, using diffusion simulations, we found that in spine heads, ORAI1 channels that allow calcium entry from the plasma membrane should be closely colocalized with SERCA pumps that refill the SA. We confirmed this organization with STED imaging of immunostained hippocampal tissues (prepared similar to Basnayake et al. 2019) and found that the average co-localization distance between SERCA and ORAI1 puncta in the spine heads containing SA have very short distances of a few tens of nanometers (106±4nm, n=378), while this distance is more than doubled (210±8 nm, n=290) at the bases of spines. Thereby, we delineated how spine's nanoscale organization determines efficiently the separation between SA replenishment and depletion conditions, preventing the simultaneous activation of both pathways. Finally, we conclude that the spine's nanoscale organization at the receptor level could underlie the differences of calcium dynamics during the induction of synaptic long-term potentiation versus depression, particularly at the region of the spine base.

Title: New structure model for postsynaptic density, which contains tubulin as a key component.

Authors: *T. SUZUKI[1], N. TERADA[1], S. HIGASHIYAMA[2], K. KAMETANI[3], Y. SHIRAI[1], M. HONDA[4], T. KAI[4], W. LI[5], K. TABUCHI[1];
[1]Shinshu Univ., Matsumoto, Japan; [2]Ehime Univ., Matsuyama, Japan; [3]Rakuno Gakuen Univ., Ebetsu, Japan; [4]Shimadzu Techno-Research, INC., Kyoto, Japan; [5]Shanghai Jiao Tong Univ., Shanghai City, China

Abstract: Structural changes in postsynaptic density (PSD) are important mechanisms for maintaining synaptic plasticity. The molecular mechanism underlying changes in PSD structure (PSD remodeling) is currently unknown. A complete understanding of the structure of PSD is indispensable to fully elucidate the molecular mechanisms of spine and PSD dynamics during the expression of synaptic plasticity. Currently, it is tacitly believed that PSD is formed as an assembly of various kinds of scaffold/adaptor proteins (Scaffold/adaptor assembly model). Based on our recent study on the purified PSD lattice, we propose a new structure model for PSD. In our initial study on this theme, we proposed "PSD lattice-based dynamic nanocolumn" model for the molecular architecture of excitatory PSD, in which the scaffold protein model and the PSD lattice model are combined (Suzuki et al., 2017, J Neurochemistry, 144: 390-497). Our latest model for PSD structure, which we provide in the meeting, is an expanded version of the above mentioned model with the addition of the concept of PSD lattice backbone structure. We found a PSD lattice backbone structure, which is constructed mainly with non-microtubule tubulin and almost free from typical PSD scaffold/adaptor proteins. In the new model, non-microtubule tubulin may play an important role as a platform to which PSD scaffold/adaptor proteins and various PSD-functioning molecules become associated while synapses mature and reorganize. Proteins associating with the PSD lattice include various proteins related with versatile functions at the postsynaptic site as well as postsynaptic scaffold/adaptor proteins. Postembedding immuno-gold EM using anti-tubulin antibody supports the role of tubulin as an essential component for PSD structure by demonstrating the presence in and around PSD in the mouse brain. Forebrains of rats (male, adult) were used for purification of the synaptic fraction.

Title: 3d sted super-resolution imaging of the ground squirrel cone photoreceptor synapse

Authors: E. A. SCHWARTZ[1], V. BINDOKAS[2], J. SHI[3], ***S. DEVRIES**[4];
[1]Pharmacol. and Physiological Sci., [2]Univ. of Chicago, Chicago, IL; [3]Ophthalmology, [4]Northwestern Univ., Chicago, IL

Abstract: The mammalian cone photoreceptor synapse plays a crucial role in daylight vision by faithfully transmitting signals associated with fine spatial and color discrimination. EM studies

reveal a compact, ~3 µm diameter concave synaptic surface that is supplied by ~20 invaginating ribbon release sites and juxtaposed with hundreds of discrete bipolar cell dendrites. Both geometry and electrophysiological responses suggest that transmitter diffusion plays an important role in shaping the responses of the bipolar cell types. While EM studies can reveal the detailed physical structure of the cone synapse, they are less informative about the localizations of cleft components that can interact with diffusing transmitter including receptors and transporters. To address this gap in our understanding at the nanoscale level, we have devised a 3D-STED microscopic technique that allows us to visualize up to 5 proteins at a time at high resolution. To obtain images, bipolar cells in some retinas were sparsely labeled with GFP by prior intravitreal injection of AAV2. Ground squirrel retinas were removed from eyecups and bathed in cold glyoxal fixative for 2 days. Both untreated and GFP-expressing retinas were labeled with primary antibodies to neuronal markers (including GFP) and synaptic proteins. Species-specific secondary antibodies were labeled in-house with Abberior and Biotium fluorophores emitting in the range of 488-680 nm. Tissue was embedded in melamine, cover slipped, and imaged with a Leica SP8 Scanning Confocal/STED Microscope. Images were processed by denoising followed by deconvolution and surface-fitting with custom routines. We found that both Off cb1a and On cb7a bipolar cells selectively contacted the center of the cone terminal. Other bipolar cell types showed less positional selectivity. Small clusters of EAAT5 transporter (70±2 per terminal) were distributed throughout the concavity and did not align with the contacts of either basally contacting Off bipolar cells (cb3a/b type) or GluK1 receptor densities. Additionally, while GluR4 receptors where localized in tight clusters close to ribbons and their anchoring protein bassoon, some On bipolar mGluR6 and Off bipolar GluK1 receptors were found in nearly equal densities both in apposition to the cone terminal and along the dendritic shafts beneath the cone terminal. Our data suggests an unexpected bullseye organization of contacts at the cone synapse, a widespread but discrete localization of EAAT5 glutamate transporters, and differences in the dendritic localization characteristics of AMPA (GluR4), kainate (GluK1), and metabotropic (mGluR6) glutamate receptors.

Title: Differential nanoscale organization of excitatory synapses onto excitatory vs inhibitory neurons

Authors: *A. D. LEVY, P. A. DHARMASRI, T. A. BLANPIED;
Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The strength of excitatory synaptic transmission relies on the precise, nanometer-scale organization of synaptic proteins. Within single synapses, presynaptic release proteins and postsynaptic receptors and scaffolds concentrate in ~80 nm sub-regions of higher protein density, termed nanoclusters (NCs). Pre and postsynaptic NC alignment across the synaptic cleft results in stronger action potential-mediated excitatory postsynaptic currents, demonstrating a role for nanostructure in regulating synaptic strength. One context in which this may be particularly important is dictating excitatory drive onto diverse cell types in a circuit. For example, in the hippocampus, excitatory synapses are made onto both dendritic spines of excitatory principal neurons as well as dendrites of parvalbumin (PV)-expressing fast-spiking interneurons. These cellular and circuit contexts require different excitatory drive - compared to principal neurons, excitatory drive onto PV neurons must be stronger to overcome the electrotonic limitations of a non-compartmentalized synapse and sustain fast spiking, enabling PV neurons to deliver rapid and precise inhibition. Despite these different requirements, excitatory synapses onto both cell types consist largely of the same widely conserved group of proteins. Therefore, we reasoned synapses on these two cell types might differentially utilize nanoscale organization to tune the strength of excitation. We used immunocytochemistry and a combination of confocal and super-resolution microscopy to compare organization of common scaffold proteins at these synapses. We find that PV neurons have larger presynaptic Munc13 and postsynaptic PSD95 puncta, consistent with stronger synapses. However, while the larger Munc13 puncta contained more Munc13 per area, PSD95 did not, suggesting a possible nanostructural difference at these two cell types. Indeed, Munc13 and PSD95 at PV cells were organized into more NCs (Munc13: 1.85x, PSD95: 1.35x) that were larger (Munc13: 1.7x, PSD95: 1.3x) than their excitatory cell counterparts. Analysis and modeling of protein localization autocorrelation, which measures nanoscale heterogeneity of protein distribution, indicates both Munc13 and PSD95 are more concentrated into nanoclusters at PV cells. These results suggest that while excitatory synapses onto PV neurons are both larger and have more protein, the nanostructure is also optimized in such a way that predicts larger responses to action potential-evoked release. More broadly, we conclude that specialized aspects of nanostructural organization may contribute to functional diversity of excitatory synapses.

Title: Large molecular assemblies are involved in synaptic transmission

Authors: *C. PAPANTONIOU[1], C. IMIG[2], A. MARTINEZ-SANCHEZ[1], U. LAUGKS[1], Z. KOCHOVSKI[1], N. BROSE[2], W. BAUMEISTER[1], B. H. COOPER[2], V. LUCIC[1];

Abstract: Neurotransmitter release is mediated by a complex and highly regulated molecular machinery. We imaged isolated synapses by cryo-electron tomography (cryo-ET), a method that utilizes faithful sample preservation and direct 3D imaging of fully hydrated, unlabeled biological material at single nanometer resolution. Our quantitative structural characterization of the presynaptic terminal showed that Munc13 and SNAP25, proteins essential for synaptic vesicle priming for release and fusion, organize synaptic vesicles at the plasma membrane. Namely, these two proteins are necessary for two different types of tethers that position synaptic vesicles with a single nanometer precision. Furthermore, Munc13 and SNAP25 reorganize both tethers and short molecular bridges that interlink synaptic vesicles (termed connectors) in a coordinated fashion. This implies that synaptic vesicle priming and further steps towards the fusion involve extended molecular assemblies comprising multiple tethers and connectors that structurally organize synaptic vesicles on the nanoscale. In a separate set of cryo-ET experiments, we showed that molecular trans-synaptic assemblies link synaptic vesicles and tethers postsynaptic ionotropic glutamate receptors. Together, our data leads to a model where synaptic transmission is governed by large molecular assemblies of variable architecture that may involve multiple weak interactions.

Title: Correlative STED and Calcium Imaging of Quantal Events in Dendritic Spines

Authors: *H. JAFRI[1], M. B. DALVA[2];
[1]Farber Inst. of Neurosci. Thomas Jefferson Univ., Philadelphia, PA; [2]Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Dendritic spines are the primary site of glutamatergic transmission in the brain. Spines are thought to be the site of plasticity in the brain, and changes in spine size are associated with synaptic and structural plasticity. Moreover, spine size is associated with increased synaptic strength and increased size of the postsynaptic density. The synapse within a spine is thought to consist of a single presynaptic release site, and contain vesicles, the active zone (AZ), precisely opposed to the postsynaptic density (PSD), containing glutamate receptors and scaffolding proteins. Super-resolution microscopy has revealed that key pre- and postsynaptic molecules, such as Synpatophysin-1, VGlut1, Bassoon, and PSD95, form nanopuncta that scale in number, but not size, with respect to spine area. These data suggest that both pre- and postsynaptic proteins may form modular structures termed “nanomodules” or “nanocolumns”. While 60% of spines contain a single nanomodule, larger spines contain two or more pairs of pre- and postsynaptic protein modules. However, it is not known how or whether these clusters of proteins relate to synaptic function. The relationship between the nanoscale organization of the synapse and presynaptic function in single dendritic spine synapses is not well understood. To explore this further, we developed an approach to visualize spontaneous events at spines with known numbers of nanomodules. Cortical neurons were transfected with FingR PSD-95-mturquoise2 (CFP) to label endogenous PSD-95 in spines, and GCaMP7f to visualize calcium signaling. The number of nanomodules in spines was determined with super resolution, Stimulated Emission Depletion (STED), nanoscopy of FingR PSD-95. In the presence of blockers of neuronal activity, AMPARs, calcium channels, and calcium stores, spontaneous calcium events were visualized within spines with identified numbers of PSD-95 nanomodules using GCaMP7f. Using line- and field-scanning, we quantified the kinetics of mini-synaptic calcium transients (mSCTs) in dendritic spines with one nanomodule of PSD95. The smallest, one quanta, events were significantly above noise and exhibited rise and decay kinetics expected of GCaMP7f. The frequency of mSCTs within single spines was 10 to 100 times less than the reported frequency of mEPSPs obtained by whole-cell patch clamp. The distribution of peak amplitudes of mSCTs was observed to fit a Poisson distribution exhibiting evenly spaced bins of increasing amplitudes, suggesting the events seen were quantal and multivesicular. Taken together our data challenge the ideas that central synapses undergo univesicular release.

Title: Probing spontaneous and evoked neurotransmission using fluorescent neurotransmitter sensors

Authors: *C. WANG[1], N. L. CHANADAY[1], L. M. MONTEGGIA[3], E. T. KAVALALI[2]; [2]Vanderbilt Brain Inst., [1]Vanderbilt Univ., Nashville, TN; [3]Vanderbilt Brain Inst., Nashville, TN

Abstract: Synaptic transmission forms the basis of neural communication. Although previously thought to be similar in structure and function, recent work has demonstrated that spontaneous and evoked neurotransmission have unique molecular mechanisms and activate distinct downstream signaling pathways. However, their relative organization at the synaptic level remains incompletely understood. Further understanding of this organization can help provide insight into the fundamental structure of synaptic transmission. Here, we show that iGluSnFR, a fluorescent probe to visualize glutamate release, can be used as an imaging tool to visualize glutamatergic activity at the single synapse level within primary hippocampal cultures. Our results suggest that evoked release sites are likely clustered within single synapses, while spontaneous release sites are more mobile and more diffusely spread across the synapse. Collectively, our results demonstrate iGluSnFR imaging can be used to probe the organization of distinct forms of neurotransmission at the synapse, creating a broader framework to understand basic principles of neurotransmission.

Title: Ionotropic glutamate receptors coordinate trans-synaptic scaffold nanostructure

Authors: *P. A. DHARMASRI, A. D. LEVY, M. ANDERSON, T. A. BLANPIED;
Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Information processing in the brain relies on the dynamic and precise organization of molecular ensembles at the excitatory synapse. Proteins subserving the mechanisms of synaptic transmission are heterogeneously organized on the nanometer scale. Presynaptic proteins such as Munc13 and RIM1 are found in ~80 nm diameter subsynaptic regions of high local density. These presynaptic *nanoclusters* (NCs) are aligned across the synapse with NCs of proteins such as PSD-95 and ionotropic glutamate receptors (iGluRs), forming a *trans-synaptic nanocolumn*. Our lab established that this nanocolumn is the preferential site of action potential evoked release and that dispersal of AMPARs from the nanocolumn to the remainder of the synapse specifically reduces the strength of the response to evoked release. This highlights how the nanocolumn is critical for synaptic transmission and underscores the importance of knowing what generates and regulates this alignment. We reasoned that a mechanism underlying trans-synaptic alignment would involve a protein that could act as either a structural or functional marker of successful transmission. Intriguingly, the iGluRs themselves embody both aspects. First, either AMPARs or NMDARs could trigger downstream mechanisms that sample receptor activation and direct receptor positioning. Second, often underappreciated, both AMPARs and NMDARs have an extended extracellular structure with distal N-terminal domains that could nucleate direct or indirect interaction with presynaptic proteins. iGluRs could also organize scaffold NCs through multivalent interactions, either through NMDAR c-tail or AMPAR TARP binding. Previous studies show that receptor structure, particularly that of the AMPAR subunit GluA2 and its N-terminal domain, influences synaptogenesis and presynaptic maturation. Thus, we hypothesized that the iGluRs align the trans-synaptic nanocolumn. To test this, we assayed nanoscale organization of Munc13, RIM1, and PSD95 in a total iGluR knockout mouse model as well as in individual knockouts of the GluA2 AMPAR subunit and NMDARs in rat primary hippocampal culture. Here we report that loss of iGluRs, even just GluA2, results in changes to pre- and postsynaptic nanoscale organization and strongly disrupted alignment. On-going experiments seek to elucidate the structural or functional influence of iGluRs. The organization of iGluRs at the synapse is typically thought to be downstream of pre-existing scaffold structure. This study instead presents an unorthodox view of AMPA and NMDA receptors: that they actively shape the structure of synapses and thus may dictate their own activation.

Title: Safety and efficacy of genetic MECP2 supplementation in the R294X mouse model of Rett syndrome

Authors: *B. E. COLLINS[1], J. K. MERRITT[2], K. R. ERICKSON[2], J. L. NEUL[3];
[1]Vanderbilt Brain Inst., Vanderbilt Univ., Nashville, TN; [2]Dept. of Pediatrics, [3]Vanderbilt Kennedy Center; Departments of Pediatrics, Pharmacology, and Special Educ., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Rett syndrome (RTT) is an X-linked neurodevelopmental disorder caused primarily by mutations in the *MECP2* gene, encoding transcriptional modulator methyl-CpG-binding protein 2. While no disease-modifying therapies are currently available for RTT, several proposed strategies, such as gene therapy, aim to restore levels of functional MeCP2. An important consideration for these strategies is the tolerable threshold of MeCP2, since *MECP2* gene duplication and subsequent gain of MeCP2 function causes a related neurodevelopmental disorder in people (*MECP2* Duplication Syndrome, or MDS). Furthermore, determining the tolerable threshold of MeCP2 for partial loss-of-function mutations could elicit mutation-specific safety profiles of MeCP2 supplementation. We addressed these questions by genetically modelling MeCP2 supplementation in the context of the partial loss-of-function R294X allele. To do so, we utilized a mouse model of MDS with a human *MECP2* transgene on an autosome (TG). We conducted a broad behavioral battery separately in male and female cohorts to evaluate rescue of RTT-like phenotypes and assess behaviors indicative of excess MeCP2. We found that male and female R294X mice share several RTT-like phenotypes, including impaired locomotor activity, breathing dysfunction, and decreased motor coordination. Additionally, male and female MDS model mice displayed opposing phenotypes, including enhanced motor coordination and enhanced fear memory. In males, RTT-specific phenotypes were rescued and bidirectionally dosage-sensitive phenotypes were normalized with genetic MeCP2 supplementation. However, female R294X TG mice demonstrated behavioral evidence of excess MeCP2 in motor coordination and forced gait assays, suggesting that the underlying motor circuitry is particularly sensitive to MeCP2 dosage in females. Quantitative Western blotting of brain tissue determined that R294X TG female mice express full-length MeCP2 at approximately 1.5x that of WT female mice. This is likely due to X-chromosome inactivation and may explain the sex specificity of these MDS-like behaviors. Collectively, these results suggest that MeCP2 supplementation is safe and effective in males and largely so in females. However, careful consideration of risk for adverse motor effects may be warranted for girls and women with RTT. While mutation type may not have impacted the therapeutic window of MeCP2 supplementation

in this study, mutation type does significantly impact clinical severity in people. Future work will investigate the mechanism of an understudied subset of mutations at the C-terminus of *MECP2*, which cause relatively mild disease in people.

Title: Directly Converted Rett Syndrome Patient Astrocytes Show Mutation Related Gene Expression and Metabolic Profiles

Authors: *S. POWERS[1], K. KINLEY[1], C. N. DENNYS[1], R. RODRIGO[1], X. ZHANG[1], F. ROUSSEL[1], S. B. LIKHITE[1], Y. RODRIGUEZ[1], S. SINHA RAY[1], M. DUNNING[2], P. R. HEATH[2], L. FERRAIUOLO[2], K. C. MEYER[1];
[1]Nationwide Children's Hosp., Columbus, OH; [2]Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Confidential: Rett syndrome (RTT) is an X linked neurodevelopmental disorder affecting approximately 1 in 10,000 girls. Patients exhibit a loss of established developmental milestones and progressive loss of motor function. Cellular pathology is characterized by a global compaction of neural somas with shortened and fewer neurites. Most RTT cases result from loss of function mutations in methyl-CpG binding protein 2 (MeCP2), an important epigenetic reader and transcription factor. MeCP2 functions by silencing/enhancing genes by interaction with various cofactors, but its mechanisms are poorly understood. Clinically, variation in MeCP2 mutations lead to differential disease severity. To further investigate the role of MeCP2 mutations on pathology, we developed a novel *in vitro* modeling system utilizing induced neural progenitor cells (iNPCs) directly converted from RTT patient fibroblasts. Using this system, we examined the morphology of neurons derived from RTT patients. We also examined the non-cell autonomous role of astrocytes in RTT through a co-culture assay with mouse neurons via automated imaging/analysis. We found that RTT neurons and astrocytes have a mutation dependent effect on neuronal morphology. To investigate the molecular mechanisms

underlying morphological differences, we performed microarray gene expression analysis, and metabolic (seahorse) screening on our patient derived cells. We found that RTT phenotypes had a basis in substantially different gene expression profiles and mutation specific differences in metabolic profiles. Biomarkers for RTT phenotypes *in vitro* identified in these screenings have been confirmed in RTT patient brain tissue and independently by our collaborators in the Gogliotti/Niswender laboratories. Our work offers new perspectives on mutation specific Rett syndrome phenotypes and their connection with mutation dependent changes in metabolism, and gene expression.

Title: Mitochondrial ROS-induced stress is atherapeutic target for Rett syndrome

Authors: *J. DI LUCENTE[1], K. BORKOWSKI[3], J. NEWMAN[3], H. WULFF[2], G. CORTOPASSI[4], L.-W. JIN[1], I. MAEZAWA[1];
[1]Pathology and Lab. Med. and MIND Inst., Univ. of California Davis, Sacramento, CA; [2]Pharmacol., Univ. of California Davis, Davis, CA; [3]West Coast Metabolomics Ctr., Davis, CA; [4]VM: Mol. Biosci., UC DAVIS, Davis, CA

Abstract: Rett syndrome (RTT), a devastating neurodevelopmental disorder, is largely caused by loss-of-function mutations in the X-linked gene encoding MeCP2. MeCP2 is a “reader” of the epigenetic codes consisting of DNA methylation marks, the absence of which results in altered gene expression. However, the mutant-driven toxic mechanisms causing RTT remain unclear. In our studies of RTT microglia, we found that MeCP2 deficiency caused enhanced mitochondrial (mt) reactive oxygen species (mtROS) production and abnormal mt function, prompting us to hypothesize that MeCP2 controls coordinated expression of bioenergetic genes as part of the recently recognized “mitonuclear signaling pathways" to maintains mt integrity, including mt

stress response (MSR). We found enhanced mtROS level, impaired OXPHOS complex I and complex IV activities, and decreased mt DNA copy number in the brain of *Mecp2*$^{tm1.1Bird/+}$ (*Mecp2-KO*) model of RTT. Furthermore, the MSR to mtROS was impaired as evidenced by reductions of ATF4 and Nrf2, two transcription factors critical for orchestrating MSR. To test the translational significance of mtROS, we employed the "mCAT" approach, in which catalase, usually not expressed in mt, was engineered to target mt to decompose overproduced H_2O_2. mCAT expression extended the lifespan of *Mecp2-KO* mice from 6-8 weeks to up to 42 weeks, and recovered the body weight gain, phenotype score, and multiple measures of respiration, neuronal plasticity, behavioral and motor performance, neuronal morphology, and mitochondrial function to almost wild-type levels. Integrated transcriptomics and metabolomics analyses demonstrated a mechanism consistent with ATF4- and Nrf2-orchestrated MSR being the main target of mCAT. To translate our findings to clinical utility, we screened a library of 1,600 FDA-approved drugs based on their "mitoactive" properties and identified dyclonine as the most promising candidate. Daily intraperitoneal injection of dyclonine at 10mg/kg to *Mecp2-KO* mice activated ATF4 and Nrf2, and showed a therapeutic efficacy parallel to mCAT expression. Together, our data provide proof-of-principle that mtROS-induced mt stress is a therapeutic target and that the FDA-approved drugs able to enhance MSR such as dyclonine are promising clinical candidates for RTT.

Title: Reversal of neurological defects by painless Nerve Growth Factor in a mouse model of Rett syndrome

Authors: A. TIBERI[1], G. BORGONOVO[1], G. TESTA[1], M. CALVELLO[1], ***S. CAPSONI**[1,2], A. CATTANEO[1,3];
[1]Scuola Normale Superiore, Pisa, Italy; [2]Univ. of Ferrara, Ferrara, Italy; [3]European Brain Res. Inst., Rome, Italy

Abstract: Rett syndrome (RTT) is a severe neurological disorder affecting 1 in 10,000 females. At the moment, there is no pharmacological treatment able to prevent or revert this neurodevelopmental disorder. We decided to investigate the efficacy of a neuroprotective

approach to counteract the neuronal loss occurring in RTT. We focussed on the neurotrophin Nerve Growth Factor (NGF) because of i) its reduced levels in RTT brain tissue , ii) of its direct neurotrophic actions on basal forebrain cholinergic neurons, that are affected in the brain of RTT patients and iii) of its broader indirect neuroprotective actions mediated by microglia cells. Despite a strong rationale, the clinical application of NGF in RTT, as well as in other neurological diseases, has been hampered by the fact that NGF cannot cross the blood brain barrier and has a strong pro-nociceptive activity. To overcome these limits, (i) we have developed painless NGF (hNGFp), a variant of NGF with a tenfold reduced pain-sensitizing activity; (ii) we demonstrated that it can be effectively delivered to the brain using an intranasal route of administration and that (iii) hNGFp have a potent neuroprotective activity, also on neurons that do not express NGF receptors, that is carried out through microglia and astrocytes. This is particularly relevant for Rett syndrome, since it has been recently suggested that conditioned medium from Mecp2 null microglia decreases neuronal branching and the number of synapses. Here, we report data obtained from two separate treatments with hNGFp performed in heterozygous $Mecp2^{+/-}$ female mice (RTT mice). The first treatment started when hindlimb clasping appeared and lasted 1 month. The second treatment started at 2 months of age in absence of any apparent sign of deficits and lasted until we had to humane sacrifice the mice due to breathing difficulties. We found that the administration of hNGFp enhanced the survival of RTT mice with 93% of hNGFp treated RTT mice surviving against 40% of PBS treated mice after 24 weeks of treatment. The neurological phenotype was also improved since we found that in both groups of treatment there was a statistically significant reduction of hindlimb clasping, immobility, gait and breathing deficits. These findings were accompanied by an improvement of brain weight. At the cellular level, we found that hNGFp restores the ramified, resting morphology of microglia and reduces the asthenic phenotype of astrocytes. Data on neuronal and inflammatory markers will also be reported. In conclusion, our study shows that hNGFp is able to ameliorate RTT-like neurological defects in Mecp2 null mice, putting forward a promising therapeutic agent for this disease.

Title: Generation and analysis of MECP2 mutant marmosets

Authors: *N. KISHI[1,2], K. SATO[3], J. HATA[1,4], M. OKUNO[1], T. ITOU[1], J. OKAHARA[1,3], H. J. OKANO[1,4], E. SASAKI[1,3], H. OKANO[1,2];
[1]RIKEN CBS, Wako-Shi, Japan; [2]Keio Univ. Sch. of Med., Tokyo, Japan; [3]CIEA, Kawasaki, Japan; [4]Jikei Univ. Sch. of Med., Tokyo, Japan

Abstract: Rett syndrome is an X-linked neurodevelopmental disorder presenting almost exclusively in girls, with a prevalence rate of one in 10,000 to 15,000. After Down's syndrome, Rett syndrome is considered the second most common genetic cause of cognitive disability in girls. Children with Rett syndrome develop relatively normally for 6-18 months, after which they undergo a period of rapid regression, with loss of purposeful hand use, deceleration of head growth, and onset of repetitive, autistic behaviors. Mutations of the MECP2 gene on the X chromosome are found in over 95% of cases of classic Rett syndrome, and MECP2 has been implicated in several other neurodevelopmental disorders, including autism, childhood schizophrenia, and X-linked cognitive disability. Although it is evident that phenotypes of Mecp2 mutant mice and symptoms of Rett syndrome are attributable to lack of the Mecp2 gene in the CNS, there is little neuropathological understanding of the abnormalities in the CNS of Mecp2-null mice as well as of patients with Rett syndrome. Although rodent models have been used for these studies, these models do not faithfully recapitulate human neurodevelopmental processes. The establishment of nonhuman primate (NHP) models that are similar to humans in many aspects, such as brain structure and higher brain functions, is very important to understand the pathogenesis of Rett syndrome. To add to our understanding of pathological mechanisms of Rett syndrome, we created MECP2 mutant marmosets suitable for research on Rett syndrome, using genome editing technology, and have analyzed the NPH models. MRI imaging shows that the brain size of MECP2 +/- marmoset was smaller than wild-type ones by approximately 15% at 24 months of age, and less active than wild-type ones in the daytime. Furthermore, we also generated MECP2-null marmosets using CRISPR/Cas9, which have smaller brains and are less active even at early developmental stages. Those results indicate that those MECP2 mutant marmosets recapitulate symptoms of Rett syndrome, and this new primate model will potentially contribute to the development of future therapeutic strategies for patients with Rett syndrome.

Abstract: Rett syndrome (RTT) is a non-inherited chromosome X-linked neurodevelopmental disorder characterized by a loss of acquired speech, hand stereotypies and gait abnormalities which appear following a period of apparently normal postnatal development. Other frequent symptoms include breathing difficulties, seizures, scoliosis and growth retardation. This syndrome is caused by mutations in the X-linked chromosome gene *Methyl-CpG-binding protein 2* (*MECP2*) encoding a transcriptional regulator. RTT accounts for up to 10% of severe intellectual disability of genetic origin in women. Currently there are no cures to treat this disease. In spite of different causative mutated gene and biological pathways affected, epidemiological and animal studies revealed abnormally elevated circulating levels of the adipocyte hormone leptin in patients with RTT and *Mecp2*-deficient mice. Besides its canonical role in the control of satiety and energy expenditure, leptin acts on many brain areas, and in doing so modulates cognitive functions, anxiety, breathing and more. Consequently, altered levels of leptin may contribute to the RTT-associated neuronal network dysfunctions. In the present study, we show that serum leptin levels are elevated in early (postnatal day (P) 30) and late symptomatic (P60) male *Mecp2-null* mice (*Mecp2$^{tm1\text{-}1}$ bird*, a well-established rodent model of RTT). We also show that daily subcutaneous injections of a validated leptin antagonist (Peg-SMLA, a competitive inhibitor of leptin BBB transport), during 10 days from P40, prevent the body weight loss, restore the hippocampal excitatory/inhibitory (E/I) balance (electrophysiological recordings on slices), slows down the progression of breathing dysfunctions (plethysmography) in the symptomatic male *Mecp2-null* mice. Conversely, leptin-treatment of wild type mice mimics some of the phenotypic manifestations observed in *Mecp2-null* mice, i.e. decreased GABAergic activity, increased hippocampal E/I balance, and increased number of apneas. These data provide further insights on the possible contribution of leptin in RTT pathogenesis and offer therapeutic perspective to alleviate RTT symptoms.

Title: Modeling from single cell electrophysiology to neuronal network interactions in human induced pluripotent stem cell derived Rett Syndrome and isogenic controls

Authors: *K. S. PRADEEPAN[1,3], G. BENIGNO[2,4], W. ZHANG[5], R. S. MOK[6,7], M. W. SALTER[5], J. ELLIS[6,7], J. C. MARTINEZ-TRUJILLO[1,3,4], L. E. MULLER[2,4,3];

Abstract: Rett syndrome (RTT) is a rare neurodevelopmental disorder that produces a distinct period of normal infancy followed by neurological regression. RTT is caused by a single heterozygous loss-of-function mutation in the gene methyl-CpG-binding protein 2 (*MECP2*) found on the X-chromosome - affecting almost exclusively females. Electrophysiological studies in mouse cortical slices, hippocampal cultures, and human induced pluripotent stem cell (hiPSC) models of RTT have shown that MECP2 mutant neurons exhibit decreased excitatory neuronal activity and synaptic connectivity. While these effects have been extensively studied at the level of single neurons, how these changes translate to network-level activity patterns remains unknown. Here we combine analysis of multielectrode array (MEA) recordings of hiPSC networks (Ellis Lab, SickKids, Toronto), single-cell intracellular recordings of hiPSC neurons (Salter Lab, SickKids, Toronto), and computational modeling to understand the network-level mechanism of RTT. By developing a tightly constrained computational modeling framework from single-neurons and networks, we find that an interplay between fast excitatory currents at the network level and slow adaptation currents at the single-neuron level can underlie changes in population spiking activity in hiPSC RTT (MECP2-null) networks.
hiPSC-derived networks exhibited bursting patterns that went from sparse firing to asynchronous bursting to synchronous bursting across 6 weeks of development. RTT networks exhibited significantly slower frequencies of network bursts compared to isogenic controls. Using data from intracellular recordings in vitro, we developed a single-neuron model to capture the subthreshold membrane potential and spiking dynamics following standard current injection protocols. We next implemented our single neuron models into a spiking network model of the excitatory hiPSC populations. The spiking network model revealed that increased adaptation currents at the single-neuron level can explain the changes in network burst frequency at the network level. These preliminary computational results implicate an interplay of single-neuron channel properties and network-level activity in changes observed in MEA recordings of RTT networks. These results further implicate channels involved in adaptation as downstream targets of MECP2, and we are currently designing new computational and experimental approaches to

create multi-scale validations of these predictions. [J.E., J.M.T., and L.M. co-supervised this work]

Title: Failure to reproduce a resting-state language laterality analysis in the ABCD data

Authors: *T. K. M. DAY[1], R. HERMOSILLO[2], G. CONAN[2], A. RANDOLPH[3,2], N. BYINGTON[2], T. HENDRICKSON[4,2], J. T. ELISON[1,3,2], D. A. FAIR[1,2,3], E. FECZKO[3,2];
[1]Inst. of Child Develop., [2]Masonic Inst. for the Developing Brain, [3]Dept. of Pediatrics, [4]Informatics Inst., Univ. of Minnesota, Minneapolis, MN

Abstract: The lateralization of language function to the left hemisphere (LH) is a conceptually robust and reproducibly measurable pattern of brain organization, and may be a marker of language development that can be revealed through task-based functional MRI (tfMRI) using comprehension and production tasks. For example, Szaflarski and colleagues (2006) described a general increase in LH lateralization between 5 years and early adulthood using tfMRI. But, under 5 years, tfMRI is challenging due to attention and motion issues, requiring that resting-state fMRI (rsfMRI) scans be used to fill this gap. Methods for calculating lateralization using rsfMRI data are much less well-defined than tfMRI methods. One proposed method for calculating lateralization with rsfMRI data is to subtract mirrored connectivity maps based on the right-hemisphere (RH) Broca and Wernicke homotopes from connectivity maps calculated from the canonical LH areas (Zhu et al., 2014). The authors reported two regions significantly more associated with LH Broca than RH; as well as six regions significantly more associated with

either LH or RH Wernicke using the NYU Test-ReTest sample (n=25; age: 20y).
Here, we attempted to reproduce Zhu and colleagues' findings using a modern surface-based, HCP-style pipeline and the Adolescent Brain and Cognitive Development (ABCD) study (age: 9-10y), as an intermediate step toward performing such an analysis in the Baby Connectome Project (age: 0-5y). We used the ABCD rsfMRI data (n=2000) with 10 min of low-motion data per scan, using Zhu and colleagues' Broca and Wernicke regions and parcels from the Gordon et al. (2016) and Glasser et al. (2016) atlases. We compare and contrast findings between region sets and present this as a case study in the advantages of newer acquisition protocols and processing methods and limitations in reproductions of older data.
We were unable to reproduce any previously reported lateralized regions. While Zhu et al. reported peak difference |Z| values in excess of 5, we found much smaller regions of lateralization near Broca and Wernicke, with lower peak values in the ABCD subsample. We will refine the most promising source regions from these exploratory analyses to replicate in a confirmatory ABCD subsample. Recent findings (Marek et al., 2020; Feczko et al., 2021) suggest this lack of replication might be a consequence of the small sample size and the limited usable data (4.5 min) in Zhu et al. (2014) compared to ABCD. It could also be because the ABCD participants are much younger than the Zhu et al. participants, which will need to be studied further. This study highlights the importance of revisiting prior results with new imaging standards.

Title: Community violence exposure during mid-adolescence is related to greater grey matter volume reduction in urban youth

Authors: *K. HILLIARD, M. STONE, X.-F. YANG, M. IMMORDINO-YANG;
Brain and Creativity Inst., USC, Los Angeles, CA

Abstract: Community violence exposure is a form of chronic stress and a significant public health issue for urban youth. It has been linked with poorer cognitive outcomes (Delaney-Black et al., 2002; Sharkey, 2010) and increased risk for psychiatric illnesses (Fowler et al., 2009). Adolescence is a period of dramatic brain maturation and intense psychosocial development, characterized by a heightened sensitivity to social influences (Albert, Chein, & Steinberg, 2003), and is likely especially susceptible to social-relational stressors. However, research examining the effect of stress on brain maturation focuses mainly on early life adversities or on clinical populations (Hart & Rubia, 2012), and the few studies examining the impact of community violence exposure on healthy adolescents are cross-sectional in nature (Butler et al., 2018; Saxbe et al., 2018). It remains unclear whether community violence exposure uniquely impacts brain development during the mid-adolescent period. Here, fifty-five adolescents (mean age 15.9 years at wave 1, SD= 1.1) from mid to low-SES families living in moderate- to high-crime neighborhoods in Los Angeles participated in two waves of structural neuroimaging scans. All were healthy non-delinquent youth, and not the direct victims or perpetrators of violence. Using a self-report survey (Margolin et al., 2009), participants reported their lifetime cumulative community violence exposure at wave 1 and the additional violence they experienced over the two-year interval at wave 2 (proximal exposure). Structural neuroimaging data were processed independently for each wave using voxel-based morphometry (CAT 12 and SPM 12; http://www.fil.ion.ucl.ac.uk/spm). We found that participants with greater proximal violence exposure during the two-year period showed greater reduction in grey matter volume in the anterior and middle cingulate cortex and the right ventral anterior insula, regions broadly involved in salience detection and autonomic regulation (Bush, Luu, & Posner, 2000; Devinsky, Morrell, & Vogt, 1995; Seely et al., 2007). The patterns were consistent with our previous cross-sectional findings (Butler et al., 2018) and with patterns seen in PTSD (Kühn & Gallinat, 2013) and combat-exposed military populations (Butler et al., 2017). Results controlled for lifetime cumulative exposure, thereby isolating the effect of proximal violence exposure during this period. These findings highlight the unique vulnerability to environmental stressors during mid-adolescence even in healthy youth, and the urgent need for intervention and prevention to protect adolescents from the detrimental effects.

Title: Intra-network connectivity in the cingulo-opercular network predicts variability in appraisals of emotional ambiguity in childhood development

Authors: *N. R. HARP[1], A. NIELSEN[2], D. H. SCHULTZ[3], M. NETA[4];
[1]Univ. of Nebraska-Lincoln, Lincoln, NE; [2]Neurol., Washington Univ., Saint Louis, MO; [3]CB3, Univ. of Nebraska, Lincoln, Lincoln, NE; [4]Ctr. for Brain, Biology, and Behavior, Univ. of Nebraska - Lincoln, Lincoln, NE

Abstract: Emotionally ambiguous signals, like a surprised expression, could be perceived as either positive (unexpected birthday party) or negative (witnessing an accident). In the absence of a clarifying context, people differ in their appraisals of these signals as having a more positive or a more negative meaning (i.e., valence bias). Valence bias is a stable, trait-like measure related to internalizing symptomology, highlighting the need to elucidate its underlying neurobiological mechanisms. Extant work suggests the initial response to ambiguity is negative, and that positivity relies on regulatory processes. Brain regions implicated in task control, like those of the cingulo-opercular network (CON), show greater activation during the resolution of emotional ambiguity in adults. Though it remains unclear whether these regions serve a regulatory role in childhood, and if resting-state connectivity is a useful predictor of individual differences in valence bias. Here, we use support vector regression (SVR) to assess this possibility that subtle differences in multivariate patterns in CON connectivity are related to individual variability in valence bias. This study includes 72 children (ages 6-17; 35 male) from Lincoln, Nebraska. Subjects completed a valence bias task, followed by a scanning session approximately one week later to collect resting-state data (15-20 mins). The resulting data were processed in a standard pipeline, including global signal regression, motion scrubbing, a bandpass filter, and spatial smoothing. Then, functional connectivity was computed for 264 whole-brain ROIs in each subject. Using SVR, intra-network connectivity in the CON (14 nodes, producing 91 edges or features) significantly predicted valence bias (R^2 = .14), even after regressing out age-related variance prior to model fitting (R^2 = .18). However, a larger network (default mode; 58 nodes, 1653 features) unrelated to task control did not (R^2 = .01). “Networks” of 14 random nodes - the same size as CON - also failed to significantly predict valence bias. We show that intra-network connectivity of the CON significantly predicts individual differences in valence bias during childhood. Together with evidence of the role of the CON in adults, these results suggest a putative regulatory role for this network in supporting positivity towards emotional ambiguity. Thus, CON intra-network connectivity holds promise as a diagnostic tool for identifying those with greater risk of developing internalizing symptomology.

Infantil de México Federico Gómez, CDMX, Mexico; [3]Physics department, Univ. Autónoma Metropolitana Unidad Iztapalapa, Cdmx, Mexico; [4]Neoruimaging department, King´s Col. London, London, United Kingdom

Abstract: Introduction: Several studies have suggested a direct association between human cognition and functional/structural connectivity patterns in the human brain; the latter, obtained through Resting State Functional Magnetic Resonance Imaging measurements (RS-fMRI). On top of this, a certain degree of cognitive impairment has been found in people who were obese during their infancy. The physiological mechanisms for these findings are still not clear.
Aim: This work was aimed at studying the RS-fMRI networks of a cohort of infants, divided into three different groups depending on their Body Mass Index (BMI). All this, to find differential brain region recruitment and interactions within-BMI groups.
Methodology: A cohort comprised of 142 children with a mean age of: 8.31 1.18 years, were classified into three groups according to BMI: normal weight, overweight and obese. RS-fMRI measurements were performed on a SIEMENS Skyra 3 Tesla scanner, with a 32-channel head coil, using a 3D Fast GE T_2* sequence. Data was latter preprocessed, analyzed and quantified with different softwares: SPM, GIFT and GRETNA. Through them we were able to obtain grouped RS networks of different kinds for each BMI group of children. Also, a series of different parameters from graphic analysis were obtained.
Results: 15 different RS-fMRI networks were consistently obtained for each BMI group. Larger volumes/surfaces were found when comparing Obese vs. Normal weight in the following networks: executive control, left and right memory networks. When comparing Normal weight vs. Obese larger volumes/surfaces were found in frontal cortex, ventral stream and bilateral frontoparietal networks.
Discussion and Conclusion: These results show differences in brain areas recruited between groups as well as a different physiological connectivity when addressing various cognitive functions. This is the first study of this type in a Mexican population and could shed some light on the reasons for the cognitive impairment found in obese children. In this work in progress, correlation of the different graphic analysis parameters from RS networks with: anthropometric measurements, IQ scores, depression scores, cognitive scores and blood and urine measurements, will be made. This way we might be able not just to see changes in RS networks, but to quantify

and find the physiological underlayer for the different cognition functionality dependance with BMI.

Title: Frontolimbic white matter pathways link prenatal cannabis exposure to child anxiety symptoms

Authors: *J. M. EVANSKI, B. BORG, A. MORALES, M. M. FARAJ, H. A. MARUSAK; Wayne State Univ., Detroit, MI

Abstract: Some pregnant women use cannabis to assuage symptoms of morning sickness or anxiety, and some cannabis-using women may have not known they were pregnant. However, research shows that approximately 1/3 of cannabis constituents, such as delta-9-tetrahydrocannabinol (THC) undergoes cross-placental transfer upon use by a pregnant woman and may therefore disrupt fetal neurodevelopment. In particular, THC may disrupt the endocannabinoid system, which plays a key role in neurodevelopment across the lifespan. Indeed, endocannabinoids and cannabinoid receptors are expressed in the fetal brain, including white matter, as early as 5 weeks into gestation. Prenatal cannabis exposure is associated with cognitive, motor, and social deficits that last into the adulthood of offspring. Here, we use data from the ongoing large-scale NIH Adolescent Brain Cognitive Development (ABCD) study to examine the impact of prenatal cannabis use on childhood anxiety and the integrity of frontolimbic white matter pathways. We focused on frontolimbic pathways that are known to be susceptible to cannabis use in adolescents and adults, and because variation in endocannabinoid signaling is to shown to be important for modulating frontolimbic development. This study reports on diffusion tensor imaging (DTI) data collected from 10,570 youth ($M \pm SD = 9.92 \pm 0.62$ years; 48% female; 55.1% White, 13.2% Black, 19.8% Hispanic, 1.9% Asian, 10.1% Other). Prenatal cannabis use was measured via parent retrospective report and anxiety was measured using the Child Behavior Checklist. Fractional anisotropy (FA) was estimated for frontolimbic white matter tracts. In this sample, 3.9% of parents (n = 410) reported using cannabis prior to knowledge of pregnancy, and 1.1% (n = 119) reported using after knowledge. Any prenatal cannabis exposure was associated with higher anxiety symptoms and lower FA of the left anterior thalamic radiations, left cingulum bundle, and right and left fornix. Cannabis

exposure before (but not after) knowledge of pregnancy was associated with lower FA of the corpus callosum. FA of the fornix was also positively associated with anxiety symptoms, and FA in the left fornix mediated the association between prenatal cannabis exposure and anxiety symptoms. These data add to the growing body of evidence linking prenatal cannabis exposure to altered neurodevelopment. These findings indicate that variation in frontolimbic white matter pathways may explain the link between prenatal cannabis exposure and elevated risk of mental health outcomes in offspring, and should be used to encourage women to abstain from cannabis use during pregnancy or pre-conception.

Title: Brain and Genetic Correlates of Psychotic Symptoms in Children

Authors: *K. KIM[1], K. KIM[1], H.-H. WANG[1], S.-Y. MOON[2], Y. JOO[4], J. CHA[3];
[1]Brain and Cognitive Sci., [2]Col. of Liberal Studies, [3]Dept. of Psychology, Seoul Natl. Univ., Seoul, Korea, Republic of; [4]Inst. of Data Sci., Korea Univ., Seoul, Korea, Republic of

Abstract: Childhood psychotic-like experiences are linked to a higher risk of diagnosis of a psychotic disorder during adulthood (Karcher, et al., 2018)., first psychotic episodes typically begin in adolescence or early adulthood (Arciniegas, 2015; Bozzatello, et al., 2019). Therefore, it is crucial to detect psychotic risk in early childhood. Here, we investigated brain and genetic underpinnings of the prodromal psychotic symptoms. We used the structural MRI of 5,629 children ages 9 to 10 years old from the Adolescent Brain Cognitive Development study. As a measure of psychotic symptoms, we used a prodromal questionnaire-brief child version (PQ-BC) including total (0 to 21) and distress score (0 to 126). Firstly, we examined the association between psychotic symptoms and brain structure (i.e., volume). The multiple linear analysis with demographic covariates (e.g., sex, age, race) showed that whole brain volume was negatively associated with total and distress score (total; standardized beta(β)=-0.040, P=0.020, distress; β=-0.046, P=0.008). To investigate the regional effect on the scores, we analyzed segmented brain regions. Right inferior parietal lobule (rIPL), right superior frontal gyrus (rSFG), right rostral middle frontal gyrus (rRMFG) have the largest effect on total score (rlPL; β=-0.704,

PFDR<0.001, rSFG; β=-0.621, PFDR=0.014, rRMFG; β=-0.565, PFDR=0.014). Interestingly, some brain regions showed a positive association with total score: right frontal superior gyrus (rFSG), right superior temporal sulcus (rSTS), angular gyrus (AG) (rFSG; β=0.466, PFDR=0.014, rSTS; β=0.417, PFDR=0.001, AG; β=0.358, PFDR=0.001). Besides, this relationship is consistent in the distress score. Secondly, we assessed genome-wide polygenic scores (GPSs) associated with psychosis using PRSice (Euesden, Lewis, and O'Reilly, 2015): schizophrenia (SCZ), autism spectrum disorders (ASD), major depressive disorder (MDD), and bipolar disorder (BIP) (Pourcain et al., 2017; Schulze et al., 2014). The multiple linear regression showed GPS of SCZ was not correlated with total and distress scores (βtotal=0.001, βdist=-0.000). Likewise, there is no correlation of ASD and BIP (ASD: βtotal=0.035, βdist=0.023; BIP: βtotal=-0.041, βdist=-0.034). However, PRS of MDD shows the correlation with total and distress scores (βtotal=0.052, PFDR(total)=0.031, βdist=0.066, PFDR(dist)=0.002). In summary, this study reveals some brain areas can be positively correlated with the symptoms. In the aspect of genetic factor, our finding shows a higher genetic risk for MDD is related to psychotic prodrome-related scores in prepubertal children.

Title: Neural correlates of semantic processing in Chinese-English bilingual children using functional Near Infrared Spectroscopy (fNIRS) imaging

Authors: *L.-Y. FAN[1], T.-L. CHOU[2], H.-C. CHEN[3], S.-Y. CHEN[4];
[1]Natl. Taipei Univ. of Educ., Taipei, Taiwan; [2]Natl. Taiwan Univ., Taipei, Taiwan; [3]Natl. Chung Cheng Univ., Chiayi, Taiwan; [4]Univ. of Taipei, Taipei, Taiwan

Abstract: Bilingual experiences may change children's neural circuitry for learning to read. Previous neuroimaging studies of language acquisition in monolingual populations have revealed increased activation in the middle temporal gyrus (MTG) and inferior frontal gyrus (IFG) associated with semantic processing as a function of skill and development. The goal of this study is to investigate whether the lexical brain areas differ in meaning processing between Chinese monolingual and Chinese-English bilingual first grader children. Two groups of children were recruited: 20 Chinese monolingual and 20 Chinese-English bilingual first graders. Monolingual children were asked to perform an auditory semantic judgment task in Chinese,

while bilingual children were asked to perform an auditory semantic judgment task in both Chinese and English. During the fNIRS imaging task, children heard two words and were asked to indicate if word pairs were related in meaning. The task included two levels of difficulty requiring either high-association (easy) or low-association (difficult). Behavioral results showed that both monolinguals and bilinguals had poor accuracy in the low-association condition than the high-association condition. In addition, bilinguals had more accurate and faster reaction time in the unrelated condition than the low-association and high-association conditions during the English semantic task. Yet, this difficulty effect was only present in English of the bilinguals but not in Chinese. In fNIRS results, our imaging findings revealed that monolinguals showed increased neural activity in the left frontal, temporal, and parietal regions relative to bilinguals. For bilingual children, Chinese semantic association produced greater activation in the right inferior frontal gyrus, whereas English semantic association produced greater activation in the left inferior frontal gyrus. These findings suggest a neuro-cognitive model of language and literacy acquisition in Chinese-English bilingual first grader children. Moreover, bilingual children might develop different patterns of neural activity for each of their languages.

Title: White matter sex differences in late childhood assessed with single- and multi-shell diffusion-weighted MRI metrics

Authors: *K. E. LAWRENCE[1], Z. ABARYAN[2], E. LALTOO[1], J. T. MCCRACKEN[3], P. M. THOMPSON[4];
[1]Imaging Genet. Center, Dept. of Neurol., USC, Los Angeles, CA; [2]Imaging Genet. Center, Dept. of Neurol., USC, Marina Del Rey, CA; [3]Dept. of Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; [4]Stevens Inst. for Neuroimaging & Informatics, Univ. of Southern California (USC), Marina Del Rey, CA

Abstract: A comprehensive characterization of sex differences in the brain is critical for improving our understanding of sex effects in health and disease. However, we still lack a complete understanding of such differences in developmental populations. Here we examined sex effects on white matter microstructure in a large-scale, community-based sample of youth

using advanced diffusion-weighted MRI measures. Study participants consisted of 9- to 10-year old children from the ABCD study (discovery/replication cohort: 3,979/3,975 youth, 47.8/48.6% female). White matter microstructure was quantified in 21 bilateral regions of interest (ROIs) across the brain using the advanced multi-shell diffusion model restriction spectrum imaging (RSI) and the traditional single-shell model diffusion tensor imaging (DTI). White matter metrics derived from RSI included intracellular anisotropic, isotropic, and total diffusion. Measures calculated using DTI included fractional anisotropy (FA), and mean, axial, and radial diffusivity (MD, AD, RD). Results were considered significant and replicable if they survived FDR correction across ROIs in the discovery cohort (q<0.05) and exhibited p<0.05 in the replication cohort. We found significant and replicable sex differences in RSI and DTI metrics for every white matter ROI examined (|std. betas|=0.06-0.48). Girls typically exhibited greater intracellular anisotropic, isotropic, and total diffusion relative to boys, suggesting that girls may exhibit greater neurite density and white matter cellularity on average. Boys generally displayed greater MD, AD, and RD across ROIs than girls on average, with higher or lower FA observed depending on the ROI. Findings were largely similar when examining the left and right hemispheres separately, as well as when adjusting for intracranial volume, head motion, pubertal status and dimensional internalizing or externalizing problems. Our results expand on previous conflicting DTI studies in developmental populations and, together with prior work in older adults, suggest that patterns of sex differences evolve over the lifespan. In sum, these findings robustly demonstrate sex effects on white matter in youth and provide an important foundation for understanding sex differences in health and disease.

Title: Profound detrimental effects of obesity on the developing connectome in early adolescence

Authors: S. J. BROOKS[1], S. M. PARKS[2], *C. STAMOULIS[3];
[1]Pediatrics, Boston Children's Hosp., Boston, MA; [2]Pediatrics, Boston Children's Hosp., Boston, NY; [3]Med., Boston Children's Hospital/Harvard Univ., Boston, MA

Abstract: Over 20% of adolescents in the US are obese, a highly alarming statistic given detrimental effects of unhealthy weight on physical, mental and cognitive health. In particular, there is growing evidence that obesity can lead to 'miswiring' of neural circuits, resulting in cognitive and behavioral deficits. During adolescence, the brain undergoes significant changes and is vulnerable to stressors and risk factors, including unhealthy weight, which may adversely impact the maturation of neural circuits supporting critical high-level functions such as decision-making and executive control, as well as mental health. To date, the effects of obesity on developing functional circuits during adolescence remain elusive. To address this significant gap in knowledge, using resting-state fMRI from 5566 early adolescents (median age = 120 months, inter-quartile range = 13.0 months; 52.1% females) from the Adolescent Brain Cognitive Development (ABCD) cohort, this study investigated the impact of obesity on the topology of developing functional brain networks. Children were included based on normal structural MRI, no history of ADHD or bipolar disorder, which may independently affect network connectivity, and quality of fMRI data. Using established age- and sex-specific thresholds for obesity (95th BMI percentile), n = 680 children (12.2% of the cohort) were identified as obese. Given overall low connectivity of brain networks at rest, for each participant the fMRI run with the lowest median connectivity was analyzed. Connectivity was estimated as the pairwise peak fMRI signal cross-correlation. Topological properties included network efficiency, clustering, modularity, robustness and stability. Statistical models were developed to compare these properties in obese versus non-obese children, adjusting for age, sex, race, ethnicity, family income and percent of censored frames in fMRI. Bilateral attention, somatomotor, default-mode, temporo-parietal, fronto-parietal control, limbic and reward networks as well as the thalamus had significantly lower median connectivity, efficiency, global clustering, robustness and stability ($p<0.001$ for all properties) in obese children. Together, these networks support cognitive processes spanning multiple domains, including sensorimotor function, memory, executive function, decision-making, the reward system and emotional processing. These results suggest that severely unhealthy weight may have profound detrimental effects on maturating neural circuits in adolescence, with widespread negative implications for cognitive function, and deficits that may persist across the lifespan.

Title: Body mass index influences the relationship between socioeconomic status and neurodevelopmental outcomes in children

Authors: *E. DENNIS[1], P. MANZA[1], N. VOLKOW[1,2];
[1]Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [2]Natl. Inst. on Drug Abuse, Bethesda, MD

Abstract: Low socioeconomic status (SES) in childhood is associated with deficits in executive function and changes in cortical morphology. Furthermore, rates of childhood obesity are greater among low SES children and childhood obesity is also associated with cortical alterations and impaired neurocognition, specifically in the domain of executive function. To investigate the influence of BMI on the relationships between SES and both neurocognition and brain morphology, we used data from the Adolescent Brain Cognitive Development (ABCD) study, a multi-site, longitudinal study following over 11,000 9-10-year olds for 10 years throughout development, to construct multiple linear regression models and conduct mediation analyses. In a sample of 8,919 subjects (mean age = 9.91 ± 0.621 years, 52.6% male), SES as measured by household income, highest level of parental education, and area deprivation index, was associated with lower BMI, greater total and prefrontal cortical volume, and better performance on assessments of executive function (The Flanker Task, the List Sorting Working Memory Test, and the Dimensional Change Card Sort Task, measuring cognitive control, working memory, and cognitive flexibility respectively). Mediation analysis indicated that BMI had a significant indirect effect on associations between area deprivation and both total and prefrontal cortical volumes, as well as on the associations between area deprivation and composite neurocognitive scores, which were driven by performance on tasks of working memory and cognitive flexibility, but not cognitive control. The findings of this exploratory research suggest that BMI should be considered in future studies investigating the relationship between low SES and poor neurodevelopmental outcomes.

Title: Exogenous Gonadal Hormone Treatment Reduces Connectivity between Prefrontal Cortex and Ventral Striatum at Rest in Transgender Adolescents

Authors: R. FRENCH[1], S. F. LIEBOWITZ[2], L. NAHATA[1], J. F. STRANG[3], W. I. MATTSON[1], *E. E. NELSON[1];
[1]Abigail Wexner Res. Inst., [2]Dept. of Psychiatry and Behavioral Hlth., Nationwide Children's Hosp., Columbus, OH; [3]Gender Develop. Program, Children's Natl. Hosp., Washington, DC

Abstract: Adolescence is characterized by enhanced reward responsiveness and reductions in inhibitory control resulting in a shift toward increased levels of motivated behavior and impulsivity. Previous research has linked these behavioral changes to the surge in gonadal hormones at puberty. Testosterone and to a lesser extent estradiol have been shown to increase activation in the ventral striatum and may also alter functional connectivity between the ventral striatum and other brain regions – particularly the prefrontal cortex. While most previous work in this area has focused on alterations in reward system as a function of changes in endogenous hormone levels at puberty as dissociated from age. The current study focused on the effects of exogenously administered gonadal hormones, testosterone and estradiol, to transgender adolescents undergoing endocrine treatment for gender dysphoria.
One hundred and two participants between 13 and 22 years of age from gender development clinics in two treatment facilities underwent a 6-10 min resting state scan on a 3 Tesla MRI. Thirty-three of 68 trans-masculine (assigned female at birth) were undergoing exogenous testosterone treatment and twenty-two of 34 trans-feminine (assigned male at birth) participants were undergoing treatment with estradiol. Some of the untreated groups were undergoing a variety of other hormonal treatments including both puberty suppression with GnRHa and spironolactone to attenuate endogenous adrogen exposure. Whole brain connectivity maps were generated for each participant from seeds placed in the ventral tegmental area (VTA) and the Nucleus Accumbens (NAcc). A second level omnibus analysis included gonadal hormone treatment (GAH) , assigned sex at birth (AS), and their interaction as predictor variables; and age and site as covariates. This analysis indicated a significant region of reduced coupling in the ventromedial prefrontal cortex in both the VTA and NAcc seed maps as a function of hormone treatment (collapsed across both testosterone and estradiol). These results indicate that gonadal hormone treatment may act to reduce connectivity between prefrontal cortex and reward regions and is consistent with similar effects with endogenous hormones at puberty. Several trend regions in which hormone treatment by sex at birth were also found. Future planned analyses examining sub-sets of the untreated groups may help further elucidate these findings.

Title: Reduced cortical volume of the default mode network in adolescents with generalized anxiety disorder

Authors: *J. BASHFORD-LARGO[1,2], R. ZHANG[1], A. MATHUR[1], J. ELOWSKY[1], A. SCHWARTZ[1], M. DOBBERTIN[1], R. R. BLAIR[1], K. BLAIR[1], S. BAJAJ[1];
[1]Boys Town Natl. Res. Hosp., Boys Town, NE; [2]Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: ABSTRACT
Background: Widespread structural alterations have been shown to be implicated in individuals with Generalized Anxiety Disorder (GAD). However, there have been inconsistent findings in cortical volume (CV) differences. Also, most structural neuroimaging studies looking at GAD used a region-based approach with relatively small sample sizes and have typically not focused on adolescents with GAD. We believe this is the first study to look at CV in adolescents with GAD using a network-based approach. The goal of the current study was to focus on three different brain networks (Limbic, Frontoparietal, and Default Mode Network [DMN]) in adolescents with GAD.**Method:** The study involved 81 adolescents with GAD and 112 typically developing (TD) comparison individuals matched on age (15.98 and 15.63 respectively), sex (42F/39M and 45F/67M), and IQ (101.90 and 103.94 respective means). Participants underwent structural MRI to look at CV and sub-cortical volume differences.**Results:** We found that adolescents with GAD showed significantly lower CV within the DMN compared to TD individuals. Within the DMN, CV was particularly reduced in the participants with GAD within prefrontal and temporal regions. Moreover, within the participants with GAD, severity of symptomatology was negatively associated with CV within the DMN (particularly within the prefrontal region of the DMN). Finally, participants with GAD showed significantly reduced hippocampal volume relative to TD participants.**Conclusion:** The current findings suggest structural alterations in adolescents with GAD, which are associated with severity of GAD in patients.

Title: In vivo cerebral connectometry study based on the diffusion tensor: obese vs normal weight children

Authors: H. RAMIREZ[1], P. DIES-SUAREZ[2], B. DE CELIS[4], E. BARRAGAN[3], P. SO[5], *S. HIDALGO-TOBON[6];
[1]UAM-Iztapalapa, Mexico City, Mexico; [2]Imagenology, [3]Neurol., Hosp. Infantil de Mexico Federico Gomez, Mexico City, Mexico; [4]BUAP, Puebla City, Mexico; [5]Kings Col., London, United Kingdom; [6]UAM-Hospital Infantil de Mexico Federico Gomez, Ciudad DE Mexico, Mexico

Abstract: Alterations in brain white matter relating to obesity have been poorly studied in childhood populations. Diffusion Tensor Imaging (DTI) provides information on the degree and directionality of water diffusion in tissues and can provide information regarding brain microstructure during brain development. Connectometry analysis is based on the central hypothesis that the associations between diffusion values and study variables suggests a common fiber pathway [1]. The cohort comprised 142 children with a mean age of (8.31 ± 1.18) years, who were classified into three by groups according to their Body Mass Index (BMI): normal weight, overweight and obese, in accordance with the World International Organization guidelines. Blood levels of low-density lipoproteins (LDL) and high-density lipoproteins (HDL) were recorded. DTI were performed on a SIEMENS Skyra 3 Tesla scanner, with a 32-channel head coil, using a 3D EPI diffusion-weighted sequence with bipolar gradients, 128 diffusion sampling directions, TE = 106ms, TR = 3200ms, flip angle 90º, a b-value of 1000 s/mm^2. DSI Studio software was used for the connectometry analysis, only the brain regions with white matter tracts that met the condition FDR < 0.05 were accepted, resulting in 16 white matter zones that were statistically significant. Variables, BMI and LDL, correlated with lower Axial Diffusivity (AD), Mean Diffusivity (MD), Radial Diffusivity (RD) and Quantified Anisotropy (QA) values, but higher Fractional Anisotropy (FA) and Generalized Fractional Anisotropy (GFA) values. The associations for HDL were generally the opposite to those for BMI and LDL. These results could indicate an increase in fatty acids in the extracellular space to increase the anisotropy of white matter axons [2]. Fatty acid accumulation could in turn, trigger an autoimmune response that leads to a low-grade neuroinflammation that decreases the anisotropy of white matter axons [3]. Interestingly, different results between adult populations and child populations, mainly in FA, have been observed [4,5], which could imply that obesity affects

developing brains differently compared to matured adult brains.

Title: Neuropsychiatric traits and their relationship with striatal volume in children and adolescents from Huntington's Disease families

Authors: *E. E. REASONER[1], E. VAN DER PLAS[1], H. M. AL-KAYLANI[1], D. R. LANGBEHN[1], A. L. CONRAD[2], J. SCHULTZ[1], E. A. EPPING[1], V. A. MAGNOTTA[3], P. C. NOPOULOS[1];
[1]Dept. of Psychiatry, [2]Stead Family Dept. of Pediatrics, [3]Dept. of Radiology, Univ. of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: Neuropsychiatric traits, broadly defined as executive dysfunction and psychiatric symptoms, are a prominent feature of Huntington's Disease (HD). Little is known about the development of these traits. Given previous evidence of atypical striatal development in mutant huntingtin (*mHTT)* carriers, we hypothesized that neuropsychiatric symptoms would be associated with striatum development. Using data from the Kids-HD study, we aimed to compare neuropsychiatric symptoms between child and adolescent carriers of *mHTT* and peers who did not inherit *mHTT*. We also sought to determine relationships between neuropsychiatric traits and striatal development.

Participants between 6-18 years old were recruited from families affected by HD. Following an accelerated longitudinal design, the sample included 59 gene-expanded (GE) individuals and 91 gene-non-expanded (GNE) individuals who provided 91 and 145 observations, respectively. The Pediatric Behavior Scale (PBS) and the Behavior Rating Inventory of Executive Function (BRIEF) were administered to assesses neuropsychiatric traits. Striatal volumes were extracted from 3T neuro-anatomical images. Multivariable linear regression models were conducted to

evaluate the impact of group, age, and striatal volume on neuropsychiatric symptoms. We found that depression/anxiety was higher in the GNE group compared to the GE group (Estimate = 4.26, $t(130) = 2.37$, $p = 0.019$). Additionally, age-dependent striatal volume (age*striatum interaction) predicted depression/anxiety scores independent of *mHTT* status (Estimate = 0.429, 95% CI 0.15:0.71, $p = 0.0029$). Increased depression was associated with smaller striatal volume in younger children; however, the inverse pattern was observed in adolescents (i.e., increased depression associated with larger striatal volume). When considered in the context of previous findings, these results suggest that differences in striatal development between GNE and GE may be associated with reduced risk of depression or anxiety in child and adolescent carriers of mHTT.

Title: Identifying novel and selective sodium channel modulators from Theraphosidae venoms

Authors: E. M. DUNCAN[1], D. MCCULLOUGH[2], S. C. C. GRACE[1,3], S. BAKER[2], *J. P. O. KAMMONEN[1], P. GRANT[2], S. A. TRIM[2], V. LAZARI[1];
[1]Early Discovery, Charles River Labs., Saffron Walden, United Kingdom; [2]Venomtech, Sandwich, United Kingdom; [3]Dept. of Biol. & Biochemisty, Univ. of Bath, Bath, United Kingdom

Abstract: Voltage-gated sodium (Na_V) channels have been extensively studied as targets for therapeutic indications such as pain, epilepsy and paralysis, where modulating these channels could be beneficial by altering action potential firing. However, small molecule interventions have been largely unsuccessful in the clinic, primarily due to challenges in developing compounds with high subtype selectivity to minimise off-target effects. Many animal venoms have evolved as Na_V channel modulators in order to subdue prey and defend against predators. Several toxin peptides are highly potent and specific to individual Na_V subtypes, and as such have become widely-used tools in research to elucidate structure and function of the channels. These venom peptides are also inherently stable due to their biology. Increasingly, toxins have been used in the development of novel therapeutics as peptide frameworks for new bioactive molecules or targeting scaffolds for drug conjugates. However very few have moved to the clinic and thus new approaches are needed. Ion channels are notoriously challenging to study in drug

discovery, due to long and laborious manual patch clamp approaches. Recent advances in automated patch clamp technologies have allowed high quantities of meaningful data to be generated quickly. We have successfully collected, fractionated and standardised venoms from 17 Theraphosidae species to produce a Targeted Venom Discovery Array (T-VDA). This T-VDA, containing 960 theraphosid venom fractions, was screened in duplicate against $Na_V1.4$ and $Na_V1.7$ channels on the Sophion Qube high-throughput automated patch clamp platform in 384 well format. We identified 33 fractions, which modulated the activity of one or both channels, thus generating a hit rate of 3.4% across both targets with the majority modulating $Na_V1.7$. Here we present our findings and discuss the advantages and challenges of using automated patch clamp technology to identify novel hits using a venom peptide library.

Title: Functional analysis of the developmental delay SCN8A G1625R mutation reveals prominent persistent currents

Authors: *S. QUINN[1], M. BRUSEL[1], H. BASSAN[2], R. BEN-SHALOM[3], M. RUBINSTEIN[1]; [1]Goldschleger eye research institute, Dept. of human molecular genetics and biochemistry, Tel Aviv university, Tel Aviv, Israel; [2]Pediatric neurology and development center, Shamir medical center, Be'er Ya'akov, Israel; [3]Ctr. for Integrative neuroscience, Kavli institute for fundamental neuroscience, Univ. of California, San Francisco, CA

Abstract: The voltage-gated sodium channel $Na_V1.6$, encoded by the gene *SCN8A,* plays an important role in neuronal firing. Mutations in the *SCN8A* gene result in a range of neurodevelopmental impairments, including developmental and epileptic encephalopathies, autism spectrum disorders, developmental delay without seizures, and movement disorders. Functional testing revealed that gain of function mutations in the *SCN8A* gene are associated

with severe epilepsy, while loss of function mutations are associated with intellectual disability with or without seizures. We performed a functional analysis of a $Na_V1.6$ mutation, G1625R, identified in a 5-year-old patient with significant global developmental delay, mild epilepsy, and quadriparetic cerebral palsy. Voltage-clamp experiments in whole-cell configuration were performed on transfected mouse neuroblastoma cells, revealing mixed gain and loss of function effects. While the maximal current amplitudes of the $Na_V1.6^{G1625R}$ currents were smaller compared to WT channels ($Na_V1.6^{WT}$ at -10 mV: -313±51.72 pA/pF, n=12; $Na_V1.6^{G1625R}$: -138.6±38.3 pA/pF, n=15, p=0.01), persistent currents were markedly enhanced ($Na_V1.6^{WT}$: 3±0.68%; $Na_V1.6^{G1625R}$: 27.23±3.9%, p<0.0001), leading to a slightly higher total current that passes through the $Na_V1.6^{G1625R}$ channel over a longer period. Additionally, $Na_V1.6^{G1625R}$ channels showed a depolarizing shift in the activation and inactivation curves. The effect of different anti-epileptic drugs was tested (Carbamazepine, Lacosamide, and Cenobamate) with the main goal of inhibiting the persistent current and shifting the inactivation to hyperpolarized potentials. Carbamazepine shifted the inactivation curve toward hyperpolarized potentials, partially correcting the gating properties, but had no effect on the persistent currents, which remained prominent in $Na_V1.6^{G1625R}$. We further investigated the effect of the mutation on neuronal firing by generating an ion channel model with biophysical properties of $Na_V1.6^{G1625R}$ .We incorporated it into a numerical model of an excitatory neuron, in order to determine the overall contribution of the mixed loss and gain of function characteristics of the mutation to the pathophysiology of this channelopathy. Together, our analysis demonstrated complex gain and loss of function properties in the *SCN8A* mutation $Na_V1.6^{G1625R}$, which are not corrected by Carbamazepine but might be corrected with a drug that will have a more specific effect on the persistent current.

Title: Phenotype and neurophysiology of Scn2a^{K1422E}mice reflect complex Na$_V$1.2 sodium channel dysfunction related to DEKA > DEEA mutation of the selectivity filter.

Authors: *D. M. ECHEVARRIA-COOPER[1,3], N. A. HAWKINS[1], S. M. MISRA[1,2,4], C. H. THOMPSON[1], A. D. NELSON[5], A. M. LIPKIN[5,6], A. L. GEORGE[1,3], K. J. BENDER[5], J. A. KEARNEY[1,3];

Lurie Children's Hosp. of Chicago, Chicago, IL; [5]Neurology, Kavli Inst. for fundamental Neuroscience, Weill Inst. for Neurosciences, [6]Neurosci. Grad. Program, Univ. of California, San Francisco, CA

Abstract: Genetic variants in *SCN2A*, encoding the Na$_V$1.2 voltage-gated sodium channel, have been described in a range of neurodevelopmental disorders. Genotype-phenotype relationships in *SCN2A* disorders can be investigated using animal models of unique variants. The variant *SCN2A*-p.K1422E is associated with infant-onset developmental delay, epilepsy, and autism spectrum disorder. Compared to wild type (WT) Na$_V$1.2 channels, K1422E channels exhibit novel calcium permeability, reduced current density, and tetrodotoxin (TTX) resistance. To investigate the pathogenic effects of this variant, we generated a mouse model using CRISPR/Cas9 genome editing. To characterize cellular effects of this variant, we performed voltage clamp recordings in dissociated hippocampal neurons, as well as current clamp recordings and 2-photon calcium imaging in neocortical slice preparations. Dissociated neurons from *Scn2a^{K1422E}* heterozygous mice (*Scn2a$^{E/+}$*) exhibited a novel TTX-resistant current with a reversal potential of 32.7 mV compared to 38.5 mV observed in WT mice. Measurements in *Scn2a$^{E/+}$* neocortical slices showed altered action potential waveforms and ectopic calcium transients during the rising phase of the action potential at the axon initial segment, demonstrating complex effects on channel function. To assess how this complex channel phenotype might contribute to seizure susceptibility, juvenile mice were implanted with EEG headmounts and monitored for ≥ 96 hours. *Scn2a$^{E/+}$* mice exhibited rare (< 1 per week) spontaneous localized seizures during sleep without observable behavioral changes. Similar events were not observed in WT mice. Due to the rarity of these seizures, we used flurothyl to induce a stereotyped progression to generalized tonic-clonic seizures (GTCS) in juvenile mice. While latency to myoclonic jerk was not affected, *Scn2a$^{E/+}$* mice took longer to reach GTCS compared to wild type (WT) controls. This indicates resistance to seizure spreading in *Scn2a$^{E/+}$* mice, consistent with the localized seizures observed using EEG. We also observed a reproducible non-unimodal distribution of GTCS latencies in *Scn2a$^{E/+}$* females compared to WT. Neurobehavioral phenotypes of *Scn2a$^{E/+}$* mice were assessed in a series of assays between 6-12 weeks of age. *Scn2a$^{E/+}$* mice exhibited reduced anxiety-like behavior and alterations in olfactory-guided social behavior. Overall, *Scn2a^{K1422E}* mice exhibit phenotypes that are similar yet distinct from other *Scn2a* models, consistent with complex effects of K1422E on Na$_V$1.2 function. This underscores how *Scn2a^{K1422E}* mice can serve as a platform to investigate phenotypic complexity of *SCN2A* disorders.

Title: The reversibility of social deficits in adult Scn2a gene-trap knockout mice

Authors: *M. EATON[1,4], J. ZHANG[1], X. CHEN[1], J. WU[2], Y. YANG[3];
[2]Medicinal Chem. and Mol. Pharmacol., [3]MCMP, [1]Purdue Univ., West Lafayette, IN; [4]Purdue Inst. for Integrative Neurosci., West Lafayette, IN

Abstract: Recent genetic studies have discovered variants in voltage-gated sodium channel $Na_V1.2$ (encoded by gene *SCN2A*) as the leading cause of monogenic autism spectrum disorder (ASD), as well as other neurodevelopmental disorders. While an estimated 400 or more new cases with *SCN2A*-associated disorders are diagnosed each year, no curable treatments are available. In the early stage of brain development, $Na_V1.2$ is suggested to be the main voltage-gated sodium channel expressed in the axon initial segment. Later in the development, $Na_V1.2$ is re-distributed to other parts of the neurons including proximal axon initial segment and dendrites, altogether contributing to the initiation, propagation, and backpropagation of action potentials. Homozygous *Scn2a*$^{-/-}$ knockout mice die perinatally. While heterozygous *Scn2a*$^{+/-}$ mice (with ~50% $Na_V1.2$ expression level) survive to adulthood, behavior abnormalities of these mice are minor to modest. To further study the relationship between the dysfunction of *SCN2A* and ASD, we have characterized a gene-trap knockout mouse model of *Scn2a* with about 75% reduction of *Scn2a* mRNA and protein expression. This mouse model has pronounced social deficits in multiple social behavior tests including empty versus novel mouse (three-chamber), fake toy versus novel mouse (three-chamber), sociability over 24 hours (home cage), stranger interaction,

and reciprocal interaction. Approaches to rescue abnormal behaviors are being explored, including the restoration of *Scn2a* expression in adult mice. Our data will demonstrate to what extent that restoration of *Scn2a* expression can correct behavioral abnormalities in adulthood. Our results will also reveal circuit mechanisms underlying abnormal social behaviors related to severe $Na_V1.2$ deficiency. Knowledge gained in our study will set a solid foundation to further determine other forms of interventions (gene therapy, small molecule drugs) using behavioral rescue as a direct, phenotypic readout.

Title: Modeling SCN2A gain-and-loss of function mutations L1342P and C959X with CRISPR-edited human-induced pluripotent stem cell-derived neurons and cortical spheroids

Authors: *M. I. OLIVERO-ACOSTA[1], Z. QUE[1], T. NGUYEN[1], L. YUNIS[1], Y. YANG[2]; [2]MCMP, [1]Purdue Univ., West Lafayette, IN

Abstract: Human-induced pluripotent stem cell (hiPSC) models are valuable tools that enable the generation of monolayer and three-dimensional neuronal cultures that recapitulate features of neurological diseases. The *SCN2A* (Voltage-Gated Sodium Channel Alpha Subunit 2) gene encodes for sodium channel Nav1.2, a protein that plays a vital role in mediating action potentials in neurons. *SCN2A* pathogenic variants have been identified in individuals with epilepsy and autism spectrum disorders (ASD). These variants leading to abnormalities in sodium channel topology and function, possibly influencing neuronal activity patterns. Two examples of variants are L1342P (p. Leu1342Pro) and C959X (p. Cys959X). The gain-of-function (GoF) L1342P variant was identified from several patients with intractable seizures. While the loss-of-function (LoF) C959X variant was identified from a patient with ASD, developmental delay, and no previous history of epilepsy. Our recent work has demonstrated that

hiPSC-derived 2D-neuronal monolayers carrying the CRISPR-Cas9-edited L1342P-mutant channel display a marked hyperexcitability phenotype. This hyperexcitability is characterized by increased intrinsic excitability, enhanced synchronous network firing, and bursting (Que et al., 2021). However, the impact that the GoF L1342P mutation could have upon the development of neurons and organoids remains unexplored. On the other hand, we are interested in modeling the *de novo* LoF C959X, a protein-truncating variant. Previous studies have shown that when the C959X mutation is transfected in HEK293 (Human embryonic kidney 293 cells), the cells presented no detectable sodium current, indicating deficiencies in ion channel formation (Ben-Shalom et al., 2017). Nonetheless, it is unknown how the mutation may impact neuronal activity and development. In the present study, we used human-induced pluripotent stem cells to generate cortical neurons and 3D spheroids to identify and compare the neurobiological phenotypes arising from *SCN2A* gain-and-loss of function sodium channel variants. Techniques applied include patch-clamp recordings, microelectrode array (MEA) recordings, live-cell calcium imaging, and neurite reconstructions. Our results will elucidate how gain vs. loss-of-function Nav1.2 variants may affect neuronal activity and development of neurons distinctly, contributing to different disease phenotypes. Our work will also provide a highly physiologically relevant platform for testing novel therapeutical interventions, including small molecules, gene therapies, and antisense oligonucleotides.

Abstract: Recent discoveries have shown that *SCN2A* genetic variants are causal for a number of neurodevelopmental disorders, including autism spectrum disorder (ASD), intellectual disability (ID), and infantile seizure disorders. *SCN2A* encodes the voltage-gated sodium channel $Na_V1.2$, with loss-of-function variants causing ASD and ID, and gain-of-function variants causing infantile seizure disorders. Given this genetic linkage to disease, we set out to discover small molecule positive modulators of $Na_V1.2$ for the treatment of ASD. We first established a novel primary high-throughput screening (HTS) fluorescence-based assay to allow the detection of voltage changes in $Na_V1.2$-expressing HEK cells in response to electrical stimulation. This physiologically relevant assay platform enabled us to complete an HTS of ~77,000 compounds, where we identified 378 $Na_V1.2$ activators and 1837 inhibitors. Follow up concentration-response assay yielded a number of potent and efficacious activators, and select compounds were followed up in a synaptic function model where a synaptically transmitted response to electrical stimulation was quantified in primary murine cortical cultures to confirm the compounds' effect. Subsequent electrophysiological characterization of one hit, BRD4032, revealed that it activates $Na_V1.2$ by changing both the voltage sensing mechanism and the inactivation kinetics of the channel, and that BRD4032 elicited marked widening of the action potential waveform in *Scn2a*$^{+/-}$ mouse brain slices. Finally, *in vivo* EEG studies showed significantly altered alpha, beta, and delta frequency bands in *Scn2a*$^{+/-}$ mice, indicating that these alterations may be useful translational biomarkers. Taken together, we have successfully implemented a robust screening strategy to identify $Na_V1.2$ modulators and are poised to follow up on the selectivity, mechanism of action, and *in vivo* effects of these compounds.

Title: The ASD-associated genes Ank2 and Scn2a converge to co-regulate dendritic excitability in neocortical pyramidal neurons

Authors: *A. NELSON[1], A. CATALFIO[2], J. PHILIPPE[2], L. MIN[2], R. CABALLERO-FLORAN[2], K. PERKINS[2], C. ELVIRA[2], A. SAHAGUN[1], S. SANDERS[1], K. BENDER[1], P. JENKINS[2];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Neuronal voltage-gated sodium channels (Na_Vs) play critical roles in action potential (AP) generation and propagation. *SCN2A*, which encodes the sodium channel $Na_V1.2$, has repeatedly emerged from whole-exome sequencing studies with some of the strongest association scores to autism spectrum disorder (ASD). In developing glutamatergic pyramidal neurons of the medial prefrontal cortex, $Na_V1.2$ is the only sodium channel subtype detected at the axon initial segment (AIS) and nodes of Ranvier. In mature neurons, $Na_V1.2$ is replaced by $Na_V1.6$ at the AIS and is relocalized to the dendrites. Here, $Na_V1.2$ promotes the backpropagation of APs from the AIS to distal dendritic arbors, an important feature of excitable dendrites that is essential for normal synaptic structure, function, and plasticity. While previous studies have shown Na_Vs are localized to the AIS by ankyrin-G (*ANK3*), the mechanisms that underlie $Na_V1.2$ localization within the dendritic membrane are unknown. We hypothesize that ankyrin-B, product of the high-confidence ASD gene *ANK2*, is the primary ankyrin that localizes $Na_V1.2$ to dendrites. Immunostaining cultured neocortical neurons at 19 days *in vitro* showed ankyrin-B is highly expressed throughout the dendrites, distinct from ankyrin-G at the AIS, which suggests that ankyrin-B is well-positioned to control the dendritic localization of $Na_V1.2$. To test this, we performed knockout-and-rescue experiments of ankyrin-B in mature cultured neocortical neurons. Knockout of ankyrin-B resulted in a significant reduction in $Na_V1.2$ levels at the dendritic membrane and rescue with wild-type ankyrin-B restored dendritic $Na_V1.2$ localization. Therefore, loss of ankyrin-B was predicted to have similar consequences on dendritic excitability as *Scn2a* loss. Consistent with this hypothesis, AP backpropagation into the distal dendrites of layer 5 pyramidal neurons was attenuated in acute brain slices from *Ank2* haploinsufficient mice, an effect we observed previously in *Scn2a* haploinsufficient conditions. Furthermore, we found subsequent deficits in excitatory postsynaptic function identical to those previously identified in *Scn2a* haploinsufficient mice. These findings highlight a novel dendritic role for ankyrin-B in the proper localization of $Na_V1.2$ and reveal convergent dendritic function for both *Scn2a* and *Ank2*, two of the most commonly disrupted genes in ASD.

Title: Severe deficiency of voltage-gated sodium channel $Na_V1.2$ elevates neuronal excitability in adult mice

Authors: *J. ZHANG, X. CHEN, M. EATON, J. WU, T. XIAO, Z. QUE, M. OLIVERO-ACOSTA, N. LANMAN, Y. YANG;
Purdue Univ., West Lafayette, IN

Abstract: $Na_V1.2$ channel, encoded by *Scn2a*, is a major voltage-gated sodium channel in the central nervous system (CNS) supporting action potential (AP) firing. $Na_V1.2$ is strongly expressed in the principal neurons of the cortico-striatal circuit, including pyramidal neurons in the medial prefrontal cortex (mPFC) and medium spiny neurons (MSNs) in the striatum. The current paradigm suggests that $Na_V1.2$ gain-of-function variants enhance neuronal excitability resulting in epilepsy, whereas $Na_V1.2$ loss-of-function or protein-truncating variants (collectively referred to as $Na_V1.2$ deficiency) impair neuronal excitability contributing to autism. This paradigm, however, does not explain why 20~30% of patients with $Na_V1.2$ deficiency still develop seizures. As hyperexcitability and hypersynchronization of neuronal firings are associated with seizure generation, it is thus intriguing how $Na_V1.2$ deficiency, predicted to reduce neuronal excitability, contributes to seizures and epilepsy. Here we report a counterintuitive finding that severe $Na_V1.2$ deficiency results in increased neuronal excitability, challenging the current dogma. Using a $Na_V1.2$-deficient mouse model, we show enhanced intrinsic excitabilities of principal neurons in the prefrontal cortex and striatum, brain regions known to be involved in *Scn2a*-related seizures. This increased excitability is autonomous, and is reversible by the genetic restoration of *Scn2a* expression in adult mice. RNA-sequencing reveals the downregulation of multiple potassium channels including $K_V1.1$. Correspondingly, K_V channel openers alleviate hyperexcitability of $Na_V1.2$-deficient neurons. This unexpected neuronal hyperexcitability revealed by our study may serve as a cellular basis underlying $Na_V1.2$ deficiency-related seizures.

Title: Microglial regulation of hyperexcitability in cortical neurons derived from human iPSCs carrying epilepsy-associated sodium channel Nav1.2 variant

Authors: *Z. QUE, M. OLIVERO-ACOSTA, J. ZHANG, J. WU, M. EATON, Y. YANG; Purdue Univ., West Lafayette, IN

Abstract: Rapid progress in the discovery of genetic variants from patients with epilepsy and autism highlights a leading role of *SCN2A* variants. Thus, understanding the pathophysiology related to SCN2A variants may help to advance the development of novel therapeutic interventions. Nav1.2, encoded by gene *SCN2A*, is predominantly expressed in the pyramidal excitatory neurons across the brain, and is responsible for action potential firing and propagation. *De novo* variants of Nav1.2 (e.g., L1342P) were discovered in patients with encephalopathy and seizures. Biophysical property of Nav1.2-L1342P variant was studied in a heterologous expression system, which revealed complex and puzzling characteristics with both gain and loss-of-function features. Therefore, how this variant perturbs neurons and shapes the overall neuronal excitability remains unclear. Using computational modeling, we suggested a gain-of-function phenotype in a single-compartmental pyramidal neuron model. To experimentally test our prediction, we used CRISPR genome editing and generated an L1342P variant and isogenic controls in reference human induced pluripotent stem cell (hiPSC) line. We found elevated action potential firings and altered firing patterns of cortical neurons derived from iPSCs carrying Nav1.2-L1342P variant. Using multi-electrode array recording, we observed a significant increase in neuronal network excitability in L1342P neuron culture. Importantly, we recapitulated features of the phenytoin-resistance effect observed in the clinical treatment. We further demonstrated that a Nav1.2 isoform-specific blocker (Ptx3) can efficiently alleviate the hyperexcitability of L1342P neurons. Neuronal hyperexcitability especially in the chemically induced seizures models can be regulated by microglia, which is an innate immune cell in the brain. However, how human microglia regulate the activity of human neurons carrying seizure-related mutations is not known. Thus, we continue our exploration to study how microglia behave in the presence of hyperexcitable neurons carrying Nav1.2-L1342P variant. Using microglia-neuron co-culture system, we studied changes of microglia calcium signaling in culture with L1342P neurons. We also studied how the microglia regulate neuronal activities

using MEA and patch-clamp recording. Understanding the relationship between hyperexcitable L1342P neurons and microglia would open the possibility of exploring the modulation of microglia as a novel approach to control neuronal hyperexcitability and eventually alleviate seizures.

Title: Constructing a novel functional interactome to study the dynamic crosstalk between neuroinflammation and neural excitability

Authors: J. VON MORGENLAND[1], A. ALLAHVERDIAN[2], R. KNORR[1], *S. VENUGOPAL[3];
[1]Undergraduate Neurosci. Interdepartmental Program, [2]Human Biol. and Genet., [3]Integrative Biol. and Physiol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Maintaining neural excitability is a key function of the nervous system and is essential for normal behaviors. Ongoing perturbations such as aging and nervous diseases can cause homeostatic shifts in excitability through modifications in the palette of intrinsic and synaptic ion channel proteins (ICPs) in neurons. Here we hypothesize that neuroinflammatory cytokines associated with injury and disease are homeostatic modulators of ICPs and neural excitability. To test this, we conducted a systematic meta-analysis of experimental evidence for cytokine modulation of neuronal excitability. Our initial approach of database search using popular bioinformatics tools such as the STRING surprisingly did not reveal strong evidence for protein-protein interactions between cytokines and ICPs. However, a more detailed examination of the scientific literature on PUBMED uncovered a few yet convincing mechanistic studies which demonstrated cytokine-induced changes in not only ICP mRNA expression, but also functional changes in ion channel conductivity and, action potential threshold and frequencies. For example, the proinflammatory cytokine TNF-α; released by resident glial cells increased voltage-gated sodium channel mRNA, channel conductivity and action potential firing. Driven by these findings, we developed a novel *functional interaction score* (FIS) through which we quantitate the strength of evidence for pleiotropic actions of cytokines on ICPs not only at the molecular level, but also at the functional levels which lead to altered neural excitability. We then used the FIS to generate protein-protein interactomes of cytokines and ICPs to better understand their functional relationships. Our analysis revealed 1-to-N and M-to-1 associations

between cytokines and ICPs. We further demonstrate application of graph theory and dynamic model simulations to analyze the functional links between neuroinflammation and homeostatic changes in neural excitability. Our results also prompt experimental work to clarify cytokines effects on neurons at pre-symptomatic stages of neurodegenerative diseases for therapeutic neuromodulation.

Title: Regulation of surface expression of the hyperpolarization activated cyclic nucleotide gated channel 2 (HCN2) through SUMOylation and interaction with the auxiliary subunit TRIP8b.

Authors: *L. A. FORSTER[1], D. J. BARO[2,1];
[1]Neurosci. Inst., [2]Biol., Georgia State Univ., Atlanta, GA

Abstract: HCN2 mediates the subthreshold conductance, Ih, that influences intrinsic cellular properties such as membrane potential, pacemaker activity and temporal summation. HCN2 is widely expressed in both the CNS and PNS, and channelopathies that alter Ih amplitude contribute to disease states such as epilepsy, chronic pain, Parkinson's disease, and major depression. HCN2 surface expression can be tuned by SUMOylation at K669, or co-expression with the interacting protein TRIP8b. Enhancing HCN2 SUMOylation at K669 or interaction with TRIP8b isoform 1a-4 produces an increase in surface expression. We are investigating if a common mechanism is involved. Increased exocytosis or decreased internalization can enhance surface expression. To test if SUMO regulated internalization, HCN2 was heterologously expressed in HEK293 cells, and Ih maximal conductance (Gmax) was characterized with whole cell patch clamp. Inclusion of SUMO peptide in the patch pipette to enhance SUMOylation increased Ih Gmax by ~61% relative to control recordings that lacked SUMO (one way ANOVA, $F(3, 31) = 4.672$, $p=0.0083$; Tukey's, $p=0.0355$). This experiment was repeated, but the clathrin inhibitor Pitstop 2, was or was not included in the superfusate and pre-applied for 20min to block endocytosis. Pitstop 2 produced a significant ~80% increase in Ih Gmax relative to controls lacking any treatment (Tukey's, $p=0.0188$); Pitstop 2 + SUMO produced a significant

~71% increase in Ih Gmax relative to control (Tukey's, p=0.0247); the effect of Pitstop 2 was not significantly different compared to Pitstop 2 + SUMO (Tukey's, p= 0.9700). These data suggest that SUMOylation prevents internalization. Consistent with this interpretation, a biotin internalization assay showed 23% of HCN2 is internalized in HEK293 cells after 2.5 hours at 18°C, however enhancing SUMOylation reduced internalization to 6.3% (t-test, p= 0.0125). The experiment is being repeated with HCN2 K669R to determine if SUMOylation at K669 is mediating this effect. TRIP8b and SUMO may act to increase HCN2 surface expression through a common mechanism. Co-expression of TRIP8b with HCN2 in HEK293 cells increased Ih Gmax by 114% compared to HCN2 alone (one way ANOVA, F (3,32) = 12.56, p<0.0001; Tukey's, p<0.0001), no further increase was observed when SUMO + UBC9 were co-expressed with TRIP8b (Tukey's, p=0.7239). This suggests that TRIP8b and SUMO may act to increase HCN2 surface expression through the same pathway. Biotin internalization assays will examine if TRIP8b is preventing internalization of the channel.

Title: The role of $P2X_2$ receptor for acetylcholine synthesis pathway

Authors: *T. MARUYAMA, A. MANO, T. ISHII, Y. KAKINUMA, M. KANEDA; Physiol., Nippon Med. Sch., Tokyo, Japan

Abstract: Acetylcholine, an excitatory neurotransmitter, is synthesized from choline and acetyl-CoA by choline acetyltransferase (ChAT) in cholinergic neurons. Currently, as choline taken up through high-affinity choline transporters is thought to be the only source for acetylcholine synthesis, the activity of cholinergic neuron is thought to correlate with the activity of high-affinity choline transporter. We have previously reported that the mouse retinal cholinergic neurons with weak immunoreactivity for high-affinity choline transporter have choline-permeable cation channels formed by $P2X_2$ receptor. In this study, therefore, we investigated whether choline transported into cells through $P2X_2$ receptors is used for the acetylcholine synthesis in recombinant system by using immunostaining, immunoblotting and HPLC techniques. We expressed $P2X_2$ receptors in both HEK293T cells and HEK293T cells stably

expressing ChAT (ChAT-HEK293T cells). In both HEK293T cells and ChAT-HEK293T cells, intracellular acetylcholine levels were significantly increased when choline uptake through $P2X_2$ receptors was activated by ATP. Our results support the idea that $P2X_2$ receptors work as a novel pathway of choline transport for acetylcholine synthesis.

Title: The effect of calcium ions on mechanosensation and neuronal activity in proprioceptive neurons

Authors: *N. PARKER[1], H. TANNER[3], R. COOPER[2];
[1]Neurosci., [2]Biol., Univ. of Kentucky, Lexington, KY; [3]Biol., Eastern Kentucky Univ., Richmond, KY

Abstract: Proprioception of all animals is important in being able to have coordinated locomotion. Stretch activated channels (SACs) transduce the mechanical force into electrical signals in the sensory endings. The types of SACs vary among sensory neurons in animals as defined by pharmacological, physiological and molecular identification. The chordotonal organs within insects and crustaceans offer a unique ability to investigate proprioceptive function. The effects of the extracellular environment on neuronal activity as well as the function of associated SACs are easily accessible and viable in minimal saline for ease in experimentation. The effect of extracellular [Ca2+] on membrane properties which affect voltage-sensitivity of ion channels, threshold of action potentials and refractory periods can be readily addressed in the chordotonal organ in crab limbs. It is of interest to understand how low extracellular Ca2+ enhances neural activity considering the SACs in the sensory endings maybe Ca2+ channels and that all neural activity is blocked with Mn2+. It is suggested that axonal excitability might be affected independent from the SAC activity due to potential presence of calcium activated potassium channels (K(Ca)) in the axons. We are experimenting to separate the role of Ca2+ on the

function of the SACs and the excitability of the axons in the nerves associated with chordotonal organs. These experiments may aid in understanding the mechanisms of neuronal hyperexcitability in hypocalcemia within mammals.

Title: Hypoglycosylation of Piezo1: new pathological mechanisms and therapeutic target for neurological disorders in phosphomannomutase-2 deficiency?

Authors: A. EDO, J. CARRILLO-GARCÍA, *J. FERNANDEZ-FERNANDEZ;
Univ. Pompeu Fabra, Barcelona, Spain

Abstract: Congenital Disorders of Glycosylation (CDG) is a disease family caused by mutations in genes involved in the glycosylation pathways. Phosphomannomutase-2 (PMM2) catalyzes an early step in N-glycosylation, and its genetic variation is associated to PMM2-CDG. CDGs involve a wide range of clinical manifestations with severe neurological alterations. Stroke-like episodes (SLEs) are among the acute neurological complications that may occur in PMM2-CDG, which are characterized by confusional status, hemiparesis and epileptic seizures. Although their pathomechanisms are not fully understood, head trauma has been recently described as a potential trigger. The brain is a mechanosensitive organ capable of transducing mechanical forces into neurological responses, and mechanosensitive ion channels have been suggested to underlie the transduction of these forces. Although the molecular nature of these channels remains unknown, Piezo family channels are well positioned candidates. Interestingly, Piezo1 has been identified as an N-glycosylated protein.
Our goal was to study Piezo1 hypoglycosylation in cellular physiology and its possible pathophysiological relevance for SLEs in PMM2-CDG. We studied the effects of Piezo1 hypoglycosylation on its activity and/or biophysical properties in both heterologous expression system and primary cultures of murine cortical neurons. Our results showed that hypoglycosylation of wild-type (WT) human Piezo1 (hPiezo1) by using the glycosylation

blocker kifunensine induced an increase in the mechanical sensitivity in response to increasing pulses of negative pressure on cell-attached patches of HEK293 cells. Additionally, hypoglycosylated WT hPiezo1 showed slower inactivation kinetics. Interestingly, asparagine-to-glutamine hPiezo1 mutants N2293Q and N2330Q mimicked the effect of kifunensine on channel mechanical sensitivity and inactivation kinetics. N885Q mutant also showed slower inactivation kinetics but similar mechanical sensitivity when compared to the WT channel. Similarly, kifunensine- and swainsonine-induced hypoglycosylation of Piezo1 in murine cortical neurons resulted in an increased calcium influx at the soma in response to Piezo1 specific agonist Yoda1. However, immunostaining of Piezo1 revealed a reduced channel density in neurites upon treatment with glycosylation blockers kifunensine or swainsonine.
Based on these results, we suggest that hypoglycosylation of Piezo1 might contribute to the neurological symptoms found in PMM2-CDG patients, by favoring neuronal excitability in response to mechanical stimulation.

Title: Trpv1-tubulin complex: a molecular target to understand chemotherapy-induced neuropathic pain

Authors: *S. MOHANTA[1,2], S. SAHA[1,2], C. GOSWAMI[1,2];
[1]Natl. Inst. of Sci. Educ. and Res., Bhubaneswar, India; [2]Homi Bhabha Natl. Inst., Mumbai, India

Abstract: <u>TRPV1-Tubulin complex: A molecular target to understand chemotherapy-induced neuropathic pain</u>Microtubule dynamics plays important function in stabilization and maturation of dendritic spines, and thereby affects overall neuronal circuit functions. Taxol and Vincristine are commonly used compounds that alter microtubule dynamics and these are also used as chemotherapeutic agents against different forms of Cancer. One major side effect of Taxol application in cancer patients is the development of severe peripheral neuropathy, which not only affects microtubule dynamics of peripheral neurons, but also other apparently unrelated functions such as mitochondrial functions and Ca^{2+}-signalling events. In last few years it has been suggested that TRP channels are involved in the development of microtubule-drug-induced Neuropathic pain regulation. In this context, cross talk between microtubule cytoskeleton with TRP channels especially with TRPV1 and TRPV4 at various level has been demonstrated. So far multiple groups have demonstrated the importance of TRPV1 in chemotherapy induced

neuropathic pain, both *in vitro* and *in vivo* experimental model systems. TRPV1, also known as the “Capsaicin receptor” is a nonselective cation channel found in a sub-set of peripheral neurons, often localizes in the nerve endings of nociceptors and is activated by different noxious stimuli such as high temperature, low pH and a plethora of endogenous as well as exogenous chemical stimuli. Taxol is known to increase the expression of TRPV1 in DRG neurons. TRPV1 seems to regulate microtubule dynamics and cytoskeletal elements in turn regulate proper localization and function of TRPV1, presenting a strong feedback mechanism. Hence detailed understanding of TRPV1-tubulin complex appears as a potential therapeutic target relevant for cancer, cancer pain, peripheral neuropathy and many other pathophysiological systems. Previously we reported the biochemical interaction between TRPV1 and tubulin and vertebrate-specific conservation of the same. In this work, we demonstrate that specific positively charged residues present within the C-terminus of TRPV1 are crucial for tubulin interaction. Substitution of these amino acids with neutral amino acids resulting in altered sensitivity to ligands, suggesting that the TRPV1-Tubulin complex is able to regulate channel function as well. We conclude that understanding the nature of interaction between TRPV1 and microtubules is highly relevant to unravel the involvement of ion channels in chemotherapy induced pain. These findings may have broader implication in human health and welfare.

Title: Pharmacology of Transient receptor potential cation M8 (TRPM8) channels using different activation stimuli

Authors: I. RINKE-WEIß[1], A. HORVÁTH[1], N. BECKER[1], T. A. GOETZE[1], G. OKEYO[2], T. STRASSMAIER[2], R. HAEDO[2], N. FERTIG[1], ***A. OBERGRUSSBERGER**[1];

Abstract: Transient Receptor Potential (TRP) channels are widely distributed throughout the mammalian central and peripheral nervous systems. The TRP channel subfamily M (melastatin) member 8 (TRPM8) is a nonselective cation channel, proposed to be the predominant thermoreceptor for cellular and behavioral responses to cold stimuli. TRPM8 channels can be found in multiple organs and tissues, and are involved in regulation of various important processes such as inflammatory reactions, immunomodulatory effects, pain, cell proliferation, migration and apoptosis, and vascular muscle tension. Disorders ranging from migraine, dry eye disease and cancer, amongst others, have been attributed to TRPM8 rendering this channel a

promising target for drug discovery. Here, we studied the responses of TRPM8 expressed in CHO cells activated using different stimuli on automated patch clamp (APC) systems. TRPM8 is activated by chemical cooling agents including menthol and icilin or by temperatures lower than ~26 °C. Using a high throughput APC device, TRPM8 was activated by increasing concentrations of menthol with an EC_{50} of approximately 20 µM. In addition, TRPM8 was activated when the system was cooled to 18°C and further activated at 12°C. A small, lower throughput APC device was also used to activate TRPM8 repetitively using solution at 10°C. This was subsequently blocked by increasing concentrations of capsazepine applied at 10°C with an IC_{50} of 12.9 µM. External solution warmed to 35°C also blocked the TRPM8-mediated current. To this end, TRPM8 could be reproducibly activated by different stimuli, and blocked by pharmacological agents or heated solution. Therefore, the use of TRPM8 expressed in cell lines coupled with high throughput APC provides a promising tool for basic research and may have important implications in drug development for compounds acting on TRPM8.

Title: Intermittent cocaine self-administration but not passive cocaine infusions reduces h-current in putative dopaminergic neurons of the ventral tegmental area

Authors: *C. CALO[1], O. VELEZ-ACEVEDO[2], K. Y. BOSQUE CORDERO[3], D. CONSUEGRA GARCIA[1], R. VÁZQUEZ-TORRES[4], C. A. JIMENEZ-RIVERA[5];
[1]UPR Med. Sci. Campus, San Juan, PR; [2]Biol., UPR Rio Piedras Campus, San Juan, PR; [3]Biol. Dept., Univ. of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico; [4]Physiol. Dept., Univ. of Puerto Rico, San Juan, PR; [5]Physiol., Univ. of Puerto Rico, Physiol. Dept., San Juan, PR

Abstract: Intermittent Access (IntA) cocaine self-administration is a protocol suggested to better simulate human addictive behavior due to the intermittent pattern of drug administration. IntA is also known to produce incentive salience and psychomotor sensitization. Dopamine (DA) neurons display a prominent mixed cation current conductance known as the hyperpolarization-activated cyclic nucleotide current, or I_h, that contributes to neural processes such as resting membrane potential, firing frequency modulation, and synaptic integration. Previous results from our laboratory demonstrated that I_h amplitude is significantly reduced after cocaine sensitization. This I_h reduction resulted in an increased temporal summation, mean depolarization and EPSP amplitude, all factors related to an enhanced excitability state. Since the cocaine sensitization model involves noncontingent drug injections given by the experimenter it is crucial to determine if electrophysiological changes in VTA DA cells are present when drugs are self-administered (contingent). In the present study we explored if DA neurons intrinsic alterations are present after exposure to IntA. Our hypothesis is that VTA DA cells intrinsic neuroadaptations are dependent on associative processes acquired during the operant conditioning. Using the whole-cell patch-clamp technique in brain slices, we investigated the effects of 3 days of cocaine IntA, and passive cocaine infusions (yoked controls) on I_h amplitude, temporal summation, and neuronal excitability. Hyperpolarizing current injections followed by sudden depolarizing steps were used to analyze rebound excitation. Increasing depolarizing current injections were used to evaluate how neurons respond to a depolarizing stimulus. To analyze synaptic integration, a 33-Hz train of 5 αEPSCs ($\alpha = 5$ ms; Imax = 50) were injected into the soma of putative VTA DA neurons when clamped at -70 mV. Our results demonstrate that an IntA protocol, but not passive cocaine infusions, produces a significant I_h amplitude reduction ($P<0.05$). No differences in rebound action potentials (APs) where observed. A depolarizing current protocol showed a significant increase in the number of APs ($P<0.05$). Temporal summation was increased at depolarized potentials in the IntA group and Yoked controls ($P<0.0001$). These results suggests that I_h modulation and intrinsic activity regulation is dependent on associative learning to drug cues. The findings also suggest that enhanced synaptic integration could possibly be a cocaine-induced pharmacological effect.

Title: Absence seizure simulations in a full virtual brain model explain the transient loss of consciousness

Authors: *P. BENQUET[1], M. YOCHUM[1], M. KUCHENBUCH[2], R. NABBOUT[3], F. WENDLING[1];
[1]INSERM U1099 -LTSI University of Rennes 1, Rennes, France; [2]Univ. de Paris, [3]INSERM UMR 1163 Hôpital Necker Enfants malades, APHP,, Paris, France

Abstract: Conscious perception results from an interplay between two processes interacting with each other: *awareness* and *wakefulness*. *Awareness* is supported by large scale cortico-cortical functional connectivity whereas *wakefulness* depends critically on thalamocortical connectivity[1]. We have recently developed a full virtual human brain computational model named COALIA able to simulate realistic EEG, as compared to real EEG recorded in human at two level of consciousness during wake and deep sleep[2].Typical absence seizures are characterized by a sudden and transient (10-15 sec) loss of conscious perceptions associated with an interruption of ongoing activities associated with a fixed gaze. At the same time, the EEG shows generalized spike-wave discharges (SWD) at 2.5-4 Hz at the level of scalp electrodes. In childhood absence epilepsy, these seizures can occur in children up to 200 times a day, which can lead to attention, cognition, memory and mood disorders and ultimately to learning disabilities at school. In this study we used COALIA to understand the neurobiological mechanisms of typical absence seizures and how these mechanisms are responsible for a transient loss of consciousness. Accounting for brain characteristics present in immature brain, and the human structural connectivity we were able to generate realistic absence seizures with our computational model. Results suggest that a focal initiation in the frontal cortex triggers a switch in the firing mode of the cognitive/associative nuclei of the thalamus from tonic to “UP and down” discharge mode due to and excessive feed forward cortico-thalamic inhibition. This thalamic bursting mode initiate spike-wave discharge onto the associative area of the cortex through an exaggerated thalamocortical feed forward inhibition (hyperexcitation of cortical SST GABAergic subtype onto pyramidal cells) that explain the large wave of the SWD. This large cortical inhibition transiently disrupts the cortico-cortical connectivity by suppression of the PV-PC loop. Simulated TMS-evoked potential confirmed a dramatic drop of the consciousness index during absence seizures.1: Decoding the circuitry of consciousness: From local microcircuits to brain-scale networks, 2020. Title: Sleep-seizure electroencephalography associations predictive of severity and death risk in epilepsy

Authors: *A. TYULMENKOVA, G. GARCIA-MENDOZA, D. KEITH, C. ISGOR;
Biomed. Sciences, Col. of Med., Florida Atlantic Univ., Boca Raton, FL

Abstract: Sleep-seizure electroencephalography (EEG) associations may serve as biomarkers to track severity of upcoming seizures in order to monitor death risk using a new mouse model of adult-onset, spontaneous epilepsy. The mice overexpress brain derived neurotrophic factor (BDNF) in the forebrain under the CAM kinase II alpha promoter (TgBDNF). TgBDNF mice develop seizures at ~4 months of age which worsen with each episode. Seizures are elicited via tail lifts and cage agitation. Seizures become more severe as indicated by increased duration of postictal cortical activity suppression (i.e., EEG flat or EEG waves in delta frequency) associated with loss of posture/consciousness. In more advanced stages, the mice expire following long period of postictal generalized EEG suppression resulting in cardiorespiratory arrest. We surgically implanted subdural cortical electrodes on the mice skulls prior to the first seizure episode (3-channel EEG system, Pinnacle Technology, KS) to record seizure and sleep EEG for 7 weeks. The recordings targeted time periods of moderate to severe phases of epilepsy. We used age- and litter-matched wild-type mice as controls. We hypothesize that as epilepsy progresses, detectable alterations in sleep structure may indicate upcoming life-threatening seizures. Twenty-four hours after seizure induction, mice were connected to EEG apparatus for recording sleep in inactive phase. We analyzed early (first 1 hr) and late (last 1 hr) sleep separately to define the changes in rapid eye movement (REM) and slow-wave sleep (SWS) phases. Data was assessed by simple regression analyses between multiple seizure and sleep parameters. A shift in increased duration of SWS in late compared to early sleep was linked to a remarkable increase in postictal generalized cortical suppression duration. Shorter delay to onset of SWS in late phase (last 1 hr) of sleep was associated with increased total seizure duration. Number of REM bout counts in early sleep was negatively associated with duration of postictal generalized cortical suppression (delta frequency), ictal duration and ictal spectral power. Number of REM bout counts in late sleep was negatively associated with length of postictal generalized cortical suppression (delta frequency) and cumulative duration of spiking wave discharges observed in seizure recovery accompanied by behavioral freezing. Our data reveals that dynamic alterations in sleep-seizure EEG measures indicate epilepsy severity progression. Identifying critical sleep-

seizure EEG associations as epilepsy progresses may predict severity of upcoming seizures and, in turn may inform impact of such episodes on sleep architecture.

Title: Interictal bursts in mouse model of acute seizure engage hippocampal pyramidal cells and resemble mini seizures

Authors: Y. CHEN[1], N. DRISCOLL[1], P. MULCAHEY[1], F. VITALE[1], *H. TAKANO[2,1]; [1]Univ. of Pennsylvania, Philadelphia, PA; [2]The Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Interictal bursts, abnormal electrographic activity characterized by brief epileptiform discharges, are commonly observed in intracranial EEG recordings from both human patients and animal models. Despite the ubiquity of these bursts, the cellular nature of interictal activity and their relationship to seizures remain unclear. In this study, we aim to understand how electrographic activity and cellular recruitment during interictal bursts change over the course of acutely induced seizures. In the hippocampus of transgenic mice expressing calcium indicator gCaMP6 in pyramidal neurons, we implanted a transparent graphene-based microelectrode array (Gr MEA). This set-up allows us to simultaneously follow pyramidal cell recruitment in the dorsal hippocampus by two-photon microscopy and record electrographic signals from the surface of the hippocampus. To induce seizures, we applied a convulsant, 4-aminopyridine, to the contralateral cortical surface. We present two main findings: 1) During interictal events, pyramidal cell recruitment corresponds to periods of high gamma activity (80 - 250 Hz). Line length in the high gamma band, a feature which measures signal energy and complexity, predicts pyramidal cells recruitment during interictal activity. 2) Interictal bursts resemble mini seizures - metrics that are elevated during seizures, such as phase locked high gamma, LFP (4 to 30 Hz), and high gamma broadband power are transiently elevated during the onset of interictal activity. Taken together, these results suggest that interictal bursts manifest as mini seizures that are rapidly quashed. Excitatory principal cell activity is enhanced during the onset of the burst, a period where the interictal activity most closely resemble seizure onset. However, they are quickly silenced. By identifying the cells that are recruited during the onset of interictal bursts,

we can speculate about the mechanisms and cellular identity of interictal activity termination. Inhibitory interneurons are a likely candidate, and the Gr MEA enables us to elucidate cell type specific dynamics during interictal bursts.

[1]ENYS - Hosp. de Alta Complejidad El Cruce Nestor Kirchner - UNAJ - CONICET, CABA, Argentina; [2]ENYS - Hosp. de Alta Complejidad El Cruce Nestor Kirchner - UNAJ - CONICET, Florencio Varela, Argentina; [3]Hosp. de Alta Complejidad El Cruce Nestor Kirchner, Florencio Varela, Argentina; [4]CONICET, Florencio Varela, Argentina; [5]Conicet, Capital Federal, Argentina

Abstract: Analysis of network changes in the kindling model of temporal lobe epilepsy
In this work we analyzed the firing rate (FR) of single neurons involved in the neural network during hippocampal rapid kindling (RK 3 days). Thirty male Wistar rats were implanted with a bipolar Macroelectrode (MacroE) for stimulation in the CA1 region of the right ventral hippocampus and also, eight Microelectrodes (MicroE) were implanted to record the electrical activity of the CA1 region of the right dorsal hippocampus. Two groups were created out of the animals that successfully completed the procedure: The RK group, consisting of 3 animals and the sham group with the remaining rat that was implanted but not stimulated. We proceeded according to the RK model stimulation parameters, and we analyzed the electrical signal. The analysis was performed in 57 single neurons in total, 47 in the RK group and 10 in the sham group. The FR was determined during the Basal (pre-stimulations) and After-Discharge (AD) periods. The analysis of the Basal and AD periods of kindled animals showed a progressive increase in the daily average of the FR along the protocol and a significant difference was found between day 3 and day 1. We also found that data dispersion increased as the stimulations progressed. On the other hand, the qualitative analysis of the FR evidenced a possible classification of the neurons, with some of them increasing their FR during the AD period -the excitatory type (35%)-, some decreasing it -inhibitory type (32%)-, and some not changing their FR at all, not directly involved in the epileptogenic network (33%). We demonstrated that the FR

is strongly affected by the epileptogenic activity associated with the RK. We believe these findings are relevant for a better understanding of kindling-associated network changes and might provide new targets for therapeutic strategies in patients with epilepsy.

Title: Automated prediction of epileptic activity in mouse models of epilepsy

Authors: *A. I. BECK[1], D. KUNDA[2], R. E. A. SANCHEZ[3], A. M. BARD[4], J. SKIBO[4], K. J. MILLEN[4], F. K. KALUME[4], H. O. DE LA IGLESIA[2];
[1]Grad. Program in Neurosci., [2]Biol., Univ. of Washington, Seattle, WA; [3]Allen Inst. for Brain Sci., Seattle, WA; [4]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

Abstract: Epilepsy is a neurological disorder characterized by the presence of excessively synchronized neural activity (seizures) and epileptiform discharge (interictal spikes). In addition, epileptic activity is modulated by circadian rhythms and the sleep-wake cycle. Because increased frequency of interictal spikes can be associated with seizure risk, real-time detection of interictal spikes could lead to seizure prediction and interventions to prevent seizures or their adverse outcomes. Using mouse models of epilepsy, we developed a machine-learning (ML) based method for autonomously detecting interictal spikes. Neural activity was chronically recorded in mice using two electrocorticography electrodes and one electromyography electrode. We used mouse models of Dravet syndrome (DS; heterozygous *Scn1a* gene deletion) and focal cortical dysplasia (FCD; PIK3CA gene mutation), along with corresponding wild-type controls. Data were normalized to a sampling rate of 400 Hz and min/max value of ±400 mV, and interictal spikes were manually scored in a subset of data. A total of 96 time- and frequency-based features were extracted in epochs of 2 seconds. The data were randomly under-sampled to ensure balanced classes and used to train a single-layer Perceptron-based ML model using L1 regularization to classify interictal spikes. The outcome was a binary classification; interictal

spike present/absent in the given epoch. The fully trained model had a mean test accuracy of 74.56 (SD=18.66%). When separated by mouse model, the accuracy was 75.39% for DS signals, 64.24% for FCD signals, and >95% for corresponding wild-type signals. The model achieved recall and precision values of 1.00 and 0.84 for epochs without interictal spikes, and recall and precision values of 0.06 and 0.75 for epochs with interictal spikes. False positive epochs tended to resemble manually labeled interictal spikes. Additionally, in DS signals, interictal spikes predicted by the model displayed circadian rhythm-modulated frequency in multi-day recordings, as well as increased interictal spike frequency and circadian rhythm disruption when transitioning between light-dark cycles. These results suggest our ML-based method captures epileptic activity in two mouse models of epilepsy with differing genetic etiology and presentation of epileptic activity. Because the model uses regularization aimed at reducing data dimensionality, this algorithm could be used to detect interictal spike frequency in real-time, and potentially forecast potential seizure onset.

Title: Sleep is Fragmented and Reduced in a Mouse Model of Temporal Lobe Epilepsy

Authors: *N. P. PEDERSEN[1], L. M. AIANI[2], L. I. ROSENBERG[2], B. J. HARVEY[3]; [1]Neurol. and Biomed. Engin., [2]Neurol., [3]Neurol. and Program in Neurosci., Emory Univ., Atlanta, GA

Abstract: Sleep and epilepsy are inextricably and bidirectionally intertwined. Sleep disruption occurs in human epilepsy, and sleep loss can result in worsening seizures. Sleep-wake brain networks determine forebrain rhythms and excitability, but the role of these circuits in epilepsy is unknown. In people with epilepsy, sleep disorders, particularly insomnia, are worse. These sleep disorders may also contribute to other comorbidities of epilepsy. We implanted 47 mice with electrocorticogram, hippocampal, and EMG electrodes. Mice were recorded for a baseline week with synchronized video before experimental mice (n =37) received intraamygdala kainate injections, and control mice (n = 10) underwent intraamygdala saline injections. Mice were then

recorded for three weeks before perfusion for histological analysis. 642 seizures were recorded in 23 experimental mice. Experimental mice with seizures (n = 10, >= 19 seizures) had significantly more wake than control mice (10.4% increase ± 3.5 (SE), two way ANOVA, $p < 0.01$). Seizures were most common in the waking state, but proportionally seizures were most common in the post-ictal state ('clustering'), REM, then wakefulness, and NREM sleep. Sleep was also fragmented in experimental mice. These data provide a parallel of human sleep disruption in epilepsy. Studies now examine the mechanisms of sleep disruption, as well as manipulations of sleep-wake circuits to treat sleep disorders in epilepsy, ameliorate comorbidities, and a as novel candidate means to treat epilepsy and seizures.

Abstract: The central nervous system (CNS) toxicity is a critical factor among possible adverse effects in clinical and non-clinical trials in drug development. Seizure and convulsions are frequent appearances of the CNS-toxicity and are the leading cause of drug development attrition. The existing state of seizure liability assessment relies on conventional behavioral batteries, such as Irwin's test and the functional observational battery (FOB), to detect seizure and convulsions susceptibility. Recently, several laboratories have developed in vitro electrophysiological assay system using hippocampal brain slices from various animal species

(rats, dogs, monkeys, and mini-pigs) for seizure liability assessment. Here, we report a novel in vitro assay system using voltage-sensitive dye (VSD) imaging in mice hippocampus. The VSD allows us to record the membrane potential change in the neurons entire membrane components under a field of view. That is, we can record action potential (AP) components and the excitatory and inhibitory postsynaptic potentials (EPSP and IPSP) even below the threshold. We prepared acute transverse hippocampal slices (350 µm thick) from the two age groups (4 - 7, and 8 - 10 weeks of female mice). Electrical stimulation was applied onto Schaffer collateral pathway from a stimulation electrode placed near the CA1/CA3 border.The responses were recorded every thirty seconds with an imaging system (MiCAM02, Brainvision Ltd.) and field potential recordings from stratum radiatum. Four convulsive compounds of picrotoxin (PiTX; 1, 10, and 100 µM), SR95331 (Gabazine; 0.1, 1, and 10 µM), 4-aminopyridine (4AP; 1, 40, and 100 µM), and pilocarpine (Pilo; 10, 30, and 100 µM) are tested. We perfused the drugs with cumulative ascending concentrations for 20 min per concentration. We designed the tests to include the stimulus-response relationships during perfusion. PiTX and gabazine ($GABA_A$ receptor antagonist) enhanced the duration of the response in the stratum radiatum (SR). An application of 4AP induced significant slow components in the SR. We found that the application of Pilo suppressed EPSP and thus action potential. The different effect on CA1 activity indicates that the system can evaluate drugs on different mechanisms in the neurons, thus examining CNS toxicity (seizure liability).

Title: Tandem transcriptional and translational analysis of gene expression in mouse models of Alzheimer's disease

Authors: G. EASTMAN[1,2], E. R. SHARLOW[1], J. S. LAZO[1], J. R. SOTELO-SILVEIRA[2], *G. S. BLOOM[1];

Abstract: Defining cellular mechanisms that drive Alzheimer's disease (AD) pathogenesis and progression is aided by studies describing how gene expression patterns change during pre-symptomatic AD and the ensuing periods of steadily declining cognition. The majority of relevant published studies have emphasized control of mRNA levels, but not translation regulation, leaving the ultimate results of gene expression relatively unexplored in the context of AD. To identify genes whose expression might be regulated at the transcriptional, and especially at the translational levels in AD, we analyzed gene expression in cerebral cortex of two AD model mouse strains, CVN (APP_{SwDI};$NOS2^{-/-}$) and Tg2576 (APP_{Sw}), and their companion wild type (WT) strains at 6 months of age by tandem RNA-Seq and Ribo-Seq (ribosome profiling). Identical starting pools of bulk RNA were used for RNA-seq and Ribo-seq. Differential gene expression analysis was performed at the transcriptional and translational levels separately, and also at the translational efficiency level. Regulated genes were functionally evaluated by gene ontology tools. Compared to WT mice, AD model mice had similar levels of transcriptional regulation, but displayed differences in translational regulation. A specific microglial signature associated with early stages of Aβ accumulation was up-regulated at both transcriptome and translatome levels in CVN mice. Although the two mice strains did not share many regulated genes, they showed common regulated pathways related to APP metabolism associated with neurotoxicity and neuroprotection. This work represents the first genome-wide study of brain translation regulation in animal models of AD, and provides evidence of a tight and early translational regulation of gene expression controlling the balance between neuroprotective and neurodegenerative processes in brain.

Title: Analysis of cell-type gene regulatory network characteristics in Alzheimer’s disease

Authors: *C. GUPTA, D. WANG;
Univ. of Wisconsin Madison, Madison, WI

Abstract: Alzheimer's Disease (AD) is a chronic neurodegenerative disorder with complex molecular mechanisms that can be highly cell-type specific. Gene regulatory networks, a key mechanism controlling gene expression of single cells, serve as powerful tools to explain the cellular heterogeneity underlying AD phenotypes. In this study, we analyzed gene regulatory networks depicting interactions between transcription factors, regulatory elements, and target genes for major cell types in the human brain: excitatory and inhibitory neurons, microglia, and oligodendrocytes. We identified genes that act as hubs in different cell types using various network centrality measures and found that several functional pathways showed centrality differences between healthy and AD conditions, such as synapse organization in neurons and neutrophil-mediated immunity in microglia. Because gene regulatory networks naturally form a hierarchy with downward information flow, we also estimated hierarchical scores of genes over each network. We found that genes related to cognition and glial cell fate commitment had the most extensive changes in the hierarchical scores in microglia and oligodendrocytes, respectively. In contrast, hierarchical changes in neuronal cells were relatively less extensive. We also estimated the level of co-regulation among genes and identified cell-type-specific modules consisting of known AD-risk genes. For example, one microglia module consists of 7 known AD-risk genes, including HS3ST1, KAT8, SORL1, TREM2, BIN1, ABI2, and ECHDC3. Furthermore, we show that the network-based features of known AD-risk genes can be used in a machine learning framework to predict new genes potentially involved in AD pathogenesis. These results suggest that our network analysis of cell-type gene regulatory networks can complement AD gene prioritization and functional interpretation. Finally, our analysis is open-source available as a general pipeline and has potential applications to other neurodegenerative diseases.

Title: Early changes in spine density and gene expression in cortex of APP/PS1 mice

Authors: *J. E. TOMORSKY, M. K. DREWS, K. R. LEBLANC, C. J. SHATZ;
Dept. of Biol., Stanford Univ., Stanford, CA

Abstract: Understanding the early pathogenesis of Alzheimer's Disease (AD) is an important step in designing treatments and preventing more advanced pathology and cognitive decline in the later stages of the disease. Early in the progression of AD, soluble forms of oligomeric amyloid beta (oAbeta) are thought to increase, leading to deficits in synaptic plasticity and synapse loss. We have previously shown that in an APP/PS1 mouse model of AD, ocular dominance plasticity is diminished as early as P30, long before plaque formation and overt cognitive defects are detectable. These early deficits in ocular dominance plasticity were rescued by knocking out the paired immunoglobulin-like receptor B (PirB), a high-affinity neuronal receptor for oAbeta. Here we show preliminary data suggesting that structural changes in synapse density might also occur at P30 in an APP/PS1 mouse model. Dendritic spine densities on L5 basal dendrites in visual cortex trended lower in APP/PS1 mice relative to healthy controls at P30. This trend was not observed when PirB was knocked out, suggesting that oAbeta may act through PirB to decrease spine density long before overt pathological or behavioral changes are detectable. We also identified several neuronal transcripts that were differentially expressed between APP/PS1 and WT mice at P30 using the RiboTag technique to isolate ribosome-bound mRNA in neurons followed by RNA-seq. Differentially expressed genes largely fell into Gene Ontology pathways relating to neuropeptide signaling, MAPK signaling, axon development, circadian rhythm, cell adhesion, memory, and apoptosis. Together these results indicate that the very early accumulation of oAbeta can trigger significant changes in neuronal gene expression which accompany disruptions in synaptic plasticity and possible synapse loss.

Title: Identifying differences in cellular and disease phenotypes across human Alzheimer's disease tissue by multiplexed ion beam imaging

Authors: *B. CANNON, K. VIJAYARAGAVAN, D. TEBAYKIN, D. MRDJEN, J. OLIVERIA, A. BARANSKI, N. GREEENWALD, M. ANGELO, T. MONTINE, S. BENDALL; Stanford Univ., Palo Alto, CA

Abstract: Identifying cell-based and regional phenotypes in human brain tissue is a necessary task to understand neurodegenerative pathologies in Alzheimer's disease. Using MIBI (multiplexed ion-beam imaging) we have simultaneously quantified tissue-level expression of 40 different targets encoding a deep set of neurological phenotypes with nanometer scale spatial resolution. To localize protein expression to specific cells or tissue restricted regions, we use a combination of single cell and single object segmentation methods. Applying this technique to multiple MIBI scans of archival human hippocampus cross-sections, we are able to identify the spatial distribution and expression heterogeneity of glial cell types and proteopathies in both cognitively healthy and diseased human brain. Using off-the-shelf and in-house developed computational strategies we are able to identify unique protein-disease relationships in neurons that may lead to additional work testing the functional significance of the descriptive work outlined here. We believe this will be a straight forward approach to discretize and select features for multiplexed imaging technologies as applied to human brain tissue in both degenerative and non-degenerative contexts.

Title: Hypothalamic RNAseq highlights lysosomal gene Laptm5 as a potential driver of cognitive and metabolic dysfunction in Alzheimer's disease

Authors: *M. DAI, A. DUNN, J. ZHANG, V. PHILIP, K. O'CONNELL, C. C. KACZOROWSKI;
The Jackson Lab., Bar Harbor, ME

Abstract: Alzheimer's disease (AD) is the most common form of dementia that leads to progressive decrease in memory, cognitive function, and eventually ability to perform daily tasks. Cognitive dysfunction in AD is often accompanied (and preceded) by metabolic dysfunction, which may worsen neurological symptoms and quality of life in patients. It has been difficult to identify gene modifiers of AD that may only make a relatively small contribution to the overall disease risk. However, we recently developed a panel of AD mouse strains (AD-BXDs; Neuner, et al. 2019) that harbors the genetic and phenotypic heterogeneity similar to

those observed in human AD patients. The AD-BXDs are an ideal resource to identify genetic modifiers of late-onset AD that manifest through molecular, neurological and metabolic phenotypes. Using this model, we performed weighted gene co-expression network analysis (WGCNA) in hypothalamic bulk RNA sequencing data. We identified several gene modules whose expression levels significantly correlate with cognitive and metabolic traits. Gene ontology (GO) enrichment search showed that functions of these modules included immune response, neuronal myelination, cell metabolic process, etc. We identified *Laptm5* as the hub gene of the immune response module, and showed it has higher expression in aged and AD mice. Multiple previous studies have proposed *Laptm5* as a target associated with amyloid-beta load in both human and mouse data (Salih et al. 2019, Chang et al. 2017, Bonham et al. 2019, Patel et al. 2020). In conclusion, we hypothesize that *Laptm5* modifies vulnerability to both cognitive and noncognitive symptoms in AD.

Title: Microglial INPP5D isoform expression in AD and AD-associated SNP contributions to allelic expression

Authors: *D. ZAJAC[1,2], J. SIMPSON[1,2], J. MORGANTI[2,3], S. ESTUS[1,2];
[1]Dept. of Physiol., [2]Sanders-Brown Ctr. on Aging, [3]Dept. of Neurosci., Univ. of Kentucky, Lexington, KY

Abstract: *INPP5D* (Phosphatidylinositol-3,4,5-trisphosphate 5-phosphatase 1), the gene encoding SHIP1, contains single nucleotide polymorphisms (SNPs) that are strongly associated with Alzheimer’s Disease (AD) risk. In the brain, *INPP5D* is expressed as several isoforms, mostly in microglia. Full-length SHIP1 is encoded by 27 exons, including an amino-terminal SH2 domain followed by the phosphatase domain. Truncated isoforms lacking the SH2 domain begin from internal transcription start sites. To better understand the function of *INPP5D* in the human brain, we investigated *INPP5D* isoform expression as a function of AD status, and AD-associated SNPs. Single cell RNAseq was performed on APP/PS1 mice to understand the relationship between *INPP5D* expression and microglial activation. The expression of microglial *INPP5D* isoforms was analyzed using quantitative polymerase chain reaction on RNA from AD

and non-AD anterior cingulate human brain samples. Samples were genotyped for the AD-associated SNPs rs35349669 and rs10933431 using TaqMan SNP kits (Thermo). Isoform expression results were analyzed as a function of microglial gene expression (ITGAM and AIF1), total *INPP5D* expression, AD status, and SNP status. In addition, reporter SNPs in the 5' UTR region were used to detect unequal allele expression in the two full-length isoforms of *INPP5D* as a function of AD SNP status. APP/PS1 mice showed an increased expression of disease-associated microglia compared to controls. *INPP5D* was expressed at equivalent levels in both homeostatic and disease-associated microglia. Expression of each *INPP5D* isoform was strongly correlated with microglial gene expression and showed an increase with AD neuropathology but did not show a significant association with AD SNPs. Sequencing of samples heterozygous for both AD SNPs provided preliminary evidence for unequal allele expression modulated by SNP status. Our next step is to quantify the unequal expression using next generation sequencing. In summary, *INPP5D* expression is uniform in both disease-associated and homeostatic microglia. Expression of *INPP5D* isoforms is increased with AD neuropathology. The mechanisms whereby AD genetics influence *INPP5D* expression is not clear, but the rs35349669 allele that increases AD risk may be associated with allelic expression.

Title: Heterogeneity of APOER2 isoforms specific to AD human brains

Authors: *C. GALLO[1,3], A. LABADORF[2], A. HO[3], U. BEFFERT[3];
[1]Pharmacol. & Exptl. Therapeut., [2]Neurology, Bioinformatics, Boston Univ. Sch. of Med., Boston, MA; [3]Biol., Boston Univ., Boston, MA

Abstract: Age and the ε4 allele of apolipoprotein E (APOE) are the two greatest risk factors for developing Late Onset Alzheimer's Disease (LOAD). APOE mediates its physiological effects in the brain by binding to cognate receptors like APOER2. Recent studies have discovered a novel link between aging, neurodegeneration and alternative splicing. Interestingly, APOER2 is highly alternatively spliced in neurons, and one alternative splicing event in APOER2 was identified

previously as altered in Alzheimer's disease (AD). Therefore, abnormal alternative splicing of receptors like APOER2 in aging and neurodegeneration may alter the interactome of the key AD risk factor APOE. Investigating how altered splicing of APOE receptors alters APOE physiological function highlights a new scientific paradigm to investigate the role of APOE in LOAD. Based on this rationale, we hypothesize that APOER2 isoform balance is progressively perturbed in AD contributing to synaptic and neuronal dysfunction. To examine APOER2 isoform distribution across the AD brain, we have utilized long-read single molecule RNA sequencing to generate novel APOER2 transcript maps from the hippocampus and the parietal cortex of three female control patients and three female Braak Stage IV LOAD patients. Our data indicates both common and unique isoforms amongst control and AD patients in the hippocampus and the parietal cortex and highlighted several isoforms of interest. Using in vitro cell based assays, we found hippocampal AD-specific APOER2 isoforms show unique functional biology compared to control-specific isoforms, indicating the combination of alternative splicing events in APOER2 is critical to defining APOER2 receptor biology. To ensure experimental rigor and analyze APOER2 splicing quantitatively, we will examine over 200 control and AD tissue samples in the hippocampus, prefrontal cortex, parietal cortex and control region cerebellum using qPCR. Our findings suggest a novel scientific model to view conferred APOE risk in AD through altered splicing of APOER2.

Title: Novel TREM2 isoforms highly expressed in human brain and their potential impact on Alzheimer's disease

Authors: *B. C. SHAW[1], H. C. SNIDER[2], D. J. ZAJAC[1], J. F. SIMPSON[1], S. ESTUS[3]; [1]Physiol., [2]Univ. of Kentucky, Lexington, KY; [3]Physiol., Sanders-Brown Ctr. Aging, Lexington, KY

Abstract: Multiple variants in *TREM2* which decrease protein function act as risk factors for Alzheimer's Disease (AD). In the brain, *TREM2* is primarily expressed in microglia. The five exons of the *TREM2* gene encode a cell surface receptor with exon 2 encoding the ligand binding

domain, while exon 4 encodes the transmembrane domain. In this study, we have found alternative splicing within *TREM2* mRNA from human brain tissue which results in skipping of exons 2, 3, and 4 (D2-, D3-, and D4-TREM2, respectively) with some isoforms having multiple exons skipped. We also show that these isoforms are not brain-specific as they are detected in multiple tissues. Quantitative PCR data indicate exon 2 is skipped at a frequency of approximately 11.4%. We are evaluating whether there is a functional genetic variant which increases exon 2 skipping. In transiently transfected HMC3 human microglial cells, we show using confocal microscopy that the novel *D2-TREM2* mRNA isoform is translated into protein and are currently investigating subcellular localization. Hence, we propose that these novel mRNA isoforms are likely translated to protein and represent alternative splicing-derived mimetics of the soluble TREM2 (sTREM2) and C-terminal fragment TREM2 which result from ADAM10 and gamma secretase proteolytic cleavage. Overall, modulating *TREM2* splicing represents a potential avenue for AD treatment strategies.

Sci., [3]Garrison Inst. on Aging, [4]Neurol., [5]Ctr. for Translational Neurosci. and Therapeut., [6]Cell Biol. and Biochem., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Alzheimer’s disease (AD) features oxidative stress, transcriptional dysregulation, and hippocampal-dependent learning impairment. The antioxidant all-trans retinoic acid (ATRA), the active form of retinol, plays dual roles as a ROS scavenger and transcriptional regulator via its

function as an agonist at retinoic acid receptors (RARs). We hypothesized that reduced bioavailability of ATRA in the hippocampal dentate gyrus (DG) is associated with AD. To investigate whether ATRA deficiency occurs in the hippocampus of human AD, we performed a secondary analysis of hippocampal transcriptomic data from post-mortem AD and control brains (van Rooij et al. 2019). ATRA-responsive genes (ADLH1A3, CYP26A1, CYP26B1, RBP1, RBP4, NGRN, GAP43, and CALB1) were downregulated, but RAR co-repressors (NCOR1, PML, ZBTB16, and TNIP1) were upregulated. Moreover, consistent with antioxidant depletion, ROS sensors Nrf1/Nrf2 (NFE2L1/NFE2L2) were upregulated. In the J20 AD mouse model crossed with a somatostatin-CRE:tdTomato (SOM:tdT) reporter mouse, we tested the hypothesis that ATRA delays AD-related behavioral, circuit, and transcriptional abnormalities in the DG (3-9 mice per group, 4.8 ± 0.8 months of age, M/F sexes, 31 mice total). We administered ATRA (20 mg/kg) or vehicle (corn oil) IP 3x/week for 8 weeks, followed by Y-maze and open field maze (OFM) testing. Consistent with the hyperactivity phenotype of J20 AD mice, vehicle-treated (VT) mice traveled a greater distance compared to WT mice ($U = 5.00$, $p = 0.009$). By contrast, ATRA-treated (RT) AD and WT mice did not vary in their overall distance traveled ($U = 16.00$, $p = 0.727$). In the OFM, a similar pattern of results was observed. We then performed correlative histological and RNA-seq analyses on DG tissue. Through SOM:tdT expression, we found that DG SOM circuits were aberrantly targeted to the DG inner molecular layer in $J20^{+/-}$ AD mice. By contrast, ATRA treatment prevented formation of this aberrant SOM:tdT circuit in 6/6 males but not in 3/3 female mice. Finally, genes differentially expressed between genotypes and treatments were analyzed using Ingenuity Pathway Analysis. Pairwise comparison of VT WT and VT AD groups indicated dysregulation of Synaptogenesis, PKA, and Ca^{2+} Signaling pathways. ATRA treatment partly normalized these pathways. In summary, chronic treatment with ATRA normalized behavior, prevented formation of aberrant SOM:tdT circuits in the DG, and normalized 6/10 of the top dysregulated pathways. Thus, these human and preclinical studies support the hypothesis that hippocampal ATRA deficiency occurs in AD, suggesting that sustained hippocampal ATRA levels delay AD pathogenesis and progression.

Title: Transcriptome-wide Involvement of the central LH receptor in the interaction between reproductive senescence and Alzheimer's disease development

Authors: *L. LABRADOR[1], M. MEY[2], H. PIONTKIVSKA[2,3], G. CASADESUS[1];
[1]Dept. of Pharmacol. and Therapeut., Univ. of Florida, Gainesville, FL; [2]Dept. of Biomed. Sci., [3]Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstract: Menopause is a knownrisk factor for Alzheimer's disease (AD) development in women. However, themechanisms underlying this increased risk remain unclear. Estrogen losshas been closely implicated in driving such risk. More recently, dataalso support the involvement of luteinizing hormone receptors in the regulationof cognition, plasticity, and AD-related cellular changes. However, themechanisms that underlie such changes are unknown. To address this question, wecarried out a transcriptomic analysis (RNAseq) in C57BL/6 and APP/PS1 miceunder reproductive intact or ovariectomized (OVX) status. A subset of theseanimals was administered an LH analog (hCG)intracerebroventricular (ICV), toaddress the mechanisms associated with central activation of the LH receptor.Animals had been characterized for cognitive function and pathology, both ofwhich demonstrated the benefits of LH receptor activation. Ourtranscriptomic analysis reveals important transcriptional changes that thehippocampus undergoes as a result of gonadal loss that can explain OVX-relatedcognitive deficits and acceleration of AD pathology. Interestingly thesechanges were genotype-dependent with different pathways enriched in C57BL/6 andAPP/PS1 mice. LH receptor activation in OVX APP/PS1 mice, which showed asignificant improvement in cognition and normalization of plaque pathology, thedifferentially expressed genes and the complete topology of the networkchanges, suggests that such effects maybe mediated through pathways associatedwith RNA homeostasis, cellular metabolism, and oxidative stress. Together ourdata further our understanding of mechanisms involved in cognitive loss andpathology regulation under gonadal loss and highlight a novel and directfunctional role of the central LH receptor in mediating AD-related cellularaspects.

Title: Nicotinic receptor modulation of early Alzheimer's disease in (mouse) hippocampus

Authors: *M. H. SABEC, U. MASKOS;
Inst. Pasteur, Paris, France

Abstract: Current treatments for Alzheimer's disease (AD) commonly rely on elevating cholinergic function in the brain, however such interventions are symptomatic and do not prevent the disease's progression. β-amyloid, a peptide thought to underlie neural disruption reported in early AD development (Busche et al, 2008), can interact with the cholinergic system though nicotinic acetylcholine receptors (nAChRs). Previous studies from our group revealed that a genetic loss of β2 nAChR subunits could protect against memory impairment which is induced by β-amyloid over-expression (Lombardo et al, 2016). The presented work therefore investigates the influence of nAChR on β-amyloid induced synaptic and network dysfunction in the hippocampus, and how such modulation may affect the manifestation of cognitive deficits in early AD pathogenesis. We developed a model of localized β-amyloid over-expression by viral transduction of adult mouse dentate gyrus (DG). This local model is used to test the impact of genetic and pharmacological inactivation of nAChRs on memory function and neural activity through behavioural analysis, *in vivo* two-photon calcium imaging, and immunofluorescent techniques. An early-onset development of cognitive deficits and DG hyperactivity was observed in the localized AD model. Furthermore, whilst pharmacological β2 nAChR inhibition was able to protect against β-amyloid induced impairments, this was not associated with a normalization of the DG network activity. Thus, β2 nAChR inactivity is able to protect against β-amyloid induced cognitive dysfunction in a manner independent to changes in overall activity levels within the DG. Identification of the specific nicotinic-β-amyloid interactions underlying the reported protection will facilitate more targeted cholinergic therapies against early AD and may provide mechanistic insights essential for the development of preventative medicine.

Title: Abl1 is downstream effector of mAβ1-42 in its impact on spontaneous synaptic release

Authors: *M. KABIROVA[1], M. REICHENSTEIN[3], D. GOROBETS[1], A. PINHASOV[1], I. MICHAELEVSKI[2];

Abstract: Amyloid plaques are one of the major hallmarks of Alzheimer's disease. While three structural species: monomers, oligomers and fibrils of amyloid beta have been identified (Kamenetz et al., 2003), oligomers and fibril were major target of the last decades investigations, providing less evidence about monomeric forms of amyloid beta (mAβ) and its function. In our research, we aimed to investigate the role of monomeric amyloid beta on spontaneous synaptic transmission. Our previous finding showed that 42 amino acids' long mAβ (mAβ42) markedly reduces spontaneous synaptic activity in cultured hippocampal neurons. Moreover, Abl kinases were shown to be downstream effectors of mAβ42 effect on spontaneous synaptic transmission (Reichenstein et al., 2021). Abelson tyrosine (Abl) kinase family consisting Abl1 (c-Abl) and Abl2 (Arg) isoforms, both are regulators of cell motility, morphology and adhesion (Colicelli, 2010). While the activity of c-Abl is crucial for proper neuronal development, it is relatively quiescent in healthy adult neurons. Activation of c-Abl in adult brain has been linked to human neurodegenerative diseases (Schlatterer et al., 2011). Here we report that Abl differentially regulates spontaneous synaptic release in excitatory and inhibitory neurons. Namely, DPH induced activation of Abl strongly impaired spontaneous transmission in excitatory neurons, while leading to enhancement of spontaneous inhibitory synaptic activity, presumably reducing E/I ratio. Interestingly, prolonged (24 h) incubation of hippocampal neurons in DPH led to reduction of both excitatory and inhibitory synapses. Surprisingly, Abl1 knock-down led to increasing of spontaneous release in both, excitatory and inhibitory neurons. Quantitative phosphoproteomic screening of Abl activity impact on synaptic machinery revealed 3813 phosphorylation sites, while further rigorous bioinformatic analysis of phosphomotifs revealed synaptotagmin 2 and complexin 2 to be the most possible candidates to mediate the effect of Abl signaling on neurotransmission. Based on our findings, we assume that Abl kinases signaling pathway could be activated by Aβ peptides, leading to protective effect from excessive excitatory activity via reduction of excitatory/inhibitory balance on the short-term time scale, while under pathological condition chronic mAβ exposure entails to synaptic disfunction/elimination.

Title: An oxidative mechanism for cholinergic dysfunction in Alzheimer's disease

Authors: *L. E. SANTOS, S. T. FERREIRA, F. G. DE MELLO;
UFRJ, Rio de Janeiro, Brazil

Abstract: The neurotransmitter acetylcholine is synthesized by the enzyme choline acetyltransferase (ChAT), which is also a phenotypic marker of cholinergic neurons. Defective cholinergic transmission is involved in the onset and development of several CNS pathologies, including Alzheimer's disease (AD). Previous work by our group, using the avian retina as a CNS model, showed that ChAT activity in cultured neurons is markedly and specifically down-regulated by amyloid-β peptide oligomers (AβOs), diffusible toxins that accumulate in AD brains. This effect was shown to be linked to excitotoxicity, being likely caused by oxidative damage to the enzyme. ChAT inhibition by AβOs precedes any changes in cell viability or enzyme levels, and requires calcium influx and nitric oxide (NO) production to occur. Here, we expand these observations to a mammalian model, using cultured neurons of the rat septal region, and attempt to identify oxidative modifications involved in ChAT inhibition, in both animal models and in postmortem tissue from AD patients. Using S-nitrosothiol resin-assisted capture and thiol labeling, we show that cysteine modification is not central to the mechanism of inhibition. Tyrosine nitration, however, is induced in post-mortem hippocampal tissue from AD patients, and in cultures exposed to AβOs, correlating well with loss of ChAT activity. In immunoprecipitated samples, we show that nitrated ChAT is increased in the hippocampus of AD patients, as compared to controls. Results suggest a novel mechanism of cholinergic dysfunction that precedes neuronal death and may be relevant in early-stage AD pathology.

Title: The metabolic syndrome plus the injection of amyloid-β 25-35 peptide into the hippocampus modifies the expression of cholinergic markers, NGF and alters spatial memory.

Authors: *I. LIMON PEREZ DE LEON[1], O. REYES-CASTRO[2], F. LUNA-MORALES[3], A. PATRICIO[4];

Abstract: The consumption of sweetened beverages has promoted the development of metabolic syndrome (MetS). MetS increases the risk of developing Alzheimer's disease (AD). In AD there is loss of cholinergic innervation in the septo-hippocampal pathway. Cholinergic neurons from the medial septum maintain acetylcholine levels with the choline acetyltransferase (ChAT) and acetylcholinesterase (AChE). On the other hand, nerve growth factor (NGF) maintains the cholinergic phenotype by being transported retrogradely to the soma of cholinergic neurons. The aim of this work was to evaluate the effect of MetS and intrahippocampal administration of the Aβ25-35 peptide on spatial memory, the expression of cholinergic enzymes, and NGF in rats. We used Wistar male rats (250-280 g) randomly assigned in the MetS and control group. MetS model was obtained by consuming a 20% sucrose solution while control group received drinking water, ad libitum for six months. All rats were yield to stereotaxic surgery to the injection of vehicle or Aβ25-35 [100µM] into CA1 subfield of Hippocampus, (AP: -4.0, L: ±2.3, P: -2.6). The groups were control+vehicle, MetS+vehicle, control+Aβ25-35 and MetS+Aβ25-35. On the 15th day post-surgery, experimental groups were tested for spatial learning in Morris Water Maze (MWM) and 5 days later, were memory tested. At the end of the spatial memory test in the MWM, the expression of ChAT, AChE and NGF in the hippocampus and medial septum was evaluated. The results indicate that all the experimental groups there were not modify spatial learning. In the memory test, the MetS + vehicle, control + Aβ25-35 and MetS + Aβ25-35 groups show damage in the spatial memory. Immunohistochemical analysis indicated that the MetS + vehicle, control + Aβ25-35 and MetS + Aβ25-35 groups significantly decrease ChAT expression in the medial septum, in the CA1, CA3 region and the dentate gyrus of the hippocampus. The expession of AChE increased in the medial septum of the MetS + Aβ25-35 group, as well as NGF in the regions of the septum-hippocampus pathway. Our findings suggest that the expression of ChAT and AChE in regions of the septohippocampal pathway are vulnerable to the presence of MetS, which is exacerbated by Aβ25-35 probably due to oxidative and pro-inflammatory mechanisms; however. These condiction damage the spatial memory. It is likely that MetS also stimulates defense mechanisms such as the release of NGF

Title: Role of orexin signaling in beta-amyloid-induced cell death in SH-SY5Y cells

Authors: H. BAE[1], B. DO[1], J.-H. JANG[2], ***G. PARK**[1];
[1]Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Dept. of Pharmacol., Sch. of Medicine, Keimyung Univ., Daegu, Korea, Republic of

Abstract: Alzheimer's disease (AD) is a degenerative disease which is accompanied by cognitive decline and progressive memory loss. It has been reported that orexin, a neuropeptide produced in hypothalamus, is responsible for regulation of sleep-awakening cycle and energy metabolism. However, roles of orexin in neurodegenerative diseases like AD has not been clearly examined as yet. In this study, we investigated role of orexin signaling in beta-amyloid (Aβ)-induced cell death in SH-SY5Y cells. Aβ induced cell deaths in a dose-dependent manner and increased the expression of orexin receptor. Pretreatment of orexin receptor 1 antagonist, SB334867 significantly inhibited Aβ-induced cell death but not orexin receptor 2 antagonist, TCS-OX2-29. SB334867 decreased apoptotic signaling induced by Aβ, including the ratio of Bax/Bcl-2 expression and cleavage of Caspase-3. In addition, Aβ increased phosphorylation of Akt/mTOR while pretreatment of SB334867 inhibited the phosphorylation of Akt/mTOR which had been induced by Aβ. Taken together, these findings suggest that orexin signaling may play a role in pathogenesis of AD and may be a potential therapeutic target for treatment of AD.

Abstract: Protective effects of SSRI Citalopram against Aβ-induced toxicities on dorsal raphe *in vivo* and *in vitro* AD models. Abstract: The purpose of our study is to understand the protective effects of selective serotonin reuptake inhibitor (SSRI), citalopram in Alzheimer's disease (AD). Depression is among the most common neuropsychiatric comorbidities in AD. Apart from its anti-depressive and anxiolytic effects, SSRI treatment also offers cellular modifications that improve synaptic transmission, neurogenesis and reduce AD pathologies, including amyloid burden, phosphorylated Tau and synaptic toxicity. Recent research also suggests besides canonical neurotransmission serotonin (5HT) increase intracellular energy metabolism and improve neuronal resilience. **Experiment design:** The current study was designed to explore the AD-related cellular changes and protective effects of SSRIs on serotonergic raphe neurons in the *in vitro* neurons and rodent raphe brain of AD. **Method:** Here we investigated the protective role of SSRI, Citalopram (Cit) *in vitro*, in rat serotonergic, medullary raphe neurons - RN46A-B14 and *in vivo*, in the dorsal raphe nucleus (DRN) region of transgenic mouse models of APP and Tau. We transfected RN46A-B14 neurons, with wild-type and mutant APP and Tau cDNAs for 24 hrs, then treated them with 20 uM Cit for 24 hrs. Harvested cells were analyzed for mRNA and protein levels of TPH2, BDNF, SERT and 5HTR1A, in addition to pTau and amyloid beta (Aβ). We also treated 10-month-old APP and Tau mice for a period of 8 weeks with Cit (20 μg/gm body weight). This was followed by cognitive behavior analyses and mRNA and protein levels assessments. **Results:** Cit treated mutant APP and Tau RN46A-B14 neurons showed reduced pTau levels while increased levels of TPH2, SERT, BDNF and 5HTR1A genes. Likewise, the Cit treated APP and Tau mice exhibited reduced cognitive decline and increased levels of serotonin related genes (TPH2, SERT and 5HTR1A) and reduced AD genes (APP and pTau) compared to the untreated ones. **Conclusion:** Taken together these findings suggest Cit could not only be a promising therapeutic drug for treating depression in AD but also mitigate AD pathologies and improve cognition, probably though increased serotonin production.

Title: Abl1 promotes axon initial segment disassembly and tau missorting in response to amyloid-β fibrils and allosteric activation

Authors: *N. STUARDO, Á. CÁCERES, A. ÁLVAREZ;
Dept. of Cell. and Mol. Biol., Pontificia Univ. Católica De Chile, Santiago, Chile

Abstract: The axon initial segment (AIS) is an axonal subdomain that is critical for correct neuronal compartmentalization and action potential initiation. AIS disassembly is a known consequence of amyloid-β (Aβ) toxicity but the specific mechanisms that underlie this process in the context of Alzheimer's disease (AD) are not fully understood. The non-receptor tyrosine kinase Abl1 is a potential candidate in the mediation of AIS disassembly, as it becomes activated by Aβ aggregates, promoting several deleterious effects on normal neuronal cytoskeleton organization including tau hyperphosphorylation and loss of postsynaptic protein clusters. To evaluate a possible role for Abl1 in AIS disassembly we used neuronal cultures (14-16DIV) treated with Aβ fibrils, Abl kinase inhibitors and DPH, an allosteric activator of Abl kinases. Immunofluorescence and western blot analyses were performed to evaluate changes in AIS cytoskeletal organization and Abl1 signaling activation. We find that short Aβ fibril treatments (15 min to 1 hr) and DPH induce AIS disassembly—evaluated by loss of localized Ankyrin G staining—, and this was prevented by inhibition of Abl kinases. Similarly, Abl1-KO neurons do not suffer AIS disassembly in response to Aβ fibril insults, further reinforcing the notion that Abl1 could play a relevant role in the collapse of this structure. We find that Aβ fibril-mediated AIS disassembly is reversible, suggesting a mechanism that involves short-lived alterations of cytoskeleton arrangement or reversible post-translational modifications. We also evaluated changes in the subcellular distribution of tau, which have been associated to AIS alterations in AD. We find that Aβ fibrils and DPH increase PHF-1 antibody signal in the cell body, a sorting defect that has previously been associated to AIS disruption. Our results suggest that Abl1 could be a key player in the process of AIS disassembly and tau missorting in the context of AD. AIS collapse could be a key event in the amyloid cascade, as this structure mediates critical processes in normal neuronal function which have been found to be altered in AD.

Title: Role of Fragile X Mental Retardation Protein in Amyloid Beta Induced Translational Suppression

Authors: *S. LIZARAZO, Y. YOOK, N.-P. TSAI;
Univ. of Illinois at Urbana Champaign, Urbana, IL

Abstract: Alzheimer's Disease (AD) is the most common cause of dementia where the accumulation of the peptide Amyloid-Beta (Aß) is the main theory linked to the pathogenesis of the disease. Fragile X Mental Retardation Protein (FMRP) is an RNA-binding protein that functions to suppress global translation. Because Aß is known to be a toxic peptide capable of inducing the Endoplasmic Reticulum (ER) stress response and because augmented translational suppression is one of the main molecular phenotypes in ER stress response, we ask whether and how FMRP is involved in Aß induced translational suppression. In this study, we observed that treatments of synthetic Aß peptides in culture primary mouse cortical neurons induce the expression of FMRP and FMRP-dependent ER stress response and subsequent translational suppression. We further characterized that two translational regulators, eukaryotic translation initiation factor 2α (eIF2α) and eukaryotic translation elongation factor 2 (eEF2), are involved in Aß induced translational suppression and are dysregulated in the absence of FMRP. Mechanistically we found that FMRP is responsible for regulating the levels of Protein Phosphatase 2 (PP2A) and Protein Phosphatase 1 (PP1) that differentially modulate the phosphorylation status and thereby the activity of eIF2α and eEF2 following treatment of Aß. Using a pharmacological approach to inhibit PP2A and PP1 with Okadaic Acid, we were able to rescue the impairment of eIF2α and eEF2 as well as the translational suppression in the absence of FMRP. These results suggest a novel function of FMRP in regulating translational suppression following Aß treatment by fine-tuning two distinct signaling pathways involved in global translation.

Title: Parp-1 activation is a key mediator of pathogenesis in familial alzheimer's disease model

Authors: *A. JHALDIYAL[1], T.-I. KAM[2], T. M. DAWSON[3], V. L. DAWSON[4]; [1]JOHNS HOPKINS UNIVERSITY, Baltimore, MD; [2]Inst. for Cell Engineering/ Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Ellicott City, MD; [3]Inst. for Cell Engin., Johns Hopkins Univ. Inst. for Cell Engin., Baltimore, MD; [4]Inst. Cell Engin., Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Alzheimer's disease (AD) is the most common form of dementia. It affects about 5.7 million people within the United States. This disease is marked by occurrence of two major pathological proteins- Amyloid-beta plaques (A plaques) and Tau mediated Neurofibril tangles (NFT), wherein emergence of A plaques precede decades before NFT pathology. The clinical outcome of these protein aggregations is the progressive loss of memory further leading up to the inability to perform daily tasks. A major roadblock in the field is the lack of understanding of how amyloid pathology is connected to tau pathology. We report that Poly [ADP-ribose] polymerase 1 (PARP-1) activation is the missing link between these two pathologies. PARP-1, a DNA damage sensing enzyme, plays a major role in stress-mediated signaling. Our data in primary cortical neuron cultures show that oligomeric A (oA_{1-42}) treatment results in robust Poly [ADP-ribose]/PAR activation, concomitant with increased tau phosphorylation. We show that this PAR activation is upstream of tau phosphorylation and PARP-1 inhibitor decreases tau phosphorylation in these oA_{1-42} treated neurons. Additionally, we performed genetic deletion of PARP-1 in the 5xTg Familial AD mice model and found increased neuron survival and decreased gliosis. Taken together, our data show that PARP-1 plays a pivotal role in AD pathogenesis and is a very potent target for therapeutic intervention in this disease.

Title: Amyloid beta deposition in the lumbosacral spinal circuit impairs both the short-term and long-term neuroplasticity of locomotion

Authors: *R. HUANG[1], M. S. JOSEPH[2], H. ZHONG[1], R. ROY[1], J. CHANG[1], M. IGLESIAS[1], P. A. TRUONG[1], S. SHAHRESTANI[3], M. MADHAVAN[1], Y. ZHOU[1], K. LI[1], J. LEITER[4], E. KOO[5], R. EDGERTON[1], D. C. LU[6];

[1]Univ. of California Los Angeles, Los Angeles, CA; [2]California State University, Los Angeles, Los Angeles, CA; [3]USC, Los Angeles, CA; [4]Dartmouth, Hanover, NH; [5]UCSD, San Diego, CA; [6]UCLA, Los Angeles, CA

Abstract: Sensorimotor perturbations are often reported in patients with Alzheimer's disease (AD) and attributed to cortical and not spinal dysfunction. This is due to the fact that one canonical biomarker of AD, amyloid-β (Aβ) plaques, are rarely observed in the spinal cord of AD patients. However, more evidence supporting spinal cord involvement in AD is emerging. Atrophy of the spinal cord, neurofibrillary pathology, and increased amyloid-beta precursor protein (APP) expression levels in the spinal cord have been identified in the spinal cord inAD patients and AD animal models. Furthermore, APP and soluble Aβ can impair neuronal functions even without forming the plaques. In this study, we investigated the contribution of spinal APP and its proteolytic products to locomotor functions by studying the lumbar locomotor circuit of J20 mice. To rule out the impact of the supraspinal structures, we transected the spinal cord completely at thoracic level 10 to cut off all connections between the lumbosacral spinal cord and all the rostral parts of the central nervous system (CNS). The short-term plasticity of the lumbosacral locomotor circuit was evaluated by an instrumental learning model, paw withdrawal paradigm (PaWL) and the long-term plasticity was investigated by the weekly bipedal treadmill stepping paradigm. Both 4mon and 13mon J20 mice showed significant decreases in the PaWL compared to their WT littermates ($p = 0.0075$). The spontaneous bipedal locomotion recovery was also inhibited in spinal J20 mice when compared to WT littermates ($p = 0.0031$). Notably, these impairments of lumbar circuit plasticity was reversed by the administration of a gamma-secretase inhibitor (Benzodiazepine-type LY-411575) in the spinal J20 mice, suggesting the generation of amyloid-beta in local spinal cord circuit contribute to the locomotor deficits.

Title: Entorhinal-hippocampal desynchronization in a mouse model of Alzheimer's disease pathology

Authors: *L. M. VETERE, L. CHEN, Z. CHRISTENSON WICK, D. J. CAI, T. SHUMAN; Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Background: Alzheimer's disease (AD) is a devastating neurodegenerative disease characterized by memory loss and progressive age-related cognitive decline. While leading hypotheses have posited that accumulation of amyloid-beta (Aβ) and tau proteins drives neurodegeneration, reducing these proteins without preventing or reversing functional changes may be insufficient to alleviate memory impairments. Therefore, it is critical to understand the functional changes that occur in brain circuits required for memory. Impairments in hippocampal function are well established in AD, but it is unclear whether this is driven by local changes or abnormal inputs, such as those from medial entorhinal cortex (MEC).
Methods: To understand how AD pathology impacts communication within and between brain regions that are critical for memory, we used 3xTg mice, which express mutations in APP, presenilin, and tau. We performed acute *in vivo* silicon probe recordings to simultaneously record from 512 channels across hippocampus and MEC layers II and III. Head-fixed mice were trained to run on a virtual reality track to receive water rewards and recorded during active navigation. By recording two age groups, we were able to compare neural activity before and after the onset of memory impairments and examine how and when synchrony of individual cells and local field potentials breaks down.
Results: Our data suggest that synchrony between MEC and hippocampus is impaired in 3xTg mice compared to WT controls prior to the emergence of spatial memory impairments. In MEC, we found reduced theta power and altered phase locking of single units to ongoing theta oscillations. We also found reduced theta coherence between MEC and hippocampus. Interestingly, these effects were observed at 6 months of age, before the onset of spatial memory impairments. In the hippocampus, we found that theta power was largely intact at 6 months of age but significantly decreased at 8 months, when memory deficits are observed. These findings support the hypothesis that entorhinal dysfunction precedes and may contribute to later hippocampal changes. Possible factors driving early entorhinal dysfunction include hyperexcitability of MEC stellate cells or loss of MEC parvalbumin interneuron function.

Title: Differential impact of amyloid β pathology on population activity along dorsal-ventral axis of CA1 in APP/PS1 mice

Authors: *U. CHOCKANATHAN, K. PADMANABHAN;
Univ. of Rochester, Rochester, NY

Abstract: Alzheimer disease (AD) causes a range of cognitive and behavioral symptoms that often lead to loss of independence, decreased quality of life, and death. A major histopathological hallmark of AD is the amyloid beta (Aβ) plaque. The hippocampus (HPC), an important region for learning and memory, is particularly susceptible to amyloid pathology. Recent studies have documented significant anatomical and functional variations along the longitudinal hippocampal axis, with dorsal HPC implicated in episodic memory and spatial cognition and ventral HPC involved in affective processing and social cognition. As most animal studies of Aβ pathology have been performed in dorsal HPC, comparatively little is known about how Aβ affects ventral HPC, specifically how the molecular and cellular changes associated with Aβ affect the activity of neuronal networks and, in turn, behavior. To address this question, we made high density recordings of neuronal populations in the APP/PS1 mouse model of Aβ pathology. Using high-density silicon electrode arrays, we recorded large populations of neurons in dorsal CA1 (dCA1) and ventral CA1 (vCA1) in awake head-fixed mice as they ran in a virtual reality environment.
First, we found no differences in single-neuron activity, such as spatial information or mean firing rate, between the two subregions across APP/PS1 and control mice. However, we found that features of collective activity, such as pairwise correlations, were higher in dCA1 than vCA1 in control mice, but that this difference was abolished in APP/PS1 mice. These functional interactions were critical for the population-level encoding of position, as the collective spatial information of the population was higher in dCA1 than vCA1 in controls, but this difference was abolished in APP/PS1 mice. Our results point to two critical features of Aβ-associated disruptions in hippocampal activity: 1) Aβ may differentially affect the responses of single neurons as compared to network activity and 2) these effects vary along the longitudinal axis of the HPC. This suggests that the effects of Aβ are highly variable within a single brain region, which may, in turn, provide insight into the diversity of behavioral symptoms observed in AD.

Title: App modulates excitability through the axon initial segment and node of Ranvier with implications for Alzheimer's disease

Authors: *F. MA, H. AKOLKAR, R. BENOSMAN, K. HERRUP;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Alzheimer's disease (AD) is the most common cause of dementia of the elderly. Although rare, familial AD is most often caused by one of only three known disease genes one of which is *APP*(amyloid precursor protein). APP is the source of the Aβ peptide fragment, whose aggregation produces the characteristic amyloid plaques found in AD brains. Indeed, the amyloid cascade hypothesis - the most widely cited disease model - assumes Aβ is the driver of AD. Yet dozens of clinical trials based on Aβ removal have been unsuccessful, leading many to question the central role of the amyloid cascade. Curiously, the genetics of familial AD identify *APP*, not Aβ, yet over the years the normal function of the APP holoprotein itself has received only scant attention. In striving to fill this gap in our understanding we have found that APP functions in the brain as a damage response protein. Gene expression doubles within minutes of an excitotoxic stimulus and the excess APP protein dampens neuronal activity through its ability to regulate the length and position of the axon initial segment (AIS) and the node of Ranvier (NOR). APP protein is not only present in neurons. In both mouse and human there is a striking presence of APP in the myelin sheath. Primary cultures of oligodendrocytes confirm the colocalization of APP and MBP. We verified the APP-dependent changes in the AIS had electrophysiological consequences. We used high density multielectrode-arrays to demonstrate that APP-overexpression reduced the firing rate of neurons in the in vitro networks. Our results support the idea that the cognitive decline in Alzheimer's disease, while perhaps modulated by Aβ is caused primarily by the alterations in neuron firing potential and action potential propagation brought about by dysregulation of the APP holoprotein acting through the AIS and the NOR. Our study proposes an alternative explanation for Alzheimer's disease that might be called 'APP Cascade Hypothesis'.

Title: An age-related shift in the distribution of epileptiform spikes across sleep-wake states in a transgenic mouse model of Alzheimer's disease

Authors: *M. SILVA-PÉREZ, J. PARK, J. CHIN;
Baylor Col. of Med., Houston, TX

Abstract: In Alzheimer's disease (AD) patients and mice, there is an increased incidence of seizures and epileptiform activity, which may be underestimated due to the prevalence of nonconvulsive seizures, and the observation that seizures and epileptiform spikes primarily occur during sleep. In AD patients, epileptiform spikes are non-uniformly distributed across sleep-wake states and occur predominantly during nonrapid eye movement (NREM) sleep. The mechanisms that give rise to epileptiform spikes, and their preferential occurrence during NREM sleep, are not clear. Several mouse lines that express human amyloid precursor protein (APP) containing AD-linked mutations also exhibit epileptiform spikes primarily during sleep. In APP mice from Line Tg2576, epileptiform spikes occur only during rapid eye movement (REM) sleep at early stages of disease, but invade NREM sleep as disease and age progress. APP mice from Line J20 have been found to also primarily exhibit epileptiform spikes during REM sleep at early stages of disease. However, whether the occurrence of epileptiform spikes shifts to other brain states as disease and age progress in J20 mice is unclear. Determining if the occurrence of epileptiform spikes in specific sleep states is similar between patients and mice is necessary for assessing the extent to which insights gained from mouse models can be translated to the human disease. To investigate whether the distribution of epileptiform spikes across sleep-wake states changes with age in J20 APP mice, we performed video-EEG monitoring of mice at early and later stages of disease. Wakefulness, NREM sleep, and REM sleep were scored in Spike2 according to the EEG activity in the delta (0.5-4 Hz), theta (6-10 Hz), and high-frequency (100-300 Hz) ranges. Epileptiform spikes were identified by Spike2 using duration and amplitude criteria, manually verified, and spike number and rate were calculated. In young mice at early stages of disease, REM sleep exhibited a higher rate of epileptiform spikes than NREM sleep. Despite the proportionally low abundance of REM sleep, half of total daily epileptiform spikes occurred during REM sleep. At later stages of disease, the proportion of epileptiform spikes during NREM sleep increased, demonstrating a shift in prevalence over time. This shift from REM to NREM sleep indicates that the epileptiform activity exhibited by aged APP mice more closely reflects that observed in AD patients. These results also suggest that identifying the mechanisms in APP mice that give rise to epileptiform spikes, and underlie the shift from REM to NREM sleep, may provide novel insights into the basis of epileptiform activity in AD patients.

Title: Seizure-induced changes in sFRP3 expression contribute to dysregulation of adult hippocampal neurogenesis in a transgenic mouse model of Alzheimer's disease

Authors: *C.-H. FU[1], J. PARK[1], U. TOSI[2], X. ZHANG[3], Y. ZHENG[1], J. CHIN[1];

[3]Dept. of Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Alzheimer's disease (AD) is associated with hippocampal dysfunction, and one contributing factor may be the dysregulation of adult hippocampal neurogenesis. Neurogenesis in the adult dentate gyrus (DG) is important for cognition and mood, both of which are affected in AD. We previously showed, using a transgenic mouse model overexpressing mutant human amyloid precursor protein (APP), that seizure activity that begins early in disease progression aberrantly increases the proliferation of a finite pool of neural stem cells (NSCs) in the DG. Such increased proliferation was associated with accelerated depletion of the NSC pool and impaired spatial discrimination, a behavior that relies on adult-born neurons. These alterations were prevented by treatment with an anti-seizure drug. However, the specific molecular mechanisms that drive such seizure-induced activation and depletion of NSCs is unclear. Using RNA-sequencing, we queried which components of the Wnt signaling pathway, a pathway critically involved in inducing neurogenesis in both development and adulthood, were differentially expressed in the DG of APP mice and their nontransgenic (NTG) littermates. Surprisingly, few Wnt components were differentially expressed, of which secreted frizzled-related protein 3 (sFRP3) stood out. sFRP3 is an inhibitor of the Wnt signaling pathway, and thus acts as a "brake" on neurogenesis. It is normally constitutively expressed and secreted by mature DGCs. Notably, sFRP3 expression was decreased in APP mice, but was restored after treatment with an anti-seizure drug, suggesting that seizures drive suppression of sFRP3 in APP mice. In addition, we found that sFRP3 may be epigenetically regulated by seizure-induced transcription factors. We hypothesized that seizure activity in APP mice recruits such transcription factors to suppress sFRP3 expression, which then accelerates proliferation and depletion of the NSCs and thus impairs spatial discrimination. To test this hypothesis, we designed an adeno-associated virus (AAV) to express sFRP3 in DGCs of APP and NTG mice. We found that viral-mediated expression of sFRP3 does indeed decrease neurogenesis, and that long-term expression of sFRP3 improved spatial discrimination in APP mice. Our results suggest that sFRP3 may play a key role in the seizure-driven dysregulation of NSC proliferation and neurogenesis, and consequent cognitive impairment, in APP mice and perhaps also in AD.

Title: Selective and progressive changes in excitability of MECII stellate cells in the 3xTg mouse model of Alzheimer's disease pathology

Authors: *L. CHEN, Z. CHRISTENSON WICK, L. VETERE, D. J. CAI, T. SHUMAN; Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Alzheimer's disease (AD) is a disorder characterized by progressive cognitive impairments. In mouse models of AD pathology many studies have found deficits in spatial memory and hippocampal spatial coding. Yet it remains unclear whether these deficits are due to local circuit changes or reflect changes in upstream inputs. The medial entorhinal cortex (MEC) is the primary input into the hippocampus and an early site of AD pathology. Specifically, MEC has two distinct layers, layer II (MECII) and III (MECIII), that project to hippocampal CA1 through distinct pathways. In order to understand how spatial coding deficits emerge in AD, we examined the cellular and circuit alterations in distinct MEC cell types before and after the onset of spatial memory impairments. In the 3xTg mouse model of AD pathology, we found that hippocampus-dependent spatial memory impairments on a novel object location task appeared between 6 and 8 months of age. We then used *in vitro* whole-cell electrophysiology to investigate whether distinct MEC cell types (MECII stellate cells, MECII pyramidal cells, and MECIII excitatory neurons) were altered before and after the onset of memory impairments. We found that MECII stellate cells in 3xTg mice had altered excitability as early as 3 months, demonstrated by a depolarized resting membrane potential (RMP). However, when we injected current steps the number of evoked action potentials (eAPs) remained comparable to controls, indicating a cellular compensation to reduce spiking. This compensation was lost by 10 months of age, as MECII stellate cells in 3xTg mice exhibited increased number of eAPs in addition to a depolarized RMP. Further, by quantifying the amplitude and frequency of spontaneous excitatory and inhibitory post synaptic currents (sEPSC and sIPSC, respectively), we have found a reduction in the sIPSC frequency and a significantly increased E/I ratio in MECII stellate cells in 10-month-old 3xTg mice. Importantly, all the cellular differences were observed only in

MECII stellate cells, while MECII pyramidal cells and MECIII cells remained normal in 3xTg mice at 10 months of age. Together, our data suggests that cellular excitability deficits in 3xTg mice emerge as early as 3 months of age and are restricted to stellate cells in MEC. These changes begin well before the onset of memory impairments and progress into severe cellular and synaptic deficits by 10 months of age in the 3xTg mouse model. We propose that early disruptions in MECII stellate cell excitability leads to local and downstream circuit changes and spatial memory impairments with the progression of AD pathology.

Title: Chronic ΔFosB activity regulates key target genes in dentate granule cells and modulates neuronal excitability and recurrent seizures in APP mice

Authors: *G. STEPHENS[1], Y. ZHENG[1], J. PARK[1], A. L. EAGLE[2], J. YOU[1], C.-H. FU[1], S. CHOI[1], Y. LIU[3], A. ROBISON[2], J. CHIN[1];

Abstract: Recurrent seizures are associated with cognitive deficits in many neurological disorders, including epilepsy and Alzheimer’s disease (AD). We reported that seizures induce expression of ΔFosB, a transcription factor with an unusually long half-life that epigenetically alters gene expression and persistently impairs cognition in mouse models of epilepsy or AD. Recently, we showed that ΔFosB binds to genes involved in key pathways that may regulate excitability in dentate granule (DG) cells in mice with recurrent seizures, suggesting that ΔFosB may play a neuroprotective role in conditions associated with excitotoxicity. Understanding which ΔFosB target gene pathways are most influential in moderating DG cell excitability and seizure activity may guide novel therapeutic strategies to enhance endogenous mechanisms of neuroprotection in AD and other conditions with recurrent seizure activity. To determine the impact and time-course of ΔFosB activity on DG excitability and seizure activity, we used viral strategies to overexpress or block ΔFosB activity in the dentate gyrus of amyloid precursor

protein (APP) transgenic mice, a model of AD that exhibits spontaneous recurrent seizures. Whereas short-term (3-4 week) blockade of ΔFosB activity did not affect seizure activity, long-term (3 months) inhibition of ΔFosB activity in DG cells exacerbated seizure activity and spatial memory deficits in APP mice. Conversely, overexpression of ΔFosB in DG cells reduced neuronal excitability measured in electrophysiological recordings in hippocampal slices from wild-type mice overexpressing ΔFosB in the dentate gyrus. Moreover, overexpression of ΔFosB in primary hippocampal neurons was neuroprotective in an NMDA toxicity assay. We performed whole-hippocampal ChIP-sequencing to identify ΔFosB target genes that may be involved in moderating DG cell excitability in APP mice, and used GOTerm clustering analyses to find that many ΔFosB target genes in APP mice are involved in excitability and neurotransmission, including numerous epilepsy-related genes. Our results indicate that the epigenetic regulation of gene expression resulting from chronic ΔFosB activity may help constrain neuronal excitability and reduce seizure occurrence.

Title: The mode of cooperative suppression on large conductance calcium-activated potassium channel by amyloid β oligomer and amyloid precursor protein

Authors: *K. YAMAMOTO[1,2], R. YAMAMOTO[2], N. KATO[2];
[1]Natl. Hosp. Organization Utano Natl. Hosp., Kyoto, Japan; [2]Dept. of Physiol., Kanazawa Med. Univ., Ishikawa, Japan

Abstract: We have previously reported that intracellular amyloid β (Aβ) injection suppresses the large-conductance calcium-dependent potassium (BK) channel in cortical pyramidal cells from wild type (WT) mice (Yamamoto et al. 2011). In triple transgenic AD model (3xTg) mice, intraneuronal Aβ is genetically destined to accumulate, which suppresses BK channel. However, multiple lines of evidence have indicated that the amyloid precursor protein (APP) is also

causative in the toxicity attributed so far solely to Aβ in mouse AD models that overproduce APP. The possibility that not just the end product Aβ but APP per se might be harmful, still remains to be fully examined. This study investigated the mode of BK channel blockade mediated by not just amyloid β but also APP. Whole cell recordings were performed from the pyramidal neurons in frontal neocortical slices of WT or 3xTg mice. Spike properties were recorded under the intracellular injection of recombinant full length APP or various antibodies against APP or Aβ through patch pipette. An anti-Aβ-oligomer antibody (11A1), but not anti-monomer-Aβ-antibodies, was effective in restoring BK channel activity in 3xTg neurons. Other anti-Aβ-oligomer antibodies, A11 and 82E1, failed to recover BK channel activity. Antibodies against APP were also found effective. In WT neurons, APP as well as Aβ suppressed BK channels by itself. In cortical neurons from 3xTg mice that bear Homer1a knockout (4xTg mice), neither anti-APP antibodies nor 11A1, but only the 6E10 antibody that binds both APP and Aβ, rescued the BK channel activity. These results revealed a different synergy of Aβ and APP in WT and 3xTg neurons. Given that Homer1a was shown to disrupt Aβ-BK channel coupling both in WT and 3xTg neurons and Homer1a expression is activity dependent and 3xTg neurons are hyperexcitable, Homer1a is likely to be expressed sufficiently in 3xTg neurons, thereby mitigating the synergistic suppressive influence of APP and Aβ on BK channel. BK channel suppression still occur even both in intracellularly APP-injected WT neurons in the presence of 11A1, and in 3xTg neurons in the presence of Bri2, which disrupt the link between Aβ and APP, and the processing of APP to Aβ. In Aβ-injected WT neurons, BK channel suppression failed to be reversed by antibodies against APP. Considering that the APP C-terminus domain is known to bind to the Homer EVH domain, these observations suggest that long Homer and BK channel, together with APP and Aβ oligomer, may form a molecular complex that underlies synergistic BK channel suppression by APP and Aβ oligomer.

Title: Rapid calcium-dependent suppression of macroscopic homomeric Kv1.2 currents by amyloid beta (1-42) peptide: Implications for Alzheimer's disease

Authors: *D. JAMSHIDI[1], J. M. WATKINS[2], K. DEBOEUF[3], J. FARLEY[2];
[1]Indiana Univ. Program in Neurosci., Bloomington, IN; [2]Indiana Univ., Bloomington, IN;
[3]Psychology and Neurosci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Amyloid beta peptides (Aβ) have long been implicated in the pathogenesis of Alzheimer's disease (AD). Past studies have shown that Aβ is involved in the disruption of intracellular calcium $[Ca^{2+}]_i$ homeostasis, synaptic communication, learning and memory mechanisms (e.g., hippocampal long term potentiation (LTP)), as well as neuronal death. The critical molecular targets and synapto- and neuro-toxic mechanisms for Aβ remain unclear however. Because voltage-dependent potassium channels, and several Kv1 family members specifically, are activated during an action potential, regulate Ca^{2+} influx in a depolarized cell, and can be neurotoxic when suppressed, they are important candidates in studies of Aβ targets and AD pathogenesis. Previous studies from our lab of Aβ effects on murine homomeric Kv1.1 channels (-expressed heterologously in *Xenopus* oocytes) found that bath-addition of 1 μM Aβ(1-42) produced ~50% suppression of macroscopic Kv1.1 currents within 30 m (measured at +20 mV). Little or no suppression was produced by equimolar reverse peptide Aβ(40-1) or solvent controls. Previous studies also found that the Aβ(1-42) suppression involved $[Ca^{2+}]_i$-dependent signaling pathways: chelation of $[Ca^{2+}]_i$ by 1,2-Bis(2-aminophenoxy)ethane-N,N,N',N'-tetraacetic acid tetrakis (acetoxymethyl ester) (BAPTA-AM), significantly attenuated the 30 min suppression value from ~50% suppression to 20%. Here we extend our observation of Aβ-suppression of Kv1-family channel currents to include (homomeric, apha-subunit) Kv1.2 channels, expressed in oocytes. Bath application of appropriately "aged" 1 μM Aβ(1-42) resulted in ~50% suppression of macroscopic Kv1.2 currents(± 5.4; n=7), after 30m., DMSO controls (± 3.46; n=10) showed little (~6% suppression). Pre-exposure of oocytes (± 6.16; n=6) to 10 μM BAPTA-AM reduced the Aβ(1-42) suppression level to ~17% at 30 m, significantly less than the 50% observed in the absence of BAPTA-AM (p =0.045).Kv1.1 and Kv1.2 play diverse functional roles in several neuronal compartments, especially in the regulation of pre- and post-synaptic membrane excitability. Kv1.2 subunits can also co-localize with over Kv1 subunits to form heteromeric channels. For example, Kv1.2 co-localizes with Kv1.1 in the nodes of Ranvier in myelinated axons, and in the brain, in particular, in axons and nerve terminals. We propose that Kv1 channels represent promising and novel targets for attempts to treat Aβ-driven pathology in AD.

Title: Identification of candidate key regulators of neural stem cell dynamics and neurogenesis in a transgenic mouse model of Alzheimer's disease

Authors: *Y. FURUTA, C.-H. FU, J. CHIN;
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Neural stem cells (NSCs) ensure lifelong neurogenesis, and reduced neurogenesis is associated with cognitive decline in Alzheimer's disease (AD). Therefore, elucidation of molecular mechanisms that regulate NSCs, and therapeutic intervention to preserve the NSC pool, may be a novel strategy for AD. Using transgenic AD model mice (APP mice), our lab previously reported that early seizure activities that occur in AD affect gene regulations of mature granule cells and drive aberrant NSC division and neurogenesis, accelerating the depletion of a finite pool of NSCs in the dentate gyrus. However, the molecular mechanisms by which the seizures that occur in AD disrupt NSCs and neurogenesis dynamics are not clear. To gain some perspective about molecules that could affect NSC and neurogenesis dynamics in AD, we examined a dentate gyrus RNA-seq dataset from our lab which provided a list of differential expressed genes between APP mice and nontransgenic littermate controls. We conducted a literature research about the functions of highly up/downregulated genes from the list up to about 200 genes. Through this work, we found 13 candidate genes which may regulate NSCs and neurogenesis, and benchtop confirmed the expression level of the genes in the RNA-seq dataset. One interesting molecule among the candidates we identified is Follistatin, a secreted protein that antagonizes various TGF-β superfamily proteins. Previous reports found that Follistatin inhibits NSC division and neurogenesis after acute excitotoxic neurodegeneration in the hippocampus. In our study, we found that the expression of Follistatin is significantly altered in APP mice. Furthermore, our data suggest that Follistatin may be under the regulation of seizure activities in APP mice. Together, these data indicate that the regulation of Follistatin expression may be one of the mechanisms by which seizure activities drive aberrant NSC and neurogenesis dynamics in APP mice.

Abstract: Dopamine is a neurotransmitter that plays critical roles in neuromodulation, such as motivation, reward, motor control, and value-based decision making. However, the nature and the exact function of dopamine is not clearly understood even though it has been studied extensively. This can in part be attributed to the challenge of measuring dopamine in vivo during behavior. In order to overcome this challenge, we customized a probe made of carbon-fiber electrode for dopamine measurement using fast-scan cyclic voltammetry, which includes an outer guide electrode that serves as a reference electrode. We collected the non-background-subtracted cyclic voltammetry responses based on known concentrations of dopamine solutions across multiple probes. An elastic-net penalized regression model was trained to predict the dopamine concentrations in held-out samples and was used for *in vivo* experiments after validation. From our preliminary results, we built a regression model that can accurately predict the dopamine concentrations of held-out data. The in vivo measurements were collected from a non-human primate (rhesus macaque) during an approach-avoidance task. In this task, the subject chose between an appetitive (juice) and aversive (bitter solution) outcome in each trial. While measuring dopamine, we also recording neural spiking activity and local field potentials from frontostriatal circuitry. We found that dopamine was modulated by the two alternative outcomes, and that selective neurons within the circuitry encoded separately each alternative. This work will have important implications in understanding approach and avoidance behaviors, the balance of which is often impaired in the presence of disease.

Psychiatry, Ctr. For Addiction & Mental Hlth., Toronto, ON, Canada; [4]CAMH, Toronto, ON, Canada; [5]Univ. Toronto, Toronto, ON, Canada

Abstract: The accumulation of amyloid beta (Aβ) in the brain has a complex and poorly understood impact on the progression of Parkinson's disease (PD) pathology. Increased Aβ burden has been associated with cognitive decline in PD, especially in PD with dementia. Some studies however have found no association between high Aβ burden and cognitive decline in PD patients, instead suggesting normal aging may be responsible for both Aβ accumulation and cognitive decline. To better understand the relationship between PD cognitive decline and Aβ deposition, our study focused on a homogeneous group of PD patients whose cognitive abilities were measured longitudinally for 2 years after their Aβ scan. Our study used PD patients and healthy control data from the Parkinson's Progression Marker Initiative (PPMI) cohort: a multi-center cohort of 25 *de novo* idiopathic PD patients and 30 healthy controls (HC). These participants underwent a [18F]florbetaben positron emission tomography scan which can measure the density of Aβ in vivo in the brain. The data was analyzed using IBM SPSS version 27 software with linear regression modeling, Pearson correlations, and hierarchical cluster analysis. A stepwise linear regression of the PD group revealed a strong adjusted R2 of 0.495 in a model explaining their Montreal Cognitive Assessment (MoCA) score 1-year post-scan using the standardized uptake value ratios from the 20 regions of interest (ROI) as independent variables. The ROIs used in this stepwise model were the left rectus, the left anterior cingulate cortex, and the right parietal cortex. We found the PD group's 20 ROIs formed three clusters, with increased Aβ burden in cluster two correlating more strongly with a poorer cognitive score, while Aβ burden in clusters one and three had a mixed effect upon MoCA score. The results suggest Aβ does have a moderate association with cognitive decline in PD, independent of age. We found Aβ accumulation in the brain has a different effect on PD cognition depending on which ROI is affected, with increased Aβ in the rectus gyrus having no detrimental effect on MoCA score 1-year post-scan. The inconsistencies in the literature regarding Aβ and PD cognitive decline may be due to the patchwork impact Aβ burden has on different brain regions.

Title: What determines selective vulnerability and circuit integration of olfactory bulb dopaminergic neurons?

Authors: *T. KUNKHYEN[1], A. A. LAUER[1], T. R. BRECHBILL[1], A. N. RANGEL[1], C. E. J. CHEETHAM[2];
[2]Dept. of Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: One of the hallmarks of many neurogenerative diseases is the selective loss of specific sub-populations of neurons. Dopaminergic (DA) neurons in the mouse olfactory bulb (OB) are highly activity dependent. While 40% of DA neurons undergo cell death after a month of sensory input blockade by naris occlusion, the remaining 60% are resilient to this loss of sensory input. Furthermore, OB DA neurons are continuously generated in the subventricular zone throughout life, enabling them to fully repopulate a month after reversal of naris occlusion. This makes OB DA neurons an ideal model system in which to determine what underlies selective vulnerability in subset of DA neurons and how newborn DA neurons are functionally integrated to replace previously lost neurons. We have developed an experimental paradigm that enables rapid elimination followed by gradual restoration of sensory input to the OB. By performing chronic *in vivo* 2-photon imaging in DAT-cre;Ai9;Ai162 mice that express both a red fluorescent protein as a morphological marker and a green genetically encoded calcium indicator in DA neurons, we can track the survival and integration, as well as the odor response properties, of individual neurons over long periods of time (10 weeks). We found that loss of DA neurons was significantly elevated during the first week after ablation of OB sensory input compared to control mice (-9.5% vs. -0.94%, $P < 0.001$, Sidak's test after two-way ANOVA). In contrast, there was no effect on DA neuron loss 7-14 days after OSN ablation (-3.0% vs. -1.4%, $P = 0.29$). We are currently analyzing whether there are differences in the vulnerability of the previously described large embryonically-generated and small postnatally-generated DA neurons. We are also quantifying the rate of newborn DA neuron integration before and after ablation of OB sensory input. Finally, we are analyzing whether there are differences in the odor response characteristics between DA neurons that are vulnerable or resilient to sensory input ablation, and whether newly integrated DA neurons share odor response properties with DA neurons that had previously been lost. This work will provide new insight into what distinguishes vulnerable neurons from their neighbors, which may inform novel targeted therapeutic strategies for the treatment of neurodegenerative diseases.

Title: Sonic hedgehog signaling onto striatal cholinergic interneurons impinges on D2 signaling via the integrated stress response pathway to mediate L-dopa induced dyskinesia induction

Authors: *S. URIBE-CANO[1], K. LIU[2], M. HOLMES[2], L. MALAVE[3], A. H. KOTTMANN[1]; [1]Physiology, Pharmacol. and Neurosci., CUNY City Col. of New York, New York, NY; [2]CUNY Sch. of Med., City Col. of New York, New York, NY; [3]Dept. of Psychiatry, Columbia Univ., New York City, NY

Abstract: Dopamine neuron (DAN) loss, a hallmark sign of Parkinson's Disease (PD), is treated with L-Dopa therapy which attenuates bradykinesia and akinesia in patients. Unfortunately, prolonged treatment with L-Dopa leads to a debilitating side effect called L-Dopa induced dyskinesia (LID) in a majority of medicated PD patients. Cholinergic interneurons of the striatum (CIN), which are projection targets of DAN and undergo pathophysiological changes in response to DAN degeneration, have been increasingly implicated in LID. However, the mechanistic underpinnings of how L-Dopa-derived Dopamine (DA) signaling onto CIN interacts with the pathophysiological changes CIN undergo following DAN degeneration to produce LID remains poorly understood. CIN express both inhibitory D2 and facilitatory D5 receptors. In the work presented here, we probe the degree to which DA action via D2 on CIN following L-Dopa administration may be responsible for LID induction. Amazingly, selective ablation of the D2 receptor from CIN in 6-OHDA animals treated with L-Dopa attenuated LID and reduced levels of the LID cytochemical marker p-ERK among CIN. Unexpectedly however, quantification of the neuronal activity marker p-rpS6 in CIN suggested that D2 ablation leads to lower activity levels in CIN following L-Dopa administration. In parallel lines of study, we recently found that release of the signaling peptide sonic hedgehog (Shh) from DAN to CIN is crucial in the prevention of aberrant CIN physiology and LID induction. Prior work from our group has also demonstrated that Shh signaling onto CIN impinges on the Integrated Stress Response pathway (ISR), suggesting that changes in physiological cell stress among CIN following DAN degeneration are mediated by changes in Shh signaling. These findings are made relevant to D2 signaling on CIN given recent work by Helseth and colleagues (2021) demonstrating that attenuation of the ISR pathway in CIN can produce an inversion of D2 from acting as inhibitory to excitatory. Specifically, we hypothesize that altered ISR activity in CIN mediated by changes in Shh signaling can lead to disruptions of physiological D2 signaling and promote LID. Here, alongside our characterization of how D2 ablation from CIN prevents LID induction, we begin to investigate how Shh signaling impinges on the ISR pathway and impacts D2 signaling on CIN to prime LID formation following DAN degeneration in PD.

Title: Global remodelling of afferent and efferent projections of the A13 region following unilateral nigrostriatal degeneration using 6-hydroxydopamine

Authors: *L. H. KIM[1], T. CHOMIAK[2], M. A. TRAN[3], S. TAM[3], C. MCPHERSON[3], S. E. A. EATON[3], Y. OU[5], Z. H. T. KISS[4], P. J. WHELAN[3];

Abstract: Parkinson's disease (PD) is a complex disease affecting many facets of movement and cognitive function. Gait abnormalities worsen over time and remain difficult to treat. We found previously that the A13 nucleus of rostromedial zona incerta (ZI) projects to brainstem locomotor regions, suggesting that a parallel dopaminergic pathway in addition to the nigrostriatal pathway exists. Dopaminergic cells within the ZI-hypothalamic region are preserved in the advanced PD brain despite a global remodelling of the dopaminergic system following nigrostriatal degeneration. To explore alternative targets to treat gait dysfunctions in PD, we targeted the A13 connectome. We used an established unilateral 6-OHDA PD model (N=8, male C57BL/6 mice 7-8 weeks of age). Sham mice (N=3) received a vehicle solution of the same volume. AAV8-CamKII-mCherry and AAVrg-CAG-GFP were microinjected at the ipsilesional A13 region. Brains were processed 5 weeks later using a modified iDISCO clearing method and imaged on a lightsheet microscope (LaVision Biotech UltraMicroscope). Brains with insufficient quality in labelling were excluded from analysis. Immunolabeled cells were manually counted, and fibres were segmented using Ilastik and ImageJ. WholeBrain software was used to register with the Allen Brain Atlas. Segmentations from any given brain region were normalized to the total amounts across all regions per mouse and analyzed using Spearman's cross-correlation matrices. Despite A13 cells being largely preserved, there was a remarkable change in both the afferent and efferent A13 connectome. The sham group showed strong interconnections with the cerebral cortex and A13 region. Although these cortical-A13 afferents and efferents were

downregulated most severely following nigrostriatal degeneration, afferent projection patterns from the isocortical (motor, sensory, visual, and prefrontal) areas remain anti-correlated with the rest of the neuraxis. In contrast, the efferent projection patterns show greater cross-correlation across the neuraxis. In a human PD patient brain with gait dysfunction we found substantial degeneration of the substantia nigra compacta with preservation of the A13 and the locus coeruleus. Our findings suggest that executive control of behavioural response, which could be modulated by descending ZI efferents, remains intact following nigrostriatal degeneration. This work provides a comprehensive insight into the plasticity in A13 connectome that could contribute to heterogeneity of progression and severity in PD.

Title: Pharmacological functional ultrasound imaging to characterize the effects of NMDA-antagonist MK-801 on blood perfusion in the mouse brain

Authors: *K. AGYEMAN[1], L. CROWN[2], I. HOANG[3], N. LAZKANI[5], C. LIU[3], V. N. CHRISTOPOULOS[6], D. J. LEE[4];
[1]UC Riverside, Riverside, CA; [2]Univ. Of Arizona, Tucson, AZ; [4]Neurolog. Surgery, [3]USC, Los Angeles, CA; [5]Univ. of California Riverside, Riverside, CA; [6]Div. of Biol. and biological Engin., Caltech, Pasadena, CA

Abstract: NMDA hypofunction has been proposed as a mechanism underlying the cognitive deficits observed in neuropsychiatric disorders such as schizophrenia. MK-801 is a potent and selective NMDA antagonist and has been used to model NMDA hypofunction in rodents. Despite its widespread use as a research model, little is known about the effects of MK-801 on blood perfusion in brain regions and circuits important to cognitive function. Pharmacological functional ultrasound (Pharmaco-fUS) is a relatively new technique that uses functional ultrasound imaging (fUSI) to quantify the effects of pharmacologically induced changes to blood perfusion with unprecedented spatiotemporal resolution (100 μm and up to 10 ms). In this study, we assess the pharmacodynamics of blood perfusion changes in the mouse hippocampus, thalamus and isocortex induced by MK-801. We acquired baseline cerebral perfusion recordings

for 5 minutes followed by an intraperitoneal injection of MK-801 (1 mg/kg) in a group of 14 isoflurane-anesthetized male C57BL/6 mice. Drug effects were compared to saline-vehicle injection in another group of 14 animals. By recording fUS activity for 40 min post injection, we found that MK-801 causes a significant reduction in blood perfusion in cortical and sub-cortical regions [MEAN +/- 95% Confidence Interval (CI) over the last 5min; hippocampus (-2.88 +/- 0.27 %, p = 2.22e-4), isocortex (-4.22 +/- 0.60 % p = 0.0047), and thalamus (-4.89 +/- 0.68% p = 0.0042)]. No significant changes of blood perfusion were found over time in the saline control animals [mean difference 0.357 % (p = 0.918)]. The greatest change in blood perfusion was observed in the thalamus, which exhibits a relatively linear decrease in blood perfusion over time following MK-801 injection [average rate, -0.114 +/- 6.0e-4 % per min, 95% CI]. Blood perfusion in the hippocampus also decreased [average rate, -0.066 +/- 6.0e-4 % per min, 95% CI] in a linear manner as well. Intriguingly, blood perfusion in the isocortex exhibited an immediate perfusion decrease [average rate, -0.624 +/- 0.012 % per min, 95% CI], restoring increase [average rate, 0.282 +/- 0.012 % per min, 95% CI], followed by decrease [average rate, -0.186 +/- 6.0e-3 % per min, 95% CI] in perfusion akin to that observed for the thalamus and hippocampus. Together, these preliminary results indicate that pharmacologic NMDA receptor antagonism has regionally distinct effects on blood perfusion. These insights may shed light on the dynamics of pharmacological models of NMDA hypofunction, providing further insight into models of altered brain function in neuropsychiatric disorders.

Title: Gpr139, a modulator of mu opioid receptor, is a target of sonic hedgehog signaling in cholinergic interneurons of the adult striatum and modulates cholinergic activity

Authors: *D. ZUELKE[1,2], S. BERNAL[3], A. WALLS[1,2], A. H. KOTTMANN[1,2];
[1]Physiology, Pharmacology, and Neurosci., CUNY Sch. of Med., New York, NY; [2]Biol. PhD Program, [3]The Grad. Center, CUNY, New York, NY

Abstract: Cholinergic interneurons (CIN) are key components of striatal circuits. CIN have been implicated in various processes including learning, aging, addiction, and Parkinson's disease (PD). The gold standard treatment for PD is dopamine (DA) substitution therapy with L-Dopa,

which aims to mitigate the functional consequences of dopamine cell loss. However, long-term treatment leads to the development of debilitating L-Dopa induced dyskinesia (LID). We have previously shown that activation of the GPCR Smoothened (Smo) on CIN attenuates L-Dopa induced dyskinesia (LID) in rodent and macaque models of PD (Malave et al., 2021). The predominant source of the physiological ligand for CIN expressed Smo, Sonic Hedgehog (Shh), are ventral midbrain DA neurons (DAN) (Gonzalez et al., 2012). To elucidate possible mechanism(s) by which loss of Shh signaling from DAN might mediate CIN pathophysiology in PD, we identified CIN-specific downstream transcriptional targets of Smo. We utilized translating ribosome affinity purification (TRAP), to isolate mRNA selectively from CINs for RNAseq in mice with conditional ablation of Shh from DAN and controls. The results from the RNAseq analysis identified the orphan G-coupled receptor GPR139 as a potential target for further investigation. Subsequent experiments showed that striatal GPR139 expression is reduced in mice with conditional ablation of Shh from DAN compared to controls. GPR139 expression in the wild-type striatum reveals a prominent low (medial) to high (lateral) expression gradient that matches the expression gradient of the transcriptional effector of Shh signaling, Gli3. GPR139 is a cell autonomous negative modulator of endo-opioid signaling acting downstream of mu-opioid receptor (MOR) activation by morphine and fentanyl. Previous studies have shown morphine decreases ACh release, while antagonists of MOR increase striatal ACh. Further, antagonists of MOR were previously found to attenuate LID in animal models of PD. Thus, we hypothesized that Shh signaling might attenuate LID by modulating the CIN response to MOR activation. We used fiber photometry with DA- and ACh- sensors to monitor *in vivo* extracellular levels of DA and ACh combined with localized micro-fluid injection of drugs in the striatum and detected increased striatal ACh levels in response to GPR139 agonist. To test if this effect is cell autonomous, we performed acute, Cre-dependent CIN CRISPR knock-down of GPR139. Using this novel paradigm, we will present pharmacological epistasis experiments that investigate the molecular details of the modulation of MOR signaling by Smo in CIN and the effect of GPR139 pharmacology on LID.

Title: Associated white matter connectivity networks with the patterns of striatal dopamine depletion in Parkinson's disease

Authors: *Y. KIM[1], S. CHUNG[3], Y. JEONG[2], P. LEE[3], Y. SOHN[3];
[1]Program of Brain and Cognitive Engin., [2]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [3]Dept. of Neurol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Recent studies suggest that the patterns of nigrostriatal dopaminergic denervation are associated with clinical heterogeneity in Parkinson's disease (PD), and the patterns have individuality and are consistent over the disease progression. In our previous study, we identified the four patterns of striatal dopamine depletion by the factor analysis based on the dopamine transporter (DAT) availability in each striatal subregion. The results suggest that the patterns could provide information on the long-term prognosis of early-stage PD patients, and could also be contributed as a predictive marker of motor complications or dementia, which reflects the heterogeneity in PD. In this regard, this study aims to investigate whether the striatal dopamine depletion pattern is associated with a white matter (WM) connectivity network in drug-naïve early-stage PD. A total of 240 patients (age = 70.6 ± 8.9; female, No. (%) = 125(52.1%)) with newly diagnosed PD who underwent ^{18}F-FP-CIT PET scans and diffusion tensor imaging at initial assessment were enrolled. Factor analysis-derived striatal dopamine loss patterns were estimated in each patient for four striatal sub-region factors (*caudate*, *more-affected sensorimotor striatum*, *less-affected sensorimotor striatum*, and *anterior putamen*). Here, a higher value of the factor indicates DAT availability of that factor is relatively preserved than other striatal sub-regions. Then, the structural networks associated with the composite scores of each striatal sub-region factor were identified. Lastly, Pearson's correlation analyses were performed to assess the relationship of cognitive domain with the composite scores of each striatal sub-region factor, and with the connectivity strength of identified subnetworks. The composite score of *caudate* was associated with strong structural connectivity in a subnetwork composed of the left caudate and left frontal gyri. Selective dopamine loss in the caudate was associated with strong connectivity in the structural subnetwork whose hub nodes were bilateral thalami and left insula that was connected to the anterior cingulum. Whereas there was no subnetwork correlated with other striatal sub-region factors. The composite score of *caudate* and the connectivity strength of positively correlated subnetwork with *caudate* showed a significantly positive association with the frontal/executive function domain. These findings suggest that different patterns of striatal dopamine depletion are closely associated with WM structural alterations, which may contribute to heterogeneous clinical features in individuals with PD, particularly in terms of cognitive function.

Title: In vitro models: Tools to advance Parkinson’s disease research

Authors: *J. KS, S. KANDASAMY, P. D, P. SWAMYNATHAN, H. SRIDHARAN, *S. SAJJA;
Thermo Fisher Scientific, Bangalore, India

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder that predominantly affects the dopaminergic (DA) neurons of the brain and results in loss of motor function. Studying the underlying molecular mechanisms and subsequent drug development against Parkinson's disease is often challenging with primary human dopaminergic neurons not being accessible. Stem cells therefore serve as powerful tools in generating specific cell types *in vitro.* These differentiated stem cell models can then be used to study the disease in the right biological context. Here, we show human induced pluripotent stem cells (iPSCs) being differentiated into dopaminergic neurons which were then characterized using specific antibodies against cell specific markers like TH, DAT, LMX1B and FOXA2: TH is an enzyme which is involved in the conversion of L-tyrosine into dopamine precursor L-DOPA. DAT is a transmembrane transporter which is vital in maintaining the dopamine levels. LMX1B and FOXA2 are transcription factors that regulate specification and differentiation of DA neurons. Mutations on genes like PARK7, SNCA, LRRK2, MAPT, PINK1 and PARK2 have been found to be linked with Parkinson’s disease. Knockout models for these key genes were generated and were used to ascertain specificity of Invitrogen antibodies against these targets. Antibodies against these genes are incredibly useful in understanding disease progression and arrive at novel methods of treatment. Given the importance of PD, it is imperative that scientists are provided with the necessary resources or tools which will enable them to take their research forward. Recognizing this critical need, Invitrogen offers several specific and extensively validated antibodies for the key players of this disease. The data here shows that these antibodies were tested in the most relevant cell models and have been confirmed for specificity.

Title: Early synaptic dysfunctions associated with Parkinson Disease-relevant alpha-synuclein pathology

Authors: *R. J. RAE[1], M. SCARDUZIO[2], C. F. BRZOZOWSKI[3], D. THRASHER[5], L. A. VOLPICELLI-DALEY[6], L. L. MCMAHON[4];
[1]Univ. of Alabama, Birmigham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL; [4]Dept Cell, Developmental, and Integrative Biol., [3]UAB, Birmingham, AL; [5]Univ. of Alabama, Birmingham, AL; [6]Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The main pathological hallmarks of Parkinson's Disease (PD) are loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) and accumulation of alpha-synuclein (α-syn) in intracellular, insoluble inclusions in cell bodies and axons, collectively termed Lewy pathology (LP). α-Syn normally localizes to membranes at the presynaptic terminal where its interaction with SNARE proteins has been implicated in synaptic transmission. Aggregated synuclein corrupts presynaptic endogenous α-syn to form pathologic aggregates. Experimentally, aspects of progressive α-syn pathology can be recapitulated in model systems by exogenous introduction of recombinant α-syn preformed fibrils (PFFs). Templated α-syn aggregation reduces spine density *in vitro* and *in vivo* hippocampal primary neurons in rodent models. This causes increased frequency of miniature excitatory postsynaptic currents (EPSCs) and presynaptic docked vesicles, suggesting enhanced presynaptic function. These observations suggest that one of the initial consequences of α-syn pathology may be dysfunctional synaptic transmission preceding neurodegeneration and DA terminal loss. However, research focused on identifying these early synaptic alterations *in vivo,* in circuits relevant to PD symptomatology, is lacking. Indeed, the role aggregated α-syn in the impairment of corticostriatal synaptic transmission and plasticity remains incompletely studied despite cumulative evidence that dysfunction of these synapses plays a key role in mediating the deficits associated with PD. We investigated synaptic transmission and plasticity at dorsolateral corticostriatal glutamatergic synapses onto spiny projection neurons, in adult male mice 8 weeks post intrastriatal injection of α-syn preformed fibrils (PFF) or monomer α-syn. Using whole cell patch clamp recordings, we found that compared to monomer, PFF-injected mice had increased basal synaptic transmission, enhanced spontaneous release of glutamate and increased presynaptic sensitivity to Ca2+, as indicated by increased paired pulse ratio. Despite the enhanced glutamatergic transmission, corticostriatal synapses in PFF injected animals were not able to express long-term synaptic potentiation (LTP) assessed in extracellular recordings, and LTD was decreased. Altogether, this data reveals an early deficit in glutamatergic corticostriatal synaptic transmission and plasticity induced by α-syn pathologies.

Title: Integrated Stress Response in Alpha-Synucleinopathy

Authors: *C. FANG[1], D. JANGIR[1], P. GRIFFIN[1], R. KARIM[1], J. MEINTS[1], S. MORE[1], M. K. LEE[2];
[2]Neurosci., [1]Univ. of Minnesota, Minneapolis, MN

Abstract: Abnormalities in α-synuclein (αS) is directly linked to the pathogenesis of Parkinson's disease (PD) and related disorders called α-synucleinopathies. We showed that α-synucleinopathy in a αS transgenic model (TgA53T) and humans causes chronic endoplasmic reticulum stress (ERS)/unfolded protein response (UPR)/Integrated Stress Response (ISR). Treatment of TgA53T with salubrinal, a compound that inhibits dephosphorylation of eIF2α and attenuates ERS induced toxicity, can significantly delay onset of αS pathology and motor deficits. To further establish ERS/UPR/ISR as an important pathogenic factor in α-synucleinopathy, we examined if reducing phosphorylation of eIFα by the Protein kinase R-like ER Kinase (PERK), exacerbates α-synucleinopathy. We show that conditional deletion of PERK in neurons of TgA53T mice leads to significantly earlier onset of α-synucleinopathy, showing the pathologic importance of PERK-eIF2α pathway. While salubrinal inhibits both the protein phosphatase 1 regulatory subunit 15A (PPP1R15A, Gadd34) and PPP1R15B (CReP), studies show that inhibition of Gadd34 could be neuroprotective. Significantly, neither the pharmacological inhibition of Gadd34 or genetic loss Gadd34 function attenuated α-synucleinopathy in TgA53T model. Significantly, treatment of TgA5t model with an CReP inhibitor delays disease onset and attenuates pathology in TgA53T model. Our data suggest ISR components, particularly inhibition of CReP, is a therapeutic target for α-synucleinopathy.

Abstract: Parkinson's Disease (PD) is a neurodegenerative disorder characterized by loss of dopamine (DA) neurons of the Substantia Nigra (SN). There is a big body of evidence suggesting that alpha-synuclein (aSyn) plays a central role in the pathogenesis of PD. However, there is no molecularly precise, single cell in vivo transcriptomic studies with accurately defined aSyn overload. Here we describe a novel strategy and recent results achieved based on AAVs engineering and transgenic animals. The engineered MNM008 AAVs capsid, capable of retrograde transport in DA neurons, is injected in the striatum of TH-Cre rats and DAT-Cre mice. The vector carries uniquely barcoded aSyn genomes or barcoded-nonpathogenic tagBFP. Injecting in the striatum with Cre-recombinase restriction of the expression to DA neurons of the SN, we avoid possible injection-related inflammation and cell loss. The nuclei from the microdissected SN area are enriched for DA neurons using FANS. This is achieved thanks to the viral vector prep containing a Cre-inducible histone-linked GFP (H2B-GFP), which is only expressed in the population of interest. Using a novel combinatorial-indexing based single nuclei sequencing approach called Sci-Fi Seq we can pre-label all mRNA in each nucleus with an identifier for that specific sample. These samples are then pooled together and prepared for sequencing using 10X genomics droplet technology. Immunohistochemistry results showed that the virus injected in the striatum was retrogradely transported and expressed in DA neurons of the SNpc. The FANS enrichment strategy for our population of interest expressing the virus showed to be robust and consistent with an average of 2500 GFP positive (DA) nuclei retrieved per animal. Transcriptomic analysis on the GFP positive sorted nuclei revealed DA markers specific to the SN population, and the viral vector expression was restricted to this population, confirming the high selectivity of our approach. The combinatorial indexing and molecular barcoding will allow us to accurately measure the aSyn expression level in each DA neuron arranging them into disease stages in what we call pseudo-time. Moreover, this approach will identify genetic triggers and causative cascades of changes at the transcriptional level. From this study, we will further our knowledge on PD disease progression as well as possible new treatments.

Abstract: Parkinson disease (PD) is an adult-onset, intractable neurodegenerative disease characterized byslowly progressive symptoms, including motor, sleep, and olfactory disturbances. Here, we describe transgenic marmoset lines carrying a pathogenic mutation in *SNCA*(A30P) as forming a nonhuman primate (NHP) model of PD. The animals exhibited diverse late-onset PD-like behaviors, including REM sleep disruptions and agait disturbance that was partly responsive to dopamine replacement. Multiple subcortical regions along with the dopaminergic system exhibited α-synuclein-related pathologies, and long-term loss of dopamine transporters and oligomerization of α-synuclein (but not Lewy-like inclusions) were observed in the prodromal phase. Analysis of several animals at different ages and stages of disease progression indicated that this model animal exhibited hallmark pathologic abnormalities at various phases of disease, including as α-synuclein oligomerization at a preclinical/prodromal phase and Lewy body-like α-synuclein inclusions at a later phase. This work documents the first transgenic NHP in which α-synuclein anomalies were demonstrated to be associated with the late-onset symptoms and diverse pathologiesof PD. We propose that this modelwill enable the identification of predictive biomarkers and the assessment of preemptive and disease-modifying therapiesfor PD.

Title: Longitudinal single-cell tracking to assess survival of human neurons: application to synucleinopathy

Authors: *J. CHOI[1], H. KII[2], J. NELSON[1], Y. YAMAZAKI[2], F. YANAGAWA[3], A. KITAJIMA[2], T. UOZUMI[2], Y. KIYOTA[2], D. DOSHI[1,4], H. SADLISH[1], K. RHODES[1,5], R. SCANNEVIN[1,6], C. CHUNG[1];

Abstract: Developing proper phenotypic assays and analysis methods is an important step in the drug discovery process. Assays using iPSC-derived human neurons are emerging as powerful tools for the treatment of neurological disease. We have previously shown that the longitudinal single cell tracking enabled the detection of survival/death of neurons after overexpression of mutant alpha synuclein (A53T), a familial Parkinson's disease mutation. The reliance of this method on manual counting, however, renders the process labor intensive, time consuming and error prone. To overcome these hurdles, we developed algorithms for automated detection of neurons using BioStation CT live imaging system and CL-Quant software. With these algorithms, we successfully measured the risk of neuronal death caused by the overexpression of A53T alpha synuclein with similar accuracy and improved consistency compared to manual counting. It also provided an additional key readout of neuronal fitness: total neurite length and the number of nodes from which neurites were projected from the cell body. The algorithm was able to detect the beneficial effects of BDNF treatment in A53T alpha synuclein overexpressing neurons. These data show that the automated algorithm will improve the consistency of the neuronal health measurement and considerably shorten the assay time, making this assay amenable for small molecule screening.

Title: A novel genetic sensor and "Seek and Rescue" strategy to unravel the pathogenic role of environmental risk factor-driven neuronal DNA damage response in sporadic neurodegenerative disorders

Authors: *M. S. GRAMES[1], M. B. W. EL-SAADI[1], X. TIAN[1], K. M. KEYS[1], M. REN[1], C. E. HAACKER[1], E. L. KNOTT[1], H. M. LI[1], S. WANG[2], L. HARRISON[3], X.-H. LU[1]; [1]Pharmacology, Toxicology, and Neurosci., [2]Biochem. and Mol. Biol., [3]Mol. and Cell. Physiol., LSU Hlth. Sci. Ctr. Shreveport, Shreveport, LA

Abstract: Parkinson's disease (PD) is the second-most prevalent neurodegenerative disease, where the vast majority of incidences have no identifiable inheritance and occur in a sporadic form. Environmental risk factors (e.g., pesticide/herbicides, exposure to metals and solvents, virus infection, and head trauma) have been speculated as a trigger to the sporadic PD. To explore the causal and pathogenic evidence of environmental triggers, we developed a genetic

sensor exploiting the interaction of DNA virus with host cell DNA damage response (DDR) as an innate antiviral defense mechanism. We harnessed the recombinant Adeno-associated virus (rAAV) genome-processing machinery and the instability of a hypermutable repeat sequence to detect neuronal genomic instability and visualize neurodegeneration in post-mitotic differentiated neurons. We demonstrated the viral genetic probe is sensitive in detecting neurons with increased DNA damage response. To quantify DDR in vivo, we developed an efficient mutation reporter assays using the DNA Endonuclease T7E1, targeted next-generation sequencing, and capillary electrophoresis. Exposure to paraquat, a PD-associated environmental toxicant, heightened neuronal genomic instability and elicited neuropathology revealed by single-cell analysis. The increased neuronal genomic instability was also probed in a genetic alpha-synuclein (aSyn) transgenic mouse model infused with pre-formed fibrils. Based on the neuronal burden of synucleinopathy, we documented four pathological stages of Lewy body formation in vivo. We identified a possible "initiation stage," where aSyn aggregates colocalized with DNA damage foci inside the nucleus without cytoplasmic Lewy body formation. A similar pathology was also observed in the caudate nucleus of patients with Lewy body dementia, suggesting a pathogenic causal role of DNA damage response in aSyn aggregation/propagation and proteotoxicity. To determine the causal link and to explore the potential for disease-modifying therapies, we developed a novel genetic strategy to "Seek-and-Rescue" neurons with DNA damage non-invasively via the systemic introduction of a genetic sensor and actuator of DDR. Dose responses for various amounts of vector genomes of the genetic sensor were determined. A genetic actuator was implemented via a Cre-dependable conditional shRNA to knockdown ATM, a major orchestrator of the DDR in the hope to slow down the progression of neurodegeneration. These studies can pave the way for new paradigms to determine the causal and pathogenic roles of DDR and exposure to environmental toxicants in the progression of dementia and identify therapeutic targets.

Res. Inst. (IDIBGI), Salt, Spain

Abstract: Parkinson's disease (PD) is characterized by a progressive loss of dopaminergic neurons in the substantia nigra compacta (SNc) and accumulation of α-synuclein (α-syn), which underlies complex functional and structural changes in striatal spiny projection neurons (SPNs). Although a reduction in SPNs dendritic spine density has been reported in either postmortem studies of advanced PD patients or animal models of parkinsonism, it is unknown if these alterations occur since the onset of the nigrostriatal dopaminergic degeneration. Thus, our aim was to study the temporal sequence of functional and structural changes in striatal dendritic spines in the premotor stage of parkinsonism. For that purpose, rats were inoculated in the SNc with an adeno-associated viral vector coding for A53T mutated human α-syn (hα-syn) and evaluated at 72h, 1, 2 and 4 weeks post-inoculation (p.i.). Synaptic plasticity by chemical stimulation of LTP (cLTP) in isolated striatal synaptosomes and measurement of striatal dopamine by HPLC were assessed. The analysis of the dendritic arborization and the density and morphology of SPNs dendritic spines was performed by microinjection and high-resolution confocal microscopy. The ultrastructure of the dendritic spines and the presence of the spine apparatus (SA) were analysed by electron microscopy. The hα-syn group showed an inhibition of cLTP ($p<0.001$) and a decrease in dopamine content ($p<0.01$) since 72h p.i. even before the presence of hα-syn in the striatum and significant dopaminergic neurodegeneration. These functional alterations are followed by a dendritic spine remodelling, as observed by a significant loss of thin spines ($p<0.05$) at 4w p.i., along with an increase in the head volume of mushroom spines ($p<0.01$). In addition, we observed a decrease in the proportion of spines with SA since the 1st w p.i. in hα-syn group ($p<0.05$), along with an increase in SA_{area}/$SpineHead_{area}$ at 4w p.i ($p<0.01$). These structural changes occur before the development of parkinsonian motor signs and could represent a compensatory mechanism to enhance the function of existing spines, balancing the observed decrease in spine turnover. Thus, our results indicate dysfunctional dopaminergic neurotransmission by impaired striatal synaptic plasticity since very early time points, leading to dendritic spine remodelling and ultrastructural changes indicative of increased protein synthesis, before the manifestation of motor impairment.

Title: Connecting neural networks: a new model to study alpha-synuclein pathology and spreading in Parkinson disease

Authors: *G. GOMEZ-GIRO, D. FRANGENBERG, G. ROBERTSON, J. SCHWAMBORN; Luxembourg Ctr. for Systems Biomedicine (University of Luxembourg), Belvaux, Luxembourg

Abstract: Parkinson Disease (PD) is the second most common neurodegenerative disorder affecting around 1-2 % of the population above 65 years. The number of people with PD is expected to double by 2030. The primary neuropathology appears to be the chronological accumulation of alpha-synuclein (in Lewy bodies and neurites) in various parts of the brain and nervous system. The staging system of the PD brain pathology suggests that the protein aggregates are first seen in the posterior part of the brainstem. From there, the pathology takes an ascending course, reaching different nuclei in the pons and then the midbrain, affecting the dopaminergic neurons in the *substantia nigra* (SN). Furthermore, the influential hypothesis of Braak (2006) suggests that these aggregates might find their origin in the gut and are transported retrogradely via the enteric nervous system (ENS) towards the central nervous system (CNS). *In vitro*, there is growing evidence of transneuronal transport of different forms of alpha-synuclein, including potentially toxic oligomeric protein. In this project, we are aiming to model the complex interaction between the peripheral nervous system and the CNS through the incorporation of both cell types in compartmentalized devices, building on nervous-system-on-chip (NoC) technology. To represent the CNS, we use human induced pluripotent stem cell (hiPSC)-derived midbrain/hindbrain
organoids (MOs), and as a peripheral nerve contribution, we generate hiPSC-derived enteric neurons. Using PD as a showcase, we derive both cellular types from controls and a PD patient line that carries a triplication on the alpha-synuclein gene (3xSNCA). Up until this point in the project, using a specific protocol for extracting soluble and insoluble protein fractions, we succeeded in finding an increase of insoluble α-synuclein in the PD organoids compared to the controls (N=3). Additionally, we applied high content imaging and in-house built algorithms to detect alpha-synuclein and of its phosphorylated form (pS129), associated with aggregation and consequent toxicity. Considering the results obtained thus far, we can conclude that the successful development of our model in this project will enable, for the first time, to study a simple nervous system connection *in vitro*, instead of isolated tissues. Moreover, it might reveal new PD signatures in the context of alpha-synuclein pathology and spreading, providing a strong and innovative basis for the next generation *in vitro* on-chip disease models, which ultimately will reduce the need for pre-clinical animal studies and increase the efficacy of drug development.

Title: Alpha-synuclein and Tau are abundantly expressed in the appendix of humans and the ceca of common marmosets and rhesus macaques.

Authors: *A. D. ZINNEN[1], J. VICHICH[1], J. M. METZGER[1], J. C. GAMBARDELLA[1,2], V. BONDARENKO[1], H. A. SIMMONS[1], M. E. EMBORG[1,2,3];

Abstract: α-Synuclein (α-syn) proteinopathy in the neurons of the enteric nervous system is proposed to have a critical role in Parkinson's disease (PD) onset and progression. Interestingly, the human appendix harbors abundant α-syn, and appendectomy has been linked to decrease risk and delayed onset of PD, suggesting that the appendix may influence PD pathology. Common marmosets and rhesus macaques lack a distinct appendix (a narrow closed-end appendage with a distinct change in diameter at the junction with the cecum), yet the cecal microanatomy of these monkeys is similar to the human appendix. Sections of human appendix (n=2) and ceca from common marmosets (n=4) and rhesus macaques (n=3) were evaluated to shed light on the microanatomy and the expression of PD-related proteins. Analysis confirmed that the human appendix and marmoset and rhesus ceca present thick walls comprised of serosa, muscularis externa, submucosa, and mucosa plus abundant lymphoid tissue. Expression of α-syn and tau in the cecum/appendix was present within myenteric ganglia and along nerve fibers of the muscularis externa and mucosa in all species. In the myenteric ganglia α-syn, p-α-syn, tau and p-tau immunoreactivities (ir) were not significantly different across species. The percent area above threshold of α-syn-ir and tau-ir in the muscularis externa and mucosa were greater in the human appendix than in the nonhuman primate cecum (α-syn-ir $p<0.0001$; tau-ir $p=0.0006$). Overall, this study provides evidence that the common marmoset and rhesus macaque ceca are remarkably similar to the human appendix as they share comparable microanatomy and dense immunoreactivity of α-syn, p-α-syn, tau and p-tau.

Title: Altered cholinergic neurotransmission in the ENS of mThy1-hSNCA mice

Authors: *E. ZIEHL[1], N. YELLESWARAPU[2], J. J. GALLIGAN[3];
[1]Michigan State Univ. Neurosci. Program, East Lansing, MI; [2]Neurosci., [3]Neruoscience Program, Michigan State Univ., East Lansing, MI

Abstract: α-synuclein (α-Syn), a presynaptic terminal protein, is the pathological biomarker in Parkinons's disease (PD) causing cell death of dopaminergic neurons and resulting in motor deficits. Many patients with Parkinson's disease also have several gastrointestinal (GI) symptoms, the most common of which is constipation. As α-Syn is also found within the nervous system of the gut, the enteric nervous system (ENS), we hypothesize that overexpression of α-Syn within the ENS disrupts neurotransmission and results in colonic dysmotility. We used the mThy1-hSNCA, which expresses four-fold human α-Syn, and wild-type (WT) littermate mice to measure food intake, whole gut transit time, fecal pellet output, and transmural electrical stimulation on longitudinal smooth muscle contractions in the duodenum, ileum, and proximal and distal colon in the isometric tension isolated organ baths. We found that male mThy1-hSNCA mice have significantly decreased distal colon longitudinal muscle contractions compared to WT mice whereas female mThy1-hSNCA mice have significantly decreased duodenal longitudinal muscle contractions compared to WT mice. As contractions in the smooth muscle of the gut are primarily mediated by cholinergic neurotransmission, we predict that an overexpression of α-syn is altering cholinergic neurotransmission. This work supports our previous findings showing that α-Syn plays an important role in modulating enteric neurotransmission.

Title: Implications of heat shock protein family A member 6 (HSPA6) in neurological diseases based on in vivo analyses of a novel transgenic mouse line

Authors: *C. HOLT[1], S. CHENNAREDDY[2], S. GONZALEZ[1], R. G. GOGLIOTTI[1];
[1]Loyola Univ., Chicago, IL; [2]Vanderbilt Univ., Nashville, TN

Abstract: The heat shock protein 70 (HSP70) family is a multigene group of proteins that are highly conserved and many of its members are well studied in their role in neurological disorders. Increased expression of the *heat shock protein family A member 6* (*HSPA6*) gene is a conserved finding in autopsy samples from patients with Alzheimer's disease, Parkinson's disease, idiopathic autism, and Rett syndrome; however, unlike many of its HSP70 family members, *HSPA6* is not expressed in common model organisms. As a result, its contribution to these common neurological disorders remains unknown. While highly homologous to other HSP70 family members, *in vitro* data suggests that HSPA6 plays a functionally unique role in shuttling RNA-polymerase (Pol) II between nuclear speckles and sites of active transcription during times of cellular stress and recovery. In this context, HSPA6 may control the rate of transcriptional recovery to insult; a neuroprotective mechanism that is presently absent from most disease models. To address this critical knowledge gap, we have generated the first HSPA6 transgenic mouse (*HSPA6-TG*). Our novel HSPA6-TG mouse contains the human HSPA6 locus and the entire 3kb endogenous promoter. The entire construct is flanked by Lox-P sites, rendering it "conditional-off" in the presence of Cre-recombinase. Here we will report our progress establishing a baseline characterization of the HSPA6-TG mouse, including its temporal and spatial expression pattern, responsiveness to hyperthermia, and capacity to be induced by the HSP90-inhibitor 17-Dimethylaminoethylamino-17-demethoxygeldanamycin (17-DMAG).

Title: The role of ferroptosis in microglia during neurodegeneration

Authors: S. RYAN[1], M. ZELIC[1], L. CHEN[2], L. GUO[2], C. LI[2], F. PONTARELLI[1], E. TEEPLE[2], M. SADEGHI[2], H. YINGNAN[2], D. KUMAR[2], M. ZHANG[2], A. BLAZIER[1], J. GANS[2], B. ZHANG[2], D. OFENGEIM[1], *T. HAMMOND[2];
[1]Rare and Neurologic Dis. Therapeut. Area, [2]Sanofi, Framingham, MA

Abstract: Ferroptosis is an iron-dependent form of regulated cell death. This pathway, as well as iron dysregulation, has been implicated in multiple neurodegenerative disorders, including Parkinson's disease (PD). Mutations in iron handling can lead to a rare set of disorders known as Neurodegeneration with brain iron accumulation. While neuron susceptibility has been well established, the role of ferroptosis in microglia during disease is not well understood. However, iron-loaded microglia have been found in affected brain regions of many disorders, including Multiple Sclerosis, Amyotrophic Lateral Sclerosis, and Alzheimer's Disease. We determined that microglia are susceptible to ferroptosis, which can be rescued by standard ferroptosis inhibitors. In a tri-culture of human iPSC-derived neurons, astrocytes, and microglia, the microglia were the most sensitive to ferroptosis at the transcriptomic, protein, and functional level. Single-cell RNA sequencing (RNA seq) revealed a distinct ferroptotic signature in the microglia which correlated with marked increases in Ferritin at the protein level and increases in IL-8 and IL-1β production. These ferroptotic signatures were rescued with pharmacological inhibitors. A genome wide CRISPR screen revealed potential regulators of ferroptosis in microglia associated with necroptotic pathways and G protein-coupled protein receptor signaling. Transcriptional analysis of PD patient blood samples revealed changes in iron, mitochondrial, and IL-8 signaling, and single cell RNA seq of PD patient brain tissue revealed a ferroptotic signature in microglia. This work places microglial ferroptosis in the context of disease, reveals a potential role for this pathway in driving neuroinflammation, and suggests that further research into therapeutics that mitigate ferroptotic stress in not just neurons but also microglia, may be of interest in treating neurodegenerative disorders.

Title: Dolutegravir-mediated integrated stress response activation induces neurotoxicity

Authors: *N. ALBOLOUSHI[1], C. AKAY-ESPINOZA[2], K. JORDAN-SCIUTTO[2];
[1]Doctor of Sci. in Dent. Candidate, Sch. of Dent. Med., [2]Dept. of Basic and Translational Sciences, Sch. of Dent. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: *Keywords:* Human immunodeficiency virus; antiretroviral drug; integrated stress response; dolutegravir; neuron *Title:* Dolutegravir-mediated integrated stress response activation induces neurotoxicity *Background:* The incidence of human immunodeficiency virus (HIV)-associated dementia has been decreasing with the advent of antiretroviral therapy (ART) due to efficient systemic viral control; however, the prevalence remains high, partially due to increase life expectancy. Interestingly, about 50% of the HIV-infected patients have minor cognitive impairment, which led us to hypothesize that antiretroviral drugs (ARVs) induce integrated stress response (ISR), leading to neuronal dysfunction and damage, contributing to the changing clinical picture seen in HIV-positive individuals. *Methods:* We treated primary rat cortical neurons with the commonly prescribed integrase inhibitor dolutegravir (DTG) in therapeutically relevant doses and assessed whether ISR activation led to neuronal death. *Results:* We found that DTG led to neuronal death after 24 hours of treatment, as determined by MAP2 loss. In addition, we found that ISR was activated, as detected by the increased phosphorylation of eIF2alpha and ATF4 expression. Our data also suggest that pretreatment with the trans-ISRIB, which prevents eIF2alpha phosphorylation, might inhibit DTG-mediated neuronal death. *Conclusion:* Overall, understanding the underlying mechanisms of toxicity will lead to the development of new strategies to develop adjunctive therapies to complement ART while providing crucial information about potential neurotoxic side effects in the development of new ARVs.

Title: Inducible hypoxia tolerance is associated with downregulation of gene expression involved in Ca^{2+} homeostasis

Authors: *A. ALVAREZ[1], J. M. SANTIN[2];
[1]Univ. of North Carolina Greensboro, Greensboro, NC; [2]Univ. of North Carolina At Greensboro, Greensboro, NC

Abstract: Under hypoxic/ischemic conditions the brain fails to regulate ion homeostasis. Ion dysregulation in such pathologies leads to high levels of Ca^{2+} entering the cytosol, triggering neuronal dysfunction and cell death (termed "excitotoxicity). In health, various Ca^{2+} transporters and buffering mechanisms finely regulate Ca^{2+} entry and removal from the cytosol, while others buffer it by sequestering Ca^{2+} within organelles such as the endoplasmic reticulum (ER) or the mitochondria. Most vertebrates exposed to anoxic (no oxygen) conditions perish within minutes, and the model we use, the American Bullfrog (*Lithobates Catesbeianus*) is no different; after a few minutes of energy deprivation, rhythmic output from the brainstem respiratory network fails within a matter of minutes. However, after hibernation, when subjected to O_2 deprivation, the circuit becomes robustly tolerant and maintains steady rhythmic output for up to 4 hours, making a within-species model for inducible hypoxia tolerance. We hypothesized that one factor involves a coordinated modification of Ca^{2+} regulators such that transporters involved in removing and buffering Ca^{2+} are upregulated, while those that import it into the cytosol are downregulated, ultimately preventing Ca^{2+} overload. To test this hypothesis, we identified 16 Ca^{2+} pumps, exchangers, and channels in the bullfrog genome and designed quantitative PCR assays to determine if mRNA gene expression of each regulator correlated its role in an "anti-excitotoxic" phenotype (n=7 control, n=7 hibernation/hypoxia-tolerant). Surprisingly, we observed decreases in mRNA expression for 12/16 genes involved in Ca^{2+} homeostasis. The only downregulated targets consistent with protecting neurons from Ca^{2+} overload involved the IP_3 receptor and 4 non-selective cation channels (TRP channels). Therefore, our study suggests hypoxia tolerance corresponds with altered gene expression for Ca^{2+} homeostasis, specifically in plasma membrane and ER ion channels. Future studies are required to determine if these processes contribute to a large improvement in neuronal function during anoxia.

Title: Brain metabolic dysfunction in in vitro neurons

Authors: *L. BOLENG, N. SAWANT, S. KSHIRSAGAR, L. E. BUNQUIN, H. P. REDDY, A. P. REDDY;
Texas Tech. Univ., Lubbock, TX

Abstract: Metabolic dysfunction resulting from obesity and diabetes-induced inflammation is a significant risk factor in Alzheimer's disease (AD) and other dementias. Brain metabolic dysfunction affects multiple physiological pathways in the systemic and central nervous systems, adding to the complexity of AD and Alzheimer's disease related dementias (ADRD). The long-term effect of defective energy homeostasis is loss of synaptic transmission, hypometabolism, and neuronal death, and metabolic dysfunction indirectly affects neural resilience by increasing mitochondrial stress. Our research aims to investigate metabolic dysfunction in neurons that primarily contribute to dementia and comorbidities of obesity and depression. Metabolic dysfunction of serotonin in the neurons of three distinct brain areas contribute to depression, diabetes, and dementia—obesity: hypothalamus, depression: raphe, and dementia: hippocampus. The immortalized embryonic neuronal cell lines of the mouse-specific hypothalamus (mHypo), raphe (RN46A-B14), and hippocampus (HT22) express dopaminergic, serotonergic, and cholinergic neuronal characteristics, respectively, and have neurotransmitter expression. The aim of this research is to induce metabolic dysfunction by using high glucose and palmitic acid then treating with citalopram, a selective serotonin reuptake inhibitor, to assess improved energy homeostasis and cellular resilience. We propose that if treated with palmitic acid and high glucose, mHypo, RN46A-B14, and HT22 immortalized embryonic neurons will show a metabolic dysfunction phenotype, and citalopram treatment will improve cellular resilience. Cells were treated with 100 μM palmitic acid, 4% glucose, and citalopram for 24 hours. Control and treated cells were harvested and analyzed for mRNA levels of genes representing the preadipocyte to adipocyte transitions. We used qRTPCR based low-density array to analyze genes related to mitochondrial dysfunction, immune and cytokine function, serotonin pathways, synaptic signaling, and development. Immunocytochemistry and immunoblotting were conducted on adiponectin, IL6, and TNFα, PI3K, and Glut4. Results confirm that the immortalized mouse neurons show metabolic dysfunction and cellular susceptibility to mitochondrial stress. Together, these findings suggest that the use of multiple drug targets can combat comorbid diseases.

Title: Differential expression of endocannabinoid signaling proteins in response to oxidative stress in human neural progenitor cell-derived neurons

Authors: R. S. DUNCAN, ***P. KOULEN**;
Univ. of Missouri Kansas City, Kansas City, MO

Abstract: OBJECTIVE: Determine which neuroprotective endocannabinoid signaling proteins are expressed by differentiated neural precursor cells (NPC) and how oxidative stress affects expression levels of these proteins.
RATIONALE: Rodent primary neurons and cancer cell lines have been used extensively to study neurodegeneration and identify potential neuroprotectants, including endocannabinoids. NPC-derived neurons are potentially an effective replacement for these traditional cell culture models to use in neuroprotection studies, but it is not clear whether they express proteins involved in neuroprotective endocannabinoid signaling.
HYPOTHESIS: We hypothesized that NPC-derived neurons express critical endocannabinoid signaling proteins implicated in neuroprotection and that their expression levels are altered in response to oxidative stress.
METHODS: Human NPC (MilliporeSigma, Burlington, MA) were grown in neural stem cell maintenance medium (MilliporeSigma) differentiated by withdrawing basic fibroblast growth factor (Gibco, Frederick, MD) and epidermal growth factor (Gibco) from the media for 7 - 10 days leading to cells that ceased dividing, exhibited well-defined neurites and displayed high levels of neural cell adhesion molecule (NCAM) and microtubule associated protein 2 (MAP2) immunoreactivity (IR). We exposed these differentiated neuronal cells to sub-lethal oxidative stress (addition of 2 or 10μM tert-butyl hydroperoxide to the culture medium for 24 hours). IR for endocannabinoid signaling proteins, cannabinoid receptor 1 (CB1), cannabinoid receptor 2 (CB2), fatty acid amide hydrolase (FAAH), *N*-acylethanolamine acid amidase (NAAA) and *N*-acyl-phosphatidylethanolamine-hydrolyzing phospholipase D (NAPE-PLD), was determined with immunocytochemistry and confocal microscopy imaging.
RESULTS: NPC-derived neuronal cells displayed IR for CB1, CB2, NAPE-PLD, FAAH and NAAA. Exposure to oxidative stress led to an increase in NAAA IR and a decrease in CB1, NAPE-PLD and FAAH IR, while oxidative stress had no effect on CB2 IR.
CONCLUSIONS: Critical endocannabinoid signaling proteins involved in neuroprotective signaling are expressed in NPC-derived neuronal cells, and their expression levels are modified differentially in response to oxidative stress.

Title: Asthma, Allergic Rhinitis, Nonsuicidal Self-Injury, and Suicide Attempts

Authors: *E. JO, G. KIM, J.-W. HUR;
Sch. of Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: A growing body of literature has shown that asthma and allergic rhinitis are associated with mental health problems such as suicidality and self-harm. However, to our knowledge, there are no studies to date that have examined the link between nonsuicidal self-injury (NSSI) and such diseases. In this study, we aimed to investigate whether and to what extent the diagnosis of asthma or allergic rhinitis was linked to the NSSI and suicide attempts. A total of 696 participants (age range = 19-29) enrolled in the study, including 317 in the NSSI with suicide attempts (SA) group, 240 in the NSSI without SA group, and 139 in the control group. We compared a medical history of asthma and allergic rhinitis, NSSI acts, suicide attempts, and demographic characteristics, including gender and socioeconomic status, among the groups. The associations between dysregulated immune systems, NSSI, and suicide attempts were estimated through odds ratios from multinomial logistic regression. Results showed that the NSSI without SA group had a significant association with a diagnosis of allergic rhinitis even after adjusting demographic variables. The findings also suggest that individuals diagnosed with asthma, allergic rhinitis, or asthma with allergic rhinitis had a greater risk of co-occurrence of NSSI and SA, respectively. However, only the effect of asthma with allergic rhinitis on NSSI with SA remained significant after adjustment. This study provides novel evidence for the relationship between NSSI and the disturbance in inflammatory conditions, including asthma and allergic rhinitis. Our findings also indicate a need for a closer examination of the history of inflammatory diseases required for individuals at high risk of self-harm.

Title: Radiation and temozolomide induces tunneling nanotubes formation in glioblastoma tumors that promote tumor survival and adaptation to treatment

Authors: S. VALDEBENITO[1], K. P. L. BHAT[2], *E. EUGENIN[1];
[1]Neuroscience, Cell Biol. and Anat., Univ. of Texas Med. Br., Galveston, TX; [2]Dept. of Translational Mol. Pathology, Div. of Pathology-Lab Med. Div., MD. Anderson Cancer Ctr., Houston, TX

Abstract: Glioblastoma (GBM) is an aggressive and heterogeneous type of primary brain cancer with a poor prognosis (5 years of median survival) despite the advances in treatments. The only suggested treatment involves surgical resection, with subsequent radiation and temozolomide (TMZ) regiment, which results in an incremental increase in 5% survival. TMZ is a DNA alkylating, which triggers the mismatch repair system leading to a double-stranded break of the genome resulting in apoptosis. TNTs are minimally expressed under physiological conditions and only induced under cancer conditions, providing a unique therapeutic target to reduce the devastating consequences of GBM. Our preliminary data indicate that GBM tumors are highly communicated via TNTs, resulting in the spread of organelles and soluble factors between communicated cells. We detected that compromised mitochondria with deletions and mutations in the cytochrome B gene can be transferred. The transfer of mitochondria with mutated DNA enables non-tumor cells to become adapted to the tumor environment. Here we use primary glioma stem cells to study the transfer of mitochondria and tumor adaptation metabolism, using a co-culture model to examine TNT mediated transfer. We perform live cells imaging using mitotracker, immunofluorescence, Western blot, and Seahorse. Our results showed that the transfer of these mitochondria via TNTs enables cells to survive tumor growth, provide a better adaptation to environmental metabolic changes, and resist radiation and TMZ treatment. In conclusion, our data indicate that diffusion of key metabolites by TNT enables treatment-sensitive tumor cells to survive treatment and adapt non-tumor cells to the tumor microenvironment. Thus, blocking TNT communication induced by the tumor and treatment can provide an alternative mechanism to treat glioblastoma cells.

Title: Expression of pro-apoptotic proteins and Bcl-2 by exposure to ozone in rat´s cerebellum, frontal cortex, hippocampus and striate

Authors: *P. RODRÍGUEZ QUINTERO[1], W. MORENO ROMAN[2], M. RUBIO OSORNIO[3], R. LUNA[2], L. HERNÁNDEZ LÓPEZ[2], J. BRITO BRITO[2], C. RUBIO[2];
[1]Inst. Nacional De Neurologia Y Neurocirugia Ma, Ciudad De México, Mexico; [3]Dept. de Enfermedades Neurodegenerativas, [2]Inst. Nacional de Neurologia y Neurocirugia MVZ, Mexico City, Mexico

Abstract: Ozone (O_3) is one of the major air pollutants around the world, it is created by a photochemical reaction of volatile organic compounds, nitrogen oxides, and carbon monoxide that accumulates in the troposphere. According to the world health organization, O_3 concentrations above 100 µg/m3 (510 parts per million) with an exposure of 8 hours can be dangerous for humans causing moderate to severe effects on health. Several studies about the exposure to O_3 have been made in animal models, concluding to an increase in oxidative stress, resulting in lipoperoxidation, inflammation, metabolic disturbances, alteration in cell signaling, and the possible initiation of cell death in vulnerable areas such as the olfactory bulb, cerebellum, striatum, hippocampus and frontal cortex which are not fully described. The inflammatory response can represent an initial factor of cell death since a high concentration of TNF-α can activate caspase 3, which is one of the main effectors to bind substrates such as immune molecules that causes cell death. Apoptosis is a programmed cell death, which activates caspases leading to DNA fragmentation, forming and phagocyting apoptotic bodies with or without an inflammatory response. Apoptosis onset can occur through 2 pathways: intrinsic (mitochondrial) and extrinsic (death receptors), where multiple proteins interfere. Therefore, we aim to evaluate the participation of caspase 3 and caspase 8, Bcl-2, cytochrome C, VDA-C, TUNEL, and BAX proteins, in the initial damage resulting from ozone exposure in rat´s cerebellum, frontal cortex, hippocampus, and striatum. We used twenty male Wistar rats, who were randomized, in two groups, control and experimental equally divided. The experimental group was subjected to a hermetic ozone chamber for 12 hours provided with 1 ppm of O_3. Subsequently, they were immediately sacrificed to perform immunohistochemistry analysis. Compared to the control group, we found a decrease in Bcl-2, an anti-apoptotic protein, and an increase in TUNEL, caspase 3, 8, and BAX who trigger the cell death, this indicates that the two pathways (extrinsic and intrinsic) were activated. We also found a decrease in VDA-C and cytochrome C, this could be explained due to the release of cytochrome C. Also, cytochrome C is independent of its oxidation state and it becomes reduced in the cytosol. O3 induces cell death

through the extrinsic and intrinsic apoptotic pathways, this could explain some manifestations in the rats such as motor alteration, lack of memory, sleep disturbances, among others.

Title: Neuronal Nrf2 modulates glaucoma pathogenesis onset and severity

Authors: *S. NAGUIB[1], J. R. BACKSTROM[2], E. ARTIS[2], P. GHOSE[2], J. ANG[3], D. J. CALKINS[2], T. S. REX[2];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Vanderbilt Univ., Nashville, TN

Abstract: NRF2, a transcription factor that modulates a cell's response to reactive oxygen species (ROS), has been implicated as a therapeutic target in models of neurodegeneration including glaucoma. We used the well-characterized microbead occlusion model of glaucoma (MOM) to elevate intraocular pressure (IOP). This model causes retinal ganglion cells (RGC) degeneration and death over time. We have previously demonstrated that there is an increase in ROS at 1- and 2- weeks post-IOP elevation in this model. We also detected an NRF2-mediated endogenous antioxidant response at 2-weeks post-IOP elevation. Notably, detectable pathology in the MOM does not occur until 4-weeks later. The goal of this study was to determine if NRF2 activation occurred within the RGCs. We intravitreally injected $Nrf2^{fl/fl}$ mice with an adeno-associated vector driving Cre from the mouse RGC-specific gamma synuclein (mSncg) promoter (AAV2/2.mSncg.Cre.IRES.TdTomato). We then elevated the IOP and assessed the endogenous antioxidant response at 2-weeks and pathology at 5-weeks post-IOP elevation. The mice with knock-down of Nrf2 in the RGCs had a greater increase in nitrotyrosine labeling in the RGC layer, a marker for ROS, compared to mice injected with the control vector, AAV2/2.eGFP. The

retinas from these mice had a 33% decrease in levels of PRDX6 and a 35% decrease in levels of SOD3 as compared to the AAV2/2.eGFP controls. These are two examples of the many antioxidant enzymes regulated by NRF2-dependent activation of the antioxidant response element (ARE). At 5 weeks post-IOP elevation, the RGC-specific Nrf2 knock-down mice had a 37% decrease in their photopic negative response (PhNR) amplitude and a 26% decrease in the visual evoked potential (VEP) amplitude in comparison to AAV2/2.eGFP injected controls. The PhNR measures RGC function and the VEP measures activity from the visual cortex *in vivo.* In a separate group of C57Bl/6 mice, we overexpressed Nrf2 in ganglion cell layer neurons by intravitreal injection of AAV2/2.CMV.Nrf2. Nrf2 overexpression resulted in lower superoxide levels, preservation of the PhNR amplitude, and decreased axon degeneration. Together, these data suggest that the endogenous Nrf2/ARE-mediated protective response is driven, at least in part, by RGC localized NRF2. Further, RGC-directed Nrf2 over-expression is a viable therapeutic approach for the treatment of glaucoma that should be explored further.

Title: Obese Zucker rats express dendritic retraction in neurons of the hippocampal trisynaptic circuit and deficits in spatial memory

Authors: *D. MANUEL SÁNCHEZ[1], D. LIMÓN[2], A. B. SILVA[3];
[1]Fac. of Biol. Sci., Benemérita Univ. Autónoma De Puebla, Amozoc, Mexico; [2]Fac. of Chem. Sci., [3]Fac. of Biol. Sci., Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Obesity is a chronic disease characterized by excessive fat accumulation and is related to the appearance of other chronic diseases such as hypertension and type II diabetes mellitus. In recent years, it has been suggested that obesity may cause brain damage, and this relationship is being studied using animal models. The aim of the present study was to analyze the spatial memory capacity and the neuronal morphology of the hippocampal trisynaptic circuit in obese Zucker rats. We use male the Zucker rat that is an animal model of genetic obesity caused by a mutation in the leptin receptor. Five month-old animals were grouped into 2 sets of 16 rats each (8 male rats of the Long Evans strain as the control group and 8 male rats of the Zucker strain as the experimental group). We monitored the weekly body weight and morphometric parameters

of the rats and determined the glucose, cholesterol, and triglyceride serum concentrations. The first set of animals was subjected to a learning and spatial memory test in a Morris water maze to measure the following variables: escape latency, average speed, maximum speed, number of entries to the white quadrant, time spent in the white quadrant, latency to the first crossing to the white quadrant, and distance traveled. The second set of organisms was used to evaluate the morphology of CA1, CA3, and entorhinal cortex pyramidal neurons, as well as granular neurons of the dentate gyrus, where we obtained the parameters of dendritic arborization, length by branching order, and total length and density of dendritic spines using Golgi-Cox staining and Sholl analysis. Our results showed that Zucker rats exhibited clear signs of an obese phenotype and metabolic dysregulations related to increases in glucose, triglyceride, and cholesterol concentrations. In addition, deficiencies were observed in the learning test on the first two days of testing and a decrease in swimming speed. Furthermore, during the memory phase, the obese rats showed a lower number of entries to the quadrant containing the platform and traveled a shorter distance in the same quadrant. With respect to the neuronal morphology, we observed a decrease in dendritic arborization and dendritic length of hippocampal pyramidal neurons and granular neurons of the dentate gyrus, as well as a loss of dendritic spines in all neurons. These results indicate that obesity and its comorbidities cause dendritic retraction in the neurons that compose the trisynaptic circuit of the hippocampus. In conclusion, our work shows that there is an evident alteration in the neuroanatomy of the neurons that make up the trisynaptic circuit of the hippocampus, causing deficits in spatial memory capacity.

Title: Lead-induced hippocampal changes in BDNF and TrkB gene expression and neuronal survival

Authors: *K. CORDERO PADILLA[1], E. CARTAGENA LOPEZ[2], K. M. CARDONA JORDAN[1], C. M. VELAZQUEZ-MARRERO[1];
[1]Inst. of Neurobio. - MSC, San Juan, Puerto Rico; [2]Univ. of Puerto Rico, Cayey, Puerto Rico

Abstract: Lead, a non-biodegradable metal, is one of the most ubiquitous persistent toxicants present in the environment. Previous studies showed that the hippocampus was an important area where gene expression changes occur due to lead (Pb) exposure. These changes most pronounced during childhood and may negatively modify important neuronal pathways in the hippocampus, cortex, and thalamus implicated in synaptic plasticity, cell survival and expression. The brain-derived neurotrophic factor (BDNF), along with its receptor TrkB (tyrosine kinase) is a protein known for promoting the development and survival of nerve cells within the hippocampus by playing a role in the growth, differentiation, and maintenance of these cells. This is a known target of Pb contamination in CNS. In this study we address the transgenerational effect of a range of consumption; 0 or 27 ppm (low-dose mice equivalent concentration) to parents and 0 ppm or 27 ppm to offspring, of Pb on hippocampal neuronal survival and brain expression of relevant proteins in adolescent female and male mice. We hypothesize that changes in BDNF and TrkB gene expression are key in determining known changes in neuronal survival due to physiologically relevant concentrations of Pb exposure specifically in the hippocampus. Results have shown that lead exposure at 27 ppm during two weeks in adult mice decreases both BDNF and TrkB expression in the hippocampus. These results correlate with neuronal survival rates. Furthermore, mice exposed in utero also showed significant changes in both survival and BDNF/TrkB expression. This study will contribute to our understanding of the effects of physiologically relevant concentrations of Pd-exposure to the hippocampus regions in both adults and in early adolescence, after in-utero exposure.

Title: Stau1 modulation of p53-mediated apoptosis

Authors: *M. GANDELMAN[1], S. PAUL[2], W. DANSITHONG[1], K. P. FIGUEROA[1], D. R. SCOLES[3], S. M. PULST[1];
[1]Univ. of Utah, Salt Lake city, UT; [2]Neurol., Univ. of Utah, Salt Lake City, UT; [3]Neurol., Univ. of Utah, SALT LAKE CITY, UT

Abstract: STAU1 is an RNA-binding protein that becomes highly overabundant in multiple neurological diseases, including amyotrophic lateral sclerosis (ALS), Parkinson's disease, Alzheimer's disease and spinocerebellar ataxia type 2 (SCA2) and in response to numerous pharmacological stressors [1, 2, 3]. Increased levels of STAU1 form cytoplasmic aggregates, impair the progression of autophagy, induce ER stress with activation of the integrated stress response (ISR) and cause apoptosis [1, 2]. The transcription factor p53 has a central role in cellular stress responses, including induction of apoptosis. In ALS, elevated levels of p53 are found in motor neurons in regions that are selectively vulnerable to the disease, and p53 has been shown to drive neurodegeneration caused by mutations in C9ORF72 associated with ALS. The objective of this study was to determine if STAU1 functions as a modulator of p53-mediated apoptosis and if targeting STAU1 could prevent apoptosis triggered by C9ORF72 mutations. We found that STAU1 modulates the p53 pathway at multiple levels. Elevation of STAU1 induced p53-mediated apoptosis and enhanced apoptosis triggered by various p53 activators, evidenced as increased levels of cleaved caspase 3 and of p53-upregulated modulator of apoptosis (PUMA) in HEK293 cells. Conversely, STAU1 knockdown prevented p53-dependent apoptosis triggered by a wide variety of stressors. STAU1 knockdown increased antiapoptotic factors and key DNA repair proteins. Additionally, RNA-seq of cells after STAU1 knockdown and hallmark pathway analysis showed p53 and apoptosis pathways were negatively enriched. To test whether STAU1 can prevent p53-dependent apoptosis triggered by C9ORF72 mutation, we knocked down STAU1 in human fibroblasts derived from a patient with C9ORF72 expansion. We found that this resulted in decreased levels of PUMA and cleaved caspase 3. Our results suggest that STAU1 may be a novel target to prevent neurodegeneration in ALS and other neurological diseases where p53 has a role in neuronal death.

Title: Oxidative stress induces Progranulin expression to control neurite outgrowth in HT22 cells

Authors: *A. SHIMODA, T. TANABE, T. SATO, T. NEDACHI;
Toyo Univ., Gunma, Japan

Abstract: Progranulin (PGRN) is a multifunctional growth factor abundantly expressed in central nervous system. When heterozygous mutations occur in the *Pgrn* gene, it will cause

PGRN haploinsufficiency. PGRN haploinsufficiency has been reported for the association with frontotemporal lobar degeneration (FTLD), but it's mechanism(s) has not been clarified, so it is crucial to understand the physiological and pathophysiological roles of PGRN. Moreover, although PGRN expression is regulated by various stressors (e.g., oxidative stressors), its regulatory mechanism(s) has not been completely clarified. In this study, we have investigated physiological roles of the oxidative-stress induced PGRN expression in HT22 murine hippocampal cells. In addition, we also analyzed the molecular mechanism(s) of how the oxidative stressors control PGRN expression. First, we investigated the oxidative stress-dependent response of HT22 cells (e.g., neurite length, number, and cell body size) and found that lengths and numbers of neurites are significantly increased by oxidative stress. *Pgrn* knockdown (KD) experiments suggested that at least partially of these changes were mediated by oxidative stress-induced PGRN expression. Interestingly, the addition of exogenous recombinant PGRN did not alter the length and number of neurites, which suggested that the increase in neurite length and numbers induced by oxidative stress was mainly mediated by the intracellular PGRN, not by the secreted PGRN. We then investigated signaling pathway(s) responsible for PGRN induction by oxidative stress in HT22 cells. We observed the activation of Erk1/2, JNK and p38 MAP kinase by adding oxidative stressors, and SB203580, a potent and selective inhibitor of p38 MAP kinase, attenuated PGRN induction by oxidative stress. On the other hand, significant effects of U0126 (an inhibitor of MEK1 and MEK2) and SP600125 (an inhibitor of JNK) were not observed. Overall, these results suggested that oxidative stress on HT22 cells induce PGRN via p38 MAP kinase pathway, thereby controlling neurite outgrowth of the cells. Importantly, the intracellular PGRN accumulation by oxidative stress appears to be crucial for neurite outgrowth at least in HT22 cells. Further studies will reveal the physiological differences between the intracellular PGRN and secreted PGRN, which may be an useful information to understand the progression of FTLD.

Abstract: Chronic stress is one of the main risk factors for depression and other neuropsychiatric diseases. Long exposure to chronic stress results in changes in brain gene expression that are deleterious for organisms. Due its relevance to human health, our goal is to investigate the molecular pathways disrupted by chronic stress to understand how this leads to such diseases. Using rodent models of chronic stress, we found that stress alters neuronal protein GPM6A. GPM6A participates in neuronal differentiation and morphology establishment and human *GPM6A* has been linked to schizophrenia, bipolar disorder, claustrophobia and suicide patients. This links GPM6A to the stress phenomenon and depression. Nevertheless, there is a gap between the cellular GPM6A functions and its role in systemic stress response. To fill this gap, we use the nematode *Caenorhabditis elegans* as model due to shared features between nematode and mammal nervous system and because of the genetic tools available. *C. elegans* exhibits a GPM6A ortholog, the neuronal membrane glycoprotein 1 (NMGP-1), thus, here we used *C. elegans* as a simpler model to study NMGP-1 participation in stress response. First, worms expressing GFP under the *nmgp-1* promoter indicated us that *nmgp-1* expresses in sensory amphid and phasmid neurons and in the egg-laying apparatus. Second, we have characterized NMGP-1 functions using RNAi knockdown and two non-null, hypomorphic mutant alleles. Analysis of dsRNA (*nmgp-1)*-treated or mutant alleles showed an increased recovering time from the stress-resistant dauer stage and a reduced egg-laying rate with respect to control worms. In addition, defects in egg-laying induced egg retention (bag of worms) in *nmgp-1*-deficient worms. Also, worms lacking NMGP-1 showed a normal response to the attractant diacetyl, but an altered repulsive response to SDS. Moreover, morphologically, *nmgp-1*(RNAi) worms showed alterations on ASJ chemosensory neurons located at the nerve ring, responsible of dauer exit. Altogether these results suggest that NMGP-1 is involved in the stress response in *C. elegans*. To move forward, we will present and discuss a battery of experiments to score stress response: Temperature acute and chronic exposure, oxidative and osmotic stress. The characterization of stress response in worms lacking *nmgp-1* will allow us to deepen on the stress molecular bases and mental diseases.

Title: Investigating the significant roles of PKR on systemic inflammation triggered neuroinflammation, tau phosphorylation and cognitive dysfunctions

Authors: *W. Y. CHENG[1], Y. S. HO[3], R. C. C. CHANG[1,2];
[1]Lab. of Neurodegenerative Diseases, Sch. of Biomed. Sciences, LKS Fac. of Med., [2]State Key Lab. of Brain and Cognitive Sci., Univ. of Hong Kong, Hong Kong, China; [3]Sch. of Nursing, The Hong Kong Polytechnic Univ., Hong Kong, China

Abstract: Increasing lines of evidence have shown that systemic inflammation may contribute to neuroinflammation and accelerate the progression of neurodegenerative diseases. Double-stranded RNA-dependent protein kinase (PKR) is one of the key signaling molecules regulating immune responses by regulating macrophage activation, different inflammatory pathways, and inflammasome formation. In this study, we aim at investigating whether PKR can be a pharmacological target to prevent both systemic inflammation-triggered neuroinflammation, tau phosphorylation and cognitive dysfunctions. Laparotomy, a non-bacterial endotoxin mouse model, is adopted to address the systemic inflammation triggered by surgery.
We have shown that laparotomy induced systemic inflammation and neuroinflammation in male C57BL/6J mice. At 4 h after laparotomy, a significant increase in interleukin-1β (IL-1β) and MCP-1 was detected in the liver of the laparotomy group compared with the control group. The expression of IL-1β was also significantly upregulated in the hippocampus after laparotomy. On POD 1, no significant differences in cytokine expression were observed in the liver. This suggests that the induced systemic inflammation is transient. Meanwhile, the level of IL-1β remained high in the hippocampus after surgery. Second, on POD 14, for the laparotomy group, a significant increase in tau protein phosphorylation (AT8 and pS416) was observed in the frontal cortex.By immunohistochemical analysis and flow cytometry, an increased number of CD68-eGFP-positive cells was observed in the laparotomy group compared with the control, implying macrophage infiltration or an increased number of activated microglia.Moreover, cognitive impairment was observed after laparotomy in the form of reduced recognition memory with lower discrimination index in the NOR test. By genetic knockout of PKR in mice, it potently downregulated the increased IL-1 expression induced by laparotomy in both the liver and frontal cortex. Meanwhile, a significant reduction in tau protein phosphorylation (AT8 and pS416) was observed in frontal cortex of PKR-KO mice. Furthermore, recognition memory remained intact in PKR-KO mice after laparotomy.
This study reveals that genetic knockout of PKR in mice could attenuate laparotomy induced systemic inflammation, neuroinflammation, abnormal tau phosphorylation and cognitive impairment.Further studies will be performed to examine the effect of knockout of PKR in macrophages and cholinergic neurons on systemic inflammation, neuroinflammationand cognitive functions.

Title: Axonal injury in central nervous system white matter precedes retrograde neuronal degeneration during experimental autoimmune encephalomyelitis

Authors: *G. M. MEY[1], K. S. EVONUK[1], L. M. WOLFE[1], M. CHAPPELL[1], R. SINGH[2], J. C. BATOKI[2], M. YU[2], B. ANAND-APTE[2], N. S. PEACHEY[2], T. M. DESILVA[1];

Abstract: Background: Multiple sclerosis (MS) is a chronic demyelinating disease of the central nervous system (CNS) that eventually results in permanent neuronal loss. Immunomodulatory therapies can reduce relapses, but there are no effective indicators or treatments for the degenerative phase of MS. Evidence of visual system impairments have been shown in MS, presenting a unique system to monitor disease. The pathology underlying visual assessments and how it relates to pathology in the rest of the CNS, however, remains ill-defined.
Objectives: The purpose of this study was to investigate the spatiotemporal relationship between demyelination/axonal injury and neurodegeneration in the visual system and spinal cord during experimental autoimmune encephalomyelitis (EAE).
Methods: EAE was induced in adult male C57BL6J mice using MOG_{35-55} peptide. Histopathological analyses were coupled with visual assessments including optical coherence tomography (OCT) to track retinal thickness and visually evoked potentials (VEP) to test the neuronal response to visual stimuli. Assessments were performed at 15, 35, and 60 days post-EAE induction (dpi) compared to naïve age-matched controls. OCT images and VEP recordings were collected at baseline, 15 dpi, and 35 dpi.
Results: Our data show that $CD3^+$ T cells robustly infiltrate both the spinal cord and optic nerve white matter at 15 dpi. Concurrently, demyelination and axonal loss and reactive gliosis were observed in both of these regions and sustained at 35 dpi. Loss of $NeuN^+$ neurons in the ventral horn of the spinal cord and $Brn3a^+$ retinal ganglion cells (RGCs) in the retina, however, was not observed until 35 dpi. No neuronal loss was observed in the ventral posterolateral nucleus (VPL) nor in the lateral geniculate nucleus (dLGN) of the thalamus at any time point during EAE, but synaptic loss was observed in the dLGN beginning at 15 dpi. Consistent with RGC loss, a

significant reduction in retinal nerve fiber layer thickness shown by OCT was observed at 35 dpi. Functional visual deficits began at 15 dpi with delayed VEPs, followed by a decrease in VEP amplitude at 35 dpi.
Conclusions: Our data suggest a retrograde loss of neuronal cell bodies following demyelination and injury of their respective axons. Neuronal loss was not observed anterograde to axonal injury, further supporting a prominent retrograde neurodegeneration. Our results also indicate that the visual system presents a similar time course of EAE pathology to that in the spinal cord. Along with OCT imaging showing loss of RGCs in chronic EAE, our data suggest that the visual system may be an important marker of neurodegeneration in the CNS.

Title: TRPV4 deletion increases neuroinflammation and neurodegeneration in murine model of chronic multi-symptom illness-associated with gulf war veterans

Authors: *D. BOSE[1], P. SAHA[1], R. SETH[1], S. LASLEY[2], K. SULLIVAN[3], P. JANULEWICZ[3], N. KLIMAS[4], W. LIEDTKE[5,6], S. CHATTERJEE[1,7];

Ctr., Columbia, SC

Abstract: Chronic multi-symptom Illness (CMI) is a condition affecting war veterans like Gulf War (GW) veterans and elderly. Neurological symptoms, memory loss and cognitive dysfunction are among the major symptoms reported in CMI. However, the pathophysiology of CMI remains elusive. Our previous studies in GW mouse models indicated increased neuroinflammation and neurodegeneration. Recently, it was reported that transient receptor potential vanilloid 4 (TRPV4) an osmo-mechano sensitive cation channel regulates the blood brain barrier (BBB) and is associated with neuroinflammation. Our lab showed previously that TRPV4 deletion increased

CYP2E1 mediated toxicity. In this study we exposed GW chemicals pyridostigmine bromide (2mg/kg) and permethrin (200mg/kg) in adult C57BL/6J (n=6) and TRPV4 knockout (TRPV4KO) (n=6) mice for 15 days to study if deletion of TRPV4 modulated GW chemical exposure-associated brain pathology. Compromised BBB was observed by a decreased expression of tight junction protein Claudin 5 and increase in matrix metalloproteinase 9 in GW chemical exposed TRPVKO mice over wild type mice. GW chemical exposure significantly increased the expression of proinflammatory cytokine interleukin 1β and 6 in the frontal cortex of TRPV4KO mice compared to wild type mice. Increased expression of translocator protein (TSPO), a mitochondrial membrane protein also indicated neuroinflammation with microglial activation in TRPV4KO mice exposed to GW chemicals. Furthermore, increased expression of cytochrome P4502E1 and lipid peroxidation stable adduct 4-hydoxynonenal indicated heightened oxidative stress in GW chemical exposed TRPV4KO mice. Administration of GW chemicals increased neurodegeneration in TRPV4KO mice as seen by an increase in Tau level and decreased expression of brain-derived neurotrophic factor. Hence, deletion of TRPV4 exacerbated GW chemical associated neuroinflammation and neurodegeneration suggesting TRPV4 as hitherto underappreciated therapeutic target for CMI.

Title: Effect of GR 82334, neurokinin 1 (NK1) receptor antagonist, on the induction of osteoarthritic pain in rat models with MIA-induced osteoarthritis (OA)

Authors: *M. KWON[1,2], H. YOO[1,2], T. KIM[1], D. NAM[1], J. KIM[1,2,3,4];

Science, Korea Univ., Seoul, Korea, Republic of; [4]Dept. of Physical Therapy, Col. of Hlth. Science, Korea Univ., Seoul, Korea, Republic of

Abstract: Osteoarthritis (OA) is a degenerative disease leading to functional deterioration in joint and surrounding tissue and inducing chronic pain of joint which make patients uncomfortable in their life. Substance P, one of neuropeptides, induces secretion of inflammation mediated-cytokines followed by vasodilation and edema in tissue and transmit pain signal to PNS and CNS in pathologic environment of OA. The aim of this study is to investigate the role of NK1 receptor on the development of chronic pain following OA, using GR 82334, the NK1 receptor antagonist, in rat with MIA-induced OA. OA was induced by injecting monosodium iodoacetate (MIA; 4 mg/50 µl) into the right knee joint of rats. GR 82334 10 µM diluted with 30 µl of saline were injected by single intra-articular injection with 30 gauge insulin syringe, to animals of pre administration group 30 minutes before MIA injection and to animals of post administration group 1 day after MIA injection. Any administration was not performed to the MIA group after MIA-induced OA. Paw withdrawal threshold (PWT), knee joint diameter, knee bending test, and weight bearing test were performed before and after MIA injection. Histological change of knee joint was evaluated by safranin O fast green (SOFG) staining and immunohistochemistry was used to quantify the expression of SP and calcitonin gene related-peptide (CGRP) in L3-5 of spinal cord. Knee bending score and knee joint diameter in the both pre- and post-GR 82334 group were smaller than those of MIA group at 3 days after MIA injection. At 10 and 14 days after MIA injection, PWT in the post-GR 82334 group was significantly higher compared to the pre-GR 82334 and MIA group. Also, the expression of SP and CGRP at spinal cord significantly less in post administration group than pre administration and MIA group at day 14. There were no significant differences in values of PWT among three groups at 28 days after MIA injection. The present data demonstrated that NK1 receptor antagonist is effective for inhibiting inflammation and induction of pain following OA in MIA-induced OA rat models. These results suggest that SP-NK1 signal might contribute in pathophysiology of OA from acute inflammation to central sensitization inducing chronic pain and be a key target for fundamental therapeutic approach to treat OA.

Title: Antibodies in primary progressive multiple sclerosis CSF impair remyelination of lysolecithin-induced lesions

Authors: N. M. CELESTIN, *J. K. WONG, S. A. SADIQ;
Tisch MS Res. Ctr. of New York, New York, NY

Abstract: Multiple sclerosis (MS) is characterized by inflammatory demyelination, astrogliosis and axonal loss in the CNS. Most patients present with relapsing-remitting MS (RRMS) then eventually enter a phase of disease progression termed secondary progressive MS (SPMS). However, approximately 10-15% of patients diagnosed with primary progressive multiple sclerosis (PPMS) experience unremitting disease progression from disease onset. This progressive clinical course of PPMS suggests that remyelination is impaired in contrast to relapsing-remitting forms of the disease. We previously reported that intrathecal injection of cerebrospinal fluid (CSF) from PPMS patients, but not RRMS or SPMS patients, delayed spontaneous remyelination in lysolecithin-induced lesions. However, the PPMS CSF factors contributing to impaired remyelination have yet to be identified. Here, we investigated whether antibodies present in PPMS CSF are responsible for delayed remyelination of lysolecithin-induced lesions. CSF obtained from untreated PPMS patients was passed through a tangential flow filtration system to remove components larger than 100 kDa (including antibodies). Adult C57BL/6 female mice underwent a laminectomy at cervical level 5 (C5) and 1µl of 1% lysolecithin was injected into the dorsal column. At 5 days post lysolecithin injection, mice received 3µl injections into the C5 subarachnoid space of either: 1) CSF from PPMS patients, 2) filtered PPMS CSF, or 3) PPMS or RRMS recombinant antibodies (rAbs) produced after FACS sorting B-cells in CSF then DNA sequencing IgG variable regions. Mice were perfused 12 days after lysolecithin injection. Spinal cords were post-fixed overnight in 4% paraformaldehyde, cryoprotected in 30% sucrose, then cryosectioned for histological analyses. Luxol fast blue staining revealed significantly larger lesion volumes in PPMS CSF-injected mice compared to mice injected with filtered PPMS CSF, suggesting that the factor in PPMS CSF responsible for impeding remyelination is larger than 100 kDa. Preliminary data suggest that mice injected with PPMS rAbs also have larger volumes of demyelination than mice injected with RRMS rAbs, implicating a role of antibodies in PPMS CSF in delaying remyelination. Together, these data suggest therapeutic strategies that reduce or remove CSF antibodies may ameliorate disease progression in PPMS.

Title: The Role of Sympathetic Neuronal Pathways in Regulating HSV1 and HSV2 Genital Infection

Authors: *G. A. MOORE, S. LEE, A. A. N. ABBOTT, A. M. IVES, A. S. BERTKE; Virginia Tech., Blacksburg, VA

Abstract: Herpes simplex virus 1 (HSV1) and HSV2 are known to establish latency and reactivate in sensory neurons after orofacial or genital infection. However, the viruses are also found in autonomic ganglia, including both sympathetic and parasympathetic branches of the autonomic nervous system (ANS) in humans and in animal models. HSV1 shows a preference for sympathetic pathways and HSV2 shows preference for parasympathetic pathways, suggesting that autonomic pathways may provide an alternative reservoir for reactivating virus that may contribute to different recurrence frequencies of HSV1 and HSV2. To determine the contribution of sympathetic pathways to acute genital disease and recurrence frequency, guinea pigs were treated with 6-hydroxydopamine (6-OHDA) prior to infection to ablate sympathetic neuronal axons. Chemical ablation of sympathetic axons using 6-OHDA allows selective removal of sympathetic neurons, making them unavailable for infection and the establishment of latency, resulting in significantly reduced severity and neurological involvement during acute disease for HSV1, but not HSV2. Animals treated with 6-OHDA prior to infection also had reduced clinical recurrences by nearly 75% for HSV1 and by 50% for HSV2 ($p \leq 0.001$). Furthermore, viral shedding in genital secretions was significantly reduced, as determined through the analysis of daily vaginal swabs. Thus, sympathetic neurons and pathways play a significant role in acute disease severity and neurological involvement of HSV1, but not HSV2. Additionally, sympathetic pathways are responsible for a significant portion of HSV1 and HSV2 recurrences, with a greater impact on HSV1 than HSV2.

Title: Understanding the Impact of Chronic, Low-Dose GCR Particles on Behavior and Systemic Inflammation in Mice

Authors: *C. LAFRENIER[1], P. FRIEND[1], B. GLEESON[1], P. NOLTE[1], F. RULISON[2], P. DEYOUNG[2], P. RIVERA[1];
[1]Biol., [2]Physics, Hope Col., Holland, MI

Abstract: A major component of NASA's 2018 strategic plan was to send astronauts to and beyond our lunar orbit within the next couple of decades. A potential risk to mission success is an astronauts' exposure to galactic cosmic radiation (GCR), a mixture of low-dose, high-charge ion particles (HZE). However, studies examining the impact of low-energy GCR particles on long-term mission success are scarce. Therefore, our first study examined the effects of chronic, low-dose proton radiation on behavior and systemic inflammation in mice. We tested the hypothesis that chronic low-dose proton radiation negatively impacts mouse behavior by causing lasting systemic inflammation. Mice were divided into three treatment groups: Irradiation (IRR), No-Irradiation/Constraint (No-IRR), and Home Cage (HC). The irradiation group of mice received approximately 0.17mGy/day of proton radiation on 13 non-consecutive days over a period of 50 days. Ten weeks after irradiation, all mice underwent anxiety- and depressive-like behavioral tests. Then, mice were euthanized and brain, liver, and spleen samples were extracted for molecular analysis. Results suggest that mice irradiated with a cumulative dose of ~2.5 mGy of protons exhibit an increase in overall activity and compulsive-like behavior. Our secondary study examined the impact of chronic low-dose neutrons on sociability and cognitive learning. Mice were irradiated at a dose of 0.005 mGy 33 times over 70 days, resulting in an expected cumulative dose of approximately 0.165 mGy. We expect to see a differential effect of neutron radiation on sociability behaviors and cognitive spatial learning in a sex-dependent manner. We suspect that these behavioral differences will be the result of systemic inflammation. Taken together, proton and neutron chronic low dose radiation may negatively impact long-term mission success to Mars.

Title: In vivo neuroinflammation modelling by acute, sub-chronic and chronic LPS-administration, and in transgenic APP, APPxPS1, TAU and APPxTAU mouse models of Alzheimer's disease

Authors: *A. TANGHE, **T. CORNELISSEN**, W. DEJONCKHEERE, S. CARMANS;
CRO, reMYND nv, Heverlee, Belgium

Abstract: Compelling evidence indicates that the etiology of Alzheimer's disease (AD) is multifactorial, with neuroinflammation, and its capacity to exacerbate Aβ and Tau pathology, taking a center stage in the AD pathogenesis (see e.g., Onyango *et al.*, 2021). Albeit none of the currently available AD animal models are a faithful reproduction of the human disease, they have been and will remain essential tools to improve our understanding of AD biology and to evaluate specific therapeutic approaches, including the role of neuroinflammation and the potential of anti-inflammatory therapies (see e.g., Saito & Saido, 2018). In mice, systemic inflammation and neuroinflammation ensuing peripheral or central injections with the pro-inflammatory component lipopolysaccharide (LPS), have shown to evoke an elevation in Aβ levels, in Tau hyperphosphorylation and tangle formation, and in neuronal cell death, finally resulting in cognitive impairment (Zhao *et al.*, 2019; Batista *et al.*, 2019). Encouraged by the robust yet transient effects obtained in acute and sub-chronic intraperitoneal LPS-administration regimens, we set out to develop a chronic LPS-induced neuroinflammation mouse model both in wild type and Tau-transgenic mice, with read-outs of AT8-responsive Tau and CD68-responsive phagocytic microglia. Optimization of the LPS-concentration, the number of administrations and the time of sacrifice after the last dosing, provided insights in the transient or sustained character of the effects, assessed via the abovementioned read-outs as well as via TNF alpha-levels in serum and a qPCR-based panel of inflammasome markers. We compared the data of the acute, sub-chronic and chronic LPS-induced neuroinflammation models with the neuroinflammation hallmarks in a series of related AD transgenic models (APP-London, APP-London x PS1, TauP301S, and APP-London x TauP301S) and discuss the discriminative and complementary value of the altogether of these models for the assessment of therapeutic interventions. In the APP-London x TauP301S transgenic, we confirmed the previously postulated temporal development and spatial co-localization of amyloid, Tau and neuroinflammation pathology. As a next step, we are extending the above set of models and concomitant neuroinflammation read-outs to a second-generation APP knock-in model. Humanizing animal models at the level of microglia, to bridge the species barrier upfront, is another exciting avenue that we are exploring. This will open a whole new array of questions that can be more credibly posed already in preclinical stage.

Title: Expression of ASIC1 channels throughout the pain pathway in the CNS in the formalin acute pain mouse model

Authors: M. N. GOBETTO, N. E. CONTRERAS, L. C. SALINAS CASTELLANOS, **O. D. UCHITEL**, *C. WEISSMANN;
IFIBYNE-CONICET, Buenos Aires, Argentina

Abstract: Hindpaw injection of formalin in rodents is used to assess acute intense, short-lasting (minutes to tens of minutes) persistent pain. The response to formalin is biphasic, with an initial response in the first minutes, and a later response around 40min after the injection with an increase in licking of the paw. The initial response is thought to be contributed by inflammatory, peripheral mechanisms, while the latter is linked to central mechanisms. This model has been especially useful to analyze the effect of drugs at either phase. Different channels have been shown to be involved in these responses according to specific drugs used. Acid-sensing ion channels (ASICs) regulate synaptic activities and play important roles in neurodegenerative diseases as well as in pain conditions. Psalmotoxin-1 (Pctx-1), a toxin that inhibits ASIC1a-constituted channels, as well as antisense ASIC1a RNA, injected in mice before the formalin test, have been previously shown to affect both phases (Mazzuca et al. 2007). However, whether ASIC1 protein levels are affected remains controversial, as most work focused on mRNA levels as protein levels proved difficult to detect. We decided to analyze ASIC1a protein levels at different levels in the pain pathway centrally, in regions in which ASIC1a channels are enriched (spinal cord, SC, and the anterior cingulate cortex, ACC, of the brain). In addition, we subdivided the areas into different lumbar (L) segments (SC at L3, L4 and L5 levels) as well as ipsilateral and contralateral to the injection for ACC-to avoid the dilution of any contributing effect- in formalin and PBS (control) injected mice. Our results showed the biphasic behavior of mice to formalin. This behavior was accompanied by an increase in ASIC1 levels at the ipsilateral ACC compared to the contralateral ACC and greater than in ACC of animals injected with PBS. At the spinal cord, the effect of ASIC1 levels follows a gradient stronger at L3 levels and decreasing towards L5 in formalin-injected mice. This work highlights the important role ASIC1 channels play in pain and the potential role of pharmacological therapies aiming at this channel.

Title: An experimental animal model of disseminated cerebral aspergillosis

Authors: *B. N. SULLIVAN[1], C. GUILLORY[2], M. A. BAGGETT[2], M. JONES[3], C. STEELE[3]; [1]Neurosci. Grad. Program, [2]Neurosci., [3]Microbiology & Immunol., Tulane Univ., New Orleans, LA

Abstract: Invasive pulmonary aspergillosis (IPA), a leading cause of death in immunosuppressed patients, is an infection most often attributed to the opportunistic fungi *Aspergillus fumigatus* (AF). The most common site of primary infection with this invasive disease is the lungs, and the most prevalent site of secondary infection following hematological dissemination is the central nervous system (CNS). Dissemination of AF to the CNS, termed cerebral aspergillosis (CA), occurs in up to 40% of immunocompromised patients with IPA and has a mortality rate approaching 90%. While the experimental murine model of IPA and the resulting immune response have been extensively characterized, the current models available for CA are inconsistent and physiologically irrelevant. This lack of relevant models results in a considerable gap in knowledge for the neurological pathogenicity of infection. To address this gap, we infected wild-type male and female C57BL/6 immunocompetent, or immunosuppressed (via high-dose corticosteroid) mice with AF intranasally. Following immunosuppression and infection, mice were monitored for severe weight loss (>20%), neurological symptoms (e.g., altered-gate, severe head-tilt, and/or spinning in cage), and mortality daily over 8 to 10 days. Brains were assessed for fungal burden at the time of death, study end, or at a specific time point (3 days post-infection (PI)). Predictably, primary pulmonary infection occurred in immunocompetent and immunosuppressed mice. However, encouragingly, significant weight loss, neurological symptoms, and fungal burden in the brain were found exclusively in immunosuppressed mice, occurring in as little as 3 days PI. Further, in the immunosuppressed infected group, we observed a significant correlation between weight loss and neurological symptoms indicating the successful induction of severe disease. Interestingly, like immunosuppressed humans with IPA, cerebral dissemination, defined by detection of AF in the brain, was observed in approximately 50% of immunosuppressed mice. In conclusion, we have developed a well-defined, physiologically relevant, model of disseminated CA in immunosuppressed mice with primary pulmonary infection. This model will serve to advance understanding of the disease mechanism, identify immunopathogenic processes, and aid in defining the neuroinflammatory response to CA.

Title: Circadian influences on chemotherapy efficacy in a mouse model of brain metastases of breast cancer

Authors: *W. H. WALKER, II[1], S. A. SPROWLS[2], J. R. BUMGARNER[1], J. A. LIU[1], O. H. MELÉNDEZ-FERNÁNDEZ[1], J. C. WALTON[1], P. R. LOCKMAN[2], A. C. DEVRIES[3], R. J. NELSON[1];

Abstract: Chemotherapy is more effective in the treatment of peripheral tumors than brain metastases, likely reflecting the reduced ability of chemotherapy to cross the blood brain barrier (BBB) and/or blood tumor barrier (BTB) at efficacious concentrations. Recent studies demonstrate circadian regulation of the BBB. Thus, we sought to determine whether BBB/BTB permeability to chemotherapeutic agents displays circadian regulation. We predicted that optimally timed chemotherapy would increase anti-tumor efficacy in a murine model of brain metastases of breast cancer (BMBC). Female NU/NU mice received a 1oo µl intracardiac injection of the human brain seeking Her2+ breast carcinoma cell line, JIMT-1BR3-Luc ($1.75x10^5$ cells). First, we characterized novel daily alterations in BBB permeability to a commonly used chemotherapeutic, ^{14}C-paclitaxel, within BMBC following injections given at four time points across the day. Peak and trough ^{14}C-paclitaxel concentrations within BMBC occurred during the mid-dark phase and at the beginning of the light phase, respectively. Next, we assessed the functional significance of increased ^{14}C-paclitaxel concentrations within BMBC by monitoring the onset of neurological symptoms and cell death within BMBC. Mice received a 1oo µl intracardiac injection of the cell lines, JIMT-1BR3-Luc ($1.75x10^5$ cells) or 4T1-BR5-Luc ($1.75x10^5$ cells) . Mice were randomly assigned to treatment groups, ZT0 or ZT17, and received once a week injections (2 weeks total) of paclitaxel (13 mg/kg) corresponding to either the peak or trough of BBB/BTB permeability (determined in Exp.1). Mice that received chemotherapy injections during the dark phase demonstrated increased cell death within BMBC and delayed onset of neurological symptoms relative to mice that received injections during the light phase. Together, these data provide strong evidence that chrono-chemotherapy is a novel and potentially effective treatment strategy for BMBC, and emphasizes the importance of time of day when administering chemotherapy to patients.

Title: Is time the answer? Chonopharmacological approach of the novel drug 1A116 for glioblastoma treatement

Authors: *L. L. TREBUCQ[1], G. A. CARDAMA[2], P. LORENZANO MENNA[2], D. A. GOLOMBEK[1], L. MARPEGAN[3], J. CHIESA[1];
[1]Laboratoy of Chronobiology, Natl. Univ. of Quilmes, Bernal, Argentina; [2]Lab. of Mol. Oncology, Natl. Univ. of Quilmes, Bernal, Argentina; [3]Natl. Comission of Atomic Energy, Bariloche, Argentina

Abstract: Glioblastomas (GBM) account for almost half of the malignant central nervous system tumors. Current therapy for GBM is generally very aggressive, combining chemotherapy, radiotherapy, and surgical removal and increased the life expectancy only from 11 to 14 months, but almost no significant advances were made in the last decades. Taking this into account, more effective compounds and new strategies need to be developed. The novel drug 1A-116 specifically blocks the interaction of the Rho GTPase Rac1 with some of its activators (GEFs proteins, such as Tiam1) inhibiting cell motility and proliferation of GBM. One strategy is to find a circadian time of maximal effectiveness and minimum toxicity (i.e., chronopharmacology). Thus, we studied the therapeutic response to 1A-116 at different circadian times, of LN229 glioblastoma cell line in vitro, and in xenogenic implants in nude mice. LN229 wild type and bmal1 knock down cell lines, obtained by Crispr/Cas9, were synchronized with serum shock (50% serum) and transfected with Bmal-luc plasmid for testing circadian rhythmicity. Cell lines treated at different circadian times with 1A-116 were assessed for proliferation, migration and apoptosis, and circadian oscillation of BMAL1 and TIAM1 mRNA and proteins was studied by qPCR and in cell western. In vivo studies were performed using xenogenic LN229 striatum implants in nude male mice (n=11), evaluating survival as result of daily treatment with 1A-116 at two circadian times (ZTs). Cell cultures displayed a functional circadian clock measured by Bmal1-luc activity and BMAL1 and PER1 protein expression. Circadian rhythm was also found for TIAM1 expression. We found that the effectivity of 1A-116

is rhythmic showing a minimum inhibition of proliferation when applied at 23 HPS after a serum shock, and a maximum when applied at 10 HPS. When applying the drug at 10 HPS, we found over 50% inhibition of migration and augmented apoptosis, with no significant results at 23 HPS. In LN229 bmal1 knock down cells, we found no difference in proliferation, when applying 1A-116 at different circadian times, and both BMAL and TIAM1 rhythms were abolished. In nude mice, we performed Kaplan-Meier survival curves, and found that the median survival of the mice treated at ZT3 was 68 days and at ZT12 was 73 days. These results suggest that a chronopharmacological approach based on the drug 1A-116 is a feasible strategy to improve GBM treatment outcomes. The loss of circadian variation of the effectiveness of 1A-116 and the rhythmicity of TIAM1 in bmal1 knock downs, suggests that 1A-116 is under circadian control, as well as Rac1 pathway.

Title: Invivo gene therapy in glioblastoma multiform: Using olfactory ensheathing cells containing thymidine kinase gene

Authors: *F. TIRGAR[1], Z. AZIZI[2], M. HADJIGHASSEM[1];
[1]Neurosci. and Addiction Studies, [2]Mol. Med., Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: Gene therapy is a new approach to treat glioblastoma multiform (GBM), which has attracted many scientists around the world as an alternative to existing treatments. Suicide gene therapy is the most common gene therapy strategy against gliomas in preclinical studies and clinical trials. The main challenge here is how to transfer the desired genes. The fact that olfactory ensheathing cells (OECs) have high ability of migration even with long distances, makes these cells appropriate for gene therapy. In the current study, we used OECs as carrier for transfer of the lentivirus containing Herpes Simplex Virus-thymidine kinase (HSV-tk) gene to glioblastoma tumoral cells for the first time and examined the possible migration capacity and apoptosis induction ability of these cells in vivo. To achieve this goal, OECs were isolated from the rat olfactory bulbs, cultured and characterized by p75 antibody. OECs were then transfected with lentivirus containing thymidine kinase gene (OEC-tks). For In vivo studies, 49 male Wistar

rats (weight 200-220gr, about 8 weeks old) were divided into 7 groups. After inducing glioblastoma model with the injection of 106 of C6 cells in the frontal lobe of rats, 106 OEC-tks or PBS was injected ipsi-laterally or contra-laterally, followed by treatment with Ganciclovir (GCV; 50mg/kg) or saline intra-peritoneally daily for 5 consecutive days. Then Western blot analysis for Bcl-2 and bax proteins was performed to determine apoptosis (n=3/group). The tumor size was measured by Magnetic Resonance Imaging (MRI; n=4/group). The findings demonstrated that the injection of OEC-tks into the tumor area followed by GCV treatment, induced apoptosis. One-Way ANOVA analysis revealed that Bax expression as a proapoptotic protein was significantly upregulated ($p<0.001$) while Bcl-2 expression as an antiapoptotic protein was significantly downregulated ($p<0.01$) compared to the control. Injection of these cells into the contralateral hemisphere also showed similar effects on protein expression ($p<0.05$ for both proteins) which indicates high migration capability of these cells to the tumor site. On the other hand, One-Way ANOVA analysis showed significant reduction in tumor size in animals which received OEC-tks ipsi-laterally ($p<0.01$). There was a similar finding in tumor size reduction in animals which received this construct contra-laterally ($p<0.05$). Also there was no reduction in protein expression or tumor size in the case of injection of OEC-tks, GCV or PBS alone ($p>0.05$). Taken together, the results from this study supports this hypothesis that OEC-tks can provide a novel carrier for genetherapy and reduce in vivo glioma tumor progression.

Title: Analysis of the transcriptome and DNA methylome of human neural stem and progenitor cells after irradiation and/or lithium treatment: Roles for BMP signaling and DNA demethylation

Authors: C. NEOFYTOU[1], V. RAILAITE[1], K. BLOMGREN[2], ***O. HERMANSON**[1]; [1]Dept. of Neuroscience, Karolinska Institutet, Stockholm, Sweden; [2]Karolinska Institutet, Stockholm, Sweden

Abstract: Brain tumors in kids show increasingly improved prognosis and survival, at least in part due to improvements in cranial radiotherapy. However, these survivors instead experience late side effects due to the irradiation, including cognitive deficits that prohibit a normal life quality. Even with retained intellectual capacity, the patients show tiredness and fatigue along with problems to focus which make education and normal working life very difficult. The population of adult childhood cancer survivors with late effects are now estimated to around 11,000 only in Sweden and soon millions world-wide. Efficient therapies for this population are thus urgent.
Lithium, a well-known mood stabilizer, has neuroprotective and antitumor effects. We have found lithium treatment to reverse radiation-induced damage in rodents, by among other things regulating the expression of glutamate decarboxylase 2 (GAD2) - associated with neuronal signaling and differentiation - via promoter demethylation (Zanni et al., Mol Psychiatry, 2021). It is however yet unknown whether such lithium-induced gene expression changes also occur in human neural progenitors.
We analyzed the transcriptome and DNA methylome of hiPSC-derived human neural stem and progenitor cells (hNSPCs) that had been exposed to irradiation (4Gy), lithium (3mM), or both, 48 hours after initiation of the experiment.
Our main findings were that lithium treatment of irradiated hNSPCs i) promoted neuronal differentiation by upregulating GAD2 expression similar to previous rodent data, ii) inhibited astroglial differentiation possibly by influencing BMP signaling that in turn was increased by irradiation, iii) increased expression of the DNA dioxygenase TET3 and decreased methylation of the TET3 activator GADD45A promoter in accordance with a decreased methylation of a subset of regulatory regions, iv) specifically decreased DNA methylation of the GREM1 gene, encoding the BMP inhibitor Gremlin-1.
These mechanistic insights provide the molecular basis to support lithium treatment of childhood cancer survivors suffering from cognitive deficits after irradiation.

Title: Cocktail Therapy with Neonatal Erythropoietin and Melatonin Prevents Executive Function and Attentional Deficits in Adult Rats with Cerebral Palsy

Authors: *S. HAMIMI[1], L. L. JANTZIE[2], S. ROBINSON[3];
[1]Neurosci., [2]Pediatrics, [3]Neurosurg., Johns Hopkins Univ., Baltimore, MD

Abstract: Cerebral Palsy (CP) is the most common motor disability in childhood. In the USA, CP is most commonly caused by very preterm birth, typically from chorioamnionitis. Children born preterm are prone to executive function deficits. They exhibit particularly poor performance as cognitive tasks become more challenging. Using our preclinical model of CP secondary to chorioamnionitis (CHORIO), we tested if cognitive and executive function abnormalities could be mitigated using a clinically relevant, extended course of erythropoietin (EPO) plus melatonin (MLT). CHORIO was induced in pregnant rat dams on embryonic day 18 by performing a laparotomy followed by uterine artery occlusion for 60min and intra-amniotic injection of lipopolysaccharide (4ug/sac). Shams underwent anesthesia and laparotomy only. On postnatal day (P)0, pups were randomly assigned to sex-balanced groups to receive a neonatal neuroreparative regimen of EPO plus MLT or saline vehicle. In adulthood, rats were trained on a touchscreen operant platform to assess executive function, including attention. Rats performed a visual discrimination task followed by a 5-Choice Serial Reaction Time Task (5-CSRTT), to assess performance on a progressively more challenging task. Passing criteria for each task was set a priori as 80% correct on one day for 5CSRTT and on two consecutive days for VD. Statistically significant differences were determined using Kruskal-Wallis with Dunn's corrections, with $p<0.5$ considered significant. Results confirm that vehicle-treated CHORIO rats grow up to have gait deficits similar to spastic-like CP, including toe-walking, shorter strides and ataxia. Touchscreen assessments reveal that adults in all groups (Sham (n=15), CHORIO veh (n=24), and CHORIO E+M (n=10)) can successfully pass VD. However, while all groups performed similarly during the 30s and 15s 5CSRTT time intervals, CHORIO veh rats had impaired performance as time intervals decreased and the task became more challenging. CHORIO veh rats needed more sessions to achieve passing criteria ($p=0.02$), and produced more errors than CHORIO E+M rats ($p=0.02$). Additionally, CHORIO veh rats made more omissions compared to shams ($p=0.03$), which was corrected by E+M treatment ($p=0.02$). CHORIO veh rats also had more premature responses compared to both Shams and CHORIO E+M rats ($p= 0.025$), indicative of poor inhibitory control. No difference was found between groups in reaction time or magazine latency. Our results show that a translatable dosing regimen of EPO+MLT can modulate deficits of attentional control, behavioral inhibition and executive function in adult rats with CP secondary to CHORIO.

Title: Optimizing vagus nerve stimulation therapy to improve recovery of somatosensation

Authors: *A. RUIZ, K. MALLEY, F. AHMAD, C. MOTA BELTRAN, A. NABEEHA, M. KILGARD, S. HAYS;
Univ. of Texas At Dallas, Dallas, TX

Abstract: More than 20 million people in the United States have some form of peripheral neuropathy. Vagus nerve stimulation (VNS) paired with rehabilitative training has been shown to enhance recovery after various neurological injuries, including nerve damage. This improved recovery is mediated by VNS-dependent facilitation of synaptic plasticity. Thus, paradigms of VNS therapy that promote greater plasticity may further improve recovery. Here, we systematically varied a number of parameters known to influence the magnitude of VNS-dependent plasticity, including stimulation intensity, interstimulation interval, and spaced and massed delivery, and explored the degree of recovery. These findings confirm that VNS paired with tactile rehabilitation enhances recovery of somatosensory function after peripheral nerve damage. Parameter exploration is important for clinical translation in order to create safe and effective therapies that reduce the burden patients carry.

Title: Alcohol and PARP inhibition on Ribosome-bound RNA pathways in cortical excitatory neurons

Authors: G. VALLERINI[1], H. R. KRISHNAN[2], H. E. GAVIN[3], D. P. GAVIN[4], ***R. P. SHARMA**[5];
[1]O2M Technologies LLC, Chicago, IL; [2]Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [3]Student, Chicago, IL; [4]Private Industry, Chicago, IL; [5]Univ. of Illinois at Chicago, Chicago, IL

Abstract: We report on the effects of ethanol (EtOH) on the distribution of ribosomal-bound RNA transcripts in prefrontal cortical (PFC) pyramidal neurons. We hypothesized that the

pattern of RNA distribution aligned with either ribosomal attachment (ribosome-bound) or genomic expression (transcriptome, total-RNA) is altered by EtOH, and these distributions could be reversed via the inhibition of Poly (ADP-ribose) polymerase (PARP enzyme). We utilized the translating ribosome affinity purification (TRAP) technique to isolate cell-specific RNA. Transgenic mice with EGFP-tagged Rpl10a ribosomal protein expressed only in CaMKIIα-expressing pyramidal cells were administered EtOH or normal saline (CTL) i.p. twice a day, for four consecutive days. On the fourth day, a sub-group of mice that received EtOH in the previous three days received a combination of EtOH and the PARP inhibitor ABT-888 (EtOH+ABT). PFC tissue was processed to isolate CaMKIIα pyramidal cell-specific ribosomal-bound RNA (TRAP) and whole-tissue un-specified genomically expressed total-RNA (INPUT). Both TRAP and INPUT samples were submitted for RNA-seq. We observe EtOH effects on ribosomal-bound transcripts in pyramidal cells. We further demonstrate that treatment with a PARP inhibitor 'normalizes' the effect of EtOH on this ribosomal-bound pool. Further we report, that the PARP inhibitor ABT-888 reversed 82%, of the EtOH-induced changes in ribosomal engagement (more or less bound) (TRAP samples-translatome), and similarly 83% in the total-RNA transcripts (INPUT sample- transcriptome). We identify Insulin Receptor Signaling as highly enriched in the PARP regulated ribosome-bound pool (EtOH-affected) and validate five participating genes from this pathway. To our knowledge this is the first description of the effects of EtOH on the ribosomal cell-specific capture of transcripts from total-RNA and provide insights into PARP mediated regulation of this crucial step.

Title: Functional recovery after peripheral nerve injury depends on vagus nerve stimulation parameters.

Authors: *K. MALLEY, A. RUIZ, T. DANAPHONGSE, S. HUSAIN, M. MIAN, A. SULE, N. VALMIKI, S. HAYS, M. KILGARD;
Univ. of Texas at Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) paired with rehabilitation represents an innovative approach to restore somatosensation and sensorimotor function after peripheral nerve injury (PNI). Recovery is dependent both on the timing of stimulation and the electrical stimulation parameters of VNS. Manipulating these parameters for optimal recovery is critical for clinical translation. In this study, we manipulated two of these parameters, the current amplitude and the interstimulus interval (ISI), and assessed their effect on somatosensory recovery after PNI-induced sensory loss. Animals received a PNI of their right forearm resulting in hyposensitivity of their forepaw. After an 8 week recovery, animals then underwent tactile rehabilitation, in which a brief mechanical stimulus applied to the affected paw was paired with VNS appropriate for their group . We measured sensorimotor recovery with an automated esthesiometer at multiple timepoints during treatment. A variety of other assessments were used to measure functional sensorimotor recovery and retention. In Experiment 1, rats were randomized to receive either 0 mA, 0.4 mA, 0.8 mA, or 1.2 mA VNS, with all other stimulation parameters held constant. In Experiment 2, a second cohort of animals received VNS with either a 2 second ISI or a 10 s ISI for 1 or 4 weeks, with all other parameters fixed. We found an inverted-U relationship between current intensity and recovery with a moderate intensity current being the most optimal for sustained recovery. This data corroborates other inverted-U observations, which suggests a central origin of the effect. Additionally, animals who received VNS once every 2 seconds recovered the majority of their sensorimotor function. When treatment was clustered into 1 week, animals did not recover their sensorimotor function compared to animals who received standard therapy. These results indicate that, with daily repetition, therapy can be done faster and still drive recovery if VNS is delivered at a moderate intensity, and clustering saturates after a certain number of stimulations. These data are readily translatable to a clinical setting and can be used in conjunction with other data from our lab to inform the appropriate clinical dosing and delivery of VNS.

Title: Emapunil attenuates microglial mitochondria membrane potential following LPS administration

Authors: *K. I. MCGLOTHEN, R. M. HINES, D. J. HINES;
Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: The high metabolic demand of activated microglia is linked with changes in the mitochondrial membrane potential (ΔΨm) and indicate varying inflammatory states in the brain. Examining the dynamic function of ΔΨm in microglia could provide key insight to how and when brain microglia respond to periods of inflammation and aid in the innovation of pre-symptomatic screening techniques for inflammatory disorders. In the present study, a novel approach to examine spatio-temporal changes in microglial ΔΨm was utilized. ΔΨm was measured using cell permeable dye tetramethylrhodamine ethyl ester (TMRE). Acute cortical brain slices obtained from fractalkine mice were utilized to examine the spatial and temporal metabolic processes in microglia. Administration of Lipopolysaccharide (LPS) increased the ΔΨm at 3 timepoints differentially across the microglial soma, branches, and endfeet. The application of Emapunil attenuated the increase of the ΔΨm in microglia at each of these timepoints. Similarly, immunohistochemistry showed an increase in the 18 kDa translocator protein (TSPO), a protein that is upregulated in microglia during inflammatory activation, only at microglial branches following the administration of LPS. Application of TSPO ligand Emapunil at a specified temporal window attenuated the ΔΨm. The ability to examine alterations in microglial ΔΨm and TSPO during periods of neuroinflammation presents a novel tool with broad implications for many gliotic diseases.

Title: Development of Novel 20-HETE Formation Inhibitors for Neurotherapeutics

Authors: *B. P. NELSON[1,2], S. K. SEPPI[1], C. TANG[3], P. M. KOCHANEK[1,4], A. P. ROWLEY[1,2], L. A. MCDERMOTT[3], S. M. POLOYAC[5], M. D. MANOLE[1,2];
[1]Safar Ctr. for Resuscitation Res., [2]Dept. of Pediatrics, [3]Sch. of Pharm., [4]Dept. of Critical Care Med., Univ. of Pittsburgh, Pittsburgh, PA; [5]Col. of Pharm., The Univ. of Texas at Austin, Austin, TX

Abstract: 20-hydroxyeicosatetraenoic acid (20-HETE) is a vasoconstrictive metabolite of arachidonic acid by cytochrome P450 (CYP) 4A11 and 4F2 in humans. Inhibition of 20-HETE

formation has been shown to produce neuroprotective effects in pre-clinical models of cardiac arrest and stroke; however, there are currently no 20-HETE inhibitors suitable for clinical translation.
Our primary objective was to develop clinically viable 20-HETE inhibitors that have strong potency and favorable physicochemical, metabolic stability, selectivity, solubility, CYP inhibition, and blood-brain barrier (BBB) permeability.
The study design consisted of designing, synthetizing, and evaluating 143 novel compounds in vitro. Compound 107 (UPMP107) was identified as a potential candidate, with suitable 20-HETE inhibition in liver microsomes. UPMP107 and 20-HETE levels were quantified in the brain and plasma of rats using solid phase extraction and UPLC-MS/MS analysis in a triple quadrupole mass spectrometer. Intravenous (IV) administration of UPMP107 in a pediatric rat model showed BBB penetration and exhibited a quick onset of brain 20-HETE inhibition sustained for 9 h after administration. Following initial pharmacokinetic and pharmacodynamic studies, our secondary objective was to utilize the selected compound in our pediatric rat model of asphyxial cardiac arrest (CA) to assess physiologic and neurologic outcomes. Anesthetized and intubated 17-day old rats had arterial and venous catheters placed. CA was induced for 9.5 min. Rats were resuscitated and were randomized to receive either UPMP107 (20mg/kg) or vehicle (13.3mL/kg 15% cyclodextrin in PBS) (n=6/group). Rats received a second dose of UPMP107 or vehicle at 8 h post-resuscitation. Mean arterial pressure, $PaCo_2$, PaO_2, pH, lactate, and HCO_3 were measured at baseline and at 10, 30, and 60min timepoints following the arrest. Physiological variables did not differ between the two groups. In conclusion, UPMP107 appears to be a suitable candidate for clinical translation. Further studies evaluating the neurological outcome, dosing, and administration of UPMP107 in the CA model are planned.

Title: Motor and sensory neuron subtypes differ in axon regeneration after nerve injury

Authors: *S. BOLÍVAR, E. UDINA;
Inst. of Neurosciences, Dept. Cell Biology, Physiol. and Immunol., Univ. Autònoma de Barcelona, Bellaterra, Spain

Abstract: Specificity in regeneration after peripheral nerve injuries is the major determinant of functional recovery. Unfortunately, regenerating motor and sensory axons rarely find their original pathways to reinnervate appropriate target organs. Despite the heterogeneity of these peripheral neuron populations, little is known about their differences in regeneration. Thus, we propose the comparative study of the regenerative capacity of the most relevant neuronal populations. We used double transgenic mice that express fluorescence in specific neurons: motoneurons (ChAT-Cre/Ai9), proprioceptors (Pv-Cre/Ai9), unmyelinated nociceptors (Trpv1-Cre/Ai9) and cutaneous mechanoreceptors (Npy2r-Cre/Ai9). We performed immunofluorescence analysis of neuronal markers (parvalbumin, neurofilament, CGRP, IB4, ChAT, calbindin) to confirm the validity of these transgenic mice as specific reporters of the desired neuronal populations. We obtained the regeneration rate of each neuron type by analysing the number of axons that regenerated up to the tibial nerve after a crush in the sciatic nerve. We found that unmyelinated nociceptors regenerated faster than any other peripheral neuron population 7 days after the injury, whereas proprioceptive neurons showed the worst regeneration among groups. Number of regenerating motor and unmyelinated nociceptive axons in the tibial nerve was similar to control values after 9 days, in contrast to cutaneous mechanoreceptors and proprioceptors, that regenerated incompletely. Evaluation of neurite growth in dorsal root ganglia organotypic cultures also showed different regenerative capabilities among $Trpv1^+$, $Npy2r^+$ and Pv^+ neurons. The preferential regeneration of these populations was assessed by applying retrotracers in the cutaneous and muscular branches of the femoral nerve after a transection. All the studied neuronal populations showed an early preference for the cutaneous branch that weakened at long term. Eight weeks after the lesion, motoneurons did not demonstrate any preference, whereas proprioceptors and cutaneous mechanoreceptors showed a preference for their correct branch (muscle and cutaneous branch, respectively). Our findings reveal novel intrinsic differences between peripheral neurons, which suggest unique regeneration mechanisms in each neuronal subtype. Future work will investigate in deep these mechanisms to modulate them and improve specific reinnervation.

Title: Influence of tau on paclitaxel-induced neuropathy

Authors: E. OROZCO[1], B. BOBER[2], *S. SHAH[2];
[1]UCSD/VA, San Diego, CA; [2]UCSD, La Jolla, CA

Abstract: Paclitaxel, a popular chemotherapeutic used with high efficacy to treat several metastatic cancers, causes a particularly insidious sensory peripheral neuropathy, resulting in acute pain, chronic tingling and burning sensations, and numbness. It is accepted that paclitaxel halts cancer cell division by binding and stabilizing microtubules. However, since neurons are post-mitotic, paclitaxel must impair neuronal function by a mechanism distinct from cell division. We hypothesized that by stabilizing neuronal microtubules, paclitaxel induces microtubule bundling, which then results in several downstream adverse structural and functional impacts. Further, we hypothesized that the microtubule associated protein tau, given its widely hypothesized role in microtubule stabilization and the proximity of its binding site in the microtubule lumen to that of paclitaxel, is a strong candidate to influence the progression of paclitaxel-induced neuropathy. To test these hypotheses, we performed a number of structural and functional assessments of wild-type or tau knockout (Mapt -/-) mice injected systemically with 10 mg/kg cumulative dose of paclitaxel or Cremaphor carrier over a 5 day period. Von Frey hair testing revealed increased mechanical sensitivity in paclitaxel-treated mice. Electron microscopy and centrifugation studies combined with Western blotting confirmed microtubule bundling in peripheral (sensory) nerves of these mice, and also revealed a hyper-connected neuronal cytoskeleton. The latter was confirmed by immunohistochemistry. Consistent with mechanical hypersensitivity, paclitaxel-treated cultured neurons from dorsal root ganglia (DRG) demonstrated persistent mechanically-gated calcium influx, in contrast to more transient activity in carrier-treated neurons. Tau knockout mice treated with paclitaxel, in contrast, displayed reduced mechanical hypersensitivity, reduced microtubule bundling, and a well-organized cytoskeleton. In addition, paclitaxel-treated cultured neurons from DRG of tau knockout mice were less responsive than their wild-type counterparts to mechanical stimuli. This may be due to an inherently lower baseline sensitivity to mechanical stimuli in control (carrier-treated) tau knockout neurons. Collectively, these findings reveal compelling roles for tau in cytoskeletal stability and mechanical gating of ion channels in the peripheral nervous system, and in modulating neuropathic progression in a mouse model of paclitaxel-induced neuropathy.

Title: Carboxyl-terminal modulator protein promotes nerve injury-induced muscle atrophy

Authors: *C. L. WALKER[1,2], J. WANG[1], C. WILSON[1], L. TIERNEY[1];
[1]Biomed. Sci. and Comprehensive Care, Indiana Univ. Sch. of Dent., Indianapolis, IN; [2]Richard L. Roudebush Veterans Affairs Med. Ctr., Indianapolis, IN

Abstract: The downregulation of Akt phosphorylation and activity in denervated muscle leads to increased proteins involved in muscle breakdown. Akt prevents the transcription of E3 ubiquitin ligases, such as muscle ring-finger protein 1 (Murf-1), involved in the structural degeneration of muscle cells. In addition, reduced Akt signaling leads to aberrant protein synthesis involved in muscle degeneration. Only recently has information regarding the intracellular regulation of Akt activity in muscle cells been further detailed. We previously discovered that a known negative regulator of Akt, carboxyl-terminal modulator protein (CTMP, also known as Them4), is highly elevated in late-stage atrophic muscle in a mouse model of amyotrophic lateral sclerosis (ALS). Furthermore, knocking down CTMP in an in vitro model of muscle atrophy reverses the downregulation of Akt phosphorylation. The present study investigated whether CTMP increases in atrophic muscle caused by complete transection sciatic nerve injury (SNI) and whether loss of CTMP reverses the atrophy process and acts through Akt signaling in a knock-out mouse model of SNI. We found that CTMP significantly increased in the gastrocnemius muscle 7 days post-unilateral nerve injury relative to the contralateral non-affected muscle ($p<0.05$). Using CTMP knock-out (CTMP-KO) and wild-type (WT) mice, sciatic nerve transection elicited significantly less atrophy in the CTMP-KO gastrocnemius compared to denervated WT muscle as determined by weight comparison and muscle fiber area relative to each animal's non-denervated muscle ($p<0.05$). The denervated muscle exhibited significantly increased Akt and glycogen synthase kinase 3β (GSK3β) phosphorylation relative to the non-affected muscle in CTMP-KO mice compared to WT mice ($p<0.05$). The phosphorylation of ribosomal protein S6 and 4E-BP1 proteins were also significantly relatively upregulated in denervated CTMP-KO muscle compared to WT mice ($p<0.001$ & $p<0.05$, respectively). WT mice also showed a significantly higher relative denervated muscle expression of myostatin and the atrophy-associated Murf-1 protein than CTMP-KO mice ($p<0.05$). Our results suggest that CTMP is important in the progression of muscle atrophy post-denervation. In addition, decreased Akt signaling, and subsequently reduced protein synthesis, and increased degradation processes are likely mechanisms of CTMP's action in promoting nerve injury-induced muscle atrophy.

Title: EGFR inhibition promotes nerve regeneration in a mouse hindlimb model of nerve injury and in neurite outgrowth assays

Authors: J. PELLER[1], A.-M. CROTTY[2], M. D. KAWAJA[3], *J. HENDRY[4];
[1]Ctr. for Neurosci. Studies, [2]Dept. of Biomed. and Mol. Sci., [3]Biomed. and Mol. Sci., [4]Dept. of Surgery, Queen's Univ., Kingston, ON, Canada

Abstract: The success of nerve regeneration following injury remains limited with no FDA-approved non-surgical methods to enhance the rate of recovery. Increasing the rate of axonal regeneration could limit the degree to which chronic denervation, chronic axotomy and denervation atrophy negatively impact functional recovery. Previous studies have demonstrated that EGFR inhibition may promote axonal regeneration by preventing chondroitin sulfate proteoglycan (CSPG) inhibition of regeneration. Furthermore, blockade of the tyrosine kinase receptor ErbB2 with the antibody inhibitor trastuzumab was found to accelerate multiple metrics of nerve regeneration. We hypothesized that these effects occur by disrupting an inhibitory heterodimer formation between epidermal growth factor receptor (EGFR) and ErbB2. In this study, we investigated the impact of the dual EGFR-ErbB2 small molecule inhibitor lapatinib and EGFR inhibitor gefitinib, FDA-approved cancer drugs, on nerve regeneration using a mouse hindlimb nerve injury model (only lapatinib) and *in vitro* neurite growth assays (both lapatinib and gefitinib). Twenty-four C57Bl/6 mice underwent sciatic nerve transection and repair. Animals were administered lapatinib or vehicle control for either 10 or 28 days, at which point regeneration was assessed by retrograde labelling and quantitative nerve histomorphometry. Mechanistic exploration took place with complimentary neurite outgrowth assays, whereby adult dorsal root ganglion (DRG) neurons were cultured in the presence of inhibitory chondroitin sulfate proteoglycan (CSPG), with or without lapatinib or gefitinib. Four weeks post-injury, lapatinib administration led to a significant increase in the number of regenerated myelinated axons distal to the repair site compared with vehicle controls (lapatinib: 1042 ± 108, vehicle: 729 ± 110; $p<0.05$). No significant differences were observed in the number of retrograde labelled sensory or motor neurons or other nerve histomorphometry parameters between vehicle and control. DRG neurons cultured in the presence of lapatinib and gefitinib had significantly increased mean neurite length compared to CSPG alone. This rescue effect was seen more strongly with gefitinib than lapatinib. Dual inhibition of the EGFR and ErbB2 receptors with the FDA-approved drug lapatinib increased the number of distally regenerated myelinated axons at 28 days following sciatic nerve transection and repair. Furthermore, in vitro neurite growth assays suggest that sole EGFR or dual EGFR-ErbB2 inhibition by gefitinib or lapatinib, respectively, may act be overcoming the inhibitory effects of CSPG on axonal growth.

Title: Effects of exercise on muscle reinnervation and plasticity of spinal circuits in rat sciatic nerve crush injury models with different denervation periods

Authors: *Y. MINEGISHI[1,2], K. OZONE[1], Y. OKA[1], T. KOKUBUN[3], K. MURATA[3], N. KANEMURA[3];

Abstract: Peripheral nerves have the ability to regenerate after injury, but functional motor recovery is poor. The length of the denervation period after nerve injury is an important factor that defines motor function recovery. Failed muscle reinnervation and synapse withdrawal of primary afferent neurons from motoneurons inhibit motor function recovery. Physical exercise is an important strategy to regulate these changes and to improve motor function recovery after injury. However, the relationship between the denervation period and the effect of exercise is unclear. The purpose of this study was to examine the effect of the length of the denervation period before the initiation of exercise on the histological connectivity between reinnervation and spinal circuits, along with its relationship to motor function recovery. 10-week-old male Sprague Dawley rats (n = 32) were randomly divided into four groups: (1) sciatic nerve crush (SC group), (2) sciatic nerve crush and exercised (SC-EX group), (3) multiple sciatic nerve crush with prolonged denervation period (MSC group), (4) multiple sciatic nerve crush and exercised (MSC-EX group). Treadmill exercise was conducted at 10 m/min for 60 min, five times a week. The soleus muscle and L4-L5 spinal cord were collected 35 days after the last crush. The percentage of reinnervation was calculated by counting the neuromuscular junction (NMJ) with alpha-bungarotoxin that contacted neurofilament 200-positive fibers. Synaptic coverage of motoneurons in Lamina IX was determined from contacts between motoneurons and immunoreactive structures of synapse-associated proteins using anti-vesicular glutamate transporter 1 (VGLUT1) and anti-synaptophysin. The sciatic functional index (SFI) was used to assess motor function recovery. The percentage of SOL reinnervation tended to be lower with a longer denervation period. However, there was no significant difference between the exercise group and the non-exercise group. The synaptic coverage of VGLUT1 immunoreactivity was higher in the SC-EX group than in the SC group but did not show a significant difference

between the MSC-EX and MSC groups. In contrast, synaptic coverage of synaptophysin immunoreactivity did not show any significant difference between all groups. The SFI at 35 days after injury was higher in the SC-EX, SC, MSC-EX, and MSC groups, in that order. These results suggest that the length of the denervation period after axonotmesis affects muscle reinnervation and motoneuron synaptic changes differently, but exercise promotes motor function recovery regardless of the length of the denervation period.

Abstract: Biomaterial-based nerve guidance conduits (NGCs) have emerged as viable alternatives to autografts in peripheral nerve injuries; however, repair over long distances remains inconsistent. To address this, we have developed a filled NGC with an internal matrix consisting of aligned microporous channels containing combinations of macromolecules found in nerve extra-cellular matrix (ECM), namely fibronectin, laminin 1 and laminin 2. Using these combinations, we aim to prepare an off-the-shelf, acellular NGC with capacity to repair large nerve defects. NGCs were produced using an outer collagen conduit and an internal matrix of collagen-chondroitin sulphate augmented with ECM combinations. Porosity and pore alignment was assessed using scanning electron microscopy. The effects of the different ECM combinations were assessed for growth factor and inflammatory biomarkers using primary rat

dorsal root ganglia (DRG) cultures over 14 days. Following this, large 15 mm sciatic nerve defects were created in rats and the lead candidate NGCs were implanted and assessed after 8 weeks. Regeneration was assessed using foot withdrawal response, electrophysiology and immuno-histochemistry. Following fabrication, the internal matrix of filled conduits was found to be highly porous with unidirectional pores aligned along the longitudinal axis. When assessed over 14 days, an ECM combination of fibronectin, laminin 1 and laminin 2 at a ratio 1:4:1 significantly decreased DRGs' secretion of inflammatory markers such as interferon gamma-induced protein 10, monocyte chemoattractant protein 1 and macrophage inflammatory protein 1a and significantly increased DRGs' production of nerve growth factor, vascular endothelial growth factor (VEGF) and interleukin-6. Based on the *in vivo* analysis, regenerated tissue was found to be present throughout the NGC and functional recovery was comparable to autograft controls. Notably, ECM combinations of fibronectin, laminin 1 and laminin 2 at a ratio 1:4:1 significantly increased *in vivo* vascularisation inside NGCs when compared to NGCs without ECM, which may be associated with the capacity to increase VEGF production by DRGs observed *ex vivo*. In summary, the pro-regenerative effects of ECM in peripheral nerve repair were highly combination-dependent. This study has demonstrated that ECM combination of fibronectin, laminin 1 and laminin 2 at a ratio 1:4:1 has immune-modulatory and pro-angiogenic effect with capability to repair large peripheral nerve injuries to a level equivalent to autograft indicating its potential as a new clinical therapy for repairing large nerve defects.

Title: Alpha B Crystallin plays a role in terminating the pro-inflammatory macrophage response in the injured aged peripheral nerve

Authors: *K. M. HAGEN[1], S. S. OUSMAN[2];
[1]Neurosci., [2]Clin. Neurosciences and Cell Biol. & Anat., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: Peripheral nerve injury (PNI) affects millions of people worldwide, and those impacted are often left with debilitating motor and sensory impairments. More concerning is that regeneration of damaged peripheral axons is worse with advancing age. A decline in the functions of Schwann cells (SCs) as well as resident and infiltrating macrophages (MΦ) may contribute to the worsened regenerative capacity of the damaged aged peripheral nervous system (PNS). These cells are critical for effective PNS regeneration due to their release of neurotrophic factors and cell adhesion molecules by SCs, and together with MΦs, the phagocytosis of myelin and neuronal debris among other functions. We are interested in identifying the molecular factor(s) responsible for the impaired function of senescent SCs and MΦs. Towards this goal, we found that an age-related decline in the expression of a small heat shock protein called alphaB-crystallin (αBC) in SCs correlated with defective myelination and lipid synthesis in the injured PNS, as well as an increased presence of MΦs. Further, in younger global αBC knockout mice, there was a prolonged elevation of pro-inflammatory MΦs above that of wildtype (WT). To assess if the defect in myelination with age is related to alterations in the number of SCs and phenotype of MΦ after PNI, we quantified the number of SCs and pro- and anti-inflammatory MΦs after sciatic nerve crush injury in WT and αBC globally null mice across age. With respect

to MΦs, we found that the total number of MΦs was elevated in older mice at later time points post-injury in the αBC knockout mice, whereas older WT mice displayed a gradual decline in MΦ presence after damage, similar to that seen in younger animals. Furthermore, upon examination of the phenotype of these pathologically elevated MΦs in the αBC null animals, it appears that they are pro-inflammatory due to the significant increase in their numbers observed at the same time points as the general MΦ marker. In contrast, the number of anti-inflammatory MΦs was similar between the two genotypes after injury with an overall reduction in older animals relative to younger mice. These findings indicate that αBC may play a role in terminating the pro-inflammatory macrophage response following PNI, and that with increasing age the natural decline in αBC may result in an increased presence of pro-inflammatory macrophages that could contribute to adverse symptoms such as neuropathic pain. We are currently assessing the presence of myelinating and non-myelinating SCs.

Title: Increased inhibitory interneuron activity in S1 after peripheral nerve injury visualized in transgenic GAD1-GCaMP rats

Authors: *V. KRISHNAN[1], **L. C. WADE**[2], R. R. ISRAELI[1], G. PELLED[1,3,2];
[1]Biomed. Engin., [2]Neurosci. program, [3]Radiology, Michigan State Univ., East Lansing, MI

Abstract: Using electrophysiology, we previously demonstrated that the activity of both excitatory neurons and inhibitory interneurons are impacted in the deprived S1. This could be a possible mechanism leading to phantom limb pain. However, the exact mechanism through which nerve injury affects this population remains unknown due to their lesser number and smaller sizes of inhibitory interneurons and the fact that it is difficult to identify and obtain electrophysiology recordings from them. In order to specifically identify and study this population, we generated transgenic Sprague Dawley rats encoding GAD1-GCaMP using CRISPR technology. GAD1 is a protein that is expressed in inhibitory interneurons and this transgenic rat provides an unparalleled opportunity to visualize neural activity through genetically encoded calcium indicators (GCaMP6S). We performed forepaw denervation (severing ulnar, median, and radial nerves) 4 weeks post birth in 5 rats. Additional 7 age-

matched rats were used as controls. Fluorescent imaging was performed 2 to 3 weeks after denervation on 300 µm-thick cortical slices. A bipolar tungsten electrode was positioned in layer 2/3, in layer 5, or in the corpus callosum in the deprived S1, and delivered 100 Hz stimulation for 5 s. We analyzed the fluorescence changes of 830 GAD1-expressing neurons that were located in an ROI of 700 X 400 µm adjacent to the stimulating electrode. Out of this population, 399 neurons were considered responsive as their change in fluorescence was greater than the standard error of mean (SEM) of that group. The results demonstrate that local stimulation of layer 2/3 and layer 5 leads to increases in the number of evoked responses of GAD1-expressing neurons in injured rats compared to controls: Stimulation of layer 2/3 led to 56.8% responses in injured rats in comparison to 40.0% responses in controls ($p = 0.001276$, chi-squared); Stimulation of layer 5 led to 91.3% responses in injured rats in comparison to 50.7% responses in controls ($p < 0.00001$, chi-squared). This suggests that inhibitory interneurons are susceptible to local, intrahemispheric stimulation. Stimulation of the corpus callosum led to 21.4% responses in layer 5 in injured rats compared to 41.1% responses measured in controls ($p = 0.007586$, chi-squared), suggesting that injury impacts interhemispheric communication, leading to an overall decrease in activity. Together, our results provide direct evidence that the inhibitory interneurons' activity is altered after injury, leading to increases in inhibition in the deprived S1.

Title: Establishing a platform for neural culture of octopus neurons

Authors: *C. CYWIAK[1,2], T. VANBUREN[1,2], G. PELLED[1,2,3];
[2]Biomed. Engin., [3]Radiology, [1]Michigan State Univ., East Lansing, MI

Abstract: The octopus provides a unique model with unparalleled characteristics to study sensorimotor circuits associated with gripping behavior and decision making. The octopus's nervous system is highly developed with 350 million neurons in the eight axial cords and peripheral ganglia. The axial cord is similar to a vertebrate's spinal cord performing both sensing and motor planning and execution of movement. However, the neural ensembles encoding for different movements are unknown. We are working towards developing a platform that will enable visualizing neural activity using optical imaging methods. We have established a protocol to maintain a viable primary neural culture from neurons obtained from the arm of *Octopus*

bimaculoides. Octopus's arm neurons were dissected with collagenase P (4mg/ml), trypsin (1mg/ml) and accutase (4mg/ml) in 50% L15 - and 50% sea water, 15mM HEPES and 1mM glucose, each enzyme were incubated for 40 min. Afterwards, the cells were washed with 50% L15 - and 50% sea water and centrifuge three times to eliminated contamination. Finally, the cells were changed to a media solution containing 50% L15 - and 50% sea water, 15mM HEPES, 1Mm glucose, 1% Factor B-27, 1% PenStrip and 1% Amphotericin B and plated in a 24 well plate dish coated with matrigel. To test the viability of the neurons we used a multielectrode array system with 26,000 electrodes to record action potentials (AP) from the cultured cells (Maxwell biosystems). The cells were continuously perfused with a physiological solution. We were able record AP from these neurons up to 4 days after dissections. For neuronal validation we fixed the cells with 4% PFA for 40 min and changed to 20% sucrose media. The cells were sliced in 25µm sections, washed then incubated for 1hr with blocking solution (0.1% Triton-X 100 and 5% Goat Serum). The primary antibodies used were mouse polyclonal Antiβ III Tubulin antibody (1:250) and rabbit polyclonal poli (ADP-ribose) polymerase (PARP1) (1:250) overnight at 4◦C. Both antibodies are specific for neurons. After the cells were washed and incubated with second antibodies, FITC-conjugated goat anti-mouse IgG (1:200) and Rhodamine conjugated goat anti-rabbit IgG (1:200) for 2hrs and mounted in DAPI media solution then visualized on a Keyence Microscope. This work is important in establishing platforms to test neural function and neural assemblies in a control fashion. This preparation is also a critical step towards expressing genetically-encoded imaging probes (calcium and voltage indicators) that will be able to report on large-scale, and high resolution neural activity in the octopus.

Title: Spike recordings from an octopus disembodied arm

Authors: *R. ASHBAUGH[1], J. RICHIE[3], C. A. CHESTEK[3], G. PELLED[2];
[1]Electrical and Computer Engin., [2]Biomed. Engin., Michigan State Univ., East Lansing, MI;
[3]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: The incredible abilities of the octopus to perform complex movements and skillfully coordinate the behavior of eight arms simultaneously make it an excellent candidate for research focused on studying motion control. Furthermore, the octopus is thought to strongly utilize a

decentralized motion control mechanism, relying on much of the planning and execution to be performed in the arms themselves.
Central to understanding the mechanisms of such control is characterizing nerve firing patterns and relating them to observed motion. Here we explore approaches for recording such relevant patterns from stimulus evoked potentials in the axial nerve cord of an arm from the *Octopus bimaculoides*. Both a monopolar tungsten and carbon fiber multi-channel electrode array are used to record unit activity in the separated arm following numerous types of stimulation delivery, including chemical, electrical, and mechanical stimulation. We intend to further octopus electrophysiology work aimed at detecting patterns of motor activity (Gutfreund *et al.*, 2006; Fouke *et al.*, 2020) in an isolated octopus arm in response to stimulation.
An arm was removed and placed in a platform that was continuously perfused in a physiological solution. The arm was secured to reduce motion and the tungsten electrodes were positioned inside the axial cord. In response to chemical stimulation with NaOH, considerable activity was shown to be evoked in the axial cord, with as many as 27 spikes per second being recorded. Activity could be seen to persist for up to several minutes following stimulation. A brief tactile mechanical stimulation is also being investigated for it's ability to induce spiking activity. We are currently working on designing a multi-channel carbon fiber array which would be well suited for underwater octopus electrophysiology.
Characterization of multi-unit activity in the nerve cord of the octopus arm serves an important role in understanding the techniques used by the octopus to implement planning and motion control for it's arms to perform goal oriented behavior like hunting. Characterization of firing patterns in response to a battery of different stimuli using a variety of recording techniques may reveal novel control mechanisms and serve to advance the field of embedded soft robotic control.

Title: Il10 overexpression in mesenchymal stromal cell transplants for spinal cord neuroprotection

Authors: *I. MALDONADO-LASUNCION[1,2], F. DE WINTER[4], J. VERHAAGEN[4], M. OUDEGA[5,2,3,6];
[1]Shirley Ryan Abilitylab, Chicago, IL; [2]Physical therapy and human movement science, [3]Physiol., Northwestern Univ., Chicago, IL; [4]Lab. for Neuroregeneration, Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [5]Biologics Lab., Shirley Ryan Ability Lab., Chicago, IL; [6]Edward Hines Jr. VA Hosp., Hines, IL

Abstract: Traumatic spinal cord injuries (SCI) feature an initial mechanical injury followed by a chronic loss of nervous tissue surrounding the original injury epicenter. After injury, local immune cells become activated and waves of circulating immune cells infiltrate the injured tissue. While pro-inflammatory macrophages play an important role in clearing debris and dead tissue to prepare the spinal cord for repair, they eventually fail to switch their polarization to the anti-inflammatory and pro-resolving phenotypes that are necessary for tissue repair. The chronic presence of pro-inflammatory macrophages in SCI contributes to the expansive nature of the injury which significantly contributes to the lack of repair. Mesenchymal stromal cells (MSC) are multipotent stem cells that secrete bioactive molecules that may support nervous tissue repair. Acute intraspinal MSC transplants promote neuroprotection and immunomodulation after SCI, but the resulting therapeutic efficacy is suboptimal. In this study, we aimed at enhancing the immunomodulatory potential of MSC by inducing overexpression of the anti-inflammatory mediator interleukin-10 (IL10) using lentiviral vectors *in vitro*. We argued that this approach could increase the neuroprotective effects of an MSC transplant. We studied the effects of IL10 overexpression on MSC secretome, and their ability to induce anti-inflammatory macrophage polarization, *in vitro*. We also evaluated the neuroprotective and immunomodulatory potential of IL10-MSC transplants *in vivo*, using an adult rat model of contusive SCI.

Abstract: Spinal cord injuries (SCIs) are known to produce a myriad of effects over the acute, sub-acute, and chronic period following injury, including paralysis, altered sensation below the level of the injury, as well as aberrant autonomic responses. To date, the only FDA-approved treatment for acute SCI has been methylprednisolone, but that has fallen out of favor both domestically and internationally over the past decade. We have begun developing a cell-free, self-contained, acute-care, minimally invasive biomaterial treatment for both contusive and open SCIs that diminishes the onset and severity of secondary injury while simultaneously supporting and improving subsequent treatments (e.g., cell transplantation). Specifically, we investigated micro-scaffolds comprised of 3D-Painted Fluffy-PLG, an electrically conductive 3D-Graphene, and a blend of the two (Fluffy-Graphene). We have established the preliminary safety and lack of immunogenicity of micro-meshes made of 3D-printed Fluffy-PLG, 3D-Graphene, and Fluffy-Graphene when implanted in the spinal cords of both sham and injured rats. Additionally, all three materials demonstrate a reduction in the number of macrophages following contusive SCI when compared to injured rats without biomaterial implants. Further, we have shown that by acutely implanting the Fluffy-PLG into the injury site (via acute myelotomy), and then transplanting bone marrow mesenchymal stem cells (MSCs) directly into the biomaterial implant one day later, the immunomodulatory ability of MSCs is improved in comparison to those injured rats that received MSC transplants directly into the parenchyma at the same time point.

Abstract: Traumatic damage to the spinal cord does not spontaneously heal, often leading to permanent tissue defects with cystic cavities. Previously, WWwe previously showed have shown that injection of imidazole-poly(organophosphazene) hydrogel (I-5) bridges cystic spaces with newly assembled fibronectin-rich extracellular matrix (ECM) mediated by an imidazole moiety interacting with macrophages. The hydrogel-created ECM contains chondroitin sulfate proteoglycans (CSPGs), collagenous fibrils together with perivascular fibroblasts, and various fibrotic proteins, all of which could hinder axonal growth in the matrix. In an *in vitro* fibrotic scar model, cultured fibroblasts exhibited enhanced sensitivity to TGF-β1 when grown on CSPGs, which was prevented by recombinant arylsulfatase B (ARSB), a clinically approved enzyme to degrade CS carbohydrate chains. To alleviate the fibrotic microenvironment, the I-5 hydrogel was equipped with an additional function by making complex with ARSB via a hydrophobic interaction. Complexation of ARSB with the hydrogel allowed sustained release of the enzyme. Delivery of the I-5/ARSB complex significantly diminished the fibrotic ECM components in the lesioned spinal cord. The complex promoted serotonergic axonal growth into the hydrogel-induced matrix and enhanced serotonergic innervation of the lumbar motor neurons. Robust rRegeneration of the propriospinal axons labeled by AAV8-tdTomato was observed deepdeep into inside the matrix in animals with the I-5/ARSB complex, and some of the propriospinal axons grew to the lumbar spinal cord. and to the lumbar spinal cord was robustly increased. The enhanced axonal growth and neuronal innervation were accompanied by improved locomotor recovery in rats with the I-5/ARSB complex. Therefore, our dual functional system upgraded the functionality of the hydrogel for spinal cord regeneration by creating ECM to bridge tissue defects and concurrently facilitating axonal connections through the newly assembled ECM.

Title: Assessing consequences of intra-spinal delivery of rAAV-retro to delete PTEN on recovery of upper extremity function following cervical spinal cord injury in mice

Authors: *M. METCALFE, O. STEWARD;
Univ. California Irvine, Irvine, CA

Abstract: Previous studies have documented that conditional genetic deletion of phosphatase and tensin homolog (PTEN) enables regeneration of axons in the spinal cord after spinal cord injury (SCI). Here, we test efficacy of an approach using AAV vectors that are transported retrogradely from an injection site in the spinal cord to the majority of neurons that give rise to spinal tracts. We report results of 3 separate studies that use $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice in which Cre induces expression of tdT and simultaneously deletes PTEN. In two studies, controls were $Rosa^{tdTomato}$ mice that received rAAV-retro/Cre; in the other, controls were $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice that received rAAV-retro/GFP. 8-week old female and male mice received different genome copies (GC) of rAAV-retro at the same time as a dorsal hemisection injury at C5 (1E10 GC: $Rosa^{tdTomato}$ n=13, $PTEN^{f/f}$;$Rosa^{tdTomato}$ n=12; 6E9 GC: rAAV-retro/Cre n=9; rAAV-retro/GFP n=7; 3E9 GC: $Rosa^{tdTomato}$ n=15, $PTEN^{f/f}$;$Rosa^{tdTomato}$ n=25). The surgeon doing the injections was blind with respect to strain and vector. Forelimb motor function was assessed over time using a grip strength meter by individuals who were blind to treatment group. Following C5 lesions, average grip strength decreased to <15% of pre-operative control immediately after injury and then gradually recovered. In studies involving higher (1E10 GC) and mid (3E9 GC) doses of rAAV-retro/Cre, $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice recovered more than respective controls. Across studies, the extent of recovery was dose dependent. Mice that received 1E10, 6E9, and 3E9 GC, recovered to a peak of 88.8%, 38%, and 12.4% of pre-operative control values respectively. Although $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice that received rAAV-retro/Cre exhibited a greater initial recovery, a complication was the development of severe scratching behaviors suggesting intense sensations of itch and hindlimb motor dysfunction beginning at about 50-60 days post-injury. These late developing abnormalities were not observed in $Rosa^{tdTomato}$ control mice that received rAAV-retro/Cre or in $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice that received rAAV-retro/GFP, indicating that the abnormalities are not due to the AAV itself or the Cre cargo it expresses. We conclude that, although intra-spinal injections of rAAV-retro/Cre in $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice can lead to initial improvements in forelimb motor recovery after SCI, there are late-developing functional abnormalities with the experimental conditions used here.

Title: Development of a novel herpes simplex virus-thymidine kinase system for selection ablation of neural progenitor cells to facilitate mechanistic gain and loss of function studies

Authors: *Z. LOU[1], A. POST[1], C. E. RODGERS[2], M. CHAMANKHAH[2], J. HONG[1], C. S. AHUJA[2], M. KHAZAEI[1], M. G. FEHLINGS[3];
[1]Dept. of Genet. and Develop., Krembil Res. Institute, Univ. Hlth. Netw, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]Div. Neurosurg., Toronto Western Hosp., Toronto, ON, Canada

Abstract: Background: Neural progenitor cell (NPC) transplants are a promising therapy for treating spinal cord injury (SCI), yet their long-term role after engraftment and their relative contribution to ongoing functional recovery remains a key knowledge gap. Selective human cell ablation techniques, currently being developed to improve the safety of progenitor cell transplant therapies in patients, may also be used as tools to probe the regenerative effects attributable to individual grafted cell populations. The Herpes Simplex Virus Thymidine Kinase (HSV-TK) and ganciclovir (GCV) system has been extensively studied in the context of SCI and broader CNS disease. However, the efficacy of brivudine (BVDU), another HSV-TK prodrug with potentially reduced bystander cytotoxic effects and in vivo toxicity, has yet to be investigated for NPC ablation. Purpose: This study aims to optimize the ablational efficiency of the HSV-TK system in the spinal cord through investigating the use of BVDU separately and in combination with GCV. Hypothesis: Combinatorial treatment of HSV-TK expressing NPCs with GCV and BVDU leads to increased cell ablation over treatment with only one prodrug. Results: In the in vitro cell ablation assay, we detected an approximately 80% reduction in the number of surviving HSV-TK+ NPCs when compared to controls for both GCV and BVDU treatments at the highest concentrations used (1 µg/mL) after 96 hours. Through a TUNEL assay, we found that there were differences in bystander effect and killing efficiency between GCV and BVDU at 1 µg/mL. GCV was found to ablate cells approximately 4% more than BVDU at 73.6% and 69.8% respectively, and the bystander killing effect of GCV was 27.6% compared to 12.1% with BVDU. We observed the highest killing efficiency of 89.3% when using a combination of 0.5 µg/mL of GCV and 0.5 µg/mL of BVDU, while the bystander effect was observed to be 25.4%,

2.2% below that of GCV alone. Following transplantation of HSV-TK+ hiPSC-NPCs into the cervical spine of the rat model, we were able to demonstrate that the largest elimination of the cells occurred when the rats were injected IV with a combination of GCV and BVDU over treatment with either prodrug alone. Conclusions: In this study, we demonstrated successful generation and ablation of HSV-TK-expressing human iPSC-derived NPCs. Our findings show enhanced ablation efficiency and reduced bystander effects when targeting all rapidly dividing cells with combinatorial GCV and BVDU treatment. However, for use in loss of function studies for a single proliferating cell subpopulation, BVDU alone is optimal due to reduced nonselective cell ablation.

Title: Intermittent hypoxia, sustained hypoxia, and normoxia induce differential patterns of HIF-1a and VEGF expression in the central nervous system of uninjured adult rats

Authors: *A. L. SILVERSTEIN[1], B. A. MILLER[2], W. J. ALILAIN[1];
[1]Neuroscience, Spinal Cord and Brain Injury Res. Ctr., [2]Neurosurgery, Spinal Cord and Brain Injury Res. Ctr., Univ. of Kentucky, Lexington, KY

Abstract: Spinal cord injuries (SCIs) most commonly occur at the cervical level and often render injured people unable to breathe. Mechanical ventilation can preserve life despite respiratory motor paresis, but detrimentally affects quality of life and can lead to long-term complications including lung damage and respiratory muscular atrophy. Promisingly, moderate intermittent hypoxia (mIH) treatment can be used to induce increased respiratory output known as long term facilitation (LTF) after SCI, but recovery is transient. Seemingly subtle modifications of hypoxia treatment paradigm activate distinct cellular signaling pathways and thus respiratory motor response, even as originally demonstrated in uninjured laboratory animals. A better understanding of these signaling pathways will likely contribute to development of hypoxic dosing patterns more adaptive for achievement of full respiratory motor recovery after SCI. One key pathway involves hypoxia inducible factor 1α (HIF-1α) and vascular endothelial

growth factor (VEGF) activity. HIF-1α is a transcription factor induced by cellular hypoxia and increases in neurons after mIH treatment while VEGF is downstream and can induce LTF-like plasticity by exogenous application to the spinal cord both alone and combined with mIH treatment. However, it is unknown how endogenous HIF-1α and VEGF levels compare between animals treated with mIH and moderate sustained hypoxia (mSH). Our prediction is that a moderate level of HIF-1α and VEGF expression is adaptive for LTF and that both the low and high protein levels likely induced by normoxia and mSH treatments, respectively, will be outside the ideal range induced by mIH. Thus, with hypoxia treatment type as our independent variable, we hypothesize that mSH will induce the most HIF-1α and VEGF expression in the spinal cord and brainstem, followed by mIH and normoxia, in descending order. We treated uninjured adult Sprague-Dawley female rats with 5 consecutive days of either normoxia, mIH, or mSH (n=3 per treatment group) and harvested fresh whole central nervous system tissue (CNS) immediately following final treatment, measuring HIF-1α and VEGF via MSD and ELISA assays, respectively. Interestingly, results demonstrated that mSH induced the least expression of HIF-1α across CNS regions while paradoxically inducing the greatest VEGF expression of the three treatments. To understand this, future experiments should explore whether VEGF exerts feedback inhibition on HIF-1α expression following mSH by use of pharmacological inhibition or genetic knockout of VEGF prior to treatment with mSH and measurement of HIF-1α.

Title: Daily acute intermittent hypoxia therapy improves spontaneous urination pattern and reflex micturition event behaviors in rats with mid-thoracic moderate contusion spinal cord injury

Authors: *C. WANG[1], W. F. COLLINS, III[2], I. C. SOLOMON[1];
[1]Physiol. & Biophysics, [2]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Spinal cord injury (SCI) has a profound negative impact on bladder function, resulting in problems with urine storage and emptying of the bladder that lead to detrusor overactivity, inefficient voiding, and urine retention. Current approaches to treat bladder dysfunction following SCI are inadequate, and novel therapeutic strategies aimed at restoring bladder

function are needed. To this end, preclinical rat studies in our laboratory have been examining the impact of exposure to neuroplasticity-inducing acute intermittent hypoxia (AIH) as a strategy for improving bladder function following SCI. We have found that exposure to a single bout of AIH results in immediate short-term beneficial improvements in bladder function characterized by a reduction or elimination of non-voiding bladder contractions (NVCs), increased void volume and inter-contraction intervals (i.e., improved voiding efficiency), and decreased minimum bladder pressure (i.e., reduced urine retention). Here, we investigate whether daily AIH (dAIH) therapy for 7 consecutive days beginning at 1 week after SCI produces sustained beneficial improvements in bladder function in our contusion SCI model; daily normoxic exposures (dNx) served as a control. Examination of awake urination pattern using serial weekly overnight metabolic chamber measurements revealed that most rats exhibited functional voids that were infrequent but with large volumes at 1 week after SCI, and subsequent dAIH but not dNx treatment led to recovery of void frequency pattern (i.e., number of voids and inter-void interval) to pre-SCI levels by 4 weeks post-SCI, but with slightly increased void volumes. Further, in a subset of rats that exhibited no effective voiding events (i.e., small overnight total urine volume) at 1 week after SCI, dAIH but not dNx treatment produced partial recovery of micturition pattern behavior in a small subset of these rats by 4 weeks post-SCI. Examination of reflex micturition event (rME) behaviors elicited by continuous infusion of saline (0.04-0.09 ml/min) into the bladder under urethane anesthesia revealed that at 4 weeks after SCI (which corresponds to 2 weeks after dAIH), dAIH-treated rats exhibited predominantly a mild degree of bladder dysfunction characterized by a low incidence of NVCs and enhanced voiding efficiency, and multiple premature rMEs could be elicited by brief exposure to hypoxia. These findings demonstrate that dAIH treatment can lead to beneficial improvements in spontaneous and reflex bladder function behaviors that persist for at least two weeks following completion of dAIH therapy, and support the use of dAIH therapy to treat SCI-induced bladder dysfunction.

Title: Contrast-enhanced ultrasound imaging to assess spinal cord injury severity and the efficacy of dural decompression in rodents

Authors: *J. S. HARMON[1], L. N. CATES[1], J. E. HYDE[1], M. F. BRUCE[2], Z. Z. KHAING[1], C. P. HOFSTETTER[1];
[1]Dept. of Neurolog. Surgery, [2]Applied Physics Lab., Univ. of Washington, Seattle, WA

Abstract: Traumatic spinal cord injury (tSCI) is characterized by a near complete loss of blood flow at the injury epicenter and substantial hypoperfusion in the penumbral zone, resulting in sustained ischemia and cell death. This ischemic deficit arises from progressive hemorrhage, edema, and associated increased intraspinal pressure (ISP). We hypothesize that the extent and magnitude of hemodynamic disruption following tSCI is indicative of the injury severity, and that acute dural decompression will alleviate elevated ISP and ameliorate tissue perfusion in the spinal cord parenchyma, with the intent of preserving the maximal amount of healthy tissue. In order to quantitatively evaluate spinal hemodynamics, we developed an ultrafast contrast-enhanced ultrasound imaging modality (CEUS) capable of interrogating microcirculatory blood flow within the entire spinal cord with high spatiotemporal resolution (100 um, 20 kHz). Epidural imaging was conducted following a three-level laminectomy (T7-T9) in female Long Evans rats. CEUS data were acquired at baseline, following an experimentally-induced contusion SCI (Infinite Horizon device; 100, 150, or 200 kDyn impact force), and after dural decompression (45 min post-injury) or no intervention. Behavioral testing was conducted weekly until 8 weeks post-injury (wpi). Preliminary results indicated that the area of perfusion deficit increased in response to increasing administered impact force (e.g., 0.42 mm^2, 1.9 mm^2, and 3.4 mm^2 perfusion deficit for mild to severe injuries, respectively). Area of perfusion deficit also correlated strongly with 2- and 8-wpi behavior in the “no intervention” groups as measured using the Basso, Beattie, Bresnahan locomotor rating scale ($R^2 = 0.76$; $p < 0.05$; N=6 animals per severity). With respect to decompression, resistance to blood flow in the penumbral zone rostral to the epicenter (quantified from CEUS using bolus inflow kinetics) increased significantly following tSCI (175% change from baseline); this was immediately ameliorated following durotomy (110% change from baseline). Similar results were observed with blood flow velocity (-28% change from baseline after SCI; -20% change from baseline after durotomy), suggesting this may be a promising neuroprotective intervention. Additional studies are currently underway to evaluate the effects of dural decompression on chronic functional outcomes and tissue perfusion.

Title: Ultrasound Examination of Spinal Cord Perfusion in an Ovine Model

Authors: *E. SHAAYA[1], J. S. CALVERT[3], K. WALLACE[5], S. R. PARKER[3], R. DARIE[3], S. SYED[2], J. FRIDLEY[1], G. PARTHASARATHY[5], S. DUCLOS[5], D. A. BORTON[4];

Abstract: Ultrasound Examination of Spinal Cord Perfusion in an Ovine Model

Introduction

Patients with spinal cord injury require adequate spinal cord perfusion post-injury to avoid secondary damage to the cord from inflammation and ischemia. Currently, real time bedside imaging of spinal cord perfusion is non-existent. Post-operative imaging in SCI patients consists of MRIs to assess extent of decompression and CT scans to assess hardware integrity. Acute SCI patients are managed by augmenting blood pressure using pharmacological means and measuring mean arterial pressures. Developing an ultrasound based platform for real-time, portable perfusion measurements would help manage this patient population. We aim to develop such a platform using an ovine model.

Methods

To investigate spinal tissue perfusion, we used a GE Vivid™ iq Ultra Edition portable ultrasound system with a L8-18i intraoperative probe to image the spinal cords of two sheep. High resolution (sub-mm), broadband (16 MHz center frequency) 2D image cross-sections of the spinal cord were visualized in real time. We performed measurements of blood perfusion using the Doppler function. The sheep had an epidural electrode placed on the spinal cord and we made blood flow measurements during spinal cord stimulation.

Results

We were able to successfully characterize the intact and contused spinal cord using US intra-operatively. The white and grey matter were distinctly visualized. Hemorrhage had a distinct appearance on US from normal neuronal tissue. Doppler functionality allowed the visualization of the blood flow to the cord. When the animal was at rest, the blood flow pattern was symmetric, with regions of blood flow in both directions. When EES was applied, spikes in blood flow could be observed at distinct times when the stimulation was applied. Interestingly, the spatial locations of increased blood flow were related to the regions of stimulation.

Conclusion

Ultrasound imaging of the spinal cord has the potential to revolutionize post-injury care for patients with spinal cord injury. In preliminary work, we show that US is able to distinctly visualize the white and grey matter of the spinal cord. Moreover, spinal cord perfusion can be measured using US. Variations in spinal cord perfusion correlate with areas of increased activity.

Abstract: Spinal Cord Stimulation (SCS) delivered at titrated phases of the gait cycle has previously been shown to restore locomotor kinematics in the hindlimb of Rhesus monkeys and humans following a spinal cord injury. These techniques show great promise for restoring mobility and independence in people living with a spinal cord injury. Historically, real-time gait cycle detection algorithms have relied on electromyographic (EMG), kinematic, or corticographic recording techniques to identify the current gait phase. These techniques require additional integration of several sensors, resulting in a more complex system. In our work, we demonstrate lateralization of spinal Local Field Potentials (LFPs) recorded from two 24-contact epidural SCS arrays implanted along the lumbosacral spinal cord of two ovine models during

relevant hindlimb movements, including flexion, extension, adduction, abduction, rotation, and treadmill walking. Spinal LFPs were simultaneously recorded from all 48 electrodes, spanning the mediolateral width of the spinal cord, and extending along the L4-L6 vertebral segments. Following the identification of lateralized, time-locked responses to manipulated movements, spinal LFPs recorded during treadmill walking were decoded to predict gait cycle phase during locomotion. A decoder was constructed for each hind leg, and both decoders were trained on the same training dataset. The training data consisted of autoregressive (AR) coefficients computed over 300ms sliding epochs from approximately two minutes of treadmill walking LFP signals. Dimensionality was reduced by applying principal component analysis (PCA). The decoders predicted the gait cycle of each hindlimb independently. On a held-out validation data set, the swing-stance state fore each leg was predicted to an accuracy greater than 70%. Our results demonstrate promise for future real-time closed-loop SCS control schemes solely reliant on epidural spinal arrays for both gait prediction and restorative stimulation.

Abstract: Spinal cord injuries (SCI) result in partial or complete loss of efferent and/or afferent connections between the brain and peripheral nerves, often yielding severe functional deficits for patients. While more than 300,000 people are currently living with a traumatic SCI in the U.S., there are currently no treatments that significantly aid in functional recovery. Presently, the only approved treatments for functional improvements post-SCI rely on rehabilitative strategies. Included in these strategies are functional electrical stimulation (FES) devices which utilize electrical stimulators to control specific muscles movements (i.e. stand, walk, grasp). There is evidence from our lab, using a stroke model, to suggest that electrical stimulation of peripheral nerves following neurological dysfunction promotes functional recovery via neuroplastic repair mechanisms. Thus, we hypothesized that a similar approach could be beneficial to functional recovery in a SCI model. Here, we used male, Long Evans adult rats to investigate peripheral nerve electrical stimulation as a treatment for functional recovery and/or neural plasticity after moderate, incomplete, thoracic spinal cord contusion. Daily electrical stimulation (30 min.) was applied bilaterally to the sciatic nerves via nerve cuff electrodes for 8 weeks and functional recovery assessed weekly by BBB, horizontal ladder walk, and von Frey filament testing. The SCI contusion model resulted in diminished hindlimb functional capacity as assessed by BBB and horizontal ladder walk. Additionally, SCI resulted in hindlimb hypersensitivity 9 days post-SCI. Preliminary results suggest that the electrical stimulation parameters used here (the same used for median nerve stimulation post-stroke) were not effective in improving functional recovery beyond spontaneous levels in our SCI model. We are still analyzing the lesion site and biotinylated dextran amine tracing from the hindlimb motor cortex to determine if peripheral nerve electrical stimulation effected neuroplasticity. Our results indicate that functional improvements via peripheral nerve electrical stimulation may rely on differing parameters based on the type and location of neurological deficit. Further work is continuing to test longer daily stimulation times, which may be needed post-SCI, in contrast to the improvement seen in the impaired forelimb as we have previously reported post-stroke.

Abstract: Cervical spinal cord injuries (SCI) damage descending motor pathways that control movements of the hands and arms. We are developing a novel therapy for chronic SCIs that uses targeted activity-dependent electrical spinal stimulation (TADSS) to improve motor recovery. TADSS is designed to strengthen spared descending pathways, based on principles of spike timing-dependent plasticity. We previously showed that a single site of intraspinal TADSS synchronized to volitional contractions of an impaired forelimb muscle improved performance of female rats in a reach-and-grasp task. For this study, we sought to improve TADSS therapy and investigate mechanisms of recovery. Four weeks after a moderate-severe cervical SCI, rats were implanted with an array of penetrating platinum-iridium microwires in the ventral horn of spinal segments C5-C7 (or epidural array of electrodes) and wires in 3 muscles of the impaired forelimb for electromyographic (EMG) recording. Starting 2 weeks after implantation, animals received therapy for 5 or 14 weeks. During the therapy period, TADSS animals received 3-channels of closed-loop spinal stimulation contingent on muscle activity of the impaired forelimb muscles. For 5 hours per day, including during reaching tasks, EMG from each muscle triggered sub-movement-threshold stimulation through a spinal electrode that could elicit contractions of that muscle with higher stimulus currents. Non-stimulated control animals received only behavioral training. Multi-site TADSS (MTADSS) promoted robust functional improvements in fine motor control and strength, but only in females. These functional benefits persisted with reduced physical training and no additional stimulation for 16 weeks after then end of the 14 week therapy period. Interestingly, 5 weeks of MTADSS therapy also restored arm function but the benefits did not persist after the end of the therapy, suggesting a minimum amount of therapy is needed to produce lasting behavioral effects. Recovery after 5 weeks was similar for TADSS delivered via intraspinal or epidural electrodes. In the 5 week study, males continued to show little functional recovery. We also periodically stimulated the contralesional motor cortex and recorded evoked potentials in the spinal cord. In animals that received MTADSS therapy, there was potentiation of the evoked corticospinal response. These results demonstrate optimizations for long term functional benefits of TADSS and identify plasticity in the corticospinal pathway as a potential mechanism driving recovery. Moreover, these data identify a profound need to understand why females show greater recovery than males.

Title: Spatiotemporal distribution of electrically evoked spinal compound action potentials during spinal cord stimulation

Authors: *J. S. CALVERT[1], R. DARIE[1], S. R. PARKER[1], E. SHAAYA[2], S. SYED[2], B. L. MCLAUGHLIN[3], J. S. FRIDLEY[2], D. A. BORTON[1,4,5];

Abstract: Recent studies using Spinal Cord Stimulation (SCS) have demonstrated restoration of motor function in individuals previously diagnosed with chronic spinal cord injury (SCI). In parallel, recent advances in SCS have indicated the use of spinal evoked compound action potentials (ECAPs) in closed-loop devices to titrate delivery of stimulation in the context of chronic pain and in further understanding the mechanisms of SCS function. However, the previous characterizations of the ECAPs recorded during SCS were performed with one-dimensional electrode leads (i.e., percutaneously placed leads). Here, we describe the spinal ECAPs elicited using clinically and physiologically relevant SCS parameters and stimulation locations across both the rostral-caudal and medial-lateral directions of the sheep spinal cord. In two sheep, two 24-contact epidural SCS arrays were implanted along the lumbosacral spinal cord. Spinal ECAPs were recorded during SCS from the non-stimulating contacts of the epidural array, which were synced to bilateral electromyography (EMG) recordings from six back and lower extremity muscles. We observed a distinct triphasic P1, N1, P2 peak morphology and propagation in the ECAPs during midline and lateral stimulation. Spinal ECAP recruitment spatially and temporally correlated with lower extremity EMG recruitment. Interestingly, distinct regions of lateral stimulation produced both triphasic spinal ECAPs and motor evoked responses measured via EMG, while others exhibited neither response type. Furthermore, when high frequency SCS (e.g., 10kHz) was used to "block" low frequency SCS at a caudal location, spinal

ECAPs could still be observed rostral to the high frequency SCS. These results suggest that spinal ECAPs can be used to investigate the effect of SCS on spinal structures, and may be informative in strategies to optimize the clinical benefit of SCS in the context of both managing chronic pain and restoration of function after SCI.

Title: In vivo time lapse imaging reveals dynamics of sensory neuron structural remodeling in adult mouse skin

Authors: *R. C. CLARY, E. A. LUMPKIN;
Univ. of California - Berkeley, Berkeley, CA

Abstract: Sensory afferents that innervate the skin and encode thermal, noxious, itch, and tactile stimuli must maintain neuronal architecture despite the continuous postnatal renewal of target tissues. For example, myelinated Aβ afferents that innervate epidermal Merkel cells and respond to gentle touch stimuli must maintain connections with Merkel cells even though the cells that make up the epidermis, including Merkel cells, undergo constant renewal. To address this gap in knowledge, we developed a technique utilizing time-lapse *in vivo* two photon imaging of Merkel cells and afferent terminals.
We imaged adult transgenic mice expressing Atoh1-GFP to label Merkel cells and TrkC-tdTomato to label Aβ afferents every three days for approximately one month. Over this time

period, we noted that both Merkel cells and afferent terminals were highly plastic, with afferent terminals undergoing frequent growth and regression, as well as both Merkel cells and terminal branches being added or removed. Plasticity of Merkel cells and terminal neurites was positively correlated, but almost every time-lapse session had a higher percentage of neurites displaying plasticity than Merkel cells. Surprisingly, there were many datapoints where terminal neurites displayed plasticity even though Merkel cells were stable. Analysis of the temporal trajectories of plasticity in neuronal terminals and Merkel cells showed that plasticity occurs in phases with afferents going through periods of active remodeling and periods of quiescence. Ongoing analyses will test whether there are any biological factors that relate to temporal profiles of plasticity.
Using the TrkC-tdTomato reporter allowed us to visualize the entire extent of afferent terminals, where previous studies using Neurofilament Heavy antibodies only label the intermediate filament cytoskeleton. This reporter revealed two morphologically distinct types of axonal terminals that make apparent contacts with Merkel cells. The canonical Merkel-cell contact, which we term a kylix, cups the majority of the Merkel cell from underneath. A subset of endings lack this cup and instead appear to contact Merkel cells with a modest swelling; we term these boutons. We show that kylikes form long-lasting connections with Merkel cells while boutons are more transient. Ongoing analyses will test whether there is a defined trajectory, similar to development, in which branches grow out into boutons before becoming full kylikes.

Title: Cutaneous nerves depend on their target for proper innervation pattern in a time-dependent fashion

Authors: K. REJENT[1], W. R. GHERMAN[2], P. W. FRANK[3], *D. R. GIOVANNUCCI[2], A. MAKLAD[2];
[1]Neurosciences, [2]Neurosciences & Med. Educ., [3]Med. Educ., Univ. of Toledo Col. of Med. & Life Sci., Toledo, OH

Abstract: The current study was designed to address the question of whether a normal target is required to provide the necessary cues for a proper innervation pattern. The spontaneous mutation of the skin in nude mice that lack hair and exhibit defective formation of hair follicles

provides an excellent experimental model to test for defective targeting for cutaneous nerves. The innervation of skin in normal and nude mice was compared using three areas of the skin: dorsal skin, paw skin, and the skin of the snout. To label all populations of nerves, pan-neuronal markers such as monoclonal anti-acetylated tubulin, polyclonal anti-PGP 9.5 and anti-neurofilament were used to label nerve fibers. In addition, rabbit polyclonal anti-keratin14 was used to label keratinocytes of the hair follicle and surface epidermis in double labeling experiments. The patterns of the cutaneous nerves were disrupted in the dorsal skin in the nude mice with complete loss of the normal plexiform arrangement shown in normal mice. Innervation patterns of the paw skin and snout were normal in nude mice. We concluded that normal hair, and hair follicles are required for normal cutaneous nerve plexus formation in the skin. To address whether a normal target can correct the innervation errors of nude skin, normal skin was grafted on the dorsal interscapular region of nude mice. Analysis of innervation patterns of grafted skin after three weeks suggested that grafting normal skin in adult nude mice cannot recapitulate the patterns achieved during normal development.

Title: Plasticity of feed-forward pathways during whisker dependent sensory association training

Authors: *J. A. CHRISTIAN, E. PARK, A. L. BARTH;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Sensory responses are constructed from the interaction of both feed-forward sensory input as well as feedback information from the thalamus and other cortical areas. Previous work has shown that feedback pathways, including input from higher-order thalamic areas, are potentiated during sensory learning (Audette et al., 2018; Pardi et al., 2020), but it remains unknown how learning influences feedforward pathways in primary sensory cortex. Here we evaluated changes in synaptic strength from layer 4 (L4), the main input layer of the cortex, onto L2/3 pyramidal neurons during sensory association training in a whisker-dependent learning task (Bernhard et al., 2020). Because prior studies have shown that L4 to L2/3 synapses can be potentiated both in vivo and in vitro by whisker stimulation (Gambino and Holtmaat, 2012; Williams and Holtmaat, 2019), we predicted that sensory learning in a whisker-dependent association task would be associated with a significant increase in L4 input to L2/3 pyramidal neurons. Using the L4-restricted Scnn1a-Cre transgenic mouse for cell-type specific ChR2

expression, we evaluated changes in the strength L4 inputs across the learning trajectory. Surprisingly, we found that sensory association training did not potentiate L4 inputs onto L2/3 pyramidal neurons, despite robust synaptic plasticity at other cortical synapses. Based on these data, we hypothesize that sensory learning does not augment feedforward sensory inputs. Previously defined increases in synaptic strength from higher-order thalamic inputs (Audette et al., 2019) suggests that feedback pathways, but not feed-forward pathways, may be selectively enhanced during learning.

Title: Assessment of texture representation in the rat primary somatosensory cortex using deep learning

Authors: *K. YAMASHIRO[1], Y. IKEGAYA[1,2], N. MATSUMOTO[1];
[1]Grad Sch. Pharma Sci, Univ. Tokyo, Tokyo, Japan; [2]Inst. for AI and Beyond, Tokyo, Japan

Abstract: In this study, we took a deep-learning-based approach to decode complex tactile information from neuronal activity of a rat. Texture of a surface is high-dimensionally encoded in the somatosensory cortex (S1) and cannot be decoded from activity of a single neuron. Therefore, we focused on the local field potentials (LFPs), which collectively reflect the synaptic activity of thousands of neurons. To record neural activities from a wide region of the S1, we designed a novel 32-channel electrode array. The electrode array was implanted on the right primary somatosensory cortex, specifically including forelimb (S1FL) and hindlimb (S1HL) regions and was lowered to the depth of cortical layers 2/3. Then the animal was placed in an open field chamber (90 x 90 cm) with two different floor textures in either “dark” or in “light” conditions. LFPs were continuously recorded while the rat explored the field. All the electrophysiological data were collected under free-moving conditions at a sampling rate of 2 kHz. For classification, the channels that successfully recorded LFPs were selected for each rat. A convolutional neural network (CNN) model was used to classify the LFPs, and the score was evaluated using *k*-fold cross-validation ($k = 5$). Data were separated into 2-second bins and were predicted for each bin. From the LFPs in the “light” condition, our CNN model yielded average

classification accuracy up to 0.72. Further analysis will reveal how experiencing “dark” condition affects the representations of the floor textures.

Title: Behavioral and neural bases of tactile shape discrimination learning in head-fixed mice

Authors: *J. KIM[1], A. ERSKINE[1], J. CHEUNG[1], S. A. HIRES[2];
[2]Biol. Sci., [1]USC, Los Angeles, CA

Abstract: Tactile object recognition is an active behavior that requires both the perception of three-dimensional object shape and the association of its meaning through learning. The primary element that defines three-dimensional shape is object surface angle. Thus, we investigated how object surface angles are represented in the brain, how this representation is constructed from sensory inputs, and how it reorganizes across learning. Head-fixed mice learned to discriminate object surface angles by active exploration with one whisker. Two-photon calcium imaging of excitatory neurons in layers 2-4 of barrel cortex revealed maps of object-angle tuning before and after learning. Three-dimensional whisker tracking and mathematical modelling demonstrated that the sensory input components that best discriminate angle (vertical bending and slide distance) also have the greatest influence on object-angle tuning. This match between behavioral component and neural component suggests efficient encoding scheme of object shape in primary somatosensory cortex. To investigate how learning influences the representation of object surface angles, we compared response patterns of the same set of neurons before and after learning. About 40% of active neurons in naïve sessions became silent in expert sessions, and vice versa. Despite this high activity turnover rate, both the population distribution of object-angle preferences and individual preferences remained stable after learning. Object angle discrimination learning did not involve changes in motor strategy or sensory inputs. However, population activity pattern became better at discriminating object surface angles after learning. These results show how discrimination training enhances stimulus selectivity in the primary somatosensory cortex while maintaining perceptual stability.

Title: Effect of multidigit scanning on tactile discrimination

Authors: M. DIONE, H. DAUMAS, *R. ACKERLEY;
Lab. de Neurosciences Cognitives UMR7291, CNRS - Aix-Marseille Univ., Marseille, France

Abstract: Intensive synchronous multidigit tactile training, for example when reading Braille with several fingers or playing a music instrument, typically leads to experience-dependent

changes both at behavioral and cortical levels. At a behavioral level, tactile sensitivity and static spatial acuity are improved for the fingers stimulated conjointly during training. However, a tendency to confuse which finger is touched by a light tactile stimulus (mislocalization) has also been observed. At a cortical level, changes have been observed in the primary somatosensory cortex. The cortical representations of the trained fingers enlarge, superimpose, merge and reorganize in a way that does not respect the somatotopy. Reorganization at a cortical level has been linked to the mislocalization phenomenon. It is unclear how these changes affect tactile discrimination capacities, especially when considering dynamic tasks such as Braille reading. How do we reconcile multidigit Braille reading with mislocalizations? Is there an advantage in using multiple fingers to process tactile information or are the changes observed side effects disadvantageous for the performance? In the present study, to begin addressing those questions, we evaluated the tactile discrimination abilities of non-expert participants (N = 21) on a dynamic active task of tactile discrimination (gratings composed of parallel lines with different inter-band spacing) using one or several fingers (index, middle, ring). Tactile sensitivity and mislocalizations were evaluated before, after and in between the blocks of the discrimination task. Synchronous multidigit tactile experience (SMTE) was characterized using a questionnaire adapted from Guest et al. (2014). Results revealed that discrimination abilities were better with the index or the middle finger, compared to the ring finger in the unidigit blocks. The multidigit performance was as good as with the best finger. Mislocalizations tended to increase after the multidigit block, with the middle finger named more than the other fingers. This suggests that the mechanisms described earlier may have been initiated while performing the task with several fingers. Tactile sensitivity was not affected by the task. Finally, the participants with more SMTE had lower multidigit discrimination abilities. Altogether, our results support an equivalence rather than a disadvantage in using multidigit scanning strategies to process tactile information. However, SMTE may be disadvantageous to multidigit scanning discrimination. Further studies, including Braille readers or musicians are needed to confirm the latter result.

Title: Corticomuscular coherence during upright standing in unilateral transfemoral amputees

Authors: *C. PASLUOSTA[1], B. MEYER[1], T. KRAUSKOPF[1], K. FUCHS[1], T. BALL[2], M. MUELLER[3], L. KLEIN[2], G. W. HERGET[2], T. STIEGLITZ[1];
[1]Lab. for Biomed. Microtechnology, IMTEK-Dept Microsystems Eng, Univ. of Freiburg, Freiburg, Germany; [2]Universtity Med. Ctr. Freiburg, Freiburg, Germany; [3]Sanitaetshaus Pfaender, Freiburg, Germany

Abstract: Restoring sensory feedback by electrically stimulating nerve pathways improves balance and locomotion in lower limb amputees. Yet, bidirectional prostheses for the lower limb fail to completely restore function and sensory feedback. We argue that a major drawback in the advancement toward near-natural limb function restoral is our insufficient understanding of the structural and neurophysiological alterations that occur post-amputation. These neuromuscular adaptations occur to cope with a disrupted feedback system, loss of mechanical degrees of freedom and psychophysical alterations. Thus, quantifying these adaptations by objective measures may improve the design of stimulation paradigms to restore sensory feedback in amputees. In this work, we investigated corticomuscular coupling (CMC) during quiet standing to study adaptations in the driving neural mechanisms behind balance control in lower limb amputees. Ten patients with a unilateral transfemoral amputation and ten age-matched able-bodied control subjects were recruited. 32-channel electroencephalographic (EEG) recordings and electromyographic (EMG) data from the trunk and from the intact/dominant lower limb muscles were collected during quiet standing. Participants performed five 30-second trials with eyes open, eyes closed and while performing dual task. Data were band-pass filtered from 1 Hz to 100 Hz, notch filtered around 50 Hz and downsampled to 250 Hz. Large artefacts within the EEG data were removed by subtracting the artefact components from the original signal using wavelet transform. Further artefacts in the EEG data were removed through independent component analysis, after re-referencing the EEG data to a common average reference. To asses CMC, a multivariate autoregressive (MVAR) model was fitted, from which the normalized partial directed coherence (nPDC) was computed using the in Matlab implemented toolbox SIFT. We focused on CMC in the alpha, beta and gamma frequency ranges. Further, nPDC provides a measurement of the strength of the corticomuscular coupling as well as the direction of the coupling. This made it possible to investigate sensory feedback loops that occur during the control of posture. We observed distinct differences in coherence between the group of amputees and controls for the efferent and the afferent directions. Distinct differences in coherence were also observed between the afferent and the efferent direction within the group of amputees. Results are discussed in the context of balance control to explain sensorimotor mechanisms possible disrupted by the amputation.

Title: Are phantom referred sensations a perceptual consequence of S1 remapping?

Authors: *E. AMORUSO[1], D. B. TERHUNE[2], M. KROMM[1], D.-A. MURET[1], T. R. MAKIN[1]; [1]Univ. Col. London, London, United Kingdom; [2]Goldsmiths, Univ. of London, London, United Kingdom

Abstract: Seminal studies (Ramachandran et al., 1992, *Science;* Ramachandran et al., 1993, *PNAS)* have shown that touches on the face can evoke topographically organized sensations on the phantom hand in some amputees (referred sensations). This striking phenomenon has been classically operationalized as the perceptual correlate of the cortical remapping of the face onto the neighboring missing-hand territory in the primary somatosensory cortex (S1). Here, we investigate whether reports of referred sensations can be, at least partially, influenced by previously uncontrolled experimental factors, such as demand characteristics and suggestibility (Lush et al., 2020, *Nature Communications*). Unilateral upper-limb amputees (N=17), congenital one-handers (N=19), and able-bodied controls (N=20) were repeatedly stimulated with PC-controlled vibrations on several body-parts. They were asked to report on each trial the occurrence of any dual sensation on the hand(s) (including the phantom in amputees). Before the experiment, participants were told that they would receive 'special' vibrations (found to be able to evoke dual sensations) intermixed with 'classical' vibrations. Results show that manipulating expectations about the occurrence of the phenomenon was sufficient to induce a significant amount of referred sensations in all groups. Crucially, referred sensations reports were not more frequent in amputees than in the other groups and did not occur more often following stimulation of the face or body-parts ipsilateral to the missing hand. Together, these findings generally weaken the hypothesis that referred sensations are a behavioural consequence of post-amputation S1 remapping.

Title: Fast grip force adjustment to friction relies on localized fingerpad strains

Authors: *B. DELHAYE[1], F. SCHILTZ[2], F. CREVECOEUR[3], J.-L. THONNARD[4], P. LEFEVRE[5];
[1]Univ. catholique de Louvain, Woluwe-saint-Lambert, Belgium; [2]Univ. catholique de Louvain, Brussels, Belgium; [3]Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium; [4]Univ. Catholique De Louvain, Brussels, Belgium; [5]ICTEAM and Inst. of Neuroscience, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: When lifting objects of different mass or surface, humans adjust the grip force applied to the object such that the amount of force is minimal. In particular, it has been shown that, after changing the friction of the object-skin interface, humans can quickly adjust their grip force such that a slippery surface is squeezed more firmly than a sticky surface. To perform this adjustment, the central nervous system relies on the feedback from the mechanoreceptive afferents innervating the fingertip skin at or near the contact surface with the object. These tactile afferents encode information related to skin deformation and therefore the nature of the feedback signaling a change in friction must somehow originate from a difference in the way the skin deforms when contacting and interacting with objects of different friction.
To better understand the nature of this tactile feedback, we asked human participants to perform a grip-lifting task with a manipulandum equipped with an optical imaging system. This system enabled recording images of the fingertip-object contact and monitoring the time-varying skin deformations through transparent plates of glass. The plates had different levels of friction and were interchanged unexpectedly between blocks of 5 trials.
We observed that, following a change in friction, participants adjusted the level of grip force accordingly within 370ms after contact with the surface. By comparing the deformation patterns when switching from a high to a low friction condition, we found a significant increase in skin deformation inside the contact area, resulting from significantly larger partial slips. This increase became significant more than 100ms before the adjustment of grip force in response to changes in friction, suggesting that local and partial deformation patterns before lift-off are used by the central nervous system to adjust the grip force as a function of the frictional condition.

Title: How drops of water are encoded and perceived by humans

Authors: *L. SAMAIN-AUPIC, M. DIONE, J.-M. AIMONETTI, R. H. WATKINS, R. ACKERLEY;
Lab. de Neurosciences Cognitives - UMR 7291, Aix-Marseille Univ. - CNRS, Marseille, France

Abstract: We have receptors in our skin that allow us to sense and interact with liquids in our environment, for example, changing our grip force on a wet object so that it does not slip or for determining if it is raining. As humans do not have hygroreceptors, wetness perception relies on the integration of tactile information conveyed by low-threshold mechanoreceptors and/or temperature information conveyed by thermoreceptors. Here, we investigated how participants perceived drops of water at room temperature, by modulating the height and the mass of a drop. This acuity was tested on 20 healthy young adults using 5 drops of different masses (10, 20, 25, 40, and 50mg) or by applying the same mass of drop, but at 4 different heights (6, 12, 18, and 24 cm). The drops were applied to the palm of the hand using 1 ml syringes with different end attachments and the skin was dried between drops. For the drop mass task, participants had to compare 48 pairs of drops with one reference on each pair and had to say which one was more intense. Furthermore, in a different task, they were asked to estimate the intensity of 60 single drops of water using an unbounded scale. In the drop height task, they were asked to do the same, but estimate the intensity on 48 drops released at 4 different heights. In addition, we tested tactile sensitivity (calibrated monofilaments) and cool/warm thermal perception (QST, France) of the same skin, to compare tactile and thermal sensitivity to the perception of drops of water. We showed, with psychometric measures that the minimum difference for perceiving a difference in drop mass is 9.2mg. The second task showed that the participant needed a drop mass between 5-10 mg to perceive a difference. The height task showed that the drop intensity was perceived to increase with height. We also investigated how and which mechanoreceptors are activated by a drop of water with microneurography. We inserted a microelectrode in the median nerve of healthy participants in order to locate and stimulate mechanoreceptors. For each single afferent identified, we released 10 drops of water at room temperature 5 cm above the receptive field of the unit. Our preliminary results showed that only fast-adapting type II (Pacinian) mechanoreceptive afferents are activated following drops of water. In conclusion, there exists very little in the literature concerning our perception of wetness and we presently show that humans are able to discriminate very well between different intensities of sensation provided by changing the mass and height of drops of water. Moreover, we the perception of these drops of water seems to be encoded mainly by Pacinian mechanoreceptors.

Title: Exploring the C. elegans response to plant-derived compounds salvinorin A and analogs

Authors: *T. A. LOGAN-GARBISCH[1], S. GUHA[4], E. FRYER[6], L. ROGEL[4], E. REZAEI[4], I. MOLLHOFF[5], A. NEKIMKEN[4], A. XU[6], S. FECHNER[4], A. DAS[4], J. CASAR[4], H. FARAH[4], L. A. O'CONNELL[2], S. DRUCKMANN[2], T. R. CLANDININ[3], S. Y. RHEE[6], M. B. GOODMAN[1]; [1]Mol. and Cell. Physiol., [3]Neurobio., [2]Stanford Univ., Stanford, CA; [4]Mol. and Cell. Physiol., [5]Biol., Stanford, Stanford, CA; [6]Carnegie Inst. for Sci., Stanford, CA

Abstract: Plants and animals have co-evolved over millions of years, which has provided tools to the immobile plants in the form of chemical compounds that affect animal behavior. Additionally, humans have traditionally cultivated plants for both food and medicinal purposes, allowing for changes in relative abundance of the plants themselves as well as alterations in the amounts of specific chemicals (e.g. capsaicin content in peppers). *Salvia divinorum*, or diviner's sage, is a cultivated, clonal plant with psychoactive properties (hallucination, pain relief) in humans, known to act primarily via ***K***;-opiod receptors binding the terpenoid salvinorin A. However, *Salvia divinorum* didn't evolve to relieve pain in humans, and we know much less about its mechanism of action in non-mammalian animals. We are exploring the chemotactic responses of *C. elegans* nematodes to salvinorin A and several analogs, as well as beginning to categorize the neurons that might detect these compounds. We focused on the use of chemotaxis behavioral assays to determine attraction, repulsion, or indifference to plant-derived compounds, assessing wild-type (N2) animals alone, or N2 and mutant animals together. We conducted these behavioral assays with a minimum of three independent trial replicates, targeting a sample size of 150-300 worms per trial. We use solvent as the compound control (DMSO or water), and for larger screens, we also used known chemical attractants and repellents as reference compounds. Our team developed automated image analysis code to determine the positions of the worms along a chemical gradient and used that information to compute a standard chemotaxis index; genotype and compound remained masked until we completed data analysis. We used day 1 adult hermaphrodites reared in standard conditions for this study. So far, we have discovered that salvinorin A acts as a chemoattractant to wild-type (N2) animals, and preliminary data suggest

that all 3 analogs tested do as well. Interestingly, the salvinorin A response is mediated through two sets of chemosensory neurons: tax-4 expressing neurons and osm-9 expressing neurons, which are mutually exclusive categories. This suggests that in *C. elegans*, there is at least one, (and possibly more than one) receptor responding to salvinorin A which is certainly not a ***K***;-opiod receptor. We are currently exploring the response to the analogs in more depth, and we plan to genetically dissect which specific chemosensory neurons are involved in the detection of salvinorin A for our immediate next steps. Our data provide some intriguing insights into an invertebrate response to salvinorin A and its analogs.

Title: Mechanism for the munchies: endocannabinoid modulation of food preferences in C. elegans

Authors: *A. LEVICHEV, S. FAUMONT, R. Z. BERNER, S. R. LOCKERY;
Univ. of Oregon, Eugene, OR

Abstract: The mammalian endocannabinoid system, which is comprised of cannabinoid receptors CB1 and CB2 and their endogenous ligands, is thought to integrate internal energy state and sensory food cues to modulate feeding. For example, cannabinoids acting on CB1 can increase preference for more palatable, calorically dense food: a response called *hedonic amplification*, colloquially known as “the munchies.” In mammals, cannabinoids can increase sensitivity to odors and sweet tastes, which may underlie hedonic amplification. We are developing *C. elegans*, an omnivorous bacterivore, as a model in which to investigate the neurophysiology of hedonic amplification. We have found that exposure to N-arachidonoyl-ethanolamine (AEA), an endogenous cannabinoid common to both mammals and *C. elegans*, increases the worms’ preference for more palatable bacteria over less palatable bacteria, mimicking hedonic amplification in mammals. Furthermore, AEA acts bidirectionally, increasing consumption of more palatable bacteria while decreasing consumption of less

palatable bacteria. We also found that deletion of the CB1 ortholog, *npr-19*, eliminates hedonic amplification, which can be rescued by expression of the human CB1, establishing a humanized worm for cannabinoid signaling studies. Deletion of the olfactory neuron AWC, which directs chemotaxis to food, abolishes hedonic amplification. Consistent with this finding, calcium imaging revealed that AEA bidirectional modulates AWC activity, increasing its responses to more palatable food and decreasing its response to less palatable food. However, GFP expression analysis revealed that *npr-19* is expressed ~21 neuron classes but, surprisingly, not in AWC. Although AEA's effect could be mediated by NPR-19-expressing neurons presynaptic to AWC, nearly complete elimination of fast synaptic transmission, via the mutation *unc-13(e51)*, has no effect on modulation. Instead, AEA's effect on AWC is mediated via *unc-31*-dependent dense-core vesicle release. We are now attempting to disambiguate the other neurons involved in AEA's effect on AWC and the worms' feeding preferences.

Title: Novelty detection in early olfactory processing of the honey bee, Apis mellifera

Authors: *H. LEI[1], S. HANEY[2], C. M. JERNIGAN[3], X. GUO[4], C. N. COOK[5], M. V. BAZHENOV[6], B. H. SMITH[1];
[1]Arizona State Univ., Tempe, AZ; [2]Med., UCSD, La Jolla, CA; [3]Dept. of Neurobio., Cornell Univ., Ithaca, NY; [4]Inst. of Zoology, Chinese Acad. of Sci., Beijing, China; [5]Marquette Univ., Milwaukee, WI; [6]Dept. of Med., Univ. of California San Diego, La Jolla, CA

Abstract: Animals are constantly bombarded with stimuli, which presents a fundamental problem of distinguishing between pervasive uninformative stimuli and novel, possibly meaningful stimuli. Novelty and familiarity are commonly thought as percepts produced at higher-order synaptic levels such as the mushroom bodies of insects. We took a multidisciplinary approach to test the hypothesis that novelty and familiarity are already present in early signal processing stages. We first verified that bees respond with different behavior to novel and familiar odors. Using a video tracking software (SwarmSight), we evaluated novelty detection behaviorally in honey bees as they position their antennae differentially in an air stream carrying familiar or novel odors. Upon stimulation of the antennae of naïve bees, the bees moved their

antennae to a position lateral to the head and perpendicular to the airflow. The bees resumed movement of the antennae when odor delivery was terminated. After familiarization to one odor, stimulation with a novel odor led bees to maintain the lateral position well beyond odor delivery, which is the basis for novelty detection in our study. Bees failed to show this pattern to the familiar odor. We then used a multiunit recording method (TDT RZ2) to characterize neuronal responses to familiar and novel odors in the first synaptic relay in the brain - the antennal lobes. We found that the neurons that exhibited stronger initial responses to the odor that was to be familiarized are the same units that later distinguish familiar and novel odors. These units, including both projection neurons and local interneurons, showed a decreased response to the familiar odor but an increased response to the novel odor. In summary, our results suggest that the antennal lobe may assign a category of familiarity or novelty to an odor stimulus in addition to its chemical identity code. Therefore, the mechanisms for novelty detection may be present in early sensory processing, either as a result of local synaptic interaction or via feedback from higher brain centers.

Title: Encoding and control of odor value by Drosophila dopamine neurons

Authors: *A. KATO, H. KAZAMA;
RIKEN Ctr. for Brain Sci., Saitama, Japan

Abstract: Animals behave based on the value of sensory cues, which is constantly re-evaluated through experiences. Such adaptive behavior depends on dopaminergic neurons (DANs), whose activity has been most extensively studied in the context of associative learning. Specifically, DANs respond to an unconditioned stimulus (US) and later to a conditioned stimulus (CS) through learning. However, because some commonly used CS including odors has innate value, DANs may respond to CS and drive plasticity outside the context of associative learning. Here, we addressed whether DANs represent innate value of odors and induce neural and behavioral plasticity in a purely olfactory environment using Drosophila whose brain structure allows us to comprehensively characterize DANs. We focused on DANs innervating the mushroom body (MB) where olfactory information is modulated by reward or punishment. The MB comprises 15

compartments each of which receives input from a distinct type of DANs and provides a place for synaptic plasticity underlying learning. We performed in vivo two-photon Ca2+ imaging in a fly expressing GCaMP6f in the entire DANs innervating the MB. We recorded responses of DANs to 27 odors with a wide range of innate odor values, which were quantified based on the behavior of flies navigating in a virtual flight arena (Badel et al., 2016). We found that DANs in specific compartments differentially respond to odors with positive and negative values. Regression analysis showed that information about odor values can be decoded from the activity of a population of DANs. Because we found that odors alone can activate both olfactory and DAN pathways, moment-to-moment adaptive changes in the downstream MB neurons and behavior may take place. To test this hypothesis, we asked whether repetitive application of odors was sufficient to induce neural plasticity and indeed observed that the neural activity of MB output neurons showed plastic changes in an odor value-dependent manner. Finally, we are investigating if flies navigating in an olfactory environment exhibit DAN-dependent, online adaptive changes in behavior. In sum, our results highlight a novel role of DANs in driving odor value-based, non-associative control of neural circuits and behavior.

Title: Sensorimotor transformations underlying odor-guided locomotion in Drosophila

Authors: *L. TAO[1], S. OZARKAR[2], V. BHANDAWAT[1];
[1]Drexel Univ., Philadelphia, PA; [2]UNC Chapel Hill, Chapel Hill, NC

Abstract: The ability to flexibly modulate essential behaviors, such as locomotive food search, using sensory information is crucial to the survival of animals. The *Drosophila* olfactory system is an excellent model organism to study the role of sensory processing on behaviors due to its simplicity, the availability of genetic tools, and because odors have a marked effect on its locomotion. While much is known about the structural connectivity of the early olfactory circuit in flies, how the signals from ORNs modulate locomotion and the mechanisms by which these ORNs interact to perform this modulation are still being actively studied. In particular, while olfaction alone in the absence of directional cues such as wind has been shown to be sufficient in

eliciting broad changes in locomotion based on binary activation of ORNs, how moment by moment changes in ORN activity modulates locomotion is not well understood. Here, we investigate how optogenetic activation of precise subsets of ORNs that are activated by apple cider vinegar (an attractive odor) causes changes in locomotion in freely walking flies. Using electrophysiology, computational, and agent-based modeling, we developed a framework to capture the sensorimotor transformation from ORN activity to locomotion. We first show that both the firing rate (f) and change in firing rate (df) are necessary to describe the dynamics of the ORN response. We then show that the locomotor behavior of the fly is well described by four locomotor states (sharp turns, curved walks, stops, and boundary) each parameterized by kinematics such as speed and curvature. For any given ORN, there is a probabilistic mapping between the locomotor state kinematics and ORN activity in the f-df space. Using this framework, we show simple rules of combination between the f-df space of different ORNs. In addition to kinematics, we show that large temporal changes in ORN activity give flies a sense of their orientation relative to the stimulus and cause flies to stop walking and start turning. Based on these results, we develop an agent-based model of *Drosophila* locomotion that was able to capture much of the spatial-temporal distribution of experimental flies in our arena. These results provide insight into both sensorimotor transformations underlying olfactory locomotion and how this transformation is integrated across olfactory inputs.

Title: Active olfactomotor responses in head-fixed mice

Authors: *I. CULLEN[1], A. RANDHAWA[2], D. YEH[3], J. ACOSTA-KING[6], A. WELCH[3], A. SINGH BALA[4], M. SMEAR[5];
[1]Inst. of Neurosci., Univ. of Oregon, Robert D. Clark Honors Col., Eugene, OR; [2]Biomed. Engin., Univ. of Texas at Dallas, Dallas, TX; [3]Inst. of Neurosci., [4]Inst. of Neuroscience, Biol. Department, and Knight Campus for Accelerated Scientific Impact, [5]Inst. of Neuroscience, Dept. of Psychology, Univ. of Oregon, Eugene, OR; [6]Dept. of Neurol., Yale Univ., New Haven, CT

Abstract: Olfactomotor responses are respiratory, orofacial, and locomotive movements for sampling and reacting to odors (Rabell et al. 2017, Kurnikova, Deschênes, and Kleinfeld 2019, Findley et al. 2020, Johnson et al 2003, Wesson et al 2008, Jones and Urban 2018). Altered sensory sampling behaviors, such as eye movement, temperature insensitivity, and pain insensitivity, have been identified in individuals with Autism Spectrum Disorder (ASD). In addition, Rozenkrantz et al. (2015) showed that olfactomotor behavior is affected in children with ASD. These children do not modulate sniffing behavior to aversive odors despite correctly identifying odors as unpleasant, suggesting an altered unconscious motor response. To investigate the neural mechanisms underlying olfactomotor sampling, we investigated respiratory and orofacial responses to odor using wildtype mice. Wildtype mice are exposed to 2-phenylethanol (attractive odor), 2-methylbutyric acid (aversive odor), alpha- pinene (neutral odor), or clear air in the course of a behavioral session. We record respiration with an intranasal thermistor, and track orofacial movements using DeepLabCut. Our preliminary results in wildtype mice (n=2) suggest that mice alter their sniffing and nose movement in response to odor stimuli. This work will shed light on active olfaction and help us understand more about naturalistic olfactomotor behaviors.

Title: Understanding the neuronal substrates of sensorimotor transformations via a novel closed-loop olfactory task for mice

Authors: *M. DUSSAUZE, P. GUPTA, U. LIVNEH, D. ALBEANU;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Throughout life, via repeated experience of the closed-loop relationship between sensory inputs and movements, the brain builds sensorimotor models that predict the sensory consequences of its own actions (von Helmholtz, 1867; Craik, 1947; Barlow 1961). As such, perception can be thought of as the continuous comparison of expected (sensorimotor predictions) and actual sensory inputs. This process generates prediction errors that can be minimized by learning increasingly accurate models of the world. While odorant sampling (sniffing) is tightly coupled to motor actions (head and body movements), to date, it remains

unknown how olfactory representations are regulated by motor signals and whether such control supports sensorimotor predictions. To investigate the neural substrates of sensorimotor predictions both at behavioral and circuit-level, we established a novel closed-loop olfactory task (*Smellocator*) where head-fixed mice are trained to steer the left-right location of an odorant source by controlling a light lever with their forepaws. In this task, mice learn to link motor action to well-defined sensory expectations (odor location). Mice master the task quickly (~2 weeks, >90% accuracy), perform numerous trials per session (500-700) and show precise movements that are locked to the instantaneous sensory (odor) feedback. In expert animals, we violate these learnt sensorimotor expectations by transiently decoupling the stimulus from the current action (open-loop replay, halting of odor source, changing the gain), thus creating sensorimotor prediction errors (mismatches) **(**Schneider et al, 2014; Keller and Mrsic-Flogel, 2018). Additionally, across longer timescales (blocks of trials), we modulate the sensorimotor mapping (direction), so as to trigger updates in the animal's internal model and engage sensorimotor adaptation. Strikingly, mice readily counter these sensorimotor errors and re-center the odor via precise corrective movements which provide a behavioral read-out of the animal's internal model. To understand the sensorimotor transformations which enable this behavior, we have started monitoring neural activity in the olfactory cortex (Anterior Olfactory Nucleus and Piriform Cortex) using chronically implanted tetrode micro-drives.

Abstract: The human auditory pathway displays a robust capacity to adapt to sudden changes in the statistics of an auditory scene, an ability that helps in many real-world scenarios, such as

tracking a conversation while walking through a door from a street to a loud restaurant. Previous work has demonstrated that the auditory cortex rapidly suppresses new acoustic features arising from unexpected background noise changes. While this neural ability has been identified and characterized, its mechanism is not well understood due to the difficulty of interpreting such a nonlinear behavior. In order to understand how the brain achieves this adaptation, an important first step is to identify the simplest model that can still mimic the brain's behavior. Traditional linear models such as the spectro-temporal receptive field (STRF) are highly interpretable, due to their linearity, but fail to capture the nonlinear dynamics of neural adaptation. To overcome this limitation, we employ recent advances in a certain class of deep neural network models (DNN). These models have greatly improved capacity to learn nonlinear transformations and can be easily interpreted as dynamic STRFs (DSTRF), since a linear equivalent function to the DNN can be found for each stimulus instance. This provides a means of interpreting the nonlinear operations of the network as stimulus-dependent linear functions. In this study, we recorded intracranial EEG (iEEG) from neurosurgical patients who were asked to attend to speech overlaid on background noise that kept changing between several categories. We first demonstrate that a DNN trained to predict neural responses can produce the same rapid adaptation phenomenon as the auditory cortex significantly better than a linear STRF model. Additionally, this model can replicate a more complex phenomenon arising from adaptation, where phoneme discrimination momentarily drops and background noise encoding increases following a noise change, after which noise information is suppressed and phoneme discrimination is restored. Using the equivalent piecewise linear function of the DNN model, we analyze the computations performed by these models and show that some neural regions react to a sudden change in background noise by altering their filters to deal with the new sound statistics. By looking at how these filters change over time particularly when adapting to a new background noise, we provide evidence that can explain how the brain adapts to changing noise conditions. Hence, we show that modeling the auditory cortex with deep neural networks can help us understand the neural computations that underlie noise-robust speech perception in real-world environments.

Title: Coding of two-tone harmonic complexes by excitatory and inhibitory neurons in the mouse auditory cortex

Authors: D. MANDAL[1], A. DE[1], *S. AGARWALLA[2], S. BANDYOPADHYAY[1];
[1]IIT Kharagpur, Kharagpur, India; [2]ELECTRONICS AND ELECTRICAL COMMUNICATION ENGINEERING, INDIAN INSTITUTE OF TECHNOLOGY, KHARAGPUR, India

Abstract: Two-tone harmonic complexes (TTHC) are a common syllable type in mouse vocalization, especially in the context of courtship. Differences in the representations of each of the component tones (F_0 and F_1, fundamental and the first harmonic) and the TTHC in AC neurons would help us understand how a unified percept may form from two simultaneously presented component stimuli. Further, underlying mechanisms in such binding can be better understood from differential representation of TTHC and tones in excitatory and inhibitory neurons (EXNs and INNs) neurons as well as from the EX-EX and IN-IN network modulation by such stimuli. In the current study we first used widefield fluorescence imaging, through a cranial window, in mice expressing GCaMP6f either in Thy-1 positive EXNs or in specific INNs to first localize the primary AC (A1) using pure tone stimuli. Next with widefield imaging of responses to TTHC and responses to corresponding component pure tones, regions within A1 were found to show higher selectivity to TTHCs compared to the summed response of component tones. To further investigate such harmonic selectivity in single neurons and properties of their micro-networks, chronic 2-photon Ca^{2+} imaging was performed in the same mice. We found that EXNs and INNs showed a variety of response properties with respect to the 3 stimuli, F_0, F_1 and the TTHC depending on the relative location of the F_0 and F_1 from the BF of neurons. In particular, we find higher normalized responses to TTHC in somatostatin (SST) positive INNs compared to EXNs near BF and not away from BF when neurons respond to all 3 stimuli. However, both EXNs and SOM INNs showed higher normalized responses to TTHCs away from BF when one of F_0 and F_1 did not elicit a response indicating nonlinear interactions. Similarly a large subpopulation of neurons also showed inhibitory effects of TTHC with no response to TTHC but moderate to strong responses to either or both F_0 and F_1. Further, EXNs showed higher noise correlations and SST INNs showed no change in noise correlations during TTHC presentation compared to that during tone presentation, indicating recurrent excitatory connections being involved in coding of TTHC. Thus we find a differential representation of TTHCs in EXNs and SST INNs and their local networks compared to that of component pure tones.

Abstract: Social species are able to quickly identify vocalizations and respond accordingly. This vocal communication requires the ability to categorize sounds into meaningful units. Due to their well described auditory system and large behaviorally relevant vocal repertoire, Zebra Finches are a great model organism to study categorization of species specific vocalizations. Using a wireless lightweight electrophysiological recording device, we recorded from primary and secondary auditory regions of awake and unrestrained zebra finches as they listened to playbacks of conspecific communication calls. We used decoding analyses to understand how well single neurons and neural ensembles represent behaviorally defined call types in auditory regions. We find that the activity of single units in secondary auditory regions do not contain enough information to decode semantic call categories. However, increasing the size of ensembles of neurons quickly increases decoder performance. This result supports a selective yet somewhat distributed code hypothesis, akin to results in primate studies (Chang L & Tsao DY 2017; M. Rigotti et al. 2013) in which individual cells are selective for features that do not correspond to particular calls (or categories), but together, neural ensembles very efficiently code for behaviorally relevant categories. Finally, using a novel hierarchical clustering based approach, we compare the neural population responses to the acoustic and semantic structure of the stimuli. We find that neural ensembles represent the semantic category of calls better than the acoustic features, implicating these brain regions in the sound to meaning transformation.

Title: Unsupervised learning of stimulus invariance of natural auditory stimuli via slow feature analysis

Authors: *R. DITULLIO[1], C. K. PARTHIBAN[1], E. PIASINI[1], V. BALASUBRAMANIAN[1], Y. E. COHEN[2];

Abstract: A fundamental goal of sensory systems is to extract sensory information from the environment and convert it into perceptual representations. Because the brain does not have enough resources to simply transduce and represent all of the information present in the environment, it must find a means to extract only the sensory information that is most relevant to the animal's survival; that is, sensory systems must perform feature selection. One way a sensory system could perform feature selection is to try to encode particular statistical regularities in the sensory environment. An important statistical regularity of natural auditory stimuli is that they tend to have low temporal modulation; i.e. the powers of the frequencies that comprises natural stimuli tend to change slowly over time. Despite their ubiquitous presence in natural auditory stimuli, it is unknown whether such slow temporal regularities are sufficient to enable learning and perception of auditory object classes.To test this idea, we adapted an unsupervised temporal learning algorithm, Slow Feature Analysis (SFA), to extract the auditory features that change most slowly over time (i.e., those having the lowest temporal variance). We then used this algorithm to computationally evaluate the hypothesis that extracting these slowly varying features will capture the variance inherent within a stimulus class and the variability that differentiates between stimulus classes. We tested this hypothesis by first learning a set of slow features from rhesus macaque vocalizations and then projecting these vocalizations into the learned feature space. We then instantiated a linear classifier to determine whether the projected stimuli are linearly separable. We found that (1) pairs of vocalizations in the SFA-generated feature space were linearly separable; (2) this feature space is robust to clutter (noise) in the training data set; (3) this feature space captures enough variability for the classification of novel exemplars; (4) classes of vocalizations tend to naturally cluster together in this feature space. Together, our results suggest that if the brain can extract the slow temporal features from auditory stimuli, it may be sufficient for and underlie important components of perception.

Title: Representation of mouse vocalizations across subdivisions of the inferior colliculus

Authors: *M. ATTARHAIE TEHRANI, S. J. SHANBHAG, R. PATEL, J. J. WENSTRUP; Dept. of Anat. and Neurobio., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Subdivisions of the inferior colliculus (IC) participate in several circuits that analyze social vocalizations. We explored the representation in IC subdivisions of both ultrasonic vocalizations (USVs) and several categories of non-USV, mostly broadband calls. We examined: 1) how responsiveness to different vocal categories relates to frequency tuning, 2) vocal selectivity beyond that related to frequency tuning, and 3) the distribution of vocal responses and frequency tuning across IC subdivisions. In head-fixed, urethane-anesthetized adult CBA/CaJ mice, we used multichannel probes to extracellularly record single- and multi-unit responses to acoustic stimuli. Frequency tuning and sound level responses were assessed using tones and broad band noise. We then obtained responses to pre-recorded syllables containing a broad range of spectral components. Most IC sites were tuned below 30 kHz, with differences across subdivisions. In the external IC, all sites were tuned below 30 kHz, while dorsal and central IC also contained tuning >30 kHz. Generally, IC sites responded to vocal signals with energy corresponding to their frequency response areas. Sites tuned below 20 kHz responded to the non-USV calls only: the LFH call (fundamental 4 kHz), MFV call (fundamental ~9-15 kHz), and Noisy call (broad band >15 kHz). Sites tuned to 30-40 kHz also responded to stepped USVs that contain frequencies below 50 kHz, but not to chevron or tonal USVs limited to frequencies above 55 kHz. Only high frequency sites (>55 kHz) responded to chevron or tonal USVs. However, several of these sites also responded to the non-USVs, due either to signal energy near the peak of high frequency tuning curves or associated with the tails of these tuning curves. Thus, responses to non-USVs were observed throughout IC, but USV responses were found mostly in higher frequency regions of the central IC. Further, the more complex spectrotemporal structures of stepped USVs and noisy calls were represented in temporal response patterns of some neurons within IC populations, including both excitatory and suppressive responses. These results indicate that information about a wide range of mouse vocal signals is present both in the lemniscal projection to auditory thalamus and in non-lemniscal circuits through the medial auditory thalamus to structures such as the amygdala. Future research will explore these representations in the higher order structures of the auditory thalamus and the cortex, as well as the amygdala. These findings in normal-hearing mice are key to evaluating changes in neural mechanisms underlying acoustic communication that occur in mouse models of impaired auditory perception.

Title: Simultaneous perturbation of fundamental and formant frequencies in auditory feedback of speech

Authors: *S. HIROYA, T. MOCHIDA;
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: In speech production, vocal cord vibration and vocal tract shape are controlled simultaneously. These are expressed by speech parameters called fundamental frequency (f0) and formant frequency, respectively. In order to verify the importance of auditory feedback in each parameter, an altered auditory feedback (AAF) experiment has been conducted, and it was found that a compensatory response to the perturbation occurred. However, in these experiments, the fundamental and formant frequencies were perturbed independently. Although auditory errors at the fundamental and formant frequencies can occur simultaneously in daily speech production, there have been few AAF experiments with these perturbations simultaneously. In this study, we investigate the compensatory response when both fundamental and formant frequencies are perturbed simultaneously during vowel production. Native Japanese speakers were participated in the experiments. They were instructed to repeat 140 Japanese syllable /he/ speech. Both fundamental and formant frequencies of speech sound are gradually shifted up to the maximum perturbations. The maximum amount of perturbation of fundamental and formant frequencies was decided based on the threshold of discrimination in the speech perception. The experiment was carried out under the conditions of raising both f0 and the first formant frequency (F1) or lowering f0 and raising F1. In this experiment, we used a phase equalization-based autoregressive exogenous (PEAR) model, which is a formant estimation algorithm that is robust to f0, and a pitch synchronous overlap and add (PSOLA), which is a f0 shift algorithm, to enable highly accurate perturbation. The experimental results showed that the compensatory response to f0 occurred irrespective of the coincidence mismatch in the perturbed direction of F1, but that to F1 is affected by the perturbation direction of f0. This suggests that the f0 error may have a greater impact on speech production than the formant frequency and that F1 control is affected by the f0 error. Therefore, the auditory feedback control mechanisms of f0 and formant frequencies may be different.

Title: Effect of novel acoustic environment on lateralized activity patterns and new neuron influx

Authors: *B. FUREST CATALDO[1], J. OVETSKY[2], P. DADIKA[2], M.-N. BROOKS[2], B. BLAIR-WHIATKER[2], D. S. VICARIO[3];
[1]Rutgers Univ. Behavioral and Systems Neurosci., Piscataway, NJ; [2]Rutgers Univ., Piscataway, NJ; [3]Rutgers The State Univ. of New Jersey, Piscataway, NJ

Abstract: Lateralization is widely studied to elucidate the functions that each hemisphere serves in the context of language perception and production. However, hemispheric asymmetries are not unique to humans or to language and may subserve many functions. Like humans, songbirds are vocal learners that also exhibit lateral differences during sensory and motor processing of communication signals. In addition, the introduction of new neurons in adulthood is lateralized in the higher auditory area NCM, and the degree of lateralization is correlated with the ability to form good copies of the birds' tutor song, which in turn depends on the ability to form a proper auditory representation/memory of the tutor song. Our laboratory has used electrophysiological recordings in adult Zebra finch NCM to show that activity in response to song playback is lateralized and that the asymmetry shifts in birds passively exposed to novel heterospecific auditory environments for extended periods (days to weeks). Furthermore, shifts in lateralization are associated with enhanced ability to discriminate between heterospecific sounds, suggesting that passive exposure can evoke dynamic changes in neural representations that subserve behavior. The current study has three Aims: 1) Determine the timecourse of dynamic shifts in lateralized activity in birds exposed to a heterospecific environment; 2) Explore whether exposure to a heterospecific environment changes the lateralized introduction of new neurons in NCM; and 3) Assess the correlation between shifts in lateralized activity and the influx of new neurons into NCM in the two hemispheres. To address Aim 1, Zebra finches were implanted with a custom epidural array that enables lateralized activity, measured as event related potentials (ERPs), to be assayed longitudinally in birds exposed to a novel heterospecific environment for extended periods. To address Aims 2 and 3, a separate cohort of Zebra finches was injected with BrdU, to label new cells, and exposed to the heterospecific environment. Then, lateralized NCM activity and new neuron influx were quantified after discrete exposure periods (9,14, or 30 days). The results confirm that lateralized activity transiently shifts in birds exposed to the heterospecific environment as a function of exposure period. Preliminary observations indicate that exposure to the heterospecific environment for different periods may transiently affect the lateralized bias for new neurons in NCM, compared to birds exposed to a control environment. Furthermore, the data suggests an inverse relationship between lateralized new neuron counts and lateralized electrophysiological activity.

Title: Encoding of changes in frequency for conspecific vocalizations in auditory core and belt areas of the common marmoset

Authors: *J. LEE, X. WANG;
Johns Hopkins Med. Institutions, Baltimore, MD

Abstract: In early stages of auditory processing, neurons faithfully encode acoustic features of sounds. As we move up the auditory pathway, the auditory system is thought to represent behaviorally relevant stimuli (e.g., species-specific vocalizations) in a manner that is invariant to differences or changes in their basic acoustic parameters when such differences fall within the range of natural stimuli. This invariance is believed to be the underlying mechanism for perceptual phenomena such as categorical perception or the perceptual magnet effect that have been documented in human speech perception (Kuhl 1991). Although there have been studies investigating the emergence of such invariance regarding vocalizations in the auditory system, there is much to discover in terms of where and how it is represented by both neural populations and individual neurons in various areas of auditory cortex. In this study we investigated how core and belt areas of marmoset auditory cortex encode changes in center frequency of both pure tones and synthesized marmoset phee calls and compared the neural responses with corresponding behavioral measures. Marmoset is a highly vocal non-human primate species with a hearing range similar to that of humans. We observed that in the core area, responses to a given pair of stimuli (pure tones or phees) reflect their differences in center frequency. In the belt area, however, this was the case for the responses to pure tones, but not to phees. In particular, offset responses to frequency-shifted phees were invariant to changes in center frequency when the frequency shift was within the range of the center frequency of phee population samples recorded in our colony (Agamaite et al., 2015).

Title: Saccading does not reset neural processing of visual targets in natural viewing task

Authors: *A. D. STANKOV[1], J. TOURYAN[2], S. GORDON[3], A. RIES[2], J. KI[1], L. C. PARRA[1];
[1]Biomed. Engin. Dept., City Col. of New York, New York, NY; [2]DEVCOM Army Res. Lab., Aberdeen Proving Ground, MD; [3]DCS Corp., Alexandria, VA

Abstract: Relatively little is known about visual processing during free-viewing visual search in realistic dynamic environments. Free-viewing is characterized by frequent saccades. During saccades, visual processing is thought to be suppressed, yet we know that the pre-saccadic visual content can modulate post-saccadic processing. To better understand these processes in a realistic setting, we study here saccades and neural responses elicited by the appearance of visual targets in a realistic virtual environment. While subjects were being driven through a 3D virtual town they were asked to discriminate between targets that appear on the road. We found that the presence of a target enhances early occipital as well as late frontocentral saccade-related responses. The earlier potential, shortly after 125ms post-saccade onset, was enhanced for targets that appeared in peripheral vision as compared to central vision, suggesting that fast peripheral processing initiated before saccade onset. The later potential, at 195ms post-saccade onset, was strongly modulated by the visibility of the target. Together these results suggest that, during natural viewing, neural processing of the pre-saccadic visual stimulus continues throughout the saccade, apparently unencumbered by saccadic suppression.

Title: Foveal viewing influences subsequent peripheral stimulus processing by visual cortical neurons

Authors: *R. XIA[1], D. JONIKAITIS[1,2], T. MOORE[1,2];
[1]Neurobio., Stanford Univ., Stanford, CA; [2]Howard Hughes Med. Inst., Stanford, CA

Abstract: In humans and other primates, visual acuity decreases dramatically from the point of fixation (fovea) to the visual periphery. As a result, targets of interest must be fixated sequentially to accumulate detailed visual information contained within a scene, and this is accomplished largely by way of saccadic eye movements. Psychophysical evidence suggests that at least some visual information is integrated across sequential fixations, but the neural mechanisms underlying trans-saccadic integration remain largely unknown. In this study, we asked whether detailed visual information acquired at fixation exerts an influence on the subsequent processing of that information in the periphery by neurons in visual cortex. To address this question, we recorded neuronal activity in area V4 of rhesus monkeys using 32-channel linear probes (Plexon, Inc.) while the monkeys performed a triple-saccade task. In the task, each trial began with the monkey fixating a central fixation spot, after which a gray-scale drifting grating (3° in diameter) was presented at a peripheral location coinciding with the locations of the receptive fields (RFs) of recorded V4 neurons (5 - 10º eccentricity). The monkey maintained fixation for 500 ms (pre-foveation period) until the fixation spot disappeared, which cued the monkey to make a saccade to the grating. After fixating the grating for 500 ms, the monkey re-fixated the initial fixation spot as it re-appeared. Following another 500 ms (post-foveation period), the fixation spot disappeared again, and the monkey was rewarded for making a saccade back to the grating to complete the trial. Across trials, we varied both the direction of motion and the spatial frequency of the grating target, and compared the neuronal responses to the gratings during pre- and post- foveation periods. As expected, the magnitude of visual responses to the target gratings was diminished from the pre-foveation to the post-foveation periods, consistent with the repetition suppression effects previously described. Nonetheless, neurons remained selective to the orientation and direction of motion of the grating targets in the post-foveation period. Moreover, thus far, we find that stimulus selectivity (e.g. direction of motion) increases during the post-foveation period compared to the pre-foveation period for gratings presented at higher spatial frequencies whereas selectivity decreases for lower spatial frequency gratings. These results suggest that high acuity visual information obtained through foveal viewing influences subsequent peripheral processing and is integrated across saccades.

Title: The trans-saccadic preview effect: Neural adaptation or evidence for active vision?

Authors: C. HUBER-HUBER[1], *F. DE LANGE[1], D. MELCHER[2];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands;
[2]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Most neurocognitive research on human visual perception up until now has been carried out while the eyes of the participants were still, usually focused at a fixation cross at the center of the screen. In real life, however, we move our eyes about three times per second, each time leading to drastic and abrupt changes in visual stimulation of which we are not aware. These gaze dynamics entail that every time we perceive something foveally with high resolution we have previously seen the same with much worse resolution further in the visual periphery. There is always a visual preview. We demonstrated recently, using face stimuli and combined EEG and eye-tracking, that this pre-saccadic preview affects post-saccadic processing, which is in line with earlier work in the domain of reading research. Here, we ask whether this effect is contingent on active vision or whether it results simply from adaptation of neurons with large receptive fields which would be unrelated to eye movements. Our results show a larger preview effect in the post-saccadic N170 component for an active vision condition compared to a passive stimulation condition which suggests that real-life visual perception is fundamentally different from passive visual perception usually studied in the laboratory. In addition, we discuss further control conditions designed to rule out other types of adaptation.

Title: Dissecting the visuomotor circuit for saccadic suppression

Authors: *J. HUNT[1], G. FELSEN[2], A. POLEG-POLSKY[3];
[1]Univ. of Colorado, Anschutz Med. Campus, Denver, CO; [2]Dept. of Physiol. and Biophysics, U. of Colorado Sch. of Med., Aurora, CO; [3]Physiol. and Biophysics, Univ. of Colorado, Aurora, CO

Abstract: Many species, including mice, use saccades to actively explore their visual environment. Saccades result in a transient modification of visual perception such that perceptual thresholds are elevated relative to extra-saccadic performance, a phenomenon referred to as saccadic suppression. Saccadic suppression is associated with a decrease in the visual

responsiveness of neurons across the visual system which is believed to be the neural basis of the perceptual phenomenon. While several sources of neural suppression have been identified, including a visual-only mechanism originating in the retina, a long-standing complementary hypothesis proposes that a premotor corollary discharge (CD) broadcast by the motor (deep) layers of the superior colliculus (SC) to other nodes in the visual system triggers suppression of neuronal responses across the visual system hierarchy. Our overall goal is to test this hypothesis by dissecting the visuomotor circuitry in the SC in head-fixed mice making saccades. In particular, we seek to test the idea that premotor neurons in the deep SC relay a CD to visual neurons in the superficial SC via GABAergic interneurons. Here, in a set of preliminary experiments we used the optokinetic reflex (OKR) to elicit conjugate saccades in head-fixed mice and found that unilateral inactivation of the SC with muscimol arrested saccades directed toward contralateral visual space. This result suggests that saccades elicited through the OKR are SC dependent. We next recorded single-unit activity across the dorsal-ventral axis of the SC in response to visual stimuli presented around the time of saccades using high-density Neuropixels probes. We identified visual responses in the visual (superficial) layers of the SC, which we predict will be suppressed by coincident saccades. This predicted result would show saccadic suppression of visual responses in the mouse SC. Future experiments can then use cell-type specific tools to dissect the collicular and retinal circuitry that underlies saccadic suppression.

Title: Encoding of salience and informed choice colludes and conflicts across FEF neuronal types in the guidance of urgent saccadic decisions

Authors: *E. E. OOR, E. SALINAS, T. R. STANFORD;
Neurobio. and Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Scanning eye movements are guided by both the physical salience and behavioral relevance of items in a visual scene. Thus, each saccadic choice is the result of dynamic interplay between exogenous and endogenous mechanisms and their respective influences on evolving motor plans. Saccadic choice tasks typically preclude such interplay by serializing perceptual evaluation and motor choice stages in that order. To expose specific psychophysical and neural manifestations of this interaction, we designed an urgent color-matching task in which motor

planning precedes the perceptual evaluation. The design tracks both the subject's choice and the underlying neuronal activity as they unfold over time. By also manipulating the relative salience of the target/distracter pair, we can distinguish exogenous from endogenous contributions to target selection. Previous findings from our lab—that visual neurons in the Frontal Eye Field (FEF) primarily signal the salience of items in their response field (Scerra et al., 2019), and that exogenous signals capture attention automatically within ~100 ms of stimulus onset (Salinas et al., 2019)—make specific predictions for how a salience-driven signal would bias choices based on endogenous information. Here, we tracked the timing of oculomotor activity via single-neuron recordings from the FEF in two monkeys. Consistent with our model, we found that during an ongoing saccadic choice, exogenous mechanisms boosted performance when the salient item was the target and hindered it when it was the distracter—rapid, involuntary effects that were superseded by endogenous mechanisms ~40 ms later. Activity recorded from FEF confirmed that visual neurons select salient items regardless of target/distracter identity and thus can aid or impede selection of the endogenously defined target. Assuming FEF motor activity reflects a choice biased by the activity of visual neurons, we predicted motor activity to be accelerated or attenuated depending on whether the motor plan was congruent or opposed to the salient item. Remarkably, the activity of pure motor cells resisted such saliency selection to unambiguously signal the target regardless of its physical attributes. In contrast, the activity of visuomotor cells was most revealing of the predicted exogenous-endogenous interaction by signaling stimulus salience and then stimulus identity (target vs distracter) in rapid temporal sequence. The results reveal correlates of the interactions between exogenous and endogenous signals in FEF that are distinct across specific neuronal types and are finely orchestrated over a few tens of milliseconds to yield each saccadic choice.

Title: Active vision and the effects of saccades on perception, V1 spiking, noise correlations, and choice probability

Authors: *S. AKERS-CAMPBELL[1], J. E. NIEMEYER[2], A. GREGOIRE[1], M. A. PARADISO[1];
[1]Neurosci., Brown Univ., Providence, RI; [2]Neurolog. Surgery, Weill Cornell Med., Astoria, NY

Abstract: Perception in multiple sensory modalities is an active process that involves exploratory behaviors such as sniffing and whisking in rodents. In humans and other primates, vision results from active sensory sampling guided by saccadic eye movements. Neural recordings with EEG, LFPs, spikes, and BOLD signals show that saccades modulate activity in multiple brain areas. Psychophysical experiments in humans have revealed effects of saccades on perception and it is hypothesized that a motor signal associated with eye movements speeds and enhances object recognition and contributes to our sense of visual stability across saccades. We investigated the integration of saccades into visual processing and, more specifically, the contribution of an eye-movement related signal associated with active sensory sampling. Recordings were made from networks of macaque V1 neurons as animals performed a contrast detection task. Perceptual and neural measures were compared when an animal made real saccades that brought a stimulus into V1 receptive fields and when simulated saccades were made (identical retinal stimulation but no eye movement or corollary discharge signal). The average activity of the neurons was strongly influenced by saccades in a stimulus-specific manner. When low spatial frequency stimuli were presented, both perceptual contrast sensitivity and V1 activity were lower on saccade trials than simulated saccade trials. Conversely, with higher spatial frequency stimuli, contrast sensitivity and V1 activity were greater on saccade trials. These effects may underlie the suppression of vision during saccades and the enhancement of perception at the start of fixations. Saccades were also found to decrease pairwise noise correlations and choice probability across all spatial frequencies. Taken together, the findings suggest that an extraretinal signal related to the saccadic eye movement alters both V1 spiking and network correlations in a manner consistent with changes in visual sensitivity. More broadly, effects of motor activity (saccades) on visual perception and noise correlations appear to parallel effects observed in other sensory modalities. In rodents, active whisking and sniffing are also associated with improved sensory discrimination and decreased noise correlations and choice probability. Thus it appears that corollary-discharge signals in vision, olfaction, and somatosensation reach sensory cortex, decrease noise correlations, and modulate functional connectivity, leading to overall improved information flow and sensory discrimination.

Title: Visual and motor responses in mediodorsal pulvinar in comparison to LIP and FEF

Authors: *R. CHEN[1], *K. DOUGHERTY[1], B. WU[1], A. B. MARTIN[2,1], S. KASTNER[1];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Univ. of Arizona, Tucson, AZ

Abstract: The mediodorsal pulvinar (mdPul) is a thalamic nucleus exclusive to primates, and anatomically connected with dozens of cortical areas (Homman-Ludiye, 2019). mdPul processes both visual and motor signals and is involved in attention through interactions with the frontoparietal network (Fiebelkorn, 2019). To understand the specific role of mdPul relative to its interconnected cortex, we simultaneously recorded neuronal signals in mdPul, frontal eye field (FEF) and the lateral intraparietal (LIP) cortex with multi-contact linear arrays, while monkeys performed a change detection task. In each trial, a cue was presented briefly to indicate the location of an upcoming target. After a variable delay, a circular array of six barrel and bowtie shapes appeared, one of these items changed its contrast after a second delay, monkeys were required to make a saccade to the target to get a juice reward. We identified hundreds of well-isolated single units in each area. We classified neurons into visual, visuomotor and motor groups based on each neuron's responsiveness to visual stimuli and eye movement. We further sub-divided neurons into narrow- and broad-spiking classes according to a bimodal distribution of spike waveform widths to consider properties of putative inhibitory and putative excitatory neurons, respectively. For visual and visuomotor neurons, we found that the visual response latencies of broad-spiking units followed a hierarchical order, with responses initiating in LIP, then mdPul and finally FEF. The narrow-spiking units, in contrast, showed highly overlapping distributions of visual latencies across all three areas. Similar ratios of visuomotor units, exhibiting pre-saccadic activity, were observed across all regions for both broad- and narrow-spiking units. In contrast, a much smaller proportion of pre-saccadic motor units were present in LIP than in mdPul and FEF. In addition to considering the proportion of functional neurons across areas, and their visual latencies, we also examined variability in spiking following the visual cue and prior to saccades by computing Fano factor. We observed that the variability of neuronal responses in LIP and FEF decreased after visual stimuli or saccade onset for both broad- and narrow-spiking units. However, variability reduction in mdPul was only observed for narrow-spiking units. These results show that mdPul shares common functional properties with interconnected cortex, with the exception of spiking variability. This functional difference may result from differences in the anatomical organization of cortex and pulvinar.

Title: Pontine integration of visual motion and visual-motor gain signals in the primate smooth pursuit eye movement system

Authors: *T. R. DARLINGTON, S. G. LISBERGER;
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Voluntary movement systems combine many types of signals related to motivation, expectation, and sensory information to generate proper motor commands. Smooth pursuit eye movement is an example of such a sensory-motor behavior and allows primates to smoothly track moving objects of interest with their eyes. Two primary signals are responsible for driving smooth pursuit: visual motion and visual-motor gain. Visual-motor gain controls access of visual motion signals to the oculomotor machinery and may allow extrasensory features like expectation and reward/motivation to influence pursuit. In the cerebral cortex, the middle temporal visual area (MT) provides the visual motion input to the pursuit system; the smooth eye movement region of the frontal eye fields (FEF_{SEM}) controls visual-motor gain.
Our present goal is to move downstream in the pursuit circuit to understand how visual motion and visual-motor gain are combined to drive smooth pursuit eye movement. We recorded the extracellular activity of 63 single neurons in the dorsolateral pontine nucleus (DLPN) and 114 neurons in the nucleus reticularis tegmenti pontis (NRTP) of two monkeys. Both nuclei receive convergent cortical input, though DLPN and NRTP receive most of their input from area MT and FEF_{SEM}, respectively. Monkeys performed smooth pursuit eye movements in a speed context task that consisted of alternating blocks of trials where targets moved predominantly at either fast (80% 20 deg/s, 20% 10 deg/s) or slow (80% 2 deg/s, 20% 10 deg/s) speeds. Preparatory modulation of activity like that in FEF_{SEM} was present in both NRTP and DLPN and encoded expectation of target speed: the modulation of preparatory activity was larger during the fast- compared to the slow-context. We probed the state of visual-motor gain during motor preparation in the fast- and slow-context with brief, 50-ms pulses of local coherent motion at 5 deg/s delivered either early or late after fixation onset. In NRTP, neuronal response amplitudes to the pulses of motion were larger during the fast- versus slow-context and later versus earlier during fixation, consistent with eye speed responses to the pulses. In DLPN, responses were affected by fixation time but not by speed context. In both areas there was a continuum from small to large effects. Our results imply that either: (i) the combination of visual motion and visual-motor gain occurs gradually within NRTP and DLPN with the outputs provided by the neurons with the largest effects; or (ii) NRTP and DLPN represent an early stage of integration of visual motion and visual-motor gain signals with further integration at downstream nodes.

Title: Predictive control of smooth pursuit eye movements based on stimulus and behavioral histories

Authors: *T. MIYAMOTO[1], Y. HIRATA[2], A. KATOH[3], K. MIURA[4,5], S. ONO[1];
[1]Hlth. and Sport Sci., Univ. of Tsukuba, Ibaraki, Japan; [2]Col. of Engin., Chubu Univ., Aichi, Japan; [3]Sch. of Med., Tokai Univ., Isehara, Kanagawa, Japan; [4]Dept. of Pathology of Mental Dis., Natl. Inst. of Mental Health, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [5]Dept. of Integrative Brain Science, Grad. Sch. of Med., Kyoto Univ., Kyoto, Japan

Abstract: The human oculomotor system requires approximately 100 ms from the onset of target motion to the onset of eye movement, and this delay can lead to a loss of visual information because visual acuity declines as the target moves from the fovea to the retinal periphery. To overcome the inherent delay, the oculomotor system has the ability to perform predictive feedforward control of eye movements. Several studies have demonstrated that preceding changes in eye velocity are generated based on weighted averaging of past stimulus timing even when the target motion is unpredictable due to velocity or direction changes. Here, we attempted to clarify whether not only stimulus history but also behavior history affects predictive pursuit to randomized target velocity. Healthy 12 observers with normal or corrected to normal vision were instructed to track a small target moving horizontally over a distance of 24 deg as accurately as possible. The target moved in an irregular triangular waveform, in which the rightward velocity was fixed at 16 deg/s while the leftward velocity was either fixed (predictable) at one of seven velocities (4, 8, 12, 16, 20, 24, 28 deg/s) or randomized (unpredictable). Eye movements were evaluated when the target reversed direction from right to left. When the future target velocity was predictable, predictive pursuit corresponding to the target velocity was observed. Predictive pursuit was also found even when the future target velocity was unpredictable, but of course the responses did not correspond to the target velocity. To examine the influences of stimulus and behavioral histories on predictive pursuit to the randomized target velocity, a total of 15 linear mixed-effects models were set up with the predictive pursuit response in the current trial (n) as the dependent variable, and the target velocity (stimulus) and the pursuit response (behavior) back to the last 5 trials (n-5) as the

independent variables. These models included those in which each history alone was incorporated into the model and those in which both were incorporated. The model adopted based on the AIC, which incorporated the stimulus and behavioral histories up to the last 5 trials, showed that both histories of the previous two (n-2) or three trials (n-3) had influences on the predictive pursuit responses in the current trial. Our results suggest that the predictive pursuit system allows to track randomized target motion using the information from several previous trials, and the information of target velocity (stimulus) and motor output (behavior) in the past time sequences have partially different influences on predictive pursuit.

Abstract: Predictive optokinetic response (pOKR) was found to be acquired by goldfish after repeated temporally periodic visual stimulation (Marsh & Baker, 1997). A recent study demonstrated that the cerebellum is required for the acquisition of pOKR (Miki et al., 2018). However, despite having almost identical cerebellar neural circuitry to goldfish, zebrafish and medaka hardly acquired pOKR, while carp did (Miki et al., 2020). It was also found that all animals that acquired pOKR presented robust optokinetic after nystagmus (OKAN) which is considered as a manifestation of the velocity storage mechanism (VSM). Therefore, the VSM was hypothesized to be another determinant for the acquisition of pOKR (Miki et al., 2020). Here we conducted experiments to test the hypothesis in mice and humans. In the mice experiment, optokinetic visual stimulus (OKS) rotating at 20 deg/s horizontally was given to 3

wild type mice (C57BL/6) for 1 min and suddenly turned off to measure OKAN. The same mice were trained for 90 min with periodic velocity square-wave OKS that rotated bilaterally for 4 s (±5 deg/s) and paused for 2 s in between. Before and after the training, test OKS with twice the training stimulus period was presented for 10 cycles. As the results, the duration of OKAN was found to be very short, and pOKR was hardly acquired in all the mice tested, supporting strongly the hypothesis that pOKR is dependent on the presence of the VSM. In the human experiment, 12 participants wore a head mount display (HTC vive) in which horizontally rotating random dots were projected as OKS. OKAN was measured in each participant by giving the OKS at a constant velocity (40 deg/s) for 18 s, followed by complete darkness. We then presented 5 cycles of test OKS rotating bilaterally (±40 deg/s) for 8 s, followed by 80 cycles of OKS whose period was a half of the test OKS. Immediately after the training, another test OKS was given for 1 cycle. It was found that the duration of OKAN in humans was highly correlated with the strength of the predictive eye movement. However, learning and forgetting the predictive behavior in humans occurred far much rapidly than goldfish and carp, suggesting other mechanisms taken place than reflexive OKR, such as smooth pursuit. To confirm, we trained 5 participants with the same OKS except that foveal regions were occluded binocularly by real-time eye tracking and masking technique. We demonstrate that no predictive component was acquired after the training, confirming that smooth pursuit may play a main role in the predictive eye movement. Taken together, the VSM is required in addition to the cerebellum to acquire pOKR, and it may also determine the ability to acquire predictive smooth pursuit.

Title: Visual attention and general alertness exhibit different modulating influences on the optokinetic reflex

Authors: D. FRATTINI, *T. PANSELL, T. WIBBLE;
Karolinska Inst., Stockholm, Sweden

Abstract: Reflexive neural responses, such as the optokinetic reflex (OKR), represent a valuable clinical and psychometric tool to depict a range of neurological conditions. While previous

studies have illustrated that optokinetic responses are influenced by different levels of attention and alertness, there is currently no study illustrating how the OKN is affected throughout the visual attention spectrum while controlling for general alertness. This study measures torsional OKN (tOKN) to characterize how general alertness and visual attention affect the OKR in healthy individuals. Twelve healthy subjects (8m, 4f; mean age 33, SD = 9.36) with intact gaze-stability, visual acuity, and binocularity were recruited. Subjects were exposed to a rotating visual scene while wearing a head-mounted eye tracker equipped with an accelerometer to ensure head fixation. They were instructed to place the chin over a chin rest and maintain the fixation on a dot placed at the centre of the screen. All subjects were given three tasks requiring low, neutral, and high levels of visual attention. To control for the general level of alertness, the low visual attention engagement was achieved by submitting a distracting task, the Paced Auditory Serial Addition Test (PASAT), which had subjects shift their attentional focus to auditory cues. A repeated-measures ANOVA revealed a significant effect of visual attention on the OKN frequency responses ($F(2, 22) = 12.353$, $p < 0.001$). The number of OKN responses increased with higher attention levels and differed significantly across all conditions. General alertness significantly modulated the OKN gain, i.e., torsional velocity, ($F(2, 22) = 7.144$, $p = 0.006$). Specifically, both low and high attentional tasks, both requiring substantial cognitive alertness, increased OKN gain compared to neutral trials. Higher visual attention level resulting in higher OKN frequency hints at a more efficient integration of visual motion. Such a relationship may be expected from an evolutionary perspective, coupling an increased readiness with faster updating sensorimotor reflexes. Regarding the OKN gain, during the high attention task, it is likely caused by an increase in visual motion processing, whereas during the low attention task it may reflect the heightened alertness caused by auditory cues according to the same evolutionary principles. In conclusion, high attentional and alertness levels independently influenced different characteristics of the OKN, supporting cortical modulation on subcortical sensorimotor processes fundamental for visual perception and visually guided behaviours.

Title: Circuit mechanisms underlying the cortical modulation of optokinetic reflex

Authors: *J. LIU, Y. HE, B. LIU;
Cell and Systems Biol. ; Biol., Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: In mammals, the visual cortex has an unsurpassed capability of discriminating visual features, such as orientation, depth, and motion. This cortical area sends massive innervation to the brainstem, namely corticofugal projections. Through this pathway, the visual cortex can theoretically impact the behavior mediated by brainstem circuits. But the functional role of those projections was not fully understood. Recently evidence showed that the corticofugal projection from the visual cortex indeed modulated an innate behavior, optokinetic reflex (OKR) which is essential to stabilize retinal images. This cortical modulation can expand the behavioral repertoire of mammals and therefore help animals survive in dynamically changing environments. We decided to use this system to investigate the circuit mechanisms of cortical modulation on innate behaviors. We used viral-based circuit tracing and two-photon functional imaging to explore the structure and function of the circuit involved in this cortical modulation. We found that cortical neurons innervating the OKR circuit primarily came from specific areas. Moreover, those neurons shared similar functional properties. This functionally specific connection will provide insight into the mechanism of how the cortex modulates innate behaviors.

Title: Transformer-based computational model of human eye movements for reading

Authors: *A. DIPANI, F. SHAMSI, M. KWON;
Dept. of Psychology, Northeastern Univ., Boston, MA

Abstract: Reading is a highly complex process that involves the integration of visual sensory, oculomotor, linguistic, and cognitive information. Our brain acquires relevant information during

reading by making a series of rapid ballistic eye movements called saccades, interleaved with short fixations. Thus, understanding human eye movements in reading can help us elucidate how our brain searches for and integrates relevant low-level sensory and high-level cognitive information. However, the pattern of eye movements in reading has been primarily explained by low level sensory or oculomotor factors. Thus, little is known about how language context (e.g., the relationship between words & semantic knowledge of words) influences human eye movements for reading.

To address the issue, here we develop an ideal-observer computational model that uses visual sensory, oculomotor, lexical, memory, and language contextual information to simulate human reading behaviour. This ideal-observer model can optimally utilize the statistical properties of all the information available in the text to make saccades as it reads through the text.

To incorporate language contextual information into the model, we adopt a transformer-based language model GPT2 (Radford et al., 2019) that computes the likelihood of upcoming words based on preceding words and contextual information present in the text. We consider the memory component for reading by restricting the amount of context the language model can use. The task of our model is to read through the text in a minimum number of saccades by minimizing entropy introduced in the Mr Chips model (Legge, Klitz & Tjan, 1997). We calculate this entropy using the text information available through a retina, word alternatives using lexicon information, prediction of next word using the previously identified words as context, and the knowledge of oculomotor noise distribution.

We test our model on text excerpts from books (e.g., Alice in Wonderland). The model's saccade strategies were evaluated in terms of saccade lengths, reading speed and regression saccades compared to the Mr Chips model. The simulation results revealed a benefit of using language contextual information as observed in human readers: lesser regressive saccades, faster reading speed, and longer saccade lengths. More details on the emerging properties of the model were analyzed and compared between the two models.

Our findings suggest that our transformer-based computational model may serve as a valuable tool for studying human eye movements for natural reading in normal and clinical populations.

Title: Responses of frontal cortical neurons to changes in stimulus reliability

Authors: *S. W. EGGER[1], S. G. LISBERGER[2];
[1]Neurobio., Duke Univ. Sch. of Med., Durham, NC; [2]Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: The responses of frontal cortical neurons depend on the reliability of sensory signals that drive motor behavior. Models based on responses during perceptual decisions suggest the strength of sensory inputs to frontal cortical neurons is set according to stimulus reliability. Models based on responses during smooth pursuit eye movements suggest that reliability modulates the strength of shunting inhibition. While different in implementation, the predictions of both classes of models are quite similar in terms of neural responses at the onset of sensory and/or motor events. However, because shunting inhibition depends on the response of the neuron at any given moment, the predictions of the models diverge as steady-state pursuit behavior and the response of individual frontal neurons evolve dynamically over time.
To evaluate the mechanisms behind the sensitivity of frontal cortical neurons to stimulus reliability, we recorded from neurons in the smooth pursuit region of the frontal eye fields (FEFsem) of a monkey during the initiation and steady-state pursuit of targets that were patches of moving dots. Motion reliability was controlled by adjusting the percentage of dots coherently moving in the pursuit direction. Motion coherence had a strong effect on FEFsem responses throughout the pursuit response. At stimulus onset and during the initiation of pursuit, FEFsem neurons often responded more strongly to higher coherence than lower coherence, replicating previous results that changed reliability using stimulus contrast. The responses, however, were quite diverse if we increased or decreased the coherence of the patch of dots during steady-state pursuit. The strength and sign of the response to the change in motion reliability often was unrelated to the strength and sign of the effects during pursuit onset. We take the disparate effects at pursuit initiation versus steady-state as evidence that the pursuit-related activity of neurons in FEFsem has a non-linear effect on their responses to sensory inputs. We plan to use this result to constrain models of individual neurons that will reveal how sensory reliability and motor responses interact in the frontal cortex.

Title: Mechanisms for integrating allocentric and egocentric visual information for goal-directed movements: A neural network approach

Authors: *P. ABEDI KHOOZANI[1], V. BHARMAURIA[1], A. SCHÜTZ[4], R. WILDES[2], J. CRAWFORD[3];
[1]York Univ., North York, ON, Canada; [2]York Univ., Toronto, ON, Canada; [3]Ctr. for Vision Res., York Univ., North York, ON, Canada; [4]Philipps-University Marburg, Marburg, Germany

Abstract: Allocentric (landmark-centered) and egocentric (eye-centered) visual information are optimally integrated for goal-directed movements (Byrne et al., 2010; Klinghammer et al., 2017). Additionally, neural recordings found landmark-specific coding in supplementary and frontal eye fields when monkeys performed saccades toward a remembered visual target (Schütz et al., 2020; Bharmauria et al., 2020). Nevertheless, the intrinsic coordinate representation and underlying processes for this combination remain a puzzle, mainly due to inadequacy of current theoretical models to explain data at different levels (i.e., behavior, single neuron, and distributed networks). Here, we propose a neural network with physiologically inspired retinal / extraretinal inputs, outputs based on frontal eye field (FEF) properties, and two major 'hidden' components: First, a Convolutional Neural Network (CNN) is used to extract the allocentric and target information. Our CNN performs repeated (2 layers) convolution, rectification, and normalization to first extract low-level features from input images. With the features extracted, the challenge is to combine them to generate an abstract representation (allocentric cues and target position). We address this challenge by training a feature pooling layer at the end of our CNN network. Second, a Multi-Layer Perceptron network (MLP) is used to combine allocentric (extracted feature maps from the CNN) and egocentric information (initial gaze position fed to the network as an additional input). Our MLP consists of two fully connected hidden layers that incrementally transform the allocentric and egocentric representations into an integrated motor response. Finally, a decoder transforms motor responses into final gaze positions. The network input included retinal projection of images and somatosensory coding of initial gaze location while the output was designed to replicate frontal eye field's motor responses. The network was trained on both synthetic and actual monkey gaze behavior. MLP output units accurately simulated FEF motor responses (open-ended response fields that shifted partially with the landmark) and their decoded output achieved good correspondence (MLP: R2 = 0.80) with actual gaze behavior (Bharmauria et al. 2020). These results suggest that our framework provides a suitable tool to study the underlying mechanisms of allocentric and egocentric integration.

Title: Open multimodal iEEG-fMRI dataset from naturalistic stimulation with a short audiovisual film

Authors: *J. BEREZUTSKAYA[1,2], M. J. VANSTEENSEL[1], E. J. AARNOUTSE[1], Z. V. FREUDENBURG[1], G. PIANTONI[1], M. P. BRANCO[1], N. F. RAMSEY[1];
[1]Brain Ctr., Neurol. and Neurosurgery, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: Human intracranial (iEEG) data are a valuable but rare source of information about the brain. The few medical centers in the world that acquire iEEG for research purposes suffer from low patient rates (5-10 subjects a year), and due to various reasons cannot easily share the data. This limits iEEG potential for neuroscientific research and hampers scientific reproducibility. Here, we present the first openly shared large multimodal iEEG-fMRI dataset that is unique in several ways. First, it contains a large set of iEEG data (51 subjects who all did the same task). Second, it provides additional fMRI data from the same task (30 subjects). Third, the data were collected using a rich naturalistic stimulus - a short audiovisual film, for which detailed video and audio annotations are provided. The dataset can be used to study neural signal during speech, perception, social discourse and more; develop new analysis techniques and study neurovascular coupling. The dataset is available online (https://openneuro.org/datasets/ds003688). It includes 51 iEEG and 30 fMRI subjects, of which 18 subjects have both iEEG and fMRI data. The majority of the data was recorded from subdural electrode grids. Data have been de-identified (MRI defaced, personal metadata removed) and are provided in the iBIDS format. Handedness and language dominance hemisphere are provided per subject. As the main task patients watched a short film (6.5 minutes) edited together from scenes of Pippi Longstocking (1970) with interleaved blocks of speech and music. For iEEG, additional resting state data (3 minutes) are provided. Rest data was either acquired during a resting state task (26 subjects) or cut from natural rest in continuous 24/7 recordings (24 subjects). FMRI data contains only the audiovisual film task. Detailed annotations are provided with time stamps for spoken sentences, words and phonemes and labeling of the visual content (characters, objects and actions per frame).Subsets of IEEG data have been previously analyzed and published with respect to visual and auditory processing. For the full dataset we report strong responses to the film that are similar across iEEG and fMRI.The present dataset offers an unprecedentedly large amount of iEEG data accompanied by fMRI recordings during a naturalistic cognitive task. Extensive use of these data can help us understand neural processing that supports different aspects of high-level cognition including speech processing, which is central to research on brain-computer interfaces for communication. We believe this shared dataset will help promote collaborative and open science in the field of iEEG as well as the neuroscientific community as a whole.

Title: Human brain networks for probabilistic learning explored with ultra-high field fMRI

Authors: *T. BOUNMY[1,2], E. EGER[1], F. MEYNIEL[1];
[1]Cognitive Neuroimaging Unit (INSERM-CEA), NeuroSpin center, DRF/I2BM, CEA Paris-Saclay, Univ. Paris-Saclay, Gif-sur-Yvette, France; [2]Univ. de Paris, Paris, France

Abstract: Faced with a changing and uncertain world, the human brain is able to estimate the probability of future events based on past observations. This ability is key to interacting with our environment from perception to decision making. According to the Bayesian brain hypothesis [1], the brain relies on uncertainty (or inversely, confidence) to correctly update its beliefs. This Bayesian approach characterizes the computational level but the representational and implementational levels of probabilistic learning in humans remain to be elucidated. Here, we probed the neural activity of 26 human adults on a probability-learning task with ultra-high field (7T) MRI. Subjects were shown binary sequences of visual stimuli that follow a Bernoulli process whose probability parameters changed abruptly and unpredictably. Subjects were asked to learn this changing probability and to occasionally report it along with the associated confidence. We analyzed the latent variables of learning with a Bayesian Ideal Observer model to distinguish surprise (log improbability of each observation) and confidence (log posterior precision). Subjects' probability estimates and confidence levels tightly followed the Bayesian model. Confidence levels also showed different normative features of Bayesian inference. fMRI revealed distinct brain networks correlating with confidence (positively in ventromedial prefrontal and frontopolar cortex, anterior temporal lobe, hippocampus and negatively in intraparietal sulcus) and surprise (positively in prefrontal and visual cortices). These results extend and corroborate a previous study that used 3T MRI and a similar task (with an order-1 Markov process instead of Bernoulli process and both auditory and visual sequences) [2]. The brain correlates of confidence (which characterizes epistemic uncertainty) were not confounded by aleatoric variability (which characterizes how predictable the next stimulus is, and which was included in the regression model). By identifying brain networks correlating with the confidence that accompanies learning, our findings contribute to unraveling the neural mechanisms of

probabilistic learning. References: [1] Knill, D. C., & Pouget, A. (2004). *TRENDS in Neurosciences* 27(12), 712-719. [2] Meyniel, F., & Dehaene, S. (2017). *PNAS* 114(19), E3859-E3868.

Title: Partial face cognition in rapid serial visual presentation paradigm

Authors: *I. CHANPORNPAKDI, T. TANAKA;
Dept. of Electrical and Electronic Engin., Tokyo Univ. of Agr. and Technol., Koganei-shi, Japan

Abstract: Objective: Under the COVID-19 pandemic situation, wearing masks became a must-do action in our daily life. Regardless that some parts of the face are being covered, humans can still cognize people's faces precisely. On this account, we assumed that people could also cognize faces by only seeing some parts of the face but seeing the whole face would help them to cognize easier. This study aims to examine and compare the response of the brain related to the whole and part face cognition using rapid serial visual presentation (RSVP). Method: The part face conditions examined were faces with eyes covered, nose covered, mouth covered, eyes and nose covered, eyes and mouth covered, and nose and mouth covered to identify the part of the face that provides the most critical information for face cognition. In the experiment, we recorded an electroencephalogram (EEG) on 18 healthy volunteers, 9 male and 9 female (mean age 25.72 ± 2.66, min 21 and max 31). The experiment consisted of two cognition tasks, images displayed at 1000 ms with a button press when the target is shown, and images displayed at 200 ms without any physical responses. Each task contained six unknown faces presented at 20 times each, where one face was set as a target, and all subjects were trained to remember that face priorly. The obtained data were re-reference with an average of earlobe electrodes, filtered using a bandpass filter at 1 to 30 Hz. The artifacts such as eye blinks were removed by independent component analysis (ICA), and an event-related potential (ERP) was calculated by grand averaging among all subjects. Results: We found that part face stimulus provided a more significant event-related response, P300, than whole face cognition in both the tasks, which contrasted with our hypothesis. The face with the nose covered yielded the largest P300 among all face conditions in both a slower RSVP or button press task and a faster RSVP or no button press task. We also compared the ERP obtained in a whole face presentation and face with nose

and mouth covered condition, resembling wearing a mask. The P300 amplitudes in these conditions were produced at a similar level. This result supports the fact that wearing masks or faces with nose and mouth covered does not lower face cognition ability.

Title: Neural responses to naturalistic stimuli are heritable and related to the brain's intrinsic functional organization

Authors: *D. GRUSKIN[1], G. H. PATEL[1,2];
[1]Columbia Univ., New York, NY; [2]New York State Psychiatric Inst., New York, NY

Abstract: How do our genes shape our perceptions of the world around us? Recent work using retinotopic and task-free paradigms has established that various aspects of sensory-relevant brain function are under genetic control. However, the extent to which genetic factors underly individual differences in brain responses to dynamic, naturalistic stimuli is still unclear. In the present study, we address this gap by applying multidimensional heritability analyses to movie watching 7T fMRI data from 176 Human Connectome Project participants. First, using a pairwise intersubject correlation (ISC) analysis, we show that BOLD responses to naturalistic stimuli are heritable across both unimodal and, to a lesser degree, heteromodal cortex (average parcel-level $h^2 = .07$; maximum parcel-level $h^2 = .18$, $p_{perm} < .0001$). Network- and region-level analyses reveal that heritability effect sizes and spatial topologies are consistent within functional networks and across different stimuli and days of data collection (average spatial correlation $\rho = .92$, $p_{spin} < .001$). Next, we use functional alignment to demonstrate that this heritability in part reflects shared latent representations of sensory information that are independent from genetic similarity in functional topology. Finally, we describe relationships between individual differences in movie-evoked brain activity and variability in the brain's intrinsic functional architecture, illustrating how intra-regional activations are related to heritable patterns of inter-regional communication. Taken together, these findings establish a genetic basis for individual

differences in the neural processing of audiovisual stimuli and advance the study of genetic influences on sensory processing into the naturalistic domain.

Title: Towards a Mechanistic Account of Perceptual Curiosity

Authors: *M. COHANPOUR[1,2], M. ALY+[2,3], J. P. GOTTLIEB+[2,4];
[1]Dept. of Neuroscience, Columbia Univ., New York, NY; [2]Zuckerman Mind Brain Behavior Institute, Columbia Univ., New York, NY; [3]Dept. of Psychology, Columbia Univ., New York, NY; [4]The Kavli Inst. for Brain Science, Columbia University, New York, NY, USA, New York, NY

Abstract: Realistic environments are rife with uncertainty. Often the uncertainty is sensory, requiring us to clarify ambiguous inputs. Is the shadowy figure I see on my hike a bear or a rock? Recent results suggest that perceptual curiosity, the intrinsic desire to reduce sensory uncertainty, is crucial for sensory processing and memory but its neural basis is poorly understood. Using a novel behavioral task, we asked whether and how perceptual curiosity is related to neural representations of confidence and sensory uncertainty and how it modulates episodic memory. During fMRI, participants viewed a distorted image ("texform") of an animal or inanimate object and rated their confidence in recognizing the image and their curiosity to see the original (undistorted) image. At the end of the session, participants took a surprise memory test for the ambiguous texforms. We show that, like curiosity about trivia questions, perceptual curiosity has a negative quadratic (inverted-U) relation with confidence. Moreover, perceptual curiosity was predicted by two separate neural representations of sensory uncertainty. One was a multivariate representation of uncertainty about stimulus category in occipitotemporal cortex (OTC), measured based on the relative correlations between a multivoxel pattern evoked by a texform and separately acquired animate and inanimate template activity patterns. In addition, a portion of the perigenual anterior cingulate cortex (pgACC) provided a univariate response that correlated with subjective reports of confidence and predicted curiosity independently of the OTC. The results reveal the neural signatures of uncertainty that predict subjective judgments of

perceptual curiosity. Future analyses will uncover how the brain's memory systems interact with OTC and pgACC to support memory for ambiguous events.

Title: The role of entropy, mutual information and synchronization in perception and action

Authors: *D. GUPTA;
Husson Univ., Bangor, ME

Abstract: A large and growing volume of experimental data have shown that during action and perception there are increases in the spiking activities in the cortical areas, which are synchronized by neural oscillations of different bandwidths. The spiking activities are random (high entropy) if there is no knowledge about actions or stimulus characteristics. However, the knowledge about the action or the stimulus characteristics will resolve the surprise in the spiking patterns. The knowledge about the action or the stimulus is an outcome of a successful interaction with the physical surroundings. A successful outcome for the organism will increase the knowledge about the external stimulus or object, such as the juiciness of a fruit due to changing shape, but fixed volume - processed during interaction as a low-dimensional feature. Furthermore, note that spiking patterns, given no knowledge about the source, such as stimulus or action-initiation, are stochastic due to sparse interconnections between the cortical neurons. The decrease in entropy has an energy equivalent when there is a gain in the knowledge about stimulus (perception) and action (voluntary movement). This gives a physical basis to perception and voluntary movements that are comparable between individuals. We will investigate, using theoretical considerations, the changes in mutual information and entropy due to sensory processing and synchronization to understand the information theoretic basis of action and perception. There are increased correlations between pairs of neurons activated by different stimulus characteristics and/or low-dimensional stimulus features, which will decrease the joint entropy between pairs of neurons in the cortex, increasing the energy equivalent of the gain in the knowledge about action and stimulus (perception). The processing of sensory stimulus is responsible for the increase in entropy measured in the spiking activities. Moreover, synchronization will selectively increase the number of pairs of neurons showing correlated activity specific for the task. Consequently, there will be fewer number of possible spiking states

in the brain as a result of synchronization since synchronized neurons will represent a single macrostate, resulting in a reduction of entropy.

Title: Human parietal cortex responses to static illusory figures and their modulation by attention

Authors: *A. ARSENOVIC[1,2], A. ISCHEBECK[1,2], N. ZARETSKAYA[1,2];
[1]Dept. of Cognitive Psychology and Neurosci., Inst. of Psychology, Univ. of Graz, Graz, Austria; [2]BioTechMed-Graz, Graz, Austria

Abstract: Investigating visual processing of illusory figures is an important approach for identifying the mechanisms of perceptual organisation and their neuronal correlates. Until now, neuronal representations of static illusions, such as the Kanizsa figure, have been demonstrated in the early visual cortex and in the ventral stream of the visual processing hierarchy. On the other hand, the dorsal stream, including the superior parietal areas, has been shown to process illusory figures defined by motion. It remains unclear whether parietal cortex only reacts to motion-defined illusory shapes or to illusory shapes in general. In the current study we tested if parietal cortex also responds to static Kanizsa figures. In addition, since parietal cortex is known to be involved in attention, we also tested whether and how this shape-related activity is modulated by attention. Seventeen healthy human participants took part in one fMRI session. The participants performed a central detection task, which varied in difficulty on two levels (easy - detection of a specific colour; hard - detection of a specific symbol). Irrelevant to the task, four flickering black inducers were presented simultaneously on the display around the fixation task. The inducer configurations were either forming an illusory diamond in the centre, a triangle in the left or the right hemifield, or were inverted such that no illusory figure was formed. All conditions were presented for 12 s per trial in a block design. The task difficulty varied between the blocks. We performed a surface-based GLM analysis comparing responses to each illusory figure with the non-illusory condition for the parietal regions of interest (IPS0, IPS1, IPS2, IPS3, IPS4, IPS5, SPL1). Most of these areas showed stronger responses to the diamond compared to inverted inducers. Interestingly, IPS0-3 also showed a significant response modulation by the triangle location, preferring the triangles in the contralateral hemisphere. While the overall response to the triangles (compared to inverted inducers) was attenuated by attention, the

contralateral triangle preference was not. Our results demonstrate that, along with the motion-defined illusory shapes, parietal cortex also responds to static illusory Kanizsa figures. These responses were attenuated, but not eliminated by diverting attention to a central fixation task. Importantly, our results also show that diverting attention away from the illusory figure attenuates the overall shape response, but not the spatially specific response to the exact location of illusory triangles. Overall, they imply that the parietal cortex plays a general role in representing illusory content.

Title: Causal roles of prefrontal cortex during spontaneous perceptual switching depend on brain state dynamics

Authors: *T. WATANABE;
IRCN, Univ. of Tokyo, Tokyo, Japan

Abstract: Dynamics are among the essential properties of human cognition, and the prefrontal cortex (PFC) is thought to control such cognitive fluctuation. However, in bistable visual perception using a structure-from-motion stimulus, no direct evidence for such presumable prefrontal causal roles has been reported, resulting in debates on PFC functions in spontaneous perceptual inference. To tackle this controversy, by combining an energy landscape analysis with a non-invasive transcranial magnetic brain stimulation (TMS), we tracked brain state dynamics in an online manner and intervened a focal neural activity when the whole-brain activity pattern was staying in a specific brain state. This experiment revealed that the prefrontal causality during bistable visual perception depends on brain state dynamics. For three PFC regions—right frontal eye fields (FEF) and anterior/posterior dorsolateral PFCs (a/pDLPFCs)—, the causal behavioural responses were detectable only when we modulated the PFC activity in state-/state-history-

dependent manners. These behavioural effects were explainable by transient changes in the brain state dynamics that underpinned the fluctuating perception, and such neural responses were attributable to structural transformations of hypothetical energy landscapes. Moreover, these findings revealed how the three PFC areas affected the brain state dynamics: aDLPFC enhances the integration of the two PFC-active brain states, whereas pDLPFC supports the diversity between them; FEF stabilises one of the PFC-active states. Furthermore, we found that the state-/state-history-dependent neural stimulation had accumulative effects, indicating its clinical potential. This work resolves the controversy over the PFC roles in spontaneous perceptual switching and highlights the importance of considering brain state dynamics in investigation of brain-behaviour causality.

Title: Effects of volitional activity on detecting a tactile stimulus in individuals post-hemiparetic stroke: a pilot study

Authors: *N. CAI[1], E. G. MEDINA[2], S. A. GONZALEZ[2], A. DUONG[2], N. GURARI[3]; [1]Dept. of Physical Therapy and Human Movement Sciences; NUIN Program, [2]Dept. of Physical Therapy and Human Movement Sci., [3]Dept. of Physical Therapy and Human Movement Sciences; Dept. of Mechanical Engin., Northwestern Univ., Chicago, IL

Abstract: In populations without neurological impairments, the detection threshold of tactile stimuli can be altered during volitional muscle activation. Literature suggests that an increased threshold during movement would arise due to gating of tactile sensory signals, likely, in part, from presynaptic afferent inhibition by interneurons. In individuals with hemiparetic stroke, the baseline activity of interneurons is heightened, which could amplify the gating of tactile sensory signals. However, it remains unclear whether volitional muscle activation post stroke would further modulate interneuron activity, altering the gating of tactile sensory signals and, subsequently, ability to detect the stimulus. Therefore, here we determined the impact of volitional activation on the ability to detect a tactile stimulus in individuals with hemiparetic stroke.Four males with hemiparetic stroke (age: 63±2 years, UE-FMA: 43±10, years since

stroke: 8±2) participated in this study. Participants were situated in a Biodex chair with their forearm affixed to a mechatronic device, which was instrumented with a torque sensor. Participants verbally indicated when they detected a force stimulus, which was administered via von frey filaments (0.07g, 0.4g, 2.0g, 4.0g, 10g, and 300g). This task was performed when participants remained at rest and when they isometrically flexed at the elbow to 25% and 50% of their maximum voluntary torque (MVT). The detection threshold of this tactile stimulus was obtained at each arm using an up-down staircase method.Participants had a detection threshold with a mean±standard deviation (μ±σ) of 1.58±0.90g at the non-paretic arm and 1.56±0.90g at the paretic arm when at rest. When participants flexed their elbow to 25% MVT, their μ±σ detection threshold increased to 2.56±2.44g at the paretic arm and 2.00±0.00g at the non-paretic arm. Finally, when flexing their elbow to 50% MVT, their μ±σ detection threshold was 3.56±2.79g at the paretic arm and 2.05±0.74g at the non-paretic arm.
In both arms, the detection threshold increased during volitional activation in our participants with hemiparetic stroke, in accordance with previous studies in individuals who are neurologically intact. Additionally, when our participants increased their flexion torque, their detection threshold correspondingly increased. Finally, the increase in the detection threshold as a function of generated torque was greater at the paretic arm than at the non-paretic arm. Combined, these results provide early evidence that sensory gating differs between the paretic and non-paretic arms, possibly because of altered interneuron activity post stroke.

Title: Characteristics of speech transmission of distantly-presented bone-conducted sounds in the audible-frequency range

Authors: *H. ISHIKAWA, S. OTSUKA, S. NAKAGAWA;
Chiba Univ., Chiba, Japan

Abstract: Although the upper frequency limit of human hearing is believed to be approximately 20 kHz, several studies have reported that high-frequency sound up to at least 100 kHz can be perceived clearly by bone-conduction (BC). This audible ultrasound through BC is referred to as bone-conducted ultrasound (BCU). BCU can be perceived even by the profoundly sensorineural hearing-impaired and has been applied to a novel hearing aid. On the other hand, in BC, a vibrator needs to be pressed onto the osseous parts of the temporal bone, such as the mastoid

process. Therefore, BC is often accompanied by pain and esthetic problems. In order to solve these problems, “distant presentation” has been proposed. In the distant presentation, vibrators are presented to the neck, upper limb or trunk. Our previous studies focused on the perception and propagation characteristics of distantly-presented BCU and an application to a novel audio-interface. On the other hand, a limited number of studies have been conducted on distantly-presented BC in the audible-frequency range. We have measured hearing thresholds and frequency- and temporal resolutions of distantly-presented BC sound in the audible-frequency range and showed that although distance attenuation is occurred largely as compared to BCU, no significant degradation of frequency and temporal information occurs in the propagation process of BC sound in the body. However, the clarity and sound quality of the transmitted speech sound should be investigated in more detail. In this study, to examine the characteristics of speech transmission of distantly-presented BC sound in the audible-frequency range, word intelligibility and monosyllable articulation tests were conducted in Japanese. As results, the intelligibility and articulation decreased as the stimulus placement got further from the head. This result indicates that amplitude information of the words and monosyllables was lost in the propagation process in the body. In addition, to examine the distortion of speech generated during the propagation inside the body, we composed confusion matrices based on the result of the monosyllable articulation test. In the phonemes of /tj/, /sj/, /zj/, significant differences were observed between percent corrects when the speech sounds presented to the mastoid process and trunk. The result indicates that degradation of high-frequency components of the speech sound occurred in the propagation process and it became more difficult to perceive the phonemes whose energy is concentrated in high-frequency range.

Title: Laminar Organization of Pre-Saccadic Attention in Marmoset Area MT

Authors: *S. H. COOP[1], G. SARCH[2], J. L. YATES[3], J. F. MITCHELL[1];
[1]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY; [2]Neurosci., Carnegie Mellon Univ., Pittsburgh, PA; [3]Univ. of Maryland Col. Park, College Park, MD

Abstract: Attention leads eye movements producing perceptual enhancements at the saccade target immediately before saccades (Deubel and Schneider, 1996; Kowler et al, 1995; Rolfs and Carrasco, 2012). This pre-saccadic attention has been related to enhanced neural responses before saccades made into a neuron's receptive field in macaque visual area V4 (Moore and Chang, 2009), but it is unknown how general the phenomena is and how it is organized across cortical layers. Here, we examined pre-saccadic attention in the middle temporal area (MT) of the marmoset monkey and took advantage of their smooth cortical surface to measure neural effects as a function of laminar position. In one animal, we used high density silicon arrays (NeuroNexus, 64 channel) to record from the full cortical depth. We find that current source density (CSD) methods, traditionally used in primary visual cortex, provide estimates of the input layer in area MT based on an early latency sink. Next we examined pre-saccadic attention in a saccade foraging paradigm. In each trial, the marmoset made a saccade from a central fixation point to one of three equally eccentric stimuli (full coherence dot fields with motion sampled independently between apertures, each from 16 directions). We positioned stimuli such that one foraged location overlapped the receptive fields of neurons under study and examined how tuning functions for motion direction changed when a saccade was planned towards or away from the receptive field. We fit the neural responses from -50 to 30ms around saccade onset with an adjusted Von Mises function that estimated both additive and gain changes in the tuning. We found that saccades towards the receptive field were associated with increases in gain that were prominent only in superficial layers while additive increases were shared across all layers. We also examined the extracellular waveform shapes and found a bi-modal distribution of peak-to-trough durations (i.e., narrow and broad spiking categories). In particular, the gain increases among superficial layer neurons were specific to the broad spiking category. These results indicate a diversity of function across layer and cell type that will be important towards constraining circuit level models of pre-saccadic attention.

Title: Neuromuscular mechanisms of motor adaptation to repeated gait-slip perturbations in older adults

Authors: S. WANG, ***T. BHATT**;
Univ. of Illinois at Chicago, Chicago, IL

Abstract: Background: Individuals can rapidly develop adaptive skills for fall prevention after their exposure to the repeated-slip paradigm, and the fall-resisting skills acquired from this training session can be retained for at least 6 months. However, the changes in neuromuscular control contributing to such motor adaptation after the perturbation training remains unclear.Aim:This study investigated changes in neuromuscular control across different stages of slip-adaptation by examining changes in muscle synergies (temporal and spatial components).Method:Electromyography signals during repeated slip trials in gait were collected for 30 healthy older adults. Muscle synergies in novel slip trial, early (6 to 8) and late trials (22 to 24) were extracted respectively using non-negative matrix factorization algorithm, and then the similarity between the recruited muscle synergies in three different phases (no adaptation, early-adaptation, and late-adaptation) was analyzed.Results:Our results showed that participants made significant improvements in their balance outcomes from novel slips to the adapted slips (balance loss rate dropped from 100% to 0%), Correspondingly, there was a significant increment in the muscle synergy numbers from no-adaptation slips to the adapted slips. The participants retained majority of muscle synergies (5 out of 7) used in novel slips post adaptation (both early- and late-adaptation stages), while the activation of these common synergies became lower in the adapted slips. A few specific patterns (n=8) of muscle synergies presented in the early-adaptation stage to compensate the motor errors due to external perturbation, in the late-adaptation stage, only 2 out of these 8 new synergies were retained. Conclusion:We found that with repeated slip adaptation individuals could acquire new muscle synergies through refinement of the pre-existing ones in the late adaptation phase could produce motor strategies that could effectively assist in recovery from the slip perturbation. During the early adaptation phase the CNS generates redundancy synergies that are eliminated as the adaptation process progresses with repeated exposure to the slips. This study enhances our understanding of the neuromuscular basis for adaptation to slips, which could assist with designing perturbation-based fall prevention training.

Title: Vision and proprioceptive effects on force intersection point in quiet human standing

Authors: *K. GRUBEN[1], J. BARTLOFF[1], C. GROVE[2];
[1]Univ. Wisconsin, Madison, WI; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: This study evaluated effects of reduced and disruptive visual stimuli and altered proprioception on sagittal-plane coordination during quiet human standing. Ten human female volunteers (aged 23 to 62 years) 5 with motion sickness and 5 age-matched controls, stood quietly for 30s in various conditions, repeated on four separate days within a 6-week period. The volunteer participants provided informed consent to a protocol approved by the local IRB. Coordination was assessed with the frequency-dependent intersection point analysis which characterizes the emergent property of the ground-on-feet force (F) to exhibit an intersection point (IP) within narrow frequency bands. The height of the IP (zIP) reflects the ratios of muscle torque at the primary joints and summarizes the complex interaction between the multi-segmental inverted pendulum dynamics and neuromuscular coordination strategies. Three representative frequencies (1, 2.2, 3.4 Hz) were chosen to characterize the zIP dependence on frequency. Previous work showed that sloped surfaces and volitional co-activation alter the zIP in a systematic frequency-dependent manner. Visual and proprioceptive inputs typically contribute to feedback during quiet standing, though the contributions vary across individuals. This study manipulated visual input via reduced complexity and disruptive character. The reduced complexity stimulus displayed a single world-fixed vertical bar of white light directly in front of the individual. The disruptive stimulus was an annulus of dots that filled most of the visual field and spun counterclockwise (30 deg/s) about the visual axis. The stimuli were delivered in a visual void with a virtual reality headset. This study also altered proprioceptive feedback with a foam pad under the feet. F was measured with custom 6-axis force plates. Student's t-tests (alpha = 0.05) with Holm-Bonferroni adjustment assessed the comparisons. Results show that on a firm surface viewing the light bar in the VR headset as compared to viewing the laboratory raised the zIP at the higher two frequencies. Standing on foam, compared to firm, increased zIP at the higher two frequencies when viewing the laboratory. However, with VR, standing on foam decreased zIP at 1 Hz, regardless of visual stimulus. These results provide evidence that the zIP provides a means of discriminating among the effects of visual and proprioceptive influences on the frequency components of coordination that ensure upright posture during quiet standing. Future work is needed to elucidate the mechanisms by which visual and proprioceptive feedback are integrated into this metric of coordination.

Title: Progression of gait disturbances in people with Parkinson's disease and REM sleep without atonia

Authors: D. J. WEAVER[1], S. L. AMUNDSEN HUFFMASTER[1], J. CHUNG[2], C. LU[1], M. E. LINN-EVANS[1], S. E. COOPER[1], A. VIDENOVIC[4], M. J. HOWELL[1], *C. D. MACKINNON[3]; [1]Neurol., [2]Dept. of Neurol., [3]Univ. of Minnesota, Minneapolis, MN; [4]Neurol., Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstract: Approximately 30 to 40% of people with Parkinson's disease (PD) have REM sleep behavior disorder (RBD), a parasomnia characterized by increased muscle activity during REM sleep (termed REM sleep without atonia, RSWA) and dream enactment. The co-expression of PD with RBD is associated with increased motor and cognitive impairment, including postural instability and gait disturbances, compared to those without RBD. Little is known about the association between the presence and expression of RSWA (measured by the level of muscle activity during REM sleep) and the rate of progression of gait impairment in people with PD. This study examined the progression of gait impairment in people with mild-to-moderate PD, with and without RSWA, and healthy controls over the course of three years. We hypothesized that: (i) people with PD with RSWA (PD+RSWA) would show a significantly higher rate of progression than the group without RSWA (PD-RSWA) and controls and (ii) baseline RSWA scores would predict the rate of progression of gait impairment. Forty-one people with PD (22 PD+RSWA; 19 PD-RSWA) and 21 age- and sex-matched controls participated. Testing was conducted off Parkinson's medications. Spatiotemporal parameters of steady-state gait were obtained using a GAITRite Electronic Walkway (CIR Systems, Inc.) (minimum of 31 steps). A linear mixed model tested for differences in progression (change from baseline to follow-up) between groups and sides (least affected vs. more affected). Linear regression examined the relationship between baseline RSWA scores and gait progression in the PD groups. Forty-eight individuals were tested at follow-up (16 in each group). Of those lost to follow-up, 43% were in the PD+RSWA group (PD-RSWA: 21%, controls: 36%). The mean time between baseline and follow-up tests was 35.3 ± 6.8 months. Stride length decreased over time in both PD groups, but the change was only significantly different from controls in the PD+RSWA group ($p < 0.030$). The average percentage change in stride length was -7.9, -3.9, and -1.2% in the PD+RSWA, PD-RSWA and control groups, respectively. There were no main effects of group or side, nor

interactions, for cadence and gait speed. RSWA scores at baseline did not predict the changes in gait over three years. These findings provide evidence that the presence of RSWA in early PD is a harbinger of rapid progression in gait impairment.

Title: Mechanical coordination of wrist and MP joint motion during typing

Authors: *T. ITO, M. YOSHIDA, H. FUNAKOSHI, T. KOKUBUN;
Grad. Sch. of Saitama Prefectural Univ., Koshigaya, Japan

Abstract: [1. Motivation]Repetitive typing movements are associated with the development of tendonitis of the hand (Gerr 2002). Coordinated movements have been evaluated in single keystrokes (Dennerlein 2006), but mechanical coordination has not been evaluated in freestyle typing. In this study, we use the Induced acceleration analysis (IAA) method, which consists of inverse and forward dynamics calculations to assess the effects of the wrist and metacarpophalangeal (MP) joint muscle torques on the generation of wrist acceleration. This study aims to clarify the mechanical interaction between hand segments.
[2.Methods]The subject was one healthy adult male. He provided written informed consent, following a detailed explanation of the study's purpose and risks according to the Declaration of Helsinki. He was 21 years old, right-handed, and a 10-finger typist. We used a 3D motion capture system (Vicon) and a QWERTY keyboard (Microsoft). The task was 5,000 Japanese characters. We recorded the sagittal plane of the right side of the wrist and the MP joint of the index finger angle, velocity, and acceleration during the task. The analysis interval was the time of five consecutive keystrokes in the right-hand region. The analysis items were (1) joint angles, (2) correlation coefficients, and (3) mean values (standard deviations; SD) and coefficients of variation of the contribution of joint muscle torques by IAA. This study was approved by the ethics review committee.
[3.Results]The mean (SD), maximum, minimum value, and coefficient of variation of the wrist joint extension angle were 41.8° (2.54), 45.0°, 37.3°, 0.06. The MP joint angle was 32.7° (4.11), 37.3°, 25.1°, 0.13. The wrist joint extension angle and the MP joint flexion angle were 42.5° and 34.4°. The correlation coefficient was 0.98. The mean (SD) and coefficient of variation of the

contribution were 83.2% (0.01) and 0.01 by the wrist muscle joint torques, and 16.5% (0.01) and 0.04 by the MP joint muscle torques.
[4.Conclusion/implications]The inertia force (centrifugal force and Coriolis force) generated by joint motion distal to the wrist joint had little effect on wrist motion at any time of the keystroke. The ratio of the contribution of the wrist and MP muscle torques to the velocity of wrist flexion/extension was kept constant, and the wrist and MP joint angles changed synchronously. This kinematic strategy is thought to be related to the efficiency of hand movements and to ensure the steadiness of successive keystrokes. The disruption of this motor strategy may be one of the motor mechanisms involved in developing tendonitis of the hand.

Title: Neural control of ankle impedance is more efficient during movement than posture

Authors: *K. JAKUBOWSKI[1,2,4], D. LUDVIG[1,4], S. S. M. LEE[2,5], E. J. PERREAULT[1,3,4]; [1]Biomed. Engin., Northwestern Univ., Evanston, IL; [2]Physical Therapy and Human Movement Sci., [3]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [4]Shirley Ryan AbilityLab, Chicago, IL; [5]Dept. of Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: Regulating ankle impedance—the torque evoked by an imposed displacement—is critical for ambulation and postural control. The impedance of the triceps surae muscles and Achilles tendon are the dominant contributors to ankle impedance in the sagittal plane during plantarflexion, but the nervous system can only regulate muscle impedance. Since these structures are connected in series, the most compliant structure will largely determine ankle impedance. However, their relative impedance during the posture and movement tasks commonly performed by the ankle is unknown. The objective of this study was to quantify these relative impedances during posture and movement to determine the limits on how the nervous system can leverage the tunable mechanical properties of muscle to regulate ankle impedance. We quantify triceps surae, Achilles tendon, and ankle impedance using a technique that combines joint-level measurements with ultrasound imaging. Ten healthy young adults had their

right foot attached to a motor that controlled ankle position and measured torque. Since muscle and tendon impedance change with torque, subjects were instructed to produce a constant plantarflexion torque aided by visual feedback. Subjects completed two tasks: a movement task where the motor moved the subject's ankle through a 20-degree sinusoidal motion at 0.5 Hz and a posture task where subjects performed isometric contractions at four ankle angles within the same range as the movement task. Ultrasound imaging of the medial gastrocnemius muscle-tendon junction was used to quantify muscle and tendon motion. The motor imposed small stochastic perturbations in all tasks to estimate impedance using time-varying system identification. We present the stiffness component of these impedances.
Across all angles, we observed a 39%, 55%, and 17% decrease in ankle, muscle, and tendon stiffness during movement compared to the posture task (all $p < 0.001$). During the posture task, the muscle was 2.6 times stiffer than the tendon, but the muscle was only 1.4 times stiffer during movement. Therefore, the Achilles tendon, a passive structure, is the dominant contributor to ankle stiffness during posture, but the triceps surae and Achilles tendon contribute more equally during movement. Additionally, a unit change in muscle activity would cause only a 28% change in ankle stiffness during the posture task but a 42% change during movement. Given that the nervous system can only actively regulate muscle stiffness, the nervous system will have better control of ankle stiffness during movement compared to posture even though the net stiffness for a given level of muscle activation is lower during movement.

Abstract: The heel-rise is frequently performed to train patients who are unable to plantar flex their ankle joints. Patients are often assisted by therapists because their whole-body muscle strength is impaired. However, it is unclear how the muscle activity of the ankle plantar flexors (i.e., triceps surae) changes with the assistance. Furthermore, since patients often have neurological problems, it is important to observe not only the amplitude of the compound action potential but also the behavior of the motor units. In this study, we examined the number and frequency of motor unit firings in the triceps surae during the heel-raise in 14 healthy adults (all were females, 18-20 ages) with and without a knee contracture brace. In addition, the Peason's correlation coefficient was used to verify whether the same motor units were detected across conditions; $r > 0.8$ was considered identical. The high-density surface electromyogram used to detect the motor units was Trigno Galileo (DELSYS, Inc.). Correspondence t-test was used for comparison between conditions. Significance level was set at $p = 0.05$. As a result, the number of motor unit firings of the triceps surae was higher under the condition with orthosis ($p = 0.03$). On the other hand, there was no significant difference in the frequency of firing of motor units between the conditions. In addition, the number of the same motor units detected between the conditions was only 16.84%. We cannot conclude the efficacy of using the orthosis during training, and further verification is necessary because of the possible limitation of detecting motor units from four electrodes of the measurement device.

Title: Neural control of rhythmic limb motion is shaped by size and speed

Authors: G. P. SUTTON[1], ***N. S. SZCZECINSKI**[2], R. D. QUINN[3], H. J. CHIEL[4];
[1]Univ. of Lincoln, Lincoln, United Kingdom; [2]West Virginia Univ., Morgantown, WV;
[3]Mechanical and Aerospace Engin., Case Western Reserve Univ., Cleveland, OH; [4]Case Western Res. Univ., Cleveland, OH

Abstract: Over many size and time scales, behaviors such as locomotion or feeding require cyclic mechanical movements. Size and time in turn determine a behavior's dominant mechanical properties: mass, stiffness or viscous damping. The constraints for limbed behaviors can thus be quantified by two variables: limb size and limb cycle time, defining a 'mechanics space' that shows the relative magnitude of each mechanical property for animals ranging from fruit fly to elephant. The mechanics space is continuous, but exhibits three primary regions: 1) an inertia-dominated region; 2) a gravity or elastic-force-dominated region; and 3) a viscous-force-dominated region. In the inertia-dominated region, associated with large limbs moving rapidly, muscle work is translated primarily into kinetic energy. Thus, stable motion requires compensatory control and active damping. In the elastic-force-dominated region, associated with small limbs moving slowly, muscle energy is translated primarily into gravitational or elastic potential energy. These motions are relatively insensitive to external perturbations and may require less active control than inertia-dominated motions. Lastly, in the viscous region, associated with small limbs moving quickly, joint viscosity acts to damp actuation, enabling the joint to dissipate most disturbances passively. A consequence of this analysis is that the relevant zone for a given behavior can be determined from not only the mechanics of the behavior (directly measuring forces within the limb), but also from analysis of the phase relationship between muscle force and limb position; with a 180 degrees relationship between force and position being a hallmark of the inertial dominated region, a 0 degree (in phase) relationship being a hallmark of the elastic-dominated region, and an intermediate phase relationship being a hallmark of the viscous dominated region. The relevant biomechanical region thus depends almost entirely on the size and cycle time of limb movement. In turn, these relationships between force and motion, and responses to perturbation have major implications for neural control.

Title: Determinants of falls and recoveries following platform translations

Authors: *P.-P. VIDAL[1,2,3], D. WANG[4,2], M. LE GOIC[1], J. DUYSENS[5];
[1]Cognac G, Univ. Paris Descartes - CNRS - SSA, Paris, France; [2]Hangzhou Dianzi Univ., Hangzhou, China; [3]Univ. Cattolica del SacroCuore, Roma, Italy; [4]Univ. de Paris, Paris, France; [5]KU Leuven, Leuven, Belgium

Abstract: The ability to react to sudden unpredictable multidirectional support-surface translations was investigated in young volunteers while standing upright quietly in a standard position with their eyes open. The perturbation velocities (35 and 90 cm/s) were sufficiently challenging to trigger non-recoverable falls. The surface electromyography activity (EMG) of 14 muscles was recorded and analyzed both for latency and amplitude. Without corrective steps, all slow forward or backward translations ended in a fall. With one or more corrective steps the recoveries increased. With less steps, there were better chances of recovery. Furthermore, recovery steps tended to be faster. The longer, higher or the larger the first step, the better chances of recovery. These corrective movements were achieved by flexing all joints. The compensatory flexion occurred earlier in successful recoveries than falls. However, the peak flexion amplitudes were not significantly different between falls and recoveries at the ankle, knee and hip level. In addition, fall trials kinematics displayed higher variability than recoveries. In fast forward trials with successful recovery, the functional arm movements occurred earlier than in falls. Moreover, the arms abduction was of greater peak amplitude and reached earlier than during a failed recovery. In contrast, in falls, peak elbow flexion was significantly greater, with a similar time to peak angle. As for EMG, the latencies of most responses to fast-forward did not differ much between the 2 types of trials. Nevertheless, in the swing leg the latency of TA was significantly shorter in the fall trials as compared to the recovery trials as in erector spinae and in deltoids. Hence, fast responses do not predict success in recovery. Overall, for other muscles, the EMG responses tended to have higher amplitude in recovery, in particular for SOL and RF in the swing leg and for TA and RF in the stance leg. These higher activities were associated with larger corrective steps. Backward translations were easier to correct for and, in fact, the fast-backward translations accounted for only 11% of all falls, as compared to 31% of all falls for fast-forward translations. Furthermore, when the translation was backward, the duration of the first step was significantly shorter than in the other conditions. Leg muscles activation muscles had latencies which were similar to those seen in forward translation. Following mediolateral perturbation, side-stepping was the most popular strategy while the crossover step was seen to be favoured in fall trials. Leg muscles activation in medio-lateral perturbations showed that recovery trials were generally faster.

Title: Generalization of motor memories is governed by the contextual similarity between training and testing environments

Authors: Y. AUCIE, ***G. TORRES-OVIEDO**;
Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Generalization of movements from experienced to novel situations is a critical aspect of motor adaptation. It has been shown that augmenting the extent of motor adaptation and increasing the similarity between training and testing environments would enhance the generalization of movements from the trained to untrained contexts. However, little is known about how augmenting the extent of adaptation while decreasing the contextual similarity between the training and the testing environment would affect the transfer of movements between environments (i.e., generalization). Here we investigated the effect of augmenting the extent of adaptation on the generalization of learned movements while decreasing the similarities between the training and the testing environments. It has been demonstrated that incline walking would augment the extent of adaptation while decreasing the similarity compared to flat overground walking. To this end, a group of young, unimpaired individuals was adapted on the treadmill either incline or flat. We compared the generalization of movements from these two adaptation settings by quantifying the adaptation effects (i.e., after-effects) overground. We found that the generalization of aftereffect was larger when participants were adapted flat compared to those who adapted incline. Our results suggest that increasing the similarity between the training and the testing contexts is a more important factor than the extent of adaptation in the generalization of recalibrated movements in split-belt walking paradigms. This suggests that training that maximizes the similarity between the training and the testing settings would lead to better outcomes in new situations.

Title: Distinct perturbation-evoked cortical potentials associated with balance recovery during unexpected slipping while walking: a feasibility study

Authors: *R. M. PUROHIT[1], S. WANG[1], S. SANGANI[3], J. FUNG[4], T. S. BHATT[2];
[1]Physical Therapy, [2]Physical Therapy, Movt Sci., Univ. of Illinois at Chicago, Chicago, IL;
[3]Feil/Oberfeld/CRIR Res. Ctr., Jewish Rehabil. Hosp., Laval, QC, Canada; [4]McGill Univ., Montreal, QC, Canada

Abstract: Background: Cortical contributions to reactive balance control have recently been suggested through electroencephalography (EEG) based analysis of beta oscillatory activations and large-amplitude N1 evoked potentials in response to unexpected surface translations in standing. However, cortical dynamics involved in real-life like unexpected environmental perturbations during walking (slips and trips) have never been studied. We have previously identified different muscle synergies between falling or recovering from overground slips while walking. The present study examines cortical evoked potentials in response to large-scale overground slip perturbations in walking to contrast between balance recoveries and falls. **Methods:** Fifteen healthy young adults (8 female, 7 male; ages 18-35) were exposed to a single, novel, unannounced large-size (slip distance=65cm) right-sided overground gait-slip. Analysis of cortical responses from 32 wireless EEG channels acquired at 500Hz filtered with a band pass filter (2-60Hz) were focused bilaterally over supplementary motor (FC3, FC4) and motor areas (C3-C4, Cz) as well as posterior parietal areas (P3, P4, Pz). EEG responses were analyzed corresponding to perturbation onset and recovery responses (0-150 ms window for the negative N1, positive P1 responses; and 150-300 ms for polysynaptic (N2) responses). **Results:** All subjects experienced a backward loss of balance (BLOB) with a slip exposure. Following an unpredicted perturbation, distinct large-amplitude evoked potentials (N1 responses) were identified from baseline to the trough of first negative wave (N1) . N1 cortical responses were consistently followed by large-amplitude positive peak (P1) . N1 responses were largest (200.23 ± 50μV) for subjects who experienced a fall (7 out of 15) as compared to smaller amplitude N1 responses in those who successfully recovered by exhibiting an aborted (28.75 ± 24.17 μV) or a backward (73.75 ± 44 μV)step. The N2 ERP component could clearly be identified and robustly corresponded to the time of recovery stepping in all individuals. This polysynaptic cortical response known to reflect executive cognitive control was found to be larger in amplitude for individuals who executed a backward stepping response as compared to those who aborted their step to recover from balance loss. **Conclusion:** Distinct N1-P1 and N2 cortical responses can be identified following an unpredicted over ground slip exposure in healthy young subjects. Balance-perturbation evoked negative peak cortical responses are modulated and seem to scale according to balance recovery or fall.

Title: Neuromuscular influences on the divergence of joint angles during repetitive motion

Authors: *B. SENDERLING, N. STERGIOU, A. LIKENS;
Ctr. for Res. in Human Movement Variability, Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Introduction: Human movement contains an inherent level of variability resulting from a complex nervous system. Because of this, repetitive motions never repeat the same path and have some level of mathematical divergence. While neuromuscular activity and divergence during varied movements have been frequently investigated, the influences of one on the other have not been articulated. Therefore, we hypothesized that the divergence in human movement is related to coordination of muscles around a joint. We analyzed data from a previous study to investigate the correlation between muscle coordination and joint angle divergence during cardiopulmonary resuscitation. A reliable correlation would provide insight on a potential source of human movement variability. Furthermore, it could allow joint angle divergence to be quantified with alternative technologies. **Methods:** Sixteen individuals (11 lay-rescuers and 5 professional) performed two minutes of chest compressions on a manikin. The first and last 3 s were not used in the data analysis. Elbow, hip and knee angles were measured bilaterally with an Xsens (Enshede, The Netherlands) inertial motion capture system. Muscle activity was recorded bilaterally through 8 Delsys Trigno (Natick, MA, USA) sensors placed on the agonist-antagonist muscle pairs. State-space reconstruction and Lyapunov Exponents were used to quantify joint

angle divergence. Muscle activity was band-pass filtered between 10 and 500 Hz and enveloped with a 4 Hz low-pass filter. The variation in muscular coordination between agonist-antagonist muscle pairs was quantified as the circular standard deviation of the continuous relative phase between pairs. Bayesian linear regression with Jeffreys priors was used to find the relationship between joint angle divergence and relative phase circular standard deviation.
Results/Discussion: Regression results reported somewhat low R squared values, 0.126 ± 0.085. Relative phase standard deviation was positively related to joint angle divergence for all joint angles except the left elbow. The posterior probabilities averaged 0.797 ± 0.271. These exploratory results provide weak evidence that deviations in coordination between agonist-antagonist muscle pairs tend to be positively correlated with higher joint angle divergence values. However, the results also suggest a larger sample size will be needed in order to draw strong conclusions. If replicable, though, the results provide promising evidence that joint angle divergence could be quantified through muscle activity.

Title: Modulation of muscle synergies during locomotor adaptation in humans

Authors: *A. OSHIMA[1,3], Y. NAKAMURA[2], T. WAKAHARA[2,4], K. KAMIBAYASHI[2]; [1]Grad. Sch. of Hlth. and Sports Sci., [2]Fac. of Hlth. and Sports Sci., Doshisha Univ., Kyoto, Japan; [3]Res. Fellow of Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Human Performance Lab., Waseda Univ., Saitama, Japan

Abstract: Modulation of the walking pattern (Locomotor adaptation) has been investigated using a split-belt treadmill that has two belts. Previous studies measuring kinematics data have indicated that humans can adapt to a new walking condition by modifying their walking spatiotemporal parameters and that the central nervous system (CNS) such as the cerebellum plays a critical role in locomotor adaptation. However, it is still unclear how the CNS controls multiple muscle activities in the lower extremities during locomotor adaptation. Regarding control of numerous muscle activities in human locomotion, the muscle synergy concept has been proposed. Therefore, we aimed to investigate neural control of numerous muscle activities underlying locomotor adaptation based on the muscle synergies concept. Healthy young males

were asked to walk on the split-belt treadmill which was operated either tied-belt (two belts moved at the same speed) or split-belt (two belts moved at the different speed) condition. The walking speeds were set to 3.0 (slow) and 5.4 (fast) km/h. The baseline period was tied-belt condition at fast and slow for each 2 min. Subsequently, the adaptation period was split-belt condition with the left belt at slow and right belt at fast for 9 min. We defined the leg on the slow or fast belt during adaptation period as “slow leg” or “fast leg”, respectively. The post-adaptation period was again tied-belt condition at slow for 5 min. Electromyograms (EMGs) were recorded from 26 lower limb muscles bilaterally using surface EMG electrodes. We then extracted the muscle weightings and activation coefficients of the muscle synergies from the EMG data in each period using a non-negative matrix factorization. Approximately four muscle synergies were sufficient to explain the original EMG data in each period. In the muscle synergy which was mainly activated in the initial swing phase in the slow leg, the center of activity (CoA) shifted to the later phase within a gait cycle during adaptation period. The full width of half maximum (FWHM) of the same muscle synergy decreased during adaptation period. The CoA of the muscle synergy which was mainly recruited in the late stance phase in the slow leg shifted to the earlier phase within a gait cycle during adaptation period. On the other hand, the CoA and the FWHM of the muscle synergy which was mainly activated in the late swing phase in the slow leg were unchanged in the adaptation period. These results suggest that the CNS flexibly regulates the activity timing and the duration of neural input in some specific muscle synergies when adapting to the new walking condition.

Title: Concurrent gait adaptation to visual and split-belt perturbations

Authors: S. HOWSDEN, N. BARTELS, ***S.-J. KIM**;
California Baptist Univ., Riverside, CA

Abstract: Gait asymmetry is a common symptom in populations with neurological disorders and significantly reduces gait efficiency. To improve gait symmetry, we propose a novel gait rehabilitation paradigm that combines distinct perturbation strategies, specifically, visual feedback distortion (VFD) with split-belt treadmill (SBT) walking. In SBT walking, spatiotemporal gait adaptation can be readily made, but it quickly fades. Gait adaptation to VFD

tends to persist longer, potentially due to more involvement of implicit learning processes. Thus, we aimed to determine whether combined strategies lead to more effective gait symmetric adaptation with a longer retention. Our pilot experiment had 20 subjects participate in two trials (SBT only & VFD+SBT conditions). Each trial consisted of 3-min base, 7-min adaptation, and 15-min post-adaptation periods. During the adaptation period, only the right leg speed was increased from 2 to 3 mph by 0.2 every minute and stayed at 3 mph until the post-adaptation period started (both belt speeds became the same). Under the VFD+SBT condition, the visual bar representing only the right step length was distorted (shortened) by 8% every minute down to a total of 60% distortion. The subjects were unaware of the distortion and looked at the visual bars while adapting to SBT walking. The VFD and SBT perturbations were then removed during the post-adaptation period. Figure below shows the changes in step length symmetry and aftereffects between the two conditions. We found 9 subjects who showed adaptation (Fig. A, group A) and 8 subjects who did not show adaptation (Fig. B, group B) and three outliers (not included). Group A clearly showed an increase in the aftereffects of the new gait pattern. Although more testing will be needed, the results of this pilot study demonstrated a potential advantage of combining VFD into SBT walking to facilitate gait adaptation and improve the retention effect.

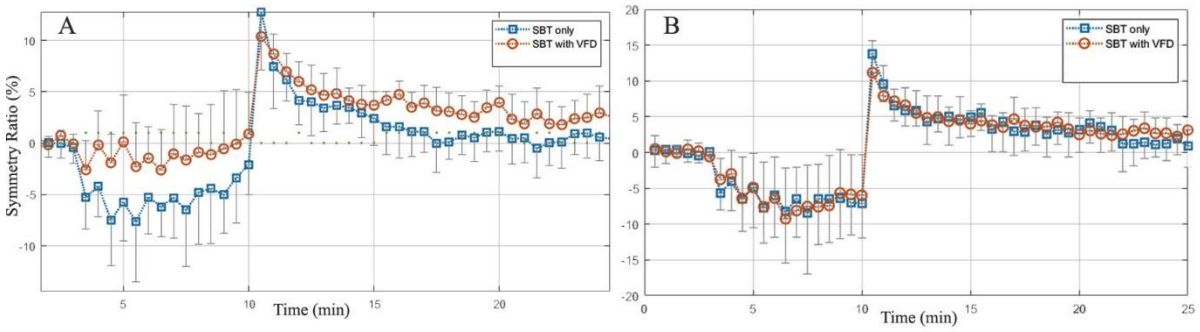

Figure. Changes in step length symmetry during adaptation and post-adaptation periods for SBT only & VFD+SBT conditions. The symmetry ratio (%) was measured by 2*(R-L)/(R+L).

Title: Trunk support improves walking in children with cerebral palsy

Authors: *S. YAN[1,2], S. PARK[1,2], R. REED[1], W. DEE[1], A.-M. ROJAS[1,2], W. Z. RYMER[1,2], M. WU[1,2,3];
[1]Legs and Walking Lab., Shirley Ryan AbilityLab, Chicago, IL; [2]Dept. of Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [3]Dept. of Bioengineering, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Children with cerebral palsy (CP) often show impaired walking ability and excessive trunk movements. Excessive trunk movements are considered not only compensation for lower limb deficits but also poor trunk control. It is unclear whether providing lateral trunk support during walking would improve gait in children with CP. The purpose of this study was to determine the effects of lateral segmental trunk support on walking in children with CP. We hypothesized that providing lateral trunk support during treadmill walking would improve gait performances in children with CP. Twelve children with CP (mean = 11yr (5yr-16yr), 4 boys) participated. Two belts were attached to the children's trunk. One belt was below the armpits for supporting the upper trunk (T7-T10), the other was above the pelvis for supporting the lower trunk (L1-L4). A D-shape ring was sewed on both sides of the belts, allowing a rope to hook and provide pulling forces to the left and right sides. On each side, the D-shape ring and the rope were connected by an extension spring (stiffness = 1.31N/mm) so that various pulling forces were applied by extending the spring. After walking on a treadmill for 1 minute at a comfortable speed (baseline), children then walked at the same speed under three randomized conditions: the springs were attached to the belt(s) positioned at the upper trunk (UTS), the lower trunk (LTS), and a combination of the upper and lower levels of the trunk (CTS). The extended length of the springs was decided based on children's tolerance before the three conditions and remained the same on both sides and all conditions. Each condition lasted for 1 minute and a 1-min break was given between conditions. We recorded kinematic signals using Xsens wearable sensors, propulsive forces with a Bertec treadmill, and muscle activities using Trigno wireless EMG system. Variables included step length, step height, sagittal hip range of motion (ROM), and the integrated muscle activity during the single-limb stance phase. For the weak side, children had greater step length and step height in CTS than those in baseline, and greater step length in UTS and CTS than that in LTS ($p < 0.05$). Changes of soleus activity of the single-limb stance phase across conditions mirrored changes of step length across conditions ($p < 0.05$). Greater sagittal hip ROM on the strong side occurred in CTS compared to baseline ($p < 0.05$). We concluded that lateral trunk support during treadmill walking can improve gait performances in children with CP. Results suggest that targeted trunk control may be applied in future training to improve gait performances in children with CP.

Title: Reactive Stepping Balance Following Balance Training for Individuals with Incomplete Spinal Cord Injury

Authors: *J. W. LEE[1,4], J. YANG[1], S. MAUCERI[1], K. CHAN[4], J. UNGER[2,4], K. E. MUSSELMAN[2,3,4], K. MASANI[1,4];

Abstract: Introduction Individuals with incomplete spinal cord injury (iSCI) often experience impairment of lower-limb sensorimotor functions, resulting in compromised reactive balance and increased fall risk. We previously reported that during a reactive stepping task, those with iSCI more frequently required multiple steps to recover from a forward fall, compared to able-bodied (AB) individuals. We also reported that inadequate foot placement for those with iSCI may contribute to the need for multiple steps to recover balance. This inadequate foot placement may improve after balance training, resulting in improved reactive balance and reduced fall risk. Here we investigated the effect of balance training on foot placement during a reactive stepping task, elicited by a simulated forward fall. We hypothesized that following balance training, foot placement of those with iSCI would become similar to that of AB individuals. Method Twenty-one individuals with iSCI participated in eight weeks of balance training. Data from ten participants were analyzed. Participants performed up to 10 trials of the Lean-and-Release (L&R) test. Participants adopted a forward lean while 8-12% of their body weight was supported by a tether, which was unexpectedly released. The L&R test was performed before and after balance training as well as 3-months after completing balance training. Kinematic and kinetic data were recorded using a motion capture system and force platform. We compared the average margin-of-stability (MOS) and intra-subject standard deviation (SD) of MOS at foot contact (FC) and 0.05s after FC. In addition, correlation of MOS at FC with scores on the Mini Balance Evaluation Systems Test (mini-BESTest) and Community Balance and Mobility (CB&M) scale were calculated. Results and Discussion The average MOS were not significantly different across three time points (FC: p=0.175; FC+0.05s: p=0.200). There was a significant effect of balance training on SD of MOS at FC (p=0.042) while not at FC+0.05s (p=0.087). In addition, average MOS was significantly correlated with both mini-BESTest scores (pre: p=0.019; post: p=0.008; follow-up: p=0.014) and with CB&M scores at post and 3-months after balance training (pre: p=0.072; post: p=0.030; follow-up: p=0.028). MOS was used to analyze the

dynamics of how foot placement changed after balance training for those with iSCI. Our findings suggest that balance training could improve foot placement during a reactive stepping task. This study contributes to a better understanding of dynamic postural control for individuals with iSCI, which may lead to the development of effective therapies and assessments for this population.

Title: Multiple modes of generating ingestive motor programs in the feeding network of Aplysia

Authors: *C. G. EVANS[1], M. A. BARRY[1], M. H. PERKINS[1], J. JING[2], K. R. WEISS[1], E. C. CROPPER[1];
[1]Icahn Sch. of Med. at Mount Sinai, One Gustave Levy Place, New York, NY; [2]Nanjing Univ., Jiangsu, China

Abstract: In many CPGs activity is reconfigured to generate different outputs. We study this process in the feeding network of Aplysia. In this system an ingestive configuration can be achieved if cycles of activity are repeatedly triggered by a command-like neuron, CBI-2. In this situation, repetition priming is observed. Cycles of activity gradually switch from an intermediate to an ingestive configuration, and a persistent state is created. Priming is largely mediated by slow modulatory effects of neuromodulators released from CBI-2.
We recently showed that there are preparations in which priming is absent (Evans 2021). Ingestive activity can be generated in these preparations by co-activation of a higher order neuron CBI-3, with CBI-2. With CBI-3 co-activation, reconfiguration occurs immediately, and rapid switches between ingestive and intermediate activity are possible. We have hypothesized that there are multiple modes of generating ingestive activity in the feeding network that serve different purposes.
To probe this idea, we sought to determine whether the absence of priming is due to deficits in neuromodulation. When priming occurs, it results from progressive increases in the firing frequency of the B8s. In part, changes in B8 activity result from neuromodulator induced excitability increases that occur during the first few cycles of activity (Dacks, 2012). However,

changes in B8 firing frequency occur subsequently, as a result of disinhibition, i.e., there are progressive decreases in the firing frequency of the inhibitory B4/5 neurons presynaptic to B8. Disinhibition is independent of neuromodulation. It results from activity dependent decreases in B4/5 intrinsic excitability.
We characterized B4/5 activity in preparations that would not prime, and found that firing frequency did not decrease despite the presence of the activity dependent mechanism that decreases intrinsic excitability. This suggests that when there is no priming, B4/5 receive increased excitatory synaptic input. Consistent with this idea we found that the phasic (presumably synaptic) depolarization in B4/5 increased after failed attempts to induce priming, but did not increase when priming was successful. Our data suggest that the absence of priming is not simply due to the lack of a neuromodulator induced increase in B8 excitability. Instead, it is due to a mechanism that actively maintains the default state inhibition of B8, i.e., maintains B4/5 activity. These data support the idea that the absence of priming does not reflect a pathology, but suggest in some conditions, ingestive responses may require CBI-3 activity.

Title: Modulator capacity corresponds with dietary diversity in three species of decapod crustaceans

Authors: *D. J. POWELL, A. I. MILLER, J. S. KAZMI, G. BUKOWSKI-THALL, P. S. DICKINSON;
Bowdoin Col., Brunswick, ME

Abstract: The central nervous systems of decapod crustaceans contains numerous amines, amino acids, and peptides that modulate the central pattern generating (CPG) circuits found within its stomatogastric nervous system (STNS) and cardiac ganglion (CG); over 30 modulators have been identified in one species of crab. CPGs in the STNS are responsible for internally chewing and filtering food into the midgut, while the CG drives the heartbeat. Neuromodulation allows these CPGs to flexibly produce a variety of output patterns; however, the variety of

modulators exceeds the variety of induced output, leading us to ask why so many modulators are present. Although modulatory capacity, a measure of the extent to which a neuronal circuit can be modulated, may be solely an inherited trait, we hypothesize a functional correlation, with decapods that need more behavioral flexibility utilizing a broader range of modulators than those with more stereotyped behaviors. We thus predicted that decapods with broad diets would have a larger modulatory capacity in the STNS, but not the CG, than those with limited diets. To test this, we compared responses of the STNS and CG CPGs in three species of majoid crabs (*Pugettia producta*, *Libinia emarginata*, and *Chionoecetes opilio*) to the same neuromodulators. *L. emarginata* and *C. opilio* both have broad diets, while *P. producta* primarily eats kelp. With one exception, each species' CG exhibited similar responses to all modulators. The STNS of crabs with broader diets responded similarly to all modulators, whereas the *P. producta* STNS showed limited responses to the same set of neuromodulators. CG responses did not follow this trend, as all crabs showed varied CG response to modulation. Modulators: *Cancer borealis* Tachykinin Related Peptide (CabTRP), Crustacean Cardioactive Peptide (CCAP), Red Pigment Concentrating Hormone (RPCH), Myosuppressin (Myo), Oxotremorine (Oxo), Dopamine (DA), Proctolin (Proc).

Title: Habitat temperatures determine the functional temperature range of central pattern generators in the crustacean stomatogastric nervous system

Authors: *L. VINK-LAINAS, W. STEIN;
Illinois State Univ., Normal, IL

Abstract: Rapid temperature fluctuations are a major challenge to neuronal function. Among other effects, temperature changes cause an imbalance of ionic conductances that are key to neuronal and synaptic activity, leading to failure of neuronal function. This is a particular threat for ectothermic species that experience rapid environmental temperature fluctuations due to natural and climate change-induced extreme weather conditions. Thus, possessing physiological mechanisms to mitigate the effects of temperature changes is essential for survival. However, the limits within which neurons can respond adequately to temperature changes and the evolutionary

pressures to temperature robustness are not well understood.
We are investigating temperature responses in the pyloric and gastric mill central pattern generators of the crustacean stomatogastric nervous system. These pattern generators control aspects of feeding, serve a vital function in survival, and have been characterized in several species. The main question driving our research is whether species' habitat temperatures affect neuronal temperature responses and robustness against failure. Using a comparative approach, we record the pyloric and gastric mill rhythms across temperatures in several related crab species: *Cancer borealis*, *Cancer magister*, and *Carcinus maenas*. We identify the range of temperatures at which the rhythms remain functional in each species and compare to their distinct habitat temperatures.
The species that experiences a greater range of temperatures in its environment had a pyloric rhythm that was functional at a greater range of temperatures. Specifically, *C. maenas*, which experiences habitat temperatures ranging 0-35°C, had a rhythm that was functional over an average range of 6-33.4 ± 1.3°C (n=10). *C. borealis*, which experiences habitat temperatures ranging 3-25°C, had a functional rhythm over an average range of 6-26.9 ± 1.4°C (n=9). The pyloric rhythm of *C. magister*, which lives in similar habitat temperatures as *C. borealis*, remained functional between 6 and 24.9 ± 3.7°C (n=9). Thus, our results show that the maximum temperatures at which the pyloric rhythm remained functional corresponded to environmental temperature ranges experienced, suggesting that habitat temperature determines the range of temperatures at which the nervous system can function. We are currently testing whether this holds true for the gastric mill rhythm as well.

Title: Excitatory neuromodulation reduces inter-animal variability of neuronal activity

Authors: *O. ITANI, A. C. SCHNEIDER, D. BUCHER, H. G. ROTSTEIN, F. NADIM; Federated Dept Biol. Sci., New Jersey Inst. of Technol., Newark, NJ

Abstract: Neural circuit output can be remarkably consistent across animals despite significant variability in the circuit building blocks. Recent experiments suggest that neuromodulators may

play a significant role in promoting such consistent circuit output. However, the mechanisms through which neuromodulators may do so remain unknown. We focused on consistency of individual neuronal activity, and used mathematical modeling to demonstrate how neuromodulation of cellular excitability may promote consistent cellular activity from a population of cells with variable underlying conductances.
We used a population of leaky integrate-and-fire (LIF) models, with their leak conductance chosen from a uniform distribution, and considered the frequency-current (fI) relationship as a measure of cellular activity. The coefficient of variation (CV_{fI}) of firing frequency measured across a range of input currents was used as the measure of variability across the population, so that a reduction in CV_{fI} was interpreted as a more consistent inter-population variability. Excitatory neuromodulation was modeled by adding an excitatory ionic current of a fixed conductance.
We could readily demonstrate that adding a fixed level of excitatory neuromodulation always reduces CV_{fI} across the population of LIF neurons. However, it is known that neuromodulatory excitation itself can be variable. To address how the LIF population responds to variable levels of excitatory neuromodulation, we examined how CV_{fI} changed with the mean and standard deviation (SD_m) of the modulatory conductance. We found that excitatory neuromodulation reduced CV_{fI} so long as SD_m remained below a threshold value.
To compare our findings with the effect of an modulatory neuropeptide acting on the crab stomatogastric lateral pyloric neuron, we extended our LIF model to include a refractory conductance within the same framework, and investigated the influence of the refractory parameter variability on CV_{fI}. This approach proved to be amenable to interpreting biological data and variability and allowed for the determination of ranges for which SD_m reduced CV_f, which could then be compared to the experimentally measured variability of the modulatory conductance.

Title: Neuropeptide-elicited neuronal switching involves modulation of multiple intrinsic properties

Authors: *R. R. SNYDER, D. M. BLITZ;
Biol., Miami Univ., Oxford, OH

Abstract: Neuronal switching contributes to internetwork coordination and flexibility of oscillatory networks to drive context-appropriate rhythmic behaviors (Dickinson, 1995, *Curr Opin Neurobiol*). In the established switching mechanism, synaptic strength modulation recruits a neuron into another network. Alternatively, in the crab *Cancer borealis* the LPG neuron switches from only fast rhythm activity (1 Hz; food filtering) to dual fast/slow (0.1 Hz; food chewing) bursting when membrane properties are altered by a modulatory neuron or its bath-applied neuropeptide Gly^1-SIFamide (SIF) (Fahoum & Blitz, 2021, *BioRxiv*). Thus far, membrane property(ies) and ion channel(s) that enable intrinsic slow bursting, which must periodically escape from fast rhythm electrical synaptic input, are unknown. We isolated LPG from both networks and first examined intrinsic properties with depolarizing current injections. We found bath-applied SIF (5×10^{-6} M) enhanced the firing frequency/current relationship (0.5 - 2.5 nA, n=7; $p<0.01$; two-way ANOVA) and decreased Spike Frequency Adaptation (SFA; Control rate of change: 0.014 ± 0.003; SIF: 0.006 ± 0.01 sec^{-1}, n=9; p=0.004, signed-rank). This increased intrinsic excitability and decreased SFA may prolong burst duration. Regarding mechanisms of burst initiation, we found that SIF enhanced post inhibitory rebound, evident as a larger depolarization above baseline post-hyperpolarization (Control integrated area: 4.1 ± 1.0; SIF: 20.5 ± 3.0 mV*ms, n=9; $p<0.001$, paired t-test). SIF increased a corresponding sag potential (Control: 1.93 ± 0.42; SIF: 5.12 ± 0.71 mV, n=10; $p<0.001$, paired t-test) indicating a hyperpolarization-activated (I_h) current. SIF + CsCl (5µM; I_h blocker) had a variable effect on LPG burst duration (n=2/5 longer, 3/5 shorter than SIF). However, SIF + CsCl elicited a longer LPG interburst interval in 5/5 experiments thus far (p=0.063, power=0.33, paired t-test), suggesting I_h contributes to burst initiation. We also used riluzole (30 µM) to block the persistent sodium current (I_{NaP}) which can support burst maintenance (Paton et al, 2006, *Nat Neurosci*). SIF + riluzole elicited a shorter burst duration than SIF only (SIF: 6.0 ± 0.4; SIF+ril: 1.5 ± 0.3 s, n=8; $p<0.001$, paired t-test) but did not alter interburst interval (n=8; p=0.063, paired t-test), implicating I_{NaP} in burst maintenance but not initiation. Thus, in a switching neuron recruited by intrinsic property modulation, we identified multiple intrinsic properties that are modified. Future goals are to determine if these modulatory actions are sufficient for intrinsic bursting capable of escaping faster, electrically-coupled rhythmic input.

Title: Multiple neuron types mediate internetwork coordination via distinct synaptic mechanisms

Authors: *S.-R. H. FAHOUM, D. M. BLITZ;
Biol., Miami Univ., Oxford, OH

Abstract: Internetwork coordination between distinct rhythmic networks is important for overall function in many systems (Steriade et al., J Neurosci 1993; Larson et al., J Neurophys 1994; Tryba et al., J Neurophys 2008; Rangel et al., Elife 2016; Blitz et al., J Neurophys 2019), but cellular mechanisms are poorly understood. Some identified mechanisms include rhythmic pre-synaptic inhibition of a modulatory input and a pivotal internetwork synapse (Bartos et al., J Neurosci 1997; Bartos and Nusbaum, J Neurosci 1999). Here, we examine intra-/internetwork interactions in the crab *Cancer borealis* stomatogastric nervous system, which contains two small, well-defined networks (pyloric [fast, ~1 s cycle period (CP)]; gastric mill [slow, ~10 s CP]) and identified modulatory inputs. In an established biological model, bath-applied neuropeptide Gly^1-SIFamide (SIF: 5 µM) mimics modulatory neuron activity by recruiting the fast-only LPG neuron into dual (fast/slow) activity that is coordinated with both networks (Fahoum and Blitz, BioRxiv 2021). We use this model to examine whether dual activity of the switching neuron LPG is required for rhythm generation (RG), intra- and/or internetwork coordination. First, we removed the two copies of LPG using photoinactivation (SIF-kill). Both rhythms occurred in the SIF-kill condition (n = 4/4), suggesting that LPG is not necessary for RG in either network. In SIF-intact, LPG slow activity is coordinated with slow network neurons in a three-phase pattern: LG/IC, LPG, DG (n = 4/4). These timing relationships are not altered in SIF-kill (SIF-intact vs SIF-kill: $p > 0.05$, n = 4, paired t-test). Thus, LPG is not necessary to coordinate slow network neurons. However, LPG may play a role in fast/slow coordination, as LPG is electrically coupled to the fast network pacemaker neurons (Shruti et al., J Neurophys 2014), and the slow network regulates fast network CP in SIF-intact (Blitz et al., J Neurophys 2019). We used fast network CP variability (coefficient of variation, CV) to measure slow network regulation of the fast network. SIF-intact increased fast network CV compared to saline ($p = 0.007$, n = 4). SIF-kill decreased CV ($p = 0.01$), but not to saline level ($p = 0.01$), suggesting LPG contributes partially to internetwork coordination. In SIF-intact, hyperpolarizing slow network neurons LG ($p = 0.004$, n = 8) or IC ($p = 0.013$, n = 10), but not DG ($p = 0.212$, n = 8), decreased CV, indicating that LG and IC also contribute to fast network regulation. These data suggest that multiple neurons, active in distinct phases of a slow rhythm and using electrical vs chemical inhibitory synapses, collectively contribute to regulating a related faster rhythmic network.

Title: Activity and energy: The effect of K-ATP channel activity on network output of the pyloric circuit in the C.borealis stomatogastric ganglion

Authors: *S. KEDIA, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: Prolonged changes in neuronal activity are triggers for homeostatic processes involved in maintaining activity levels around arbitrary 'set points'. An essential component of the homeostatic machinery is a means by which neurons can sense their own activity levels. ATP, the cell's energy currency, is intimately involved in maintaining a neuron's internal ionic environment and membrane hyperpolarization, especially in times of heightened activity. Fluctuations in levels of available ATP might serve as a signal for changing neuronal activity to balance its demand and supply. ATP-sensitive K channels have been implicated in regulating neuronal activity in response to changing glucose levels and after events such as hypoxia to balance activity levels with available energy resources. The channel is activated by increasing levels of ADP, the product of ATP hydrolysis indicating decreasing ATP levels, upon which it participates in hyperpolarizing the neuron to reduce its firing. We explore the role of K-ATP channels in regulating activity of an oscillatory system, the pyloric circuit in the *Cancer borealis* stomatogastric ganglion (STG). The network produces a rhythmic output continuously *in vivo* and continues to do so *in vitro* and has been studied for its remarkable homeostatic and adaptive properties to changing neuromodulatory and environmental conditions, however the molecular underpinnings of these adaptations remain uncovered. We wanted to examine pathways of neuronal activity modulation as a consequence of energy use in this system. We studied the effects of blocking and activating K-ATP channels pharmacologically using known sulfonylureas, tolbutamide and glibenclamide to block channel activity, and diazoxide to activate the channel. We found that pharmacological activation of K-ATP channels can result in a complete cessation of rhythmic activity in the intact circuit seen as a loss of both firing and slow wave oscillations of membrane potential of pacemaker neurons. Channels blockers, on the other hand, caused minor increases in oscillation frequency in the intact network. Removal of neuromodulatory inputs to STG neurons can result in a dramatic reduction of network activity, even a loss of network oscillations. Under these conditions we found that blocking K-ATP channels could restore oscillatory activity in the network, and in some cases, activate gastric mill neurons which are largely stimulated in the animal in the presence of food and in vitro by certain neuromodulators. Hence, we report the presence of a potent pathway in STG neurons for the modulation of their activity on the basis of their intracellular ATP levels.

Title: Structural variation among neuropeptide isoforms affects function in the lobster cardiac system

Authors: D. POWELL[1], A. J. MUSCATO[1], W. BULHAN[1], E. MACKENZIE[1], A. PUPO[1], M. ROLPH[1], A. E. CHRISTIE[2], ***P. S. DICKINSON**[1];

Abstract: Neuronal responses to peptide signaling are determined by the specific binding of a peptide to its receptor(s). For example, isoforms of the same peptide family can drive distinct responses in the same circuit by having different affinities for the same receptor, by having isoforms bind to different receptors, or by a combination of these scenarios. Small changes in peptide composition can alter the binding kinetics and overall physiological response. The heart of the American lobster, *Homarus americanus*, is neurogenic, and is controlled by the nine neurons that make up the cardiac ganglion. In the lobster, native isoforms of C-type allatostatins (AST-Cs) usually decrease heartbeat frequency and alter contraction force. However, one of the three AST-C isoforms, AST-C II, drives a cardiac response that is distinct from that elicited by the other two. This isoform differs from AST-C I and III not only in specific amino acids, but also because AST-C II is amidated, whereas AST-C I and III are not amidated. To investigate these differential responses, we altered various features of each peptide sequence. Although the presence of an amide group at the end of a peptide sequence (amidation) is often essential for determining physiological function, we demonstrate that C-terminal amidation does not dictate the AST-C response in the lobster cardiac system. However, a single amino acid substitution within the consensus sequence did account for at least a portion of the differences in specific response characteristics (e.g. contraction frequency or force).

Title: Is stretch feedback in the heart of Homarus americanus modulated by neuropeptides?

Authors: *M. THIES, E. S. DICKINSON, X. QU, D. POWELL, P. S. DICKINSON;
Bowdoin Col., Brunswick, ME

Abstract: The heart of the American lobster, Homarus americanus, is controlled by the cardiac ganglion (CG), which is responsible for generating patterned bursts of action potentials, each of which results in a contraction of the heart. The cardiac ganglion includes four premotor and five motor neurons, as well as stretch-sensitive dendrites, which extend from the CG neurons (Cooke, 2002). All of the nine neurons are electrically and chemically coupled so that the bursting of the neurons is coordinated. Two intrinsic feedback pathways modulate the bursting pattern of the CG. A negative feedback pathway using nitric oxide decreases contraction frequency, while feedback from the stretch-sensitive dendrites generally increases contraction frequency. In addition, extrinsic modulation via neuromodulators plays a key role in achieving flexibility. However, the extent to which the heart's feedback system is modulated is still unknown. Here, we asked whether neuromodulators alter the positive stretch feedback system itself. Two FMRF-amide-like peptides, SGRNFLRFamide (SGRN) and GYSDRNYLRFamide (GYS), have previously been shown to exert concentration and force dependent modulatory effects on the CG and the periphery. The previous data suggested that these peptides may alter feedback as well, with SGRN favoring positive feedback and GYS favoring negative feedback. Here we used a preparation that included the CG and the muscle surrounding the premotor neurons to record the responses to stretch of those muscles. In response to stretch, cycle frequency most often increased while burst duration decreased. However, the responses varied considerably across preparations, with some stretches inducing an excitatory response, and others inducing an inhibitory response. Application of GYS appeared to decrease the changes in the burst duration and interburst interval elicited by stretch, resulting in a significant decrease in variation in the presence of the peptide compared to the control. GYS thus may reduce positive feedback, favoring negative feedback, as was previously predicted. SGRN did not enhance feedback, as we had predicted, but instead also generally decreased the variation of change in the burst duration and interburst interval elicited by stretch. These data suggest that any change in the balance of

positive and negative feedback elicited by the peptide is more likely mediated by the negative feedback pathway.

Title: Setmelanotide improves the hypercapnic ventilatory response in diet-induced obese mice

Authors: *S. N. FRAMNES-DEBOER, A. R. SPEARS, R. NOUR, D. M. ARBLE; Marquette Univ. Dept. of Biol. Sci., Milwaukee, WI

Abstract: Setmelanotide, a melanocortin-4 receptor agonist, was recently FDA approved for weight loss in individuals with pro-opiomelanocortin, proprotein subtilisin/kexin type 1, or leptin receptor deficiency. While ongoing efforts continue to investigate the role of setmelanotide for weight loss, the effect of setmelanotide on obesity-related disease states remain largely unknown. In particular, obstructive sleep apnea occurs in nearly 70% of the obese population and is the most common form of sleep disordered breathing. Here we test the hypothesis that setmelanotide will improve the hypercapnic ventilatory response of obese mice. Setmelanotide or vehicle was provided via an intraperitoneal injection (0.2 mg/kg or 1.0 mg/kg) for 9 days in diet-induced obese C57Bl/6J mice. The hypercapnic ventilatory response was measured by whole-body plethysmography before and after treatment. We found that while both doses of setmelanotide decreased body weight, the higher dose resulted in significantly greater weight loss. Additionally, the higher dose of setmelanotide (1.0 mg/kg) significantly improved the hypercapnic ventilatory response. These data suggest that melanocortin receptor agonists may have additional physiological effects beyond weight loss alone.

Title: Mice expressing human ApoE4 genotype exhibit greater baseline respiratory rate and less robust hypoxic ventilatory response than ApoE3 mice as measured by whole body plethysmography

Authors: *C. E. TAYLOR[1], J. S. NEWTON[2], C. M. CALULOT[1], A. L. SILVERSTEIN[3], L. A. JOHNSON[1], L. E. STRATTAN[4], W. J. ALILAIN[5];

Abstract: Breathing is vital for life and is both uniquely complex and vulnerable to disruption. Disorders of breathing such as those that occur in sleep apnea and even high cervical spinal cord injury (SCI) can impair quality of life and potentiate the ill effects of comorbidities like Alzheimer's disease (AD). Indeed, studies have shown greater cognitive and cardiovascular impairments in subjects with sleep apnea and AD. Apolipoprotein E (ApoE) is a ubiquitous protein found throughout the body and CNS which aids in the regulation and transport of cholesterol and lipids. Moreover, the *E4* allele confers a higher risk of early onset AD than either the *E2* or *E3* alleles. Previous research in our lab has shown the interaction between ApoE genotype and sex differentially affects breathing motor plasticity following SCI in mice. However, it is unknown how baseline respiratory pattern and capability during hypoxic challenge may differ between uninjured individuals expressing *APOE4* and *E3* alleles. Thus, with *APOE* genotype as our independent variable, we measured the respiratory parameters of male *E3* and *E4* targeted replacement mice using whole body plethysmography (WBP), hypothesizing that *E3* animals would display a more adaptive, heightened response to hypoxic exposure than those expressing *E4*. Preliminary data comparing *E3* animals (n=9) and *E4* animals (n=8) demonstrated differences across several key measurements. At baseline, *E4* animals were shown to breathe in an energy inefficient manner as exemplified high measures in tidal volume and frequency. During sustained hypoxia, frequency, tidal volume, and minute volume initially increased across all animals, but *APOE3* animals mounted a much more robust and sustained response with *APOE4* values falling well below baseline measures prior to termination of hypoxia. These preliminary results suggest a critical role of the *APOE* genotype in regulation of baseline breathing and in response to hypoxic conditions and that possessing the *APOE4* allele may confer vulnerabilities in respiratory function and during environmental challenges leading to cognitive decline. Future directions include examining anatomically critical CNS respiratory regions and neural cell function.

Title: KCNQ2 channels preferentially regulate activity of chemosensitive neurons in the retrotrapazoid nucleus

Authors: *J. SOTO[1], D. K. MULKEY[2], A. TZINGOUNIS[3];
[1]Univ. of Connecticut, Storrs, CT; [2]Dept. Physiol. and Neurobio., Univ. Connecticut, Storrs Manfld, CT; [3]Physiol. and Neurobio., university of connecticut, Storrs, CT

Abstract: The KCNQ1-5 (Kv7.1-7.5)family of potassium channels regulates cellular activity at multiple levels ofthe respiratory circuit including neurons in the retrotrapezoid nucleus (RTN)that control breathing in response to CO_2/H^+ (i.e.,function as respiratory chemoreceptors). In particular,clinical evidence suggests both loss- (LOF) and gain-of-function (GOF)mutations in KCNQ2 disrupt respiratory function. Therefore, the goalof this study is to understand how conditional ablation (*Phox2b*$^{cre/+}$*::Kcnq2*$^{f/f}$; *Kcnq2* cKO) or expression of a human KCNQ2 GOF variant (R201C) inchemosenstive RTN neurons (*Phox2b*$^{cre/+}$*::Kcnq2*$^{R201C/+}$)effects baseline breathing and the ventilator response to CO_2. Forthese experiments RTN chemoreceptors were targeted based on Phox2b expressionand breathing was measured in 30 day old mice (mixed sex) by whole bodyplethysmography. We found that *Kcnq2*cKO hyperventilated under room air conditions (control: 189 ± 6 bpm vs *Kcnq2* cKO: 236 ± 6.37 bpm) and minuteventilation (MV) increased by 0.74 ml/min/g but with no change in theventilator response to CO_2. Conversely, *Kcnq2*$^{R201C/+}$ mice showednormal respiratory activity under room air conditions but failed to increasebreathing in response to CO2 (MV at 7% CO2 control: 10.7 ± 0.5 ml/min/g vs. *Kcnq2*$^{R201C/+}$: 7.8 ± 0.9ml/min/g). Consistent with these functional results,fluorescent *in-situ* hybridization showed that Phox2b+ RTNneurons express KCNQ2 but not KCNQ3 transcript. These resultssuggest KCNQ2 channels preferentially regulate activity of RTNchemoreceptors.

Title: Cerebral cortical control of the posterior cricoarytenoid muscle in nonhuman primates

Authors: *L. B. HELOU[1], J. M. MICHLICH[2], A. C. BOSTAN[3];
[1]Communication Sci. & Disorders, Univ. of Pittsburgh, PA, PA; [2]Communication Sci. & Disorders, [3]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Introduction: The posterior cricoarytenoid (PCA) muscle is the sole abductor of the vocal folds. It plays a critical role in valving the airway during gross and fine control of breathing and phonation. The neural substrates underlying cortical control of the PCA have not yet been defined in nonhuman primates. We used the rabies virus as a retrograde transsynaptic tracer to define regions of the cerebral cortex that are involved in the descending control of the PCA muscle.
Methods: We injected rabies virus (N2c strain, 700-1000 µL, 1 x10^10 pfu) into the left PCA muscle in juvenile (n=2) and adult (n=2) female cynomolgous monkeys. We set the survival time (106-121 hours) to allow virus to infect putatively third- and fourth-order neurons in the cerebral cortex. Rabies virus was transported transneuronally in the retrograde direction in a time-dependent manner, revealing chains of synaptically-connected neurons. Then, we processed serial sections through the brain and spinal cord to reveal the location of neurons infected with rabies virus. We plotted labeled neurons in every fourth cortical section under bright-field microscopy into Neurolucida, then translated the sections into two-dimensional reconstructions to create maps of the neural substrates underlying motor control of the PCA.
Results: We found prominent densities of neurons labeled by retrograde transport of rabies virus from the PCA in multiple cerebral cortical regions. At the earliest stage of virus transport, labeling was largely restricted to the lateral aspects of the primary motor cortex (M1). At later stages of transport, labeling expanded to include premotor areas on the lateral surface, dorsal and ventral premotor cortex, and on the medial wall, the supplementary motor area (PreSMA) and the cingulate motor areas. At the same time, we also observed neurons labeled in the anterior cingulate cortex, areas of the medial and ventrolateral prefrontal cortex, amygdala, agranular and granular insula, and auditory association regions.
Conclusions: Motor control of the PCA is coordinated with that of muscles of respiration, articulation, and phonation. The apparent co-localization of the neuronal substrate for PCA motor control with that of other intrinsic laryngeal muscles and the thoracic diaphragm substantiate a functional coordination. This detailed first description of the neural substrates underlying motor control of the PCA has theoretical and clinical implications for respiratory and vocal motor control.

Title: Inflammatory responses in central respiratory regions of offspring following maternal cigarette smoke exposure in mice.

Authors: *L. BULBUL[1], H. CHEN[2], N. M. JONES[1], N. N. KUMAR[1];
[1]Dept. of Pharmacol., The Univ. of New South Wales, NSW, Australia; [2]Sch. of Life Sciences, Fac. of Sci., Univ. of Technol. Sydney, Broadway, NSW, Australia

Abstract: Accruing evidence suggests that prenatal cigarette smoke or nicotine exposure generates reactive oxygen species or promotes apoptosis in the brainstem areas that participate in respiratory homeostasis. Maternal smoking contributes to CNS developmental delays and blunted central chemoreflex in cases of sudden infant death syndrome (SIDS). However, the relationship between pre- or postnatal cigarette smoke exposure (SE) and the pathogenesis of diminished ventilatory efforts is unclear. There is no direct experimental evidence to substantiate whether maternal SE exerts deleterious effects, specifically on inflammatory processes in respiratory regions in adult offspring following maternal SE in mice. Therefore, we aimed to explore the inflammatory responses in the brain respiratory regions (nucleus tractus solitarius (NTS), retrotrapezoid nucleus (RTN) and ventral respiratory column (VRC)) or non-respiratory regions (hypothalamus, cerebellum) in SE dams and their adult offspring. In our study, adult female BALB/c mice (6 weeks old) were exposed to 12 cigarettes/day (Winfield, VIC, Australia) in the InExposure smoke exposure system for 6 weeks before mating until the offspring were weaned. After weaning, offspring (both sexes) were exposed to 12 cigarettes/day from postnatal day (p) 63 to p91 for 1 month and then culled on p92. Non-SE dams and offspring were exposed to room air as controls. Then, fresh brain tissues (hypothalamus, cerebellum, NTS, RTN, and VRC) were micro-dissected and processed for cytokine assays. The level of interleukin-1beta (IL-1β) in the hypothalamus, cerebellum, NTS, and RTN was unchanged in SE dams compared to the control dams. IL-1β levels in the VRC of the SE dams decreased compared with non-SE dams ($P < 0.05$, Mann-Whitney U test, n =12 , 2 mice samples pooled for the cytokine assay). In adult SE offspring, IL-1β levels were increased ($P < 0.05$, Mann-Whitney U test, n = 16-18, 2 mice samples pooled for the cytokine assay) in the VRC compared with the non-SE offspring.

The levels of IL-1β in the hypothalamus, cerebellum, NTS and RTN remained unchanged in the SE compared to non-SE offspring. We propose that immune activation in the VRC from prenatal or postnatal SE offspring could potentially predispose them to breathing dysfunction in adulthood. Maternal SE may modify brain immune responses in offspring at an early age, driving brain impairment in adulthood.

Title: A Closed Loop Feature Detection Platform for Automated Neonate Cardio-Respiratory Measurements

Authors: *C. WARD[1], E. AISSI[3], D. PATEL[2], B. RUIZ[2], R. RAY[2];
[1]Dept. of Mol. Physiol. and Biophysics, [2]Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [3]Rice Univ., Houston, TX

Abstract: Sudden Infant Death Syndrome (SIDS, a leading cause of death for neonate infants 1 month to 1-year-old) and some forms of neonate death (ND, the leading cause of death for newborns 28 days old or less) are thought to result, in part, from unseen brain abnormalities affecting cardio-respiratory function, but for which no clear genetic or environmental mechanisms are known. Mouse genetic and exposure models present an opportunity to uncover potential molecular and environmental mechanisms in SIDS and ND. However, measuring cardio-respiratory function to model SIDS and ND in neonate mice is expensive, difficult, and inefficient. Previously, we have developed for in-lab facile production an inexpensive face-mask pneumotachograph system for neonate respiratory measurements. A remaining challenge is the time and effort needed to carry out neonate respiratory measurements. For example, the neonate autoresuscitation assay consisting of repeated anoxic exposures followed by recovery requires the full attention of a single observer for the duration of the assay (2-3hrs) for a single subject, thus limiting the number of pups in a litter that can be assayed. To address these inefficiencies, we sought to develop a closed-loop feature detection platform for automated neonate cardio-

respiratory measurements that can be deployed in large numbers for high throughput parallel studies by a single person. The platform design consists of three sub-systems. First, we leveraged our previously published pneumotachograph face-mask system for precise respiratory measurements (PMID: 28213294). Second, we developed a micro-controller automated bell-housing gas switching system for near square wave induction of respiratory challenges. Third, we developed a micro-computer-based data-acquisition system with real-time feature detection and response outputs for controlling gas exposure times. Through the rotational and linear actuation driven by a pair of stepper motors, the gas challenges are administered via a bell housing that is rotated into position. A python program detects specific waveform features in real-time (lag = 100ms), such as apnea and bradycardia. Upon apnea detection, the system is directed to switch to a rescue gas. The resumption of normal breathing and heart rate can also be detected and incorporated into the criteria for the automated initiation of the next anoxic exposure trial. Data is stored for later offline automated analysis. The described apparatus offers an inexpensive approach for automated high throughput neonate cardio-respiratory assessment for facile screening to yield important clues in developmental pathophysiology.

Title: Neural circuits regulating opioid-induced motor hyperactivity and respiratory depression

Authors: *A. FURDUI[1,3], C. SCARPELLINI[3], G. MONTANDON[3,2];
[1]Inst. of Med. Sci., [2]Div. of Respirology, Dept. of Med., Univ. of Toronto, Toronto, ON, Canada; [3]Keenan Res. Ctr. for Biomed. Sci., St. Michael's Hosp., Toronto, ON, Canada

Abstract: Opioid-induced respiratory depression (OIRD) is characterized by a severe decline in breathing rate that can be lethal during opioid overdose. In addition to their inhibitory effects, opioid drugs also have excitatory effects illustrated by locomotor hyperactivity in rodents. While multiple neural circuits may be involved, the distinct cellular subpopulations mediating these opioid effects remain unclear. We aimed to determine the role of mu-opioid receptors (MORs) and somatostatin (SST)-expressing cells, which are critical for normal breathing and behaviours,

in regulating opioid effects in mice. We hypothesized that deletion of MORs and MORs in SST-expressing cells will reduce OIRD and opioid-induced hyperactivity. Transgenic knockout mice lacking MORs in SST-expressing cells (SST-MOR$^{-/-}$) were developed by crossing SST-Cre$^{+/+}$ mice (Sstt$^{m2.1(cre)Zjh/J}$) with Oprm1$^{fl/fl}$ mice (Oprm1$^{tm1.1Cgrf/KffJ}$). SST-Cre$^{+/+}$ and MOR$^{-/-}$ mice (Oprm1^{tm1Kff}) were used as controls. Mice (male, 3-4 months old) were placed in a whole-body plethysmography chamber to record respiratory rate and intraperitoneal injections of fentanyl (0.3 mg/kg) or saline were administered to quantify respiratory changes. Video recordings of mouse movements were captured simultaneously to assess behaviours. We found that intraperitoneal injection of fentanyl induced a significant respiratory rate depression in SST-Cre$^{+/+}$ ($p<0.001$, n=9), MOR$^{-/-}$ ($p<0.05$, n=7) and SST-MOR$^{-/-}$ mice ($p<0.001$, n=8) but was more pronounced in SST-Cre$^{+/+}$ and SST-MOR$^{-/-}$ mice. Fentanyl injection also induced a hyperactive state (increased locomotor behaviour) in SST-Cre$^{+/+}$ and SST-MOR$^{-/-}$ mice but not in MOR$^{-/-}$ mice. To further determine whether SST-expressing cells may be mediating subtle changes in breathing and behaviours, we are currently assessing respiratory changes during different behavioural states (inactive, active and hyperactive). In conclusion, our data showed that MORs mediate the effects of fentanyl on breathing and behaviours. Although SST is highly expressed in brainstem neurons that generate breathing, such as in the preBötzinger Complex, SST-expressing cells do not mediate the effects of fentanyl on breathing and behaviours.

Title: Coordinated neural dynamics of breathing across the medulla and pons

Authors: *N. BUSH, L. QUINA, J.-M. RAMIREZ;
Seattle Children's Res. Inst., Seattle, WA

Abstract: The neural control of breathing involves the coordinated activity of diverse populations of medullary neurons distributed along the rostrocaudal aspect of the ventrolateral medulla: the so called Ventral Respiratory Group (VRG). The VRG participates in circuits with extra-medullary circuits, such as the pons, to generate robust—yet labile—rhythms.
Here, we use high-density electrophysiological recordings (Neuropixels) to record spiking

activity simultaneously from hundreds of neurons across both the VRG and pons in anesthetized, freely breathing mice. We couple this with an optogenetic tagging approach to identify ChAT, DBX1, Vgat, and Vglut2 positive neurons, and reconstruct the three dimensional location of each recorded neuron. We find diverse patterns of respiratory-related neural activity that continuously tile the entire breathing phase. Further, we observe intermingling of inspiratory and expiratory neurons across the VRG. By analyzing activity across simultaneously recorded neurons, we uncover dynamically coordinated ensembles of neurons that define "cell assemblies". These cell assemblies give rise to discretely different patterns of respiratory activity, including specific, distributed populations recruited during hypoxia induced gasping. In addition, we record from these distributed neural populations during administration of opiates (morphine) and observe that the respiratory network as a whole slows, but does not drastically reconfigure, in response to opiates. Together, these data provide an integrated view of the dynamic coordination of neural activity driving breathing in the intact animal.

Title: Inhibition of TrkB Kinase Activity Impairs Autophagy Flux in Cervical Motor Neurons

Authors: *M. PAREJA-CAJIAO[1], N. J. HELLYER[2], E. C. DUCAJI[1], H. M. GRANSEE[1], G. C. SIECK[1,3], C. B. MANTILLA[1,3];

Abstract: Autophagy is a catabolic process that eliminates damaged cytoplasmic structures. Aging-related autophagy impairment is suggested by the accumulation of damaged proteins and organelles in motor neurons and associated neuromuscular dysfunction. Signaling through the tropomyosin-related kinase receptor subtype B (TrkB) is important in maintaining neuromuscular function in the phrenic motor system including in old age. Our overarching hypothesis is that impaired autophagy flux contributes to aging-related neuromuscular dysfunction in phrenic motor neurons and that inhibiting TrkB kinase activity mimics the aging effects on autophagy in young mice. We previously reported increased expression of LC3 and p62 by 24 months of age in cervical motor neurons, indicating impaired autophagy with

autophagosome accumulation. In the present study, we leveraged an aging colony of *TrkB*^{F616A} mice, which possess a mutation that renders TrkB kinase activity susceptible to rapid and robust inhibition by 1NMPP1. Male and female *TrkB*^{F616A} mice at 6- 18- and 24- months of age received a 1-week treatment with vehicle or 1NMPP1. Relative expression of the autophagy markers LC3 and p62 in cervical motor neurons in the region of the phrenic motor nucleus was determined by immunofluorescence intensity. The effect of TrkB kinase inhibition was dependent on age. In 6-month old mice, there was an effect of 1NMPP1 treatment on both LC3 and p62 expression in motor neurons ($p < 0.01$ in both cases), and a sex difference in LC3 ($p<0.01$) but not p62 expression. There was no treatment*sex interaction. At 18- or 24- months of age, there were no effects on LC3 or p62 expression of 1NMPP1 treatment, sex, and no treatment*sex interaction. In 6-month old mice, treatment with 1NMPP1 increased the relative expression of both LC3 and p62 in cervical motor neurons by ~25% compared to control, consistent with the change in expression evident in 24-month old mice compared to 6-month old mice. Our results indicate that inhibition of TrkB kinase activity impairs autophagy flux in the motor neurons of young mice and this effect is similar to the effect of age on autophagy in motor neurons. Accordingly, the aging-related loss of TrkB signaling may impair autophagy flux and contribute to neuromuscular dysfunction in old age.

Title: Tumor Necrosis Factor alpha receptor 1 is necessary for respiratory functional and neuroanatomical changes in mice submitted to 6-OHDA model of Parkinson’s Disease

Authors: L. CABRAL[1], L. OLIVEIRA[1], T. S. MOREIRA[1], ***A. TAKAKURA**[2];
[1]Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Dept of Pharmacology, Inst. of Biomed. Science, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Introduction: Respiratory deficits are responsible for considerable deaths in Parkinson´s Disease patients. Previous studies have shown brainstem degeneration which is

probably linked to respiratory function impairment in a rat model of PD induced by 6-hydroxydopamine (6-OHDA) injection in caudate-putamen (CPu). Many mechanisms are responsible for neuronal death, including neuroinflammation which is present in many neurodegenerative diseases. **Objective:** This study aims to investigate the role of neuroinflammation mediated by glial cells in respiratory functional and neuroanatomical deficits in the animal model of PD induced by 6-OHDA. **Methods:** C57BL/6 or tumor necrosis factor receptor 1 knockout mice ($TNFR1^{-/-}$) were anesthetized with isoflurane 2.5% and received bilateral injection of 6-OHDA (10 µg/µl) or vehicle in CPu through stereotaxic surgery. 20 days after surgery, mice were submitted to whole body plethysmography under normal and hypercapnic conditions (7% CO_2). Animals were perfused and the brains were removed to anatomical analysis. **Results:** 6-OHDA destroyed TH^+ neurons in Substantia nigra (SNc) in all groups analyzed (6-OHDA WT: 77%; 6-OHDA $TNFR1^{-/-}$: 79%). Degeneration was observed in preBötzinger complex (preBötC) and in retrotrapezoid nucleus (RTN) in 6-OHDA WT group, but not in 6-OHDA $TNFR1^{-/-}$ group (preBötC: 6-OHDA WT: 43%, 6-OHDA $TNFR1^{-/-}$: 22%; RTN: 6-OHDA WT: 52%; 6-OHDA $TNFR1^{-/-}$: 15%). Astrocyte's density in SNc is enhanced in 6-OHDA WT group but not in 6-OHDA $TNFR1^{-/-}$ group (6-OHDA WT: 122%) and is reduced in preBötC in all groups analyzed ($p<0.05$), while in RTN, no change was observed. Microglia analysis indicates neuroinflammation in SNc and RTN in all groups. Respiratory assessment reveals reduction in basal respiratory rate in 6-OHDA WT group but not in 6-OHDA $TNFR1^{-/-}$ group (6-OHDA WT: 25%; 6-OHDA $TNFR1^{-/-}$: 17%). No change was observed between groups in respiratory parameters under hypercapnia. **Conclusions:** In this model of PD, respiratory deficits are associated with neurodegeneration in respiratory brainstem areas. Inhibiting TNF-α inflammation pathway, reduction in respiratory rate is prevented indicating the involvement of this pathway in the death of brainstem nucleus in this model.**Support:** FAPESP, CNPq, CAPES and Serrapilheira Institute.

Title: Purinergic signaling mediates neuroglial interactions to generate sighs

Authors: *L. J. SEVERS[1,2], N. E. BUSH[2], L. A. QUINA[2], N. J. BURGRAFF[2], T. DASHEVSKIY[2], N. A. BAERTSCH[2,3], J.-M. RAMIREZ[2,1,4,3];

Brain Res., Seattle Children's Res. Inst., Seattle, WA; [3]Dept. of Pediatrics, [4]Dept. of Neurolog. Surgery, The Univ. of Washington Sch. of Med., Seattle, WA

Abstract: Sighs are large amplitude breaths that occur periodically during normal breathing and are necessary for preventing atelectasis. Normal 'eupneic' inspirations and sighs originate from the same medullary network, the preBötzinger Complex (preBötC). Despite the importance of sighing in maintaining normal breathing, it is not understood how one circuit can produce two independently modulated and distinctly timed rhythmic behaviors. Sighs are modulated by many mechanisms both intrinsic and extrinsic to the brainstem circuits. However, a fundamental understanding of rhythm generation within the preBötC circuit is missing. We hypothesize that sighing originates within the preBötC and is regulated in part by astrocytic Ca2+ dynamics. Computational simulations predict that sighs occur with the coincidence of fast and slow Ca2+ oscillations. Experimental studies come to the same conclusion: pharmacologically increasing Ca2+ mimics in silico sigh generation. In vitro optogenetic stimulation of glia in Aldh1l1cre/Ai32 mice elicits sighs, which along with spontaneous sighs are inhibited with P2Y1 antagonists. Likewise, in vivo optogenetics stimulates sighs, but incomplete block with P2Y1 antagonists supports the idea of tightly regulated network activity and overriding influence from outside modulation. Furthermore, P2Y1 antagonist applied during short anoxic exposures in vitro eliminates the onset of sighs and reduces the augmenting eupneic phase. Our experiments currently focus on 2photon imaging of network calcium dynamics to more precisely understand the role of purinergic signaling in sigh generation, such as how timing of astrocytic Ca2+ fluctuations contribute to the temporal correlation of sighs and eupnea during different network states. Preliminary data suggests that astrocytes exhibit calcium fluctuations that loosely correspond to eupnea and sigh onset. These studies will focus on determining the source of fast and slow Ca2+ oscillations and the mechanisms by which increased glial Ca2+ through purinergic signaling contributes to both normal breathing and sighing. Taken together, our experiments suggest that the timing characteristics underlying sigh generation are a coordinated action between glial calcium oscillations and the recruitment of preBötC neurons along the inspiratory column through purinergic signaling.

Title: Chronic maternal exposure to titanium dioxide nanoparticles alters breathing in newborn offspring

Authors: *E. COLNOT[1], L. CARDOIT[1], M.-J. CABIROL[1], L. ROUDIER[2], M.-H. DELVILLE[2], A. FAYOUX[1], P. DE DEURWAERDÈRE[1], M. THOBY-BRISSON[1], L. JUVIN[1], D. MORIN[1];
[1]INCIA UMR5287, Bordeaux, France; [2]ICMCB, Bordeaux, France

Abstract: Over the last two decades, nanotechnologies and the use of nanoparticles represent one of the greatest technological advances in many fields of human activity. Titanium dioxide nanoparticles (TiO2 NPs) are one of the nanomaterials most frequently found in everyday consumer products. But, due to their particular physicochemical properties, TiO2 NPs are prone to cross biological barriers and potentially lead to adverse health effects. The presence of TiO2 NPs found in human placentae and in the infant meconium has indicated unequivocally the capacity for a materno-fetal transfer of this nanomaterial. Although chronic exposure to TiO2 NPs during pregnancy is known to induce offspring cognitive deficits associated with neurotoxicity, the impact of a gestational exposure on a vital motor function such as respiration, whose functional emergence occurs during fetal development, remains unknown. Here, using in vivo whole-body plethysmographic recordings from neonatal mice, we show that a chronic exposure to TiO2 NPs during pregnancy alters the respiratory activity of offspring, characterized by an abnormally elevated rate of breathing. Correspondingly, ex vivo experiments performed on isolated brainstem-spinal cord preparations of newborn mice and medullary slice preparations containing the central components of the breathing command, showed that the spontaneously generated respiratory-related rhythm is significantly and abnormally accelerated in animals prenatally exposed to TiO2 NPs. Moreover, whole-cell patch clamp recordings revealed that maternal exposure to TiO2 NPs during gestation affect the bioelectrical properties of pre-Bötzinger Complex inspiratory neurons by elevating their resting membrane potential and abnormally increasing their cellular excitability. Finally, such a chronic prenatal exposure was found to impair the capacity of respiratory neural circuitry to effectively adjust breathing rates in response to excitatory environmental stimuli. Our findings thus demonstrate that a maternal exposure to TiO2 NPs during pregnancy dramatically affects the normal development and operation of the respiratory centers in progeny.

Exp. Med. Hung Acad Sci., Budapest, Hungary

Abstract: Anna Jász, Laszlo Biró, Zsolt Buday, Robert Bódizs, Orsolya Szalárdy, Bálint Király, Balázs Hangya Laszlo Acsády **Post-stress activity of calretinin positive cells in the paraventricular thalamic nucleus is required for long term, stress induced disturbance of sleep behavior** Sleep disorders caused by stress affect millions of people around the world, but its neurobiological bases are still unclear. The calretinin-positive neurons of the paraventricular thalamus (PVT/CR+) are in a unique position to participate in stress induced sleep disturbances since their activity is significantly affected both by stress and by sleep-wake transitions. In this study we aimed to determine the activity of PVT/CR+ cells before and after the exposure to a natural stressor (fox odor, 2MT, 10 min) and to test causal relationship between post-stress PVT/CR+ activity and post-stress sleep behaviour using optogenetic inhibition (1 hour) of PVT/CR+ cells after the stress situation. Since sleep disturbances not only involve sleep but also the pre-sleep behaviour we separately analysed neuronal activity (216 units so far) and behaviour in the nest before sleep. Recordings involved 3 hours sessions for five days before and after stress using movable tetrodes and optogenetic tagging of PVT/CR+ cells. Sleep depth was measured by spectral slopes calculated on the basis of the power law scaling of the Fourier spectra.PVT/CR+ cells displayed strongly state dependent activity during pre-stress days. Wake activity in the nest was lower than outside the nest and firing further decreased at the onset of sleep. At the day of the exposure to 2MT both firing rate and synchrony among PVT/CR+ cells increased. Firing rate remained elevated for six days after the stress, with strongest change in the nest. Bursting activity of PVT/CR+ cells decreased during NREM sleep after the stress. These changes were accompanied by altered locomotor activity, nesting behaviour and a decrease in the spectral slope during NREM sleep, showing disturbed sleep. Optogenetic inhibition of PVT/CR+ neurons for one hour after 2MT presentation prevented altered locomotion before sleep and the normal nesting behavior were reinstated on the poststress days. These data together strongly indicate that altered post-stress activity of PVT/CR+ cells is crucial to establish the neuronal network responsible for the emergence of stress induced sleep behaviour.

Title: Does the "Night-float rotation" alter sleep/wake cycles and circadian rhythms of UPR physician residents: Modulation by chronotypes

Authors: *J. R. MARRERO[1], Y. DE JESUS[3], A. SEGARRA[4], L. ORTA ANÉS[5], C. M. NAZARIO[5], F. RAMIREZ[2], J. L. AGOSTO[1];
[1]Biol., [2]Physical Educ. and Recreation, Univ. of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico; [3]Intrnl. Med., [4]Physiol., [5]Publ. Hlth., Univ. of Puerto Rico - Med. Sci. Campus, San Juan, Puerto Rico

Abstract: Introduction: Sleep disruption during medical residency is recognized as a significant risk factor for medical trainees' exhaustion. Burnout increases the risk of medical errors and mental health deterioration, potentially leading up to physician suicide. Coaching interactions with physicians in-training revealed that some residents are struggling with sleep difficulties during the night-float rotation. We aim to explore the relationship between residents' chronotype and their misalignment with work shift as a possible reason for this observation.
Methods: This is a longitudinal cohort study of repeated measures in twenty medical residents before, during, and after the night-float rotation. Participants will complete the Composite Scale of Morningness to determine their chronotype; and the Pittsburg Sleep Quality Index to measure perceived sleep quality during each rotation. To explore confounding variables a standard questionnaire and the Demand Control Support Questionnaire will be completed. Physiologic parameters will be monitored using an actigraph and a dermal patch (Biosensor) to measure sleep quality and determine internal circadian synchronization. Salivary cortisol and melatonin levels will be measured to assess stress and explore circadian fluctuations as related to sleep disruption.
Analysis: The measure of outcome variation according to hazard exposures and other characteristics will be performed by collecting information on each participant. To increase power, measurements will be repeated on the same participants at various points in time. We anticipate a small sample size, therefore, the importance of study results would not be based solely on statistical significance, but also on clinical significance.
Conclusions: Exploring the effects of a night-float rotation in residents' sleeping pattern and its relationship to their chronotypes may reveal missed opportunities to prevent burnout syndrome in medical residencies.

Title: Desynchronization of wake-sleep rhythm and eating patterns during the social isolation by Covid-19 in a Mexican Population

Authors: L. PEREZ-PUENTE[1], A. MONTEZANO-LOPEZ[1], F. SANDOVAL-GÓMEZ[1], A. PAVON-ROSADO[1], C. GUTIERREZ-GARCIA[1], ***M. MELGAREJO-GUTIERREZ**[2]; [1]Neurobio. of sleep and metabolism, Univ. Veracruzana, Xalapa, Mexico; [2]Univ. Veracruzana, Veracruz, Mexico

Abstract: Overweight and obesity has become one of the most serious global health issues due to the high rates of prevalence that presents in different populations. The social isolation during COVID-19 pandemic had an impact of on sleep, dietary patterns and physical health. Sleep is an essential process for the brain and the maintaining of metabolism. Inadequate sleep and obesity are important public health problems. Studies provide consistent evidence that recurrent sleep curtailment and shifting time of sleep may increase the risk of obesity and diabetes. In this sense the circadian clock, controls sleep, onset of sleep, also regulates energy homeostasis and the disruption is associated with obesity.During the social isolation many people shift their sleep and had more irregular eating patterns. The aim of the present study was to investigate relationship between circadian rhythm of sleep and eating patterns during social isolation caused by the contingency Covid-19 in a Mexican population. For this purpose, a total of 2385 subjects (18-80 years) participated. The study was conducted in according to standards established by the declaration of Helsinki as well as their applied the informed consent. All subjects completed a questionnaire in a google forms, and scale parameters Pittsburght for quality and quantity of total sleep, also completed a questionnaire for identify eating patterns, light exposure and use of electronic devices. The results suggest that the population presented desynchronization of wake-sleep rhythms during the social isolation due the COVID-19 contingency and presented desynchronization of feeding-fasting rhythms, also the people had a variation in the patterns of exposure to light. Our data suggest that the social isolation impact in the energetic metabolism and circadian control of sleep, this condition might promote development and increase obesity rates and other chronic diseases in this population, promoting comorbidity with infectious diseases such as COVID-19.

Title: The first-night effect impairs neurochemical processing of visual plasticity during NREM sleep, revealed by simultaneous magnetic resonance spectroscopy and polysomnography

Authors: *M. TAMAKI[1,2], T. BARNES-DIANA[3], Z. WANG[3], T. WATANABE[3], Y. SASAKI[3];
[1]Cognitive Somnology RIKEN Hakubi Res. Team, RIKEN Cluster for Pioneering Res., [2]Ctr. for Brain Sci., RIKEN, Wako, Japan; [3]Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: How sleep disturbances affect learning and memory has remained elusive. We have previously found that performance on a visual perceptual learning (VPL) task improved after nonrapid eye movement (NREM) sleep (offline gains), and that NREM sleep plays a role in enhancing visual plasticity. Here, we investigated whether non chronic sleep disturbances impair visual plasticity by utilizing the well documented phenomenon, the first night effect (FNE) that refers to a temporary sleep disturbance that occurs only during the first session of sleep experiments in healthy young human adults. First, we tested whether the FNE affects a neurochemical plasticity index during NREM sleep. Previous studies demonstrated that increases in the neurochemical plasticity index, the ratio of excitatory (glutamate) to inhibitory (GABA) neurotransmitter concentrations (E/I ratio) in early visual areas (EVA) measured by magnetic resonance spectroscopy (MRS), were closely related to enhanced visual plasticity in VPL. Moreover, the E/I ratio increased during NREM sleep compared to wakefulness, in correlation with offline gains of VPL over sleep. We tested whether the FNE prevents the E/I ratio from increasing during NREM sleep, by measuring concentrations of glutamate and GABA in EVA during sleep using simultaneous MRS and polysomnography on day 1 (with FNE) and 2 (without

FNE). Subjects were asked to sleep inside the MRI bore for 90 min, twice with an interval of a week. There was no significant increase in the E/I ratio during NREM sleep compared to wakefulness on day 1. The E/I ratio during NREM sleep relative to wakefulness was significantly smaller on day 1 than day 2 ($p=0.004$), suggesting that the FNE impairs visual plasticity during NREM sleep. Next, we behaviorally tested whether the FNE impairs offline gains in VPL over sleep, by comparing offline gains over sleep with and without the FNE. Before subjects were asked to sleep for 90 min, they were trained on the texture discrimination task (TDT), a standard VPL task, at different visual hemifields on days 1 and 2 with an interval of a week. Because learning of TDT is specific to the trained retinal location, the state of learning on each day is safely assumed to be independent. Test sessions on TDT were performed before and after the sleep session. While significant offline gains over sleep on day 2 without the FNE ($p<0.001$) replicated previous finding, no significant offline gains found on day 1 with the FNE supports that the FNE impairs visual plasticity during sleep. Altogether, these results clearly suggest that non chronic sleep disturbances alter neurochemical processing and impair visual plasticity during sleep in healthy young adults.

Title: Involvement of microglia in sleep/wake regulation under acute social defeat stress in mice

Authors: *K. MIYANISHI[1], H. FUNATO[2], M. YANAGISAWA[1];
[1]Intl. Inst. for Integrative Sleep Med. (WPI-IIIS), Tsukuba Univ. Sch. of Med., Ibaraki, Japan;
[2]Toho Univ. Sch. of Med., Tokyo, Japan

Abstract: Microglia, the brain-resident macrophages, produce inflammatory cytokines and remove dead cells and foreign materials in diseased brains. Recently, we reported circadian changes in the morphology and function of microglia. In the prefrontal cortex, microglia displayed hyper-ramified morphology and increased phagocytosis of synapses during sleep. These results suggested that the circadian changes in microglial activity may contribute to sleep/wake regulation. However, how microglia are involved in sleep/wake behavior remains to be elucidated. Here, we examined sleep/wakefulness in mice administered with selective colony-stimulating factor-1 receptor inhibitor, PLX5622 (PLX), which depletes microglia. We further

examined whether social defeat stress alters the effect of microglial elimination on sleep/wake behavior. EEG/EMG recordings were performed after mice were fed with the PLX-formulated chow for 14 days. As a result, PLX-treatment did not change wake, NREM sleep, and REM sleep amounts. Thus, microglial elimination by PLX-treatment did not appreciably change sleep/wake behavior in adult healthy mice. Next, we examined the effects of microglial ablation on sleep/wake cycle in socially defeated mice. Social defeat stress is well-known to induce microglial activation, and previous studies reported that acute social defeat stress increased NREM sleep amounts. Following the previous studies, in our social defeat stress model, C57BL/6N mice were briefly encountered with highly aggressive ICR mice 4 times in 1 hour. We exposed mice with or without PLX-treatment to 1-hour social defeat stress during ZT11-12 and performed EEG/EMG recordings. After social defeat stress, PLX-treated mice showed further increased NREM sleep amounts compared with mice without PLX-treatment. These results suggested the possibility that microglia may be involved in sleep/wake regulation in response to social stress in mice.

Title: The role of calretinin positive neurons of the paraventricular thalamus in sleep disturbance induced by innate fear

Authors: *L. BIRO[1], A. JASZ[1], Z. BUDAY[1], G. KOMLOSI[1], S. FERENCZI[2], K. KOVACS[1], L. ACSADY[1];
[1]Inst. of Exptl. Med., Budapest, Hungary; [2]Inst. of Exptl. Medicine, Hungarian Acad. of Sci., Budapest, Hungary

Abstract: Exposure to severe stress could lead to the emergence of stress-related psychiatric disorders such as insomnia and PTSD. The paraventricular thalamic nucleus (PVT) is a midline thalamic region involved in sleep, fear, anxiety, and stress response regulation. Calretinin-positive cells of the PVT (PVT/CR+) display elevated c-Fos expression upon aversive stimulus exposure and send highly collateralized projections to stress regulatory structures. In this study, we tested whether the post-stress activity of PVT/CR+ cells is required for the manifestation of disturbed sleep behavior induced by exposure to a natural stressor (fox odor, 2MT). We studied how post-stress optogenetic photoinhibition of PVT/CR+ neurons affects nesting and sleep

behaviors, stress hormone levels, and neuronal activity in stress-responsive downstream brain regions. PVT/CR+ neurons were inhibited using the inhibitory step-function opsin SwiChR. After five pre-stress days SwiChR and control, EYFP mice were subjected to a predator odor (2MT, 10 min) followed by 1 hr laser exposure in their homecage. During stress exposure, both SwiChR and control groups exhibited similar levels of defensive behaviors (~80% time), particularly freezing and escape jumps. Compared to the pre-stress behavior after stress exposure, the EYFP group showed increased locomotion, freezing-like behavior, and disturbed sleep which was associated with marked c-Fos expression in PVT/CR+ neurons and elevated corticosterone levels. Photoinhibition of PVT/CR+ cells after the stress exposure prevented all these changes. We also tested whether post-stress photoinhibition of PVT/CR+ cells is able to reverse elevated c-fos expression in their major postsynaptic targets such as nucleus accumbens (NAc), central amygdala (CeA), prelimbic cortex (PrL), and bed nucleus of the stria terminalis (BNST). Collectively, our findings indicate that post-stress photoinhibition of PVTCR neurons resulted in decreased neuronal activity, which was sufficient to decrease stress-induced discomfort and sleep disturbance and alleviate hormonal stress reactivity.

Title: Post-traumatic stress REM sleep features and heart rate variability contributing to fear extinction memory

Authors: *Y. CABRERA[1], J. A. HOLLOWAY[1], S. N. AYALA ROSARIO[1], J. URE[2], K. KIM[2], G. R. POE[1];
[1]Dept. of Integrative Biol. and Physiol., [2]UCLA, Los Angeles, CA

Abstract: Research into rapid eye movement (REM) sleep has revealed its role in synaptic plasticity mechanisms supporting the updating of memory schema and attenuating emotionality linked to experiences. Absence of the stress neurotransmitter, norepinephrine (NE), during REM sleep is paramount to the maintenance of the REM sleep state and the depotentiation mechanisms believed to underlie adaptive emotional memory processing. REM sleep is normally characterized by large theta (5-10 Hz) frequency oscillations in the associative memory and emotion processing limbic system as well as muscle atonia and increased heart rate variability

(HRV). Evidence from our lab and others supports the hypothesis that REM sleep disturbance impairs emotional memory processing via aberrant NE signaling, causing abnormal memory retention and altered autonomic system regulation following stress which in turn lead to retention deficits in fear extinction and increase the risk of developing post-traumatic stress disorder (PTSD). Interestingly, a top symptom of PTSD is sleep disturbance like insomnia, characterized by fragmentation, non-restorative sleep, and decreased HRV. These disturbances likely reflect heightened vigilance and arousal during sleep. REM sleep micro-features and autonomic physiology after stressor exposure have not been completely characterized nor examined holistically. Thus, this study looked at sleep architecture, REM sleep theta features, and HRV to examine differences between baseline and post-traumatic stress conditions in rats exhibiting adaptive versus maladaptive responses in subsequent fear extinction learning. We hypothesized that rats showing the greatest REM sleep and HRV disruption relative to baseline would show greater deficits in fear extinction retention. Rats were implanted with electrodes over parietal and frontal brain regions, in nuchal muscles to measure atonia, and over intercostal muscles to measure heart rate. After recovery, we analyzed 24-hour recordings under baseline conditions as well as after stress enhanced fear learning (SEFL), a rodent model of PTSD. We found that increased REM sleep fragmentation, increased phasic muscle twitches, and decreased HRV relative to baseline were correlated with impaired fear extinction memory retention. Also, increased numbers of transitions to wake and decreased REM theta frequency and power were correlated with poorer extinction learning outcomes. These results, all associated with abnormal presence of NE, corroborate the importance of REM sleep stability in adaptive mnemonic and autonomic processes following stress, and may contribute to targeted sleep treatments for PTSD.

Title: At-home sleep quality measurements correlate with next-day seizure counts in individuals with Epilepsy

Authors: *K. PATEL[1,2], C. N. KATZ[1,2], M. GARINGO[2], S. ZUM[2], X. FAN[2], J. STERN[3,2], P. SABETIAN[2];
[1]Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada; [2]Novela Neurotechnologies, Toronto, ON, Canada; [3]Neurol., UCLA, Los Angeles, CA

Abstract: Epilepsy is a common, complex neurological condition that does not respond to treatment with seizure freedom for about 30% of patients. Beyond seizures, epilepsy also is associated with an array of neurological and behavioral comorbidities that collectively reduce quality of life (QoL). Among the co-morbidities, sleep disorders is one that is a well-known predictor of reduced QoL, and sleep is particularly relevant for individuals with epilepsy because of the association between sleep deprivation and seizure likelihood. These known interactions between sleep and epilepsy have been mostly established through studies that are either diary based or performed in controlled monitoring environments, such as in epilepsy monitoring units. In this study, we used daily physiologic monitoring to measure the interaction between sleep quality and seizure frequency in individuals with epilepsy in their home environments. The monitoring utilized wearable devices to record motion from 22 individuals with epilepsy over the course of 338 nights with more than 4 hours of continuous data per night. We developed an algorithm that utilizes the principles of actigraphy to identify periods of restlessness during sleep and used this algorithm to calculate total sleep duration and sleep efficiency for each night. These metrics were compared to expected values of a healthy individual of a similar age to calculate a comprehensive sleep quality score for each night. Linear regression was performed between nightly sleep quality scores and seizure counts the following day collected with an interactive data platform. We found that sleep quality had a significant negative relationship with next-day seizure counts across all patients and all sleep sessions (Pearson's R = -0.1653, p-value = 0.0023). These results suggest that a simple actigraphy-based approach can effectively capture sleep quality in this patient population via off-the-shelf wearables, and that sleep quality may be an important predictor of risk for subsequent seizures on the following day. The results also support the use of wearable physiological monitoring devices to assist in epilepsy care through sleep analysis

Title: Early propranolol administration following fear extinction training reduces sleep spindle-slow oscillation coupling and enhances fear extinction recall

Authors: *R. GUTHRIE[1], J. HOLLOWAY[1], Y. CABRERA[1], J. URE[1], S. N. A. ROSARIO[1], K. KIM[1], G. R. POE[2];

Abstract: Sleep is a critical period for the cortical transfer and memory consolidation of recent experiences involving hippocampal dependent learning. One mechanism thought to underlie this process is the coupling of hippocampal replay during ripples to cortical slow waves and spindles during non-REM sleep following learning. Exposure to psychological trauma can cause sustained norepinephrine release across sleep, which can disturb sleep continuity. Norepinephrine prevents synaptic depotentiation processes that are necessary for reversal learning including fear extinction learning and facilitates potentiation. *We hypothesized that elevated norepinephrine release during post-trauma sleep would prevent fear extinction memory consolidation and alter spindle and slow oscillation dynamics.* The present study probes the effect of sleep features following psychological trauma treatment using the beta-adrenergic receptor blocker propranolol during the critical post-learning sleep memory consolidation window. Animals implanted with electrodes in the parietal and frontal cortex were exposed to stress enhanced fear learning (SEFL) then, 8 days later, to 5 pairs of tone-shock fear conditioning. 24 h later they were fear extinction (FE) trained in a separate context. One group was given 40 mg/kg propranolol immediately after training and the other 4 h later, after the critical consolidation window. 5 days later, animals were tested in the extinction context for contextual and cued fear extinction recall (FER) as measured by freezing. Preliminary results show that animals given propranolol immediately after FE had lower freezing the next day compared to those administered propranolol after the consolidation window. Early propranolol animals showed less contextual and cued freezing on extinction recall day, a trend correlated with a reduction in sleep spindle density, slow wave density, and spindle-slow oscillation coupling in the parietal cortex. Amount of time spent in slow wave sleep did not predict freezing. Spindle-slow oscillation coupling in high-freezing animals may reflect continued consolidation of the fear memory traces in the hippocampus despite extinction training. These results highlight the importance of taking into account specific sleep features that may govern consolidation of emotional memory instead of total time spent in each state. Future work is needed to explore the mechanisms through which propranolol reduces spindle-slow oscillation coupling and the content of the memory replay in treated vs untreated animals that could support resilience from overgeneralization and sustained fear.

Title: Dissociated role of thalamic and cortical input to the lateral amygdala for consolidation of long-term fear memory.

Authors: *Y. LEE, J.-P. OH, J.-H. HAN;
KAIST, Yuseong-Gu, Daejeon, Korea, Republic of

Abstract: Coordinated communications of inter-regional brain networks during post-learning period are thought to be critical for the consolidation of memories. However, the role of specific neural circuit pathways in this process has been scarcely explored. It has been well established that auditory input to the lateral nucleus of amygdala (LA) is essential for the acquisition and retrieval of auditory fear memory. Accumulating evidence suggests that fear conditioning induces associative plasticity not only in the amygdala but also in regions outside the amygdala, including the various stage of the auditory pathways. Further, post-learning engagement of the auditory cortex is necessary for the formation of remote fear memories and the coherent cortico-amygdala theta during remote memory retrieval. Despite these findings, it is unknown whether auditory inputs to the LA is necessary during a post-learning period for consolidation of fear memory. To investigate this question, we optogenetically silenced the inputs from both auditory cortex (AuV/TeA) and thalamus (MGm/PIN) in the LA for 15 min immediately following auditory fear conditioning (FC) and examined its effect on fear memory formation in mice. Optogenetic inhibition of both inputs disrupted long-term fear memory formation tested 24 h after FC. This effect was specific such that the same inhibition did not affect short-term memory and context-dependent memory. Moreover, long-term memory was intact if the inputs were inhibited at much later time points after FC (3 h or 1 d after FC), indicating that optical inhibition for 15 min itself does not produce any non-specific deleterious effect on fear memory retrieval. Selective inhibition of thalamic input was sufficient to impair fear memory formation. In contrast, selective inhibition of cortical input disrupted remote fear memory without affecting recent memory. These results reveal a dissociated role of thalamic and cortical input to the LA during early post-learning periods for consolidation of long-term fear memory.

Title: Potentiated neurons preferentially participate in a fear memory engram during memory formation

Authors: *Y. JEONG, H.-Y. CHO, M. KIM, J.-P. OH, M. KANG, M. YOO, H.-S. LEE, J.-H. HAN;
Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Memory engram, defined as physical changes elicited by learning, is consisted of sparse neuronal networks across the brain. Such changes mainly occur on synapses in the form of long-term potentiation (LTP). LTP is a persistent strengthening of synaptic transmission between neurons and is considered a neural substrate of memory. However, due to the technical limitations of current engram labeling methods which required sufficient new protein synthesis, thus take at least hours and days, the role of synaptic plasticity during memory engram formation remained untestable. In this study, we developed an optogenetic method to prime sparse auditory-to-LA synapses which were not originally potentiated by auditory fear conditioning. We first confirmed these primed synapses were potentiated by the following learning. The activity of the primed synapses was necessary and sufficient for auditory fear memory recall. Next, visualization of neuronal activity marker, c-Fos, after retrieval revealed that the potentiated auditory neurons by priming more preferentially participated in a fear memory engram than non-primed neighboring neurons. Such preferential memory encoding was reversed by optical long-term depression (LTD) shortly after learning, while memory formation was normal. However, LTD 30 min after learning prevents fear memory recall. Finally, optical LTP shortly after learning also sufficiently induced preferential memory encoding into the potentiated neurons. Notably, the number of c-Fos-positive cells was not changed among all stimulation conditions. Taken together, these results indicate that LTP during memory formation directs which neurons will preferentially encode memory.

Title: A genetically-defined population in the lateral and ventrolateral periaqueductal grey selectively promotes active avoidance from threat

Authors: *M. LA-VU, E. SETHI, S. PEREIRA, B. TOBIAS, F. REIS, W. WANG, S. LEONARD, P. SCHUETTE, L. LIN, A. ADHIKARI;
Psychology, UCLA, Los Angeles, CA

Abstract: When encountering threat in the external world, an animal's survival depends on the engagement of appropriate defensive reactions to minimize harm or potential injury. There are major clinical implications for identifying the neural circuitry and activation patterns that produce such defensive reactions, as abnormal overactivation of these circuits is thought to underlie pathological human anxiety and fear responses. Studies using electrical stimulation, immediate early gene analysis, lesions, and excitatory amino acid injections strongly implicate the periaqueductal grey (PAG) in defense. Varying defensive functions mediated by the PAG have long been associated with anatomical column-shaped subregions along its rostrocaudal axis, generally with the dorsolateral column (dlPAG) controlling active avoidance and the ventrolateral column (vlPAG) controlling passive avoidance. Despite decades of studying the functions of these anatomical PAG subdivisions, the roles of various genetically-identified PAG populations have not been explored. Here, we show that optogenetic activation of a population of cholecystokinin-expressing (cck+) neurons in the mouse lateral and ventrolateral PAG (l/vlPAG) promoted active avoidance of open spaces and live predators, while inhibition of these cells decreased avoidance of threats, without altering any other defensive behaviors such as freezing. Finally, using in vivo fiber photometry we show cck+ l/vlPAG population activity ramped down with proximity to a predator and encoded aspects of relative safety within an environment. In contrast, activating pan-neuronal (synapsin-expressing) l/vlPAG cells promoted freezing and synapsin-expressing cells were activated in proximity to threat. Together these data show that in the l/vlPAG, a region classically known to control passive avoidance, there is a cck+ neuronal population that is sufficient and necessary for selectively controlling active avoidance from threat. These data underscore the paramount importance of investigating genetically-identified PAG cells, and show that, in addition to this region's anatomical columnar architecture, the molecular identity of PAG cells may confer an additional axis of functional organization.

Title: Higher-order fear learning in the rat basolateral amygdala complex is independent of NMDA receptors, and instead requires the activation of calcium-permeable AMPA receptors on GABAergic interneurons

Authors: *M. WILLIAMS-SPOONER[1], A. J. DELANEY[2], F. WESTBROOK[3], N. M. HOLMES[3];
[1]Concordia Univ., Montréal, QC, Canada; [2]Charles Sturt Univ., Orange, Australia; [3]Sch. of Psychology, Randwick, Australia

Abstract: In Pavlovian fear conditioning, learning about cues that signal aversive events, such as a footshock, requires the basolateral amygdala complex (BLA). In naive rats, acquiring conditioned freezing to a discrete cue paired with shock involves glutamatergic receptor activity in the BLA, including NMDA receptors (NMDAR). During fear conditioning, sensory inputs carrying information about pairings of conditioned and unconditioned stimuli (CS-US pairings) converge on principal cells in the BLA. The resulting depolarization releases the magnesium block from the NMDAR channel, enabling it to be activated by glutamate. This permits influx of calcium and triggers intracellular cascades which direct the cellular plasticity that is believed to underlie fear memories. Thus, NMDAR activation on BLA principal cells is thought to act as a coincidence detector for salient events (e.g., CS-US pairings) and a gateway for the plasticity that encodes fear learning in memory. However, recent studies on context fear conditioning in the dorsal hippocampus indicate that NMDAR activation is unnecessary when the delivery of the US is fully predicted by what the rat has already learned in prior training. Contrary to the standard view, these results suggest that NMDAR are not simply activated by the coincidence of sensory events, but by the coincidence of unexpected sensory events. To assess whether this is also true of cued fear conditioning in the BLA, we used a two-stage fear conditioning protocol, recently developed by our lab, in which rats receive S1-shock pairings in stage one, and serial-order pairings of S2-S1-shock in stage two. Here, using bilateral cannulations of the rat BLA and micro-infusions of D-AP5 to block NMDAR activation, we show that acquiring conditioned fear

to S2 in this protocol does not require NMDAR. We further show that this NMDAR-independent fear learning to S2 instead requires the activation of calcium-permeable AMPAR receptors (CP-AMPAR) in the BLA, using the CP-AMPAR antagonist, NASPM. Interestingly, CP-AMPAR were also necessary for NMDAR-dependent fear learning to S2 and S1. Finally, we use electrophysiological experiments to demonstrate that NASPM selectively inhibits interneurons, and not principal cells, in the rat BLA. These findings indicate that activation of NMDAR on principal cells and CP-AMPAR on interneurons are both necessary for learning when fear conditioning involves unexpected events, while activation of CP-AMPAR on interneurons is sufficient when fear learning to a novel cue involves events that are expected based on prior learning.

Title: Sex differences in small conductance calcium-activated potassium channel (SK) expression in rat basolateral amygdala neurons following repeated restraint stress

Authors: *J. VANTREASE[1], J. KO[2], J. H. URBAN[3], J. ROSENKRANZ[1];
[1]Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci. Chicago Med. Sch., North Chicago, IL; [2]Chicago Med. Sch., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [3]Physiol. & Biophysics, Chicago Med. Sch/Rosalind Franklin Univ. Med. & Sci., North Chicago, IL

Abstract: Mood disorders disproportionally affect women more than men. The basolateral amygdala (BLA) is critical for the expression of fear and anxiety-like behaviors and is hyperactive in mood disorders. Stress is a leading factor in the development of mood disorders and BLA activity following stress also varies between the sexes. Specifically, stress leads to an increase in BLA spontaneous activity in males, but a reduction in activity in females. Prior work has shown greater BLA activity in naïve females compared to males, but the mechanisms by which this occurs remain unknown. BLA activity is regulated, in part, by small conductance calcium-activated potassium (SK) channels, which mediate afterhyperpolarizations (AHPs) and reduce neuronal firing. Activation of the SK2 channel inhibits BLA neuronal firing in males, but the role of SK2 in females is relatively unexplored. We hypothesized that SK2 expression would

be lower in females resulting in higher spontaneous firing rate of BLA neurons compared to males, and that the expression of SK2 will be altered by stress in a sex-specific manner. In order to test this, we utilized qPCR and Western blot analysis to determine the relative expression of SK2 in the BLA of adult naïve male and female rats. Preliminary results reveal BLA SK2 mRNA levels are similar between the sexes, but BLA SK2 protein levels are lower in females compared to males. We further hypothesize that lower SK2 expression in females will correspond with a smaller SK2 channel activity contributing to increased spontaneous BLA activity. To test this we performed in vivo electrophysiology of BLA neural activity following local injections of a SK2 channel inhibitor (apamin; 1uM) or saline. Additionally, SK2 expression is reduced in response to stress in males, but it is unknown whether this trend occurs in females. Therefore, we also sought to determine whether sex differences exist in SK2 expression and function in rats following repeated restraint stress (20 min/day for 7 out of 9 days), compared to control-handled rats. Our initial findings suggest that repeated restraint stress increases spontaneous BLA activity in males and this activity is less sensitive to apamin injection compared to control-handled rats. In contrast, repeated restraint stress appears to reduce spontaneous BLA activity in females, which is then more sensitive to apamin injection. A more thorough understanding of sex differences in SK2 channel expression and activity following stress may contribute to a better understanding of the sex disparities observed in mood disorders.

Title: Amygdala Control of the Emotional Motor System

Authors: *G. HOLSTEGE[1], H. H. SUBRAMANIAN[2];
[1]The Univ. of Groningen, Groningen, Netherlands; [2]Boston Scientific Neuromodulation, Valencia, CA

Abstract: The amygdala regulates fear and anxiety. Expression of fear and anxiety is associated with changes in the emotional motor system control of breathing, cardiovascular and pelvic organ function. The amygdala via its strong projections to the periaqueductal gray (PAG) could function as one of the emotional motor pathways for the modulation of fear and anxiety. In that case, stimulation of the amygdala should have a direct causal influence on breathing as well as on cardiovascular and pelvic organ functions. This was investigated by stereotaxic glutamate

stimulation of different portions of the amygdala in both cats and rats. Glutamate only stimulates the cell bodies and not the fibers of the passage. Using this technique it was possible to find out whether within the amygdala a topographical organization of emotional functions exist. **Results from the cat studies** **Respiration:** In the cat, stimulation of the lateral amygdala generated hyperpnea and tachypnea, while stimulation of the central amygdala induced dyspnea, bradypnea, inspiratory apneusis and double diaphragm breathing patterns. Stimulation in the amygdala never generated apneas. **Cardiovascular effects:** Stimulation in both the lateral and central amygdala induced hyper- as well as hypotension. **Micturition:** In the cat stimulation of central amygdala generated micturition, but stimulation in the lateral amygdala did not. **Results from the rat studies** Focal stimulation of the central amygdala in the rat induced both tachypnea/hypertension as well as apnea/hypotension. Topical stimulation in the lateral portion of the central amygdala produced breath-hold. Focal glutamate stimulation in the lateral amygdala did not result in any cardiorespiratory effect. In the rat micturition was never generated in either the lateral or the central amygdala. **Conclusion** The lateral and the central amygdalar areas produce distinct modulations of the emotional motor system depending on its association with stress, fear and anxiety. Differences between the cat and rat exist in terms of modulation of the emotional motor system. Title: The midbrain periaqueductal gray (PAG): one stop-shop for emotional motor modulation?

Authors: *H. H. SUBRAMANIAN[1], R. J. BALNAVE[2], G. HOLSTEGE[3];
[1]Boston Scientific, Valencia, CA; [2]The Univ. of Sydney, Sydney, Australia; [3]Emeritus Professor, Rijksuniversiteit Groningen, Haren, Netherlands

Abstract: The midbrain PAG is a critical relay center of the emotional motor system and controls neural circuits that regulate breathing, blood pressure, bladder function, vocalization,

coughing, sneezing, vomiting and maintenance of abdominal and intrathoracic pressure. Dysfunction of PAG circuits lead to dysreflexia such as dyspnea, ataxic breathing, hyper & hypotension and micturition disruption (urinary incontinence). Circuit specific neuromodulation of the PAG could reverse specific types or combined dysfunctions paving way for development of neurologic clinical therapy. However, PAG circuit dynamics are unkown. For this reason, we stereotaxically mapped the PAG in the rat in vivo to investigate its neural architecture, circuit physiology and anatomical topography. The PAG was found to be predominantly quiescent in the resting state and could be activated by iontophoresis of excitatory amino acid glutamate agonists. Cells thus activated ceased function when glutamate ejection was terminated or by co-iontophoresis of muscimol (GABA agonist). Very few spontaneously active cells were found in the PAG, mainly in its dorsal region and these cells, typically fired in a slow and irregular pattern. Activation of either behavioral and/or emotional motor interventions caused immediate activation of PAG neurons mainly in the lateral and ventrolateral PAG, showing two distinct types of activity patterns; 1) single spike firing and 2) burst firing, The cells fired both tonically and phasically when correlated with specific motor output such as the diaphragm EMG. Predominantly the non-bursting PAG neurons had a near normal distribution around 200 to 250 msec, while burst-firing cells typically showing a bimodal distribution. The functional implications of PAG neuronal activity are discussed in terms of descending emotional motor control and effective translation for application of neuromodulation clinical therapy for specific emotional motor diseases. **Acknowledgement**This work was wholly undertaken in the laboratories of HHS-RJB at The University of Sydney and The University of Queensland with respective institutional ethics approvals. Title: Hippocampal volume and intrinsic functional connectivity are associated with social comparison orientation of opinion, but not ability, in older adults

Authors: *H. SUGIMOTO, T. SEKIGUCHI, M. OTAKE-MATSUURA;
RIKEN, Tokyo, Japan

Abstract: This study aimed to examine whether cognitive function and brain states in older adults are associated with social comparison orientation (SCO), which refers to the tendency to compare oneself with others. To achieve this purpose, we collected multi-modal MRI data, including T1-weighted images, resting-state fMRI, and DTI, from ninety-seven community-dwelling older adults, as well as self-reported questionnaire data of the SCO scale that contains two subscales of opinion (e.g., "I often like to talk with others about mutual opinions and experiences") and ability (e.g., "I often compare myself with others with respect to what I have accomplished in life") and behavioral data of the Japanese version of the Montreal Cognitive Assessment (MoCA). All of the MRI analyses were conducted using the general linear model with a covariate of the SCO score (opinion or ability). Age, sex, and years of education were also included in the model as nuisance covariates (total intracranial volume was additionally entered into the model for VBM and TBSS analyses). Seven participants were excluded from all analyses, due to having probable arachnoid cyst, metal artifact, or meningioma. Thus, a total of ninety participants (55 females; age, mean ± SD = 73.5 ± 4.5 years; years of education, mean ± SD = 14.5 ± 2.2 years) were included in the analyses. Behavioral results showed that the MoCA score had a significantly positive correlation with the score of opinion ($r = 0.22$, $p < .05$), but not with that of ability ($r = -0.06$, $p = .56$). DARTEL-based VBM analysis demonstrated that the left hippocampal volume positively correlated with the score of opinion (ROI-based correction by FWE, $p < .05$), but not with that of ability. No significant correlation was observed in the right hippocampal volume. In the analysis for resting-state fMRI data, the functional connectivity between the left hippocampus as a seed region and the left angular gyrus, right ventromedial prefrontal cortex, and left posterior middle temporal gyrus showed a significantly positive correlation with the score of opinion (FWE, $p < .05$), but not with that of ability. Such a functional connectivity pattern was not found when we employed the right hippocampal seed. Finally, TBSS analysis for DTI data revealed that neither the score of opinion nor that of ability had significant correlation with the DTI metrics, including fractional anisotropy, mean diffusivity, axial diffusion, and radial diffusion. These findings suggest that older adults' general cognitive function and hippocampal structure and functional connectivity are modulated by the degree to which they compare their opinion with others, but not ability, in their daily lives.

Title: Bonding scenes trigger motivation for social touch

Authors: O. GRICHTCHOUK, J. M. OLIVEIRA, C. FRANKLIN, M. F. CORRREA, V. ROCHA-REGO, *E. VOLCHAN;
Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: Proximity and interpersonal social contact are prominent components of social connection in human beings. Social interaction scenes were shown to facilitate the recruitment of pre-set cortical motor repertoires related to caress-like movements. Here, we investigated implicit predispositions for giving social touch associated with exposure to visual bonding stimuli. We explored the visuo-motor affective interplay at the final effector by monitoring the electromyographic activity of fingers flexor muscle in the absence of any overt movements. Photographs of dyads in social interaction attitudes and matched photographs of the same dyads not interacting were presented while electromyographic activity of fingers flexor muscle from the right hand was recorded. Exposure to dyads socially interacting significantly and sustainably increased participant electromyographic activity compared to exposure to dyads non-interacting, in the absence of any overt movement. When comparing each pair of matched pictures, the one depicting the interacting dyad consistently evoked higher electromyographic activity in comparison with the one depicting the same dyad non interacting. In the giver perspective, the flexion of fingers is a very important component of social touch. Here, using bonding visual priming and while participants were not making any overt movement, we were able to probe a motor output tightly implicated in the predisposition for social touch.

Title: Combined behavioral approaches for probing social motivation in young children

Authors: *B. THOMPSON[1], M. CHAVEZ[1], E. WOLFRUM[2], A. CARBAYO[1];
[1]Michigan State Univ., Grand Rapids, MI; [2]Van Andel Res. Inst., Grand Rapids, MI

Abstract: Background: Determining the neural mechanisms that underlie the heterogeneity of social-affective behaviors is challenging in developing children. The factors that influence the heterogeneity of these social behaviors in both typically developing (TD) children and children with Autism Spectrum Disorder (ASD), for whom disruptions in social behaviors are among the core deficits, are currently unknown. Objectives: We aimed to determine whether alterations in social behavior in children with ASD are driven by an aversion to, or lack of reward from, social interactions using a combination of remote eye-tracking techniques and detailed behavioral coding of social play. Methods: We adapted our previously established associative learning paradigm of conditioned place preference (CPP) in young children for use with a social unconditioned stimulus (US). In this paradigm, during an initial preference test (IPT), TD children (30-60 months) and children with ASD (36-66 months) freely explored two neutral rooms in our child-friendly castle. Then, across training trials, children alternated play between the two rooms while one of the rooms, the conditioned stimulus (CS), was paired with the US, a novel and interactive social experimenter. During the final preference test (FPT), children again freely explored both rooms, in absence of the US. Social CPP (sCPP) scores were calculated as the difference in time spent in the social-paired room during the IPT and FPT. Additionally, these children watched a 6-minute video comprised of social and non-social naturalistic scenes as well as cartoon animations. Eye movements were recorded using a Tobii Pro Spectrum eye-tracker and software. Advanced regressions were run to determine relationships between eye-tracking metrics and performance in the sCPP task. Results: We found significant heterogeneity in sCPP scores in both TD children and in children with ASD, with no differences in sCPP scores between groups. The two groups did demonstrate differences in gaze patterns across the video stimuli, though social scenes produced more frequent fixations in both groups. Preliminary statistical analyses revealed that eye-tracking metrics correlated with sCPP in these same children. Conclusions: This work provides a more comprehensive understanding of the mechanisms driving social motivation. The heterogeneity of sCPP scores provides greater insight into social motivation across young children and may help transform assessment and intervention approaches in young children.

Title: Perceived social isolation, resting parasympathetic activity, and motivated behaviors

Authors: *K. E. SMITH, S. D. POLLAK;
Univ. of Wisconsin - Madison, Madison, WI

Abstract: A critical aspect of adaptive behavior is the ability to use cues in the environment to approach and avoid potential rewards and threats. Perceived social isolation has been theorized to change how individuals approach and avoid salient information. Specifically, acute social isolation is thought to act as a signal one lacks sufficient social relationships and increase approach motivations. However, findings in this area are conflicting. Parasympathetic cardiac regulation is associated with variability in approach and avoidance behaviors, with individuals with higher resting parasympathetic activity demonstrate more flexible adaptation to salient cues. Thus, the effects of perceived social isolation on approach and avoidance may be moderated by parasympathetic functioning. Here, we examined how parasympathetic functioning and perceptions of social isolation influence approach and avoidance behaviors. We collected measures of resting parasympathetic activity and perceptions of social isolation from 74 adults (18 - 46 years). Participants underwent an instrumental conditioning paradigm assessing how they approach and avoid rewards and threats. Higher levels of perceived social isolation were associated with increased approach behaviors. This was most pronounced in individuals with higher resting parasympathetic activity. In contrast, individuals with lower resting parasympathetic activity demonstrated increased avoidance behaviors. In sum, these findings suggest that social isolation does shift motivational behaviors. Additionally, individuals with higher resting parasympathetic activity may demonstrate more adaptive changes in motivation linked to perceived social isolation.

Title: Tracing the cognitive sources of communicative challenges in Autism Spectrum Disorder

Authors: K. CAI[1], S. KOCH[1], M. MANGNUS[1], I. TONI[1], J. BASNAKOVA[1], *A. STOLK[2]; [1]Donders Inst., Nijmegen, Netherlands; [2]Dartmouth Col., Hanover, NH

Abstract: Autism Spectrum Disorder (ASD) is diagnosed on the basis of communicative challenges experienced in everyday interactions, yet the cognitive sources of those challenges remain largely unknown. A popular suggestion holds that autistic individuals struggle to predict other people's behaviors, either due to bottlenecks in bottom-up sensory processing or attenuated sensitivity to top-down priors when interpreting communicative behaviors (Pellicano & Burr, 2012). However, studies of predictive processing have produced mixed results in the perceptual domain, and few studies to date have investigated ASD predictive capabilities during live social interaction.

This eye-tracking study aims to assess bottom-up and top-down contributions to neurotypical and autistic interpretations of genuinely interactive communicative behaviors. Predictive abilities are assessed while participants solve a series of coordination problems in the two-player "tacit communication game" (Wadge et al., 2019). In each round of this game, players have to jointly reproduce a target configuration of their two given shapes on a digital game board. However, the target configuration is shown to one of the players only, the Sender. Given that the other player, the Receiver, cannot see the target configuration, the Sender needs to move her shape in a way that conveys the location and orientation of the Receiver's shape. As when interpreting everyday ambiguous words and gestures, the Receiver needs to rapidly identify relevant features from the Sender's movements to infer her target position. A benefit of the novel communicative medium is that it offers the possibility to manipulate access to top-down priors during communicative interpretation by introducing coordination problems that are more easily solved in light of previous interactions. Furthermore, the computer-controlled interactions allow for a temporally precise overlay of eye gaze and communicative behavior to determine any bottlenecks in bottom-up sensory processing.

Preliminary results (25 neurotypical and 19 ASD pairs) suggest that the communicative challenges experienced by autistic individuals cannot be attributed solely to limitations in bottom-up processing, as seen in matched durations of task-relevant fixations between neurotypical and ASD participants. Second, autistic and neurotypical individuals' eye gaze behaviors exhibited a similar susceptibility to top-down priors established during previous interactions. These findings open the way to investigate the cognitive mechanisms that integrate bottom-up and top-down processes to produce accurate inferences about other people's behavior in ASD.

Title: Influence of HVC Dopamine Receptor Subtypes on Song Production in Canaries

Authors: *C. M. HAAKENSON[1], A. E. MARQUARDT[2], J. W. VANRYZIN[3], M. M. MCCARTHY[2], G. F. BALL[4];
[1]Univ. of Maryland, Col. Park, College Park, MD; [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Univ. of Maryland, Baltimore, Baltimore, MD; [4]Univ. of Maryland, College Park, MD

Abstract: Communication is essential for social species that rely on coordinated behavior for survival and reproduction, however relatively little is known about the neural mechanisms underlying the social and motivational aspects of this behavior. We examined a species that uses vocal communication to relay social information, the canary (*Serinus canaria*), and a potential modulator of the motivation to sing - the neurotransmitter dopamine. There is evidence that dopamine in some song nuclei can influence the amount of singing directed at potential mates. In addition, activation of dopamine type 1 receptors (D1R) can have different electrophysiological effects than activation of dopamine type 2 receptors (D2R). Yet it is currently unknown how differences in the effects of D1R versus D2R action manifest in singing behavior. Therefore, in order to investigate the effects of dopamine receptor activation on song, we implanted guide cannula targeting the song control nucleus HVC. We injected drugs to both activate and inhibit dopamine receptors in this region. Each bird received injections of a D1R agonist, a D1R antagonist, a D2R agonist, a D2R antagonist, and saline with a 48-hour washout period between treatments. From songs recorded following injections, we quantified the latency to initiate singing and the quality of songs produced in the hour following drug injection. In addition, we applied a novel computational approach to identify changes in song structure following treatment – employing new dimensionality reduction techniques, density-based spatial clustering, and network diagrams. This experiment indicates that D1 receptor activation in HVC increases the latency to sing. Furthermore, song following D1 receptor agonist treatment had a reduction in three particular syllable types, while these syllable types were increased in song following D2 receptor agonist and antagonist treatment. In addition, we performed RNAscope in situ hybridization in order to characterize the cells responsible for these effects. Brains were collected 30 minutes following song and sections containing HVC were labeled with a probe for the immediate early gene Egr1, probes for dopamine receptor subtypes (D1R, D2R or D3R), a probe for GAD2 to identify inhibitory cells, and a probe for VGLUT2 to identify excitatory cells. We found that the majority of cells that expressed dopamine receptors were excitatory and a large proportion were active during singing. These results indicate that activation of dopamine

receptor types have profoundly different effects on song production, potentially modulating the type of vocalization produced to be appropriate for the social context.

Title: Molecular underpinnings of paternal behavior in prairie voles

Authors: *N. WADDELL[1], J. M. CHITAMAN[1], Y. LIU[2], Z. WANG[2], J. FENG[1];
[1]Biol. Sci., [2]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Throughout the animal kingdom most species are polygamous, yet some form social bonds with sexual partners, resembling a monogamous social relationship. Prairie voles form such strong social bonds during mating, with both father and mother showing rearing behaviors to their offspring and aggression to stranger individuals. In addition, before pup-exposure, virgin males also present split behavioral phenotypes, where some of these unbonded males demonstrate parental behavior to novel pups (i.e. “virgin paternal males”) and the rest display aggression (i.e. “virgin aggressive males”). To explore the molecular underpinnings of these biphasic paternal behavioral phenotypes of virgin male prairie voles, we investigate the transcriptome and DNA methylome in hippocampal dentate gyrus (DG) through RNAseq and RRBS, respectively. Within the four groups of adult animals (virgin aggressive males, virgin paternal males, fathers, mothers), we found the transcriptome was generally up-regulated in virgin aggressive males when compared to virgin paternal males. Interestingly many of these affected genes were similarly changed when virgin aggressive males are compared to fathers after pup exposure. For DNA methylation, we recognized comparable numbers of hypermethylated and hypomethylated CpG sites across the genome with similar genomic feature distributions when comparing aggressive and paternal virgin males. We then intersected the RNAseq and RRBS datasets and identified several significant relationships. Profiling gene ontology pathways, a number of cell signaling and neurogenesis related pathways are overrepresented. Taken together, we found widespread transcriptome and methylome changes in hippocampus that are selectively enriched within certain signaling pathways that may contribute to the paternal behavioral phenotype in male prairie voles.

Title: Waving through a window: a model of volitional social interaction in female mice

Authors: *F. HOLLOMAN[1], B. T. HOPE[1], Y. SHAHAM[1], M. VENNIRO[2], L. A. RAMSEY[1]; [1]IRP/NIDA/NIH, Baltimore, MD; [2]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Background: Mouse models of social behavior fail to account for volitional aspects of social interaction and current neurobiological investigation of social behavior is performed almost exclusively using C57BL/6J mice, the background strain of most transgenic mice. Here, we introduce a mouse model of operant social self-administration and choice, using a custom-made apparatus. **Methods:** First, we trained adolescent and adult female C57BL/6J and CD1 mice to self-administer palatable food pellets and then to lever-press under increasing fixed-ratio response requirements for access to a female social partner. Next, we tested their motivation to seek social interaction using a progressive ratio reinforcement schedule, relapse to social seeking after social isolation, and choice between food versus social interaction. We also tested social conditioned place preference (CPP) in adult female CD1 and C57BL/6J mice. **Results:** Adolescent and adult female mice of both strains showed similar rates of food self-administration. In contrast, CD1 mice demonstrated significantly stronger social self-administration than C57BL/6J mice under both reinforcement schedules. CD1 but not C57BL/6J mice demonstrated robust social seeking after social isolation. In the choice task, CD1 mice strongly preferred social interaction, whereas C57 mice strongly preferred food. CD1 but not C57BL/6J mice demonstrated robust social CPP. The strain differences were age-independent. **Conclusion:** Our data demonstrate that CD1 mice are a better strain for studying female social reward learning. Our mouse operant social model provides a tool for research on neurobiological substrates of female social reward, and disruption of social reward psychiatric disorders, using mice-specific genetic tools.

Title: The role of ghrelin in promoting the motivation for social interaction through AGRP neurons in mice

Authors: *A. ALFTIEH, B. AL-TAHIR, K. JOY, L. HYLAND, A. ABIZAID;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Ghrelin is a stomach-derived peptide that increases food intake by acting as an endogenous ligand for growth hormone secretagogue receptor (GHSR). GHSR is abundantly expressed in the brain with high expression found in agouti-related peptide (AGRP) and neuropeptide-Y (NPY) neurons within the hypothalamic arcuate (ARC) nucleus. Recent data suggests that, in addition to increasing food intake, ghrelin facilitates social interaction whereas ghrelin receptor antagonists increase social vigilance. In this present study, we investigated the effects of ghrelin on the motivation for social interaction in mice and the role of AGRP neurons in mediating these effects. Sixty-three male and female C57BL/6J mice were assigned to groups receiving intraperitoneal (IP) injections of saline or ghrelin (10ug of ghrelin in .1cc of isotonic saline) followed by injections of saline or the MC3/4 receptor agonist melanotan-II (1mg/kg of MTII in .1cc of isotonic saline) which competes with AGRP, an endogenous antagonist to the MC3/4 receptors. Thirty minutes later, mice were tested on a social interaction test to investigate how these drug treatments affected social behaviors. Results showed that, regardless of sex, ghrelin injected peripherally significantly decreased the latency to approach a conspecific and the frequency of corner observation, while increasing the total duration of social interaction. In contrast, IP injections of MTII alone resulted in a significant increase in the latency to approach a conspecific and the frequency of corner observations, while decreasing the total duration of social interaction. Mice that were given MTII and ghrelin responded like saline treated animals, and did not show ghrelin induced pro-social behaviors. Taken together, the results suggest that ghrelin promotes social interaction, and blocking the ability of AGRP from binding to its receptor attenuates these effects.

Title: Comparison of the Behavioral Effects of Chronic Intranasal Administration and Intraperitoneal Injection of Oxytocin on Male and Female Mice

Authors: M. MEADOWS, H. HUDSON, L. PAUL, I. RAMOS, *T. ROGERS;
Middle Tennessee State Univ., Murfreesboro, TN

Abstract: Comparison of the Behavioral Effects of Chronic Intranasal Administration and Intraperitoneal Injection of Oxytocin on Male and Female Mice
AuthorsM. MEADOWS[1], H. HUDSON[1], L. PAUL[1], I. RAMOS[1], ***T. D. ROGERS**[1];[1]Middle Tennessee State Univ., Murfreesboro, TN**Disclosures T.D. Rogers:** None. **M. Meadows:** None. **H. Hudson:** None. **L. Paul:** None.
While the effect of oxytocin (OT) on social behavior and anxiety-like behavior is commonly studied in animal models, differing routes of administration between studies potentially limit generalizability. The current study compared the behavioral effects of chronic intranasal administration and chronic intraperitoneal injection of the same dose of OT in male and female mice. Adult C57BL/6J mice were chronically pretreated with saline or OT (12 ug) for 14 consecutive days. Mice received either intranasal (12 ml, 6 ml per nostril) or intraperitoneal (120 ml) administration. On day fourteen, mice were tested in the elevated plus maze (EPM) to determine differences in anxiety-like behaviors. Twenty-four hours after EPM, mice were tested in the three-chamber test, commonly used to test sociability and preference for social novelty. Twenty-four hours after the three-chamber test, mice were placed in an open field arena measuring 12”x12” with a sex-matched conspecific for ten minutes to measure social behavior in a free dyadic social interaction (FDSI). Analysis of the EPM behavior indicated a significant three-way interaction (drug x route x sex) in which OT administration reduced open arm exploration only in females administered OT via intraperitoneal injection suggesting increased general anxiety-like behavior in this group ($F(1, 57) = 14.42$, $p = 0.0004$). In the three-chamber, mice that received either OT or saline via intraperitoneal injection displayed less social sniffing ($F(1, 60) = 7.93$, $p = 0.007$) and less preference for social novelty ($F(1, 59) = 5.06$, $p = 0.028$). In the FDSI, a significant main effect for the type of drug administered indicated that OT increased social approach ($F(1, 58) = 7.49$, $p = 0.008$) and reduced social anxiety-like behaviors ($F(1, 58) = 40.96$, $p < 0.0001$) compared to saline. A main effect for route of administration indicated that mice receiving intraperitoneal injections displayed more social approach than mice receiving intranasal administration ($F(1, 58) = 7.95$, $p = 0.0066$). Our findings suggest that the route by which OT is administered may affect social and anxiety-like behaviors in mice. Further these differences may be sex specific. The findings highlight the need to identify potential limitations of generalizability between studies that use varying routes of administration of OT.

Title: An fMRI study examining the role of the extended amygdala in negative emotion and inhibitory control in second language learners.

Authors: M. SUGITA-MCEOWN[1], M. MAKUUCHI[2], T. NAOE[2], J. ELLINGER[3], ***K. MCEOWN**[1];
[1]Waseda Univ., Tokyo, Japan; [2]Natl. Rehabil. Ctr. for Persons with Disabilities, Tokorozawa, Japan; [3]The Univ. of Tokyo, Tokyo, Japan

Abstract: The current studyinvestigated the role of the extended amygdala in negative emotion andinhibitory control in second language learners. fMRI scans, using a 3T MRIscanner, were used to measure neurophysiological responses to neutral and negativeemotional linguistic stimuli presented in participants' native language (i.e.,Japanese) or in a second language (i.e., English) using a modified version ofthe emotional-linguistic Go-No Go task. Data were collected from 12 healthyyoung adults (9 female; mean age = 20.3 years) who were attending a privateuniversity in Japan and learning English as a second language. The right extendedamygdala (coordinates: 21, 6, -12), right amygdala (18, -6, -18), left extendedamygdala (-18, 6, -9) and left amygdala (-24, -7, -17) were selected as regionsof interest for the current study. The region of interest of each participantwas defined as a 6mm radius sphere centered at these coordinates. We found thatleft amygdala activation was significantly lower in the English neutral wordNo-Go condition compared to the Japanese neutral word No-Go condition. Furthermore,as predicted, right extended amygdala activation was significantly lower in theEnglish negative word No-Go condition compared to the Japanese negative word No-Gocondition. These findings suggest that brain regions (i.e., the extendedamygdala) associated with negative affect are significantly less active whenparticipants are performing a task that requires inhibitory control and are exposedto negative emotional linguistic stimuli in a second language compared to when theyperform an inhibitory control task and are exposed to negative emotional linguisticstimuli in their native language.

Title: Multivoxel Patterns of Human Emotion Regulation Neurodevelopment

Authors: *J. GUASSI MOREIRA, A. MÉNDEZ LEAL, N. SARAGOSA-HARRIS, Y. WAIZMAN, E. NINOVA, J. SILVERS;
UCLA, Los Angeles, CA

Abstract: The acquisition of emotion regulation—a critical process implicated in mental health, achievement, and every day functioning—is an inherently developmental process that occurs over the course of decades. To date, much research has examined the neurodevelopmental bases of human emotion regulation using univariate methods. That is, this work predominantly focuses on using fMRI to chart the neurodevelopment of mean brain activity in individual regions of interest, or in whole-brain univariate contrasts. By comparison, relatively little work has leveraged multivoxel analytic techniques that are prevalent in other arenas of human neuroimaging. These techniques are powerful because they consider how *patterns* of brain activity—comprised of suites of voxels responses in fMRI—meaningfully encode information about psychological phenomena of interest. In this study, we leverage multivariate pattern analyses to better understand the neurodevelopment of emotion regulation. A sample of 50 youths (ages 10-22) completed four runs of an emotion regulation task while undergoing fMRI. On a trial-by-trial basis, youths were asked to either cognitively downregulate emotional responses to a series of negative stimuli, or to emotionally react to negative stimuli (as an emotional responding baseline). After data preprocessing, we examined how emotion regulation activity was encoded in multivoxel patterns using several different analyses. While controlling for age, we first investigated whether we could decode task conditions on the basis of multivoxel patterns. Next, we examined age-related effects neural representations of emotion regulation using both standard multivoxel pattern analysis techniques as well as feature encoding models. Finally, we examined whether an analytically derived neural signature of emotion regulation from our sample matched canonical signatures of adult regulation. While analyses remain ongoing, early results broadly suggest age appears to be meaningfully encoded in multivoxel representations of emotion regulation.

Title: A deep neural network model for emotion perception

Authors: *P. LIU[1], K. BO[3], L. CUI[1], Y. CHEN[1], C. T. TRAN[2], R. FANG[1], M. DING[1];
[1]Dept. of Biomed. Engin., [2]Dept. of Electrical and Computer Engin., Univ. of Florida, Gainesville, FL; [3]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Deep neural networks (DNNs) have shown to be excellent models of visual object recognition in the human and the nonhuman primate brain. Recent work has begun to explore the capability of DNNs as models of more complex cognitive constructs such as memory and emotion. We have developed a deep neural network model for perceiving emotions in affective images that includes both a visual cortex module and an amygdala/orbital frontal cortex (OFC) module. Specifically, the visual cortex module consisted of a VGG16 network pre-trained on ImageNet data, and the amygdala/OFC module consisted of three fully connected layers that receive input from the last fully connected layer of VGG16 as well as the early layers, with the latter mirroring the inferior longitudinal fasciculus (ILF) connection between the occipital and anterior temporal cortex. The model was trained to predict the valence from affective images (training data) and tested against the normative valence ratings of similar images (testing data). Four datasets were considered: the International Affective Picture System (IAPS), the Nencki Affective Picture System (NAPS), the dataset from In-Kwon Lee, and the static frames of the emotion video dataset from Alan S. Cowen. The activities of the amygdala/OFC module of the fully trained model were also compared with fMRI data recorded from human subjects viewing IAPS images using the representational similarity analysis (RSA). The results show that (1) the model was able to predict valence with high fidelity ($R>0.6$) for all four datasets, (2) the model's performance was considerably worse without the "ILF" mediated pathway, and (3) activities in the second-to-last and last layer of the amygdala/OFC module were comparable with activities in the human amygdala and OFC respectively. These results demonstrated that our DNN model has the capability to recognize the emotional content of affective images and can become a platform for formulating and testing neuroscientific hypotheses.

Title: Reappraisal-related downregulation of amygdala BOLD activation occurs only during explicit post-stimulus evaluation

Authors: *J. PIERCE[1], J. R. BLAIR[2], K. CLARK[1], M. NETA[1];
[1]Univ. of Nebraska, Lincoln, Lincoln, NE; [2]MAP, Ctr. For Neurobehavioral Res., Boys Town, NE

Abstract: During cognitive reappraisal, an individual reinterprets the meaning of an emotional stimulus, for example, to make a disturbing image seem less threatening and thus regulate the intensity of their emotional response. Prefrontal cortex activity has been found to support reappraisal and is putatively thought to downregulate the amygdala response to these stimuli. The timing of these regulation-related responses during the course of a trial, however, remains poorly understood. In the current fMRI study, participants were instructed to view or reappraise negative images and then rate how negative they felt following the presentation of each image. The hemodynamic response function was estimated in 11 a priori regions of interest for the entire time course of the trial including image viewing and rating. An analysis of the reappraisal-related activity during early and late windows of the trial indicated that although some prefrontal regions (e.g., inferior frontal gyrus) had increased activation in the early window, others (e.g., middle frontal gyrus) had increased activation primarily in the late window. Notably, the amygdala showed no evidence of downregulation in the early window, but did show such evidence in the late window, which also correlated with a measure of behavioral reappraisal success. These results highlight the importance of examining the time course of neural responses during cognitive reappraisal, as different brain regions respond to different subunits of the trial, and this pattern of results provide some insight into the underlying cognitive and affective processes.

Title: Greater mindfulness is associated with lower internalizing, externalizing, and attention problems in elementary school children

Authors: *P. MECHNIKOV[1,2], B. BORG[2], H. MARUSAK[2];
[1]Physiol., Michigan State Univ., Huntington Woods, MI; [2]Psychiatry and Behavioral Neurosciences, Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: Mindfulness-based interventions are increasingly implemented in school settings. However, empirical research on mindfulness-based interventions lag behind their widespread implementation. Here, we tested whether greater mindfulness is associated with lower internalizing, externalizing, and attention problems in elementary school children. This study included a total of 310 students (grades 2-4; 47% female, 68% Black American, 15% White, 17% Other) recruited from two public suburban schools with the same district and one nearby private school. Mindfulness was measured using the Child and Adolescent Mindfulness Measure. Internalizing (e.g., anxiety, depression), externalizing (e.g., conduct, oppositional defiance), and attention (e.g., ADHD) problems were measured by the Pediatric Symptom Checklist. Overall, greater mindfulness was associated with lower internalizing, externalizing, and attention problem behaviors. These results remained significant when controlling for gender, grade, and district. Overall boys reported more externalizing problems than girls and the association between mindfulness and externalizing symptoms was moderated by gender such that boys showed greater reductions in externalizing symptoms with higher mindfulness as compared to girls. There were no other interactive effects with gender, race/ethnicity, district, or grade. These results demonstrate the potential benefits of mindfulness for reducing internalizing, externalizing, and attention problem behaviors among diverse students from public and private schools at the elementary school level. Boys, in particular, may benefit from mindfulness-based school interventions to reduce externalizing problems. School-based programs that cultivate mindfulness may be beneficial for improving student health and outcome (e.g., academic performance).

Title: The functional connectome for emotional responses- an EEG analysis

Authors: *F. SAFFARI[1,2], K. NOROUZI[1], P. MICHAELSEN[1], T. ZOEGA RAMSØY[1];
[1]Neuronsinc, Hoje-Taastrup, Denmark; [2]Aalborg Univ., Copenhagen, Denmark

Abstract: The functional connectome for emotional responses- an EEG analysis
Background: Recently, the field of neuroimaging has been moving from "brain mapping" which focused on brain regions, to a view of the brain as a densely interconnected network. In this view, it is the "network code" of a particular function that is key, rather than any singular structure. The network code for critical functions such as emotional responses are currently being studied. In the study of emotions, there is also an ongoing discussion about the nature of emotions, and whether there are any classes of emotions that can be robustly identified across individual differences. Here, brain connectivity analyses to different emotional responses are thought of as particularly challenging. In this study, we report the results from a connectivity analysis using EEG to different emotional responses. **Method:** 57 participants exposed to videos with six types of emotional content, while their brain responses recorded using a 9-channel EEG (Fz, F3, F4, Cz, C3, C4, POz, P3, P4). The EEG data were pre-processed using band-pass Butterworth filter, re-referencing, removing bad epochs, and ICA. In analyzing the data, we used Imagery Coherence (Icoherence), to test for significant differences among emotions (sadness, happiness, neutral, anger, fear, and amusement). We applied an ANOVA test for 36 pairs of channels using different frequency ranges (Theta, Alpha, Beta, Gamma), to test which pairs of electrodes were discriminatory regarding their Icoherence values. The ANOVA table constructed via 57 observations for 6 types of emotion. In overall, 36 ANOVA were applied. A post-hoc pairwise analysis was run to test which types of emotions were different on the Icoherence value of that pair. **Result:** In the alpha band, there were 7 significant different values (p-value < 0.05); C3-Fz: AMU-HPY, F4-F3: HPY-NEU, P3-Fz: ANGR-HPY, P4-P0z: Fear-NEU, P4-C4: HPY-NEU, Fear-NEU, C4-Fz: HPY-NEU, and in beta band; F4-F3: HPY-NEU, C4-C3: Sad-NEU, F3-C4: AMU-NEU, P4-P3: AMU-HPY, AMU-NEU. There were no significant differences in theta and gamma. **Conclusion:** These results indicate that most of the unique features of functional brain connectivity during emotional responses occur in the alpha band. Moreover, these outcomes suggest that phase connectivity features can be discriminative for positive emotions (happy and amusement). This could mean that phase connectivity tracks both the arousal and valence level of emotion. However, since none of the values were significantly different among negative – negative comparison, this implies cross frequency features should be consider to produce better discriminatory features.

Abstract: In spite of decades of research on the brain bases of affective and motivational processes, we still have much to learn about the organization of brain systems underlying them. Previous studies are limited in sample size and number of affective tasks. Although a number of meta-analyses have attempted to overcome these issues by aggregating findings across multiple studies, this effort has primarily been focused on finding reliable 'hot spots' in the brain using brain coordinates from published papers and thresholded results. Establishing the generalizability, sensitivity, and specificity of brain measures for different categories of affective processes, however, requires a more complete understanding of the underlying neural architecture informed by maps with information across all brain voxels at the individual level. This can be accomplished with collaboration across multiple laboratories by utilizing data from multiple studies. Here, we introduce the Affective Neuroimaging Collaboratory (ANiC), a large-scale initiative that provides a platform to aggregate and analyze individual subject-level data across affective and motivational tasks, studies, and research groups worldwide. Our goals are threefold: 1) curate a quality-controlled data resource; 2) make data available to the consortium and subsequently the public, with contributing researcher-determined access; and 3) work collaboratively to publish articles to advance our understanding of the organization of affect and motivation in the brain. Among a number of potential outputs, we are envisioning developing brain measures that are sensitive to, and specific for particular domains of affect and motivation; evaluating which ontological structures are best reflected in the brain; providing mechanistic brain targets for translational use; and contributing to the development of a biologically-grounded understanding of brain-based disorders. As proof of concept, we compiled data from 18 studies, across three domains (pain, cognitive control, negative emotion) and nine subdomains (three modalities per domain) with a total of 270 participants (15 sampled per study), and tested if single sub-regions in the insula integrate multimodal affective processes. We found that specific insular sub-regions respond to different types of affective domains and subdomains. These results challenge the concept of a single integrative center across types of affect in the insula and provide evidence for an organizational scheme grounded in sensory systems where each insular sub-region processes different affective information characterized by different sensory modalities.

Title: Face and Emotion-Sensing in right Temporal Parietal Junction: A Dyadic Complex for Emotion Contagion

Authors: *J. HIRSCH[1,2,3,4,5], A. BHATTACHARYA[6], X. ZHANG[1], J. A. NOAH[1]; [1]Psychiatry, [2]Neurosci., [3]Comparative Med., Yale Sch. of Med., New Haven, CT; [4]Haskins Labs., New Haven, CT; [5]Dept. of Med. Physics and Biomed. Engin., Univ. Col. London, New Haven, CT; [6]Yale Col., Yale Univ., New Haven, CT

Abstract: How does the human face convey emotion to another human? Although emotional contagion is a primitive and foundational feature of social interactions, the underlying mechanisms are not well understood. Here we apply a dyadic approach to investigate the mechanisms of emotional contagion using functional near infrared spectroscopy hyperscanning. One participant, "Video-Watcher", watched emotionally provocative silent videos and the other partner, "Face-Watcher", saw only the face of the Video-Watcher, Fig 1 A. Ratings of the emotional experience (dial rotation) were acquired simultaneously for both participants at the end of each 5 sec video. Facial recognition cameras used Open Face to record Action Units of facial expressions. Partners sat across a table from each other and alternated roles as "Video-or Face-Watcher". The library of videos included "neutrals" featuring landscapes, "adorables", featuring animal antics, and "creepy crawlies" featuring spiders, worms and states of decay. All were pre-tested for emotive properties. The "Video-Watcher" rated his/her emotional feeling for each video. The "face watcher" rated his/her emotional feeling for each expression of the "Video-Watcher's" face. The correlation of emotional ratings between the "Video and Face-Watchers" ($r = 0.60$) confirmed that the emotion was transmitted by facial expressions and taken as a measure of emotional contagion. Facial Action Units of the "Video Watcher's" face were taken as the stimuli for the "Face- Watcher", and the largest units, "Lip Corner Puller" and "Dimpler Buccinator" were combined and used as a regressor on the "Face-Watcher's" neural responses. A complex of right TPJ regions consisting of supramarginal gyrus, angular gyrus, and superior temporal gyrus) was found to be responsive to these dynamic emotional expressions ($p < 0.05$, FDR corrected peak voxel, Fig 1B) and consistent with an emotion-sensing function.

Findings suggest a dyadic model of emotion contagion and face sensing where brains and faces are tuned to send and receive emotional states via facial cues.

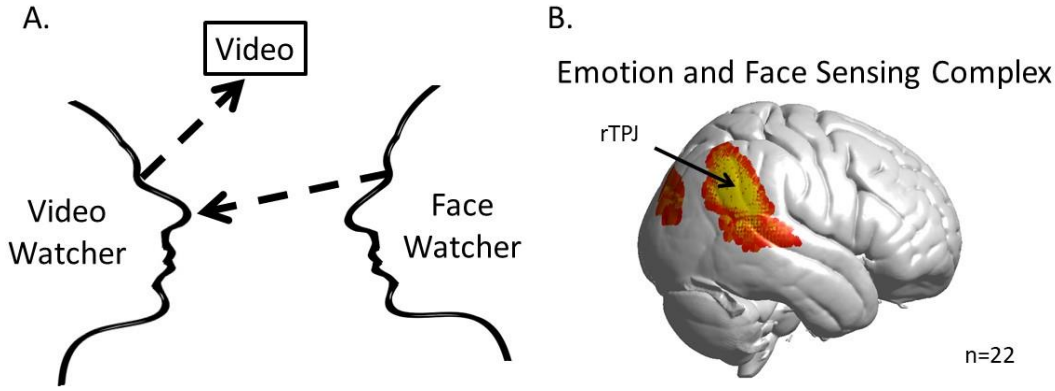

Fig 1. The "Face-Watcher's" brain activity was regressed with the "Video-Watcher's" Facial Action Units and reveals a rTPJ complex associated with emotion and face sensing.

Title: Role of the Pulvinar in Affective Scene Processing

Authors: *L. CUI[1], Y. LIANG[1], K. BO[3], A. KEIL[2], M. DING[4];
[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Dept. of Psychology and NIMH Ctr. for Emotion and Attention, Univ. of Florida, Gainesville, FL; [3]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [4]J. Crayton Pruitt Family Dept. of Biomed. Engin., Univ. Florida, Gainesville, FL

Abstract: The pulvinar is the largest nucleus of the thalamus. The proposed functions of the pulvinar range from working memory to attention to emotion. In this study we examined the role of the pulvinar in affective scene processing. Simultaneous EEG-fMRI data were recorded from

20 participants viewing pleasant (20), unpleasant (20), and neutral (20) scenes from the International Affective Picture System (IAPS). Analyzing single-trial BOLD responses using machine learning decoding techniques, we found that linear methods such as SVM were not able to detect the differences in neural representations of the three categories of affective scenes in the pulvinar, whereas a deep neural network (DNN) based model was able to do so with a decoding accuracy of 42%, which is significantly higher than the chance level of 33%. A weight map analysis revealed the particular importance of the medial pulvinar in contributing to the DNN decoding performance. Furthermore, fusing EEG-fMRI data via representational similarity analysis (RSA), we compared the temporal profiles of emotion-related activation in the amygdala and in the pulvinar and observed that emotion-related activation of the amygdala preceded that of the pulvinar. These results demonstrated that the pulvinar contributes to the processing of affective scenes and its distinct neural representations of the different categories of affective scenes may come from reentry from the amygdala.

Title: Neural architecture of negative affect: common and stimulus type-specific representations

Authors: *M. CEKO[1], P. A. KRAGEL[2], C.-W. WOO[3], M. LOPEZ-SOLA[4], T. D. WAGER[5]; [1]Inst. of Cognitive Sci., Boulder, CO; [2]Emory Univ., Atlanta, GA; [3]Ctr. for Neurosci. Imaging Res., Sungkyunkwan Univ., Suwon-Si, Korea, Republic of; [4]Univ. of Barcelona, Barcelona, Spain; [5]Psychology and Neurosci., Dartmouth Col., Hanover, NH

Abstract: How is negative affect encoded in the brain? Prior studies have provided evidence for a common neural representation and for distinct representations for different types of negative affect (i.e. induced by different stimulus types), but have largely focused on these accounts separately without direct comparisons. Here we combined a multimodal experimental paradigm and an analytic approach designed to test the hypothesis that brain representations of negative affect are conveyed both by common and stimulus type-specific representations. In Study 1 (N = 55 healthy participants) we collected fMRI responses to mechanical pain, thermal pain, aversive sounds, and aversive images of four intensities each, rated on a common aversiveness scale to facilitate direct comparisons. Brain models were developed using Partial Least Squares

Regression which allowed us to simultaneously predict common and stimulus type-specific effects. Brain models tracked negative affect and not general salience or arousal. Early sensory input areas largely predicted stimulus-type specific aversiveness, with insula and somatosensory cortex predicting pain, auditory cortex predicting auditory aversiveness and visual cortex predicting visual aversiveness. The common model of aversiveness was associated with a set of core affect areas, including medial and orbital prefrontal areas, amygdala, anterior insula and limbic forebrain. Some core affect areas, particularly the midcingulate cortex, anterior insula, amygdala and ventral striatum also served as 'hubs' integrating common and stimulus-type specific effects. We found different brain representations for negative affect induced by the two types of pain, with primary sensory cortex involved in mechanical pain and thalamus, caudate, insula and midcingulate involved in thermal pain. Aversiveness ratings in all modalities were explained by a mix of common and specific representations. Brain models generalized to new samples (Studies 2 - 4, N = 247). In conclusion, our results show that negative affect is organized in the brain as a combination of common and stimulus type-specific processes.

Title: Bringing the lab to the field: stress-related behavior and ecology of wild urban rats

Authors: *C. K. LARDNER[1], K. A. KAM[1], J. Y. ZHANG[5], K. MAYRING FASANO[1], I. MOLLICONE[1], M. HUSSAIN[2], I. KYMISSIS[3], D. DUMITRIU[4];

Abstract: Rodents are used ubiquitously in neuroscience research as preclinical models for stress-induced changes in behavior. However, inbred populations housed under laboratory conditions are meant to control for, not model, complex interactions between development, genetics, and environmental uncertainty, which ultimately foment long-term maladaptive behaviors. Alternatively, studying stress pathophysiology in wild Norway rats (*Rattus*

norvegicus) offers an opportunity to “bring the lab to the field” and close the translational gap that exists between our understanding of stress-induced behavioral changes in laboratory rodents and how these findings inform our ability to prevent and treat mental health disorders in human patients. To achieve this, we have employed a capture-mark-recapture (CMR) protocol and standard behavioral assays to characterize stress-related behaviors in wild urban rat populations in New York City over time. Initial behavioral tests were conducted on a pilot wild rat colony in which 8 individuals were captured (N = 3 males, N = 5 females) with a recapture rate of 25%. One juvenile female was captured up to 6 times over 3 weeks. Preliminary results demonstrated a high degree of neophobia that precludes comparing performance in the open field, light/dark box, and novel object preference tests to that of laboratory rat strains. In contrast, performance in the novelty-suppressed feeding task improved over consistent recapture events, suggesting the possibility that wild rat cognition and decision-making can be assayed by standard laboratory tests which utilize hedonic food and water satiety. In ongoing studies, long-term population monitoring and phenotyping of wild rat behavior and physiology will be carried out with the overall goal of establishing wild rat phenotypes associated with stress susceptibility and resiliency.

Title: Bringing the Lab to the Field: Wireless Telemetry Systems for Tracking and Monitoring Wild Urban Rats

Authors: *K. A. KAM[1], C. K. LARDNER[2], V. KUMAR[1], I. MOLLICONE[2], D. DUMITRIU[2], I. KYMISSIS[1];
[1]Electrical Engin., Columbia Univ., New York, NY; [2]Columbia Univ. Med. Ctr., New York, NY

Abstract: In preclinical neuroscience research focusing on stress pathophysiology, a “translational gap” exists between our understanding of how chronic stress contributes to mental health disorders and our ability to treat them in humans. This could be due in part to an over reliance on modeling complex human behaviors in rodents without also collecting concurrent data on internal physiological states or external environmental contexts associated with observed behaviors. In order to address this gap between research and treatment, we are developing a

wireless, implantable telemetry and tracking system optimized for use in wild Norway rats (Rattus norvegicus). Renowned for their resilience to stressors, wild rats represent the ultimate ethologically-relevant model for neuroscience. Yet, our ability to monitor their ecology, behavior, and social interactions in a city setting is limited; GPS-based tracking in urban environments often fails due to poor signal transmission and physical removal of devices when attached externally. The technology we present here overcomes these challenges by being implantable and based on long-range wide area networks (LoRaWAN), a wireless communication protocol with much lower power consumption than GPS. Further, the LoRaWAN devices are coupled with a low-noise, multi-channel, configurable silicon integrated circuit capable of reading rat ultrasonic vocalizations and biopotentials such as EEG, ECG, and EMG. Additional developments include both a custom 915MHz LoRa antenna with an efficiency of 14.86%, and a -10dB bandwidth of 42.21 MHz and a an inductive wireless power transfer system capable of transmitting up to 40mW in standard implant depths. In this work, a discussion of the system's overall hardware design, implantation methodology, wireless power transfer efficiency, and tracking capabilities are presented. Through these technical advances, experiments assaying rodent behavior that were previously limited to strict laboratory conditions can be conducted outdoors in natural environments. In future studies, an implanted wild rat's location can be triangulated via LoRa signal, its interactions with conspecifics monitored in detail, and relevant physiological data then paired with these observations.

Title: Depressive-like phenotype in mice with Mecp2 knockout in pro-opiomelanocortin neurons

Authors: *A. BAIRD, P. FRAYRE, J. FRAYRE, K. PONCE-RUBIO, M. RUIZ, J. MORENO, E. NA;
Texas Woman's Univ., Denton, TX

Abstract: Mutations in methyl-CP-G binding Protein 2 (MeCP2) gene function are implicated in neurodevelopmental disorders such as Rett syndrome, *MECP2* duplication syndrome, and autism spectrum disorder, producing learning and memory deficits, as well as anxiety phenotypes. Past

research demonstrates that knockout (KO) of *Mecp2* in hypothalamic pro-opiomelanocortin (POMC) neurons produces an overweight phenotype after prolonged high fat diet exposure, but it is not yet known if KO of *Mecp2* in POMC neurons might also affect other behaviors related to POMC function such as depression. Given that obesity and depression are highly co-morbid and that POMC is the precursor peptide to the stress hormone, adrenocorticotropin hormone (ACTH), we hypothesized that knockout of *Mecp2* may alter depressive-like or anxiety-like behaviors as a result of alterations to POMC function. POMC-MeCP2 KO mice and WT controls were maintained on an obesogenic diet and then subjected to tests that assess depression and anxiety. Body weight and high fat (HF) food intakes were recorded for all mice. We demonstrate that younger POMC-MeCP2 KO mice (2-3 months of age) had higher body weight than controls despite comparable food intake. Additionally, younger POMC-MeCP2 KO mice spent significantly more time immobile in the forced swim test than controls, demonstrating behavioral despair. The aged cohort of POMC-MeCP2 KO mice (7-8 months of age) were not significantly different in body weight or immobility in the forced swim test from WT mice. These findings suggest that phenotypic implications of MeCP2 disruption may attenuate with age in mice. Interestingly, there was no difference in anxiety-like behavior between POMC-MeCP2 KO and WT mice in either age cohort thus the effects of POMC-specific MeCP2 knockout may only affect depressive-like behavior. Taken together, our data implicate POMC-specific loss-of-MeCP2 function may adversely impact depressive-like behaviors in mice which could recapitulate the depression observed in clinical populations of obesity.

Abstract: Major depressive disorder (MDD) is a highly prevalent and debilitating disorder, the pathogenesis of which is not fully understood. Whereas the two core symptoms of MDD are depressed mood and anhedonia, it is also associated with significant cognitive symptoms, including a negative cognitive bias. Due to these cognitive biases, patients perceive, remember, or interpret information as being more negative than it actually is, which may account for their anhedonia. In order to study the neural mechanisms underlying cognitive biases, we utilized the ambiguous cue interpretation test which measures cognitive biases in rats. In this task, rats are trained to make distinct responses to two reference tones in order to receive either a sucrose reward or avoid an aversive air puff. During the test, rats are presented with ambiguous tones that are in between the frequencies of the two reference tones. The animal's response to the ambiguous tone is recorded and interpreted as their expectation of either a positive or negative outcome. Rats were trained over 1-2 months and tested prior to stress to determine their baseline performance. Multiple baseline tests were performed to ensure that repeated testing does not alter test performance. Then, the animals underwent two days of inescapable foot shock stress (IS), in which one session consists of sixty 15 second foot shocks (0.8 mA). We found that IS induced a negative cognitive bias in male rats, such that they increased their negative responses and decreased their positive responses when the ambiguous tone was played. However, IS did not alter female rats' cognitive biases in this task compared to their baseline performance. The effects of chronic unpredictable stress (CUS) were also tested. We found that three weeks of CUS in female rats did induce a significant negative bias in the ACI test. Having shown a stress-induced negative cognitive bias in this task, future studies will be aimed at investigating neural mechanisms underlying this bias and whether antidepressant treatments can reverse it.

Title: Evaluation of sertraline effects in depressive-like behavior in high and low yawning rats

Authors: *D. BRAVO DURÁN[1], J. EGUIBAR[2], C. CORTES[3];
[1]Benemerita Univ. Autonoma De Puebla, Puebla, Mexico; [2]Benemerita Univ. Autonoma De Puebla, Puebla, Pue., Mexico; [3]B. Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: High levels of stress or chronic exposition have been linked to an increased susceptibility to developing anxiety and depression. The high- (HY) and low- yawning (LY) sublines have shown that they differ in the behavioral anxiety tests, being the LY more anxious than the HY. The aim of the present study was to assess the effect of sertraline (2.5 and 5 mg/Kg) on immobility and motor responses on the LY, HY and Sprague-Dawley (SD) rats in the forced swim test (FST). Adult male rats (n = 6 per dose) were housed in standard room conditions with free access to rodent pellets and purified water. All subjects (Ss) had two swim sessions in two consecutive days, the first session with a 15 min duration and 24 h later a second session of 5 min. The Ss received sertraline at 23.5, 5 and 1 h before the second test through three i.p. injections. We scored the following behaviors: immobility, swimming, climbing, and diving. Our results shown that at 2.5 mg/kg dose of sertraline immobility time significantly decrease in the HY rats with respect to LY and SD rats ($P< 0.05$). Only swimming was increased significantly in the HY rats ($P< 0.05$). In conclusion, these results show that HY rats are not only resilient, but also better responders to low doses of sertraline with a greater antidepressant effect compared to that obtained in LY and SD.

Title: Meningealmast cell calcium activity in models of major depressive disorder

Authors: *E. SARNO, N. DUQUE-WILCKENS, W. JACKSON, A. MOESER, A. ROBISON, A. ROBISON, A. ROBISON, A. ROBISON, A. ROBISON, A. ROBISON, A. ROBISON; Michigan State Univ., East Lansing, MI

Abstract: About 20% of U.S. adults have suffered from Major Depressive Disorder (MDD) in their lifetime[1]. However, physicians are underprepared to treat this health crisis because current treatments fail in about one-third of MDD patients[1]. Over the past decade, preclinical and clinical evidence has shown that neuroinflammation is associated with and may be contributing to mood disorders, but scientists and clinicians require an improved understanding of brain immunity in order to develop new targets for depression treatment. Mast cells (MCs) are innate immune cells that orchestrate overall immune response, and they have an emerging role in mood regulation. Meningeal mast cells, found in the membranes surrounding the brain and spinal cord, sense the environment and release a variety of signaling molecules which direct the activity of blood vessels, glia, and neurons in the brain. Mice lacking mast cells display phenotypes associated with depression. Furthermore, MCs in mice exposed to stress have increased expression of the

gene *FosB* and contain higher levels of allergen-induced mediators and cytokines, including TNF-alpha and IL-6, which are elevated in patients with MDD[15]. *We hypothesize that psychological stress increases FosB expression in meningeal MCs, altering cell function, and, ultimately, driving behavioral changes associated with depression*. To address this, we have engineered a mouse line lacking *FosB* gene expression specifically in mast cells. We show here that mast cells lacking *FosB* have increased histamine and serotonin release, increased cytokine production, and altered vesicular morphology. Moreover, we present the very first GCAMP Ca^{2+} imaging of mast cells in *ex vivo* preparations of meninges as well as Ca^{2+} imaging of cultured mast cells to show that mast cells lacking *FosB* have increased Ca^{2+} signaling. These findings will be critical in understanding the role of MCs in MDD and other diseases and potentially lead to the identification of new therapies.

Title: The role of chronic caffeine administration on the attenuation of depressive behaviors in long evans rats

Authors: L. LANDAETA, D. ROEVER, C. PETERSON, S. PECK, D. G. EHLINGER, ***J. J. CORTRIGHT**;
Univ. of Wisconsin River Falls, River Falls, WI

Abstract: Caffeine, the most consumed psychoactive drug, appeals to populations with psychiatric histories due to its readily available nature and alertness exerting effects. Given the prevalence of psychiatric conditions such as major depressive disorder (MDD), in which symptoms such as lethargy are commonplace, a potential relationship between caffeine administration and attenuation of MDD behaviors has been suggested. In particular, in groups exposed repeatedly to stress, a frequent trigger of MDD, caffeine intake surges. This has led to an observed inverse correlation between caffeine intake and MDD behaviors. Clinically, the current state regarding caffeine administration as part of MDD treatment remains limited, but established. When administered in the presence of selective serotonin reuptake inhibitors (SSRIs), caffeine has shown to augment the therapeutic effects in human and animal models. However, the mechanism of action by which caffeine specifically exerts these effects remains unknown. The purpose of our study was to expand upon previous literature and to elucidate these

mechanisms by combining behavioral and morphological analysis. Subjects were exposed to 28 days of randomized stressors during early adulthood including forced swim, cage tilt, wet bedding, mild restraint and restriction of food and water. Control animals were housed in pairs, while animals exposed to randomized stress were housed in isolation. Following stress exposure, a subset of control and stress-exposed animals were orally administered caffeine (15 - 20 mg) twice daily for five weeks. Subjects were then tested for latency in a forced swim test and hot plate test, for motivation in a radial arm maze, for lethargy in an open field test, and for anhedonia using sugar pellets. Following testing, rats were deeply anesthetized, transcardially perfused with saline, and their brains were placed in a Golgi cox solution for subsequent dendritic spine density analysis in the medial prefrontal cortex (mPFC), nucleus accumbens (NAcc), hippocampus and basolateral amygdala (BAL). To date, an attenuation in latency in the forced swim test and hot plate test has been found in stress-exposed animals which had receive caffeine treatment compared to controls. Currently, the effects on depressive behaviors in other tests and dendritic spine density are being analyzed. Collectively, these findings hold significance in that they build on recent research that has aimed to link caffeine intake with the attenuation of depressive behaviors.

Abstract: Stress-related psychiatric disorders affect many individuals worldwide with broad health implications. These disorders differ in the prevalence, symptom presentation and in

response to treatment between men and women. The chronic social defeat stress (CSDS) model has been widely used to study stress-related behavior changes and circuitry alteration in male mice. It was shown that in male mice peripheral inflammation, specifically IL-6, and neurovascular pathology contribute to stress susceptibility. Using a recently developed female CSDS model, we found that stress susceptibility significantly correlates with elevated plasma levels of C-C Motif Chemokine Ligand 5 (CCL5) and blocking peripheral CCL5 significantly attenuates stress susceptibility. RNA-seq analysis in the brain found that susceptible female mice had increased expression of CCR5, a CCL5 receptor, in the prefrontal cortex (PFC). In humans, higher plasma levels of CCL5 was also reported in women with major depressive disorder (MDD) and increased CCR5 expression in human female MDD subjects based on published human RNA-seq data. Neither CCL5 nor CCR5 changes were seen in male MDD subjects. These observations suggest that CCL5/CCR5 response in CSDS may recapitulate important and unique inflammatory features of female response to stress. CCR5 is a seven-transmembrane G protein-coupled receptor expressed in microglia, astrocytes and neurons in diverse brain regions. Ligand activation of CCR5 has been show to suppress adenylyl cyclase, activate PI3K/AKT and MAPK signaling and alter intracellular Ca2+ mobilization, all of which can influence synaptic function. Using RNAscope combined with immunohistochemistry we found microglia to be the main cell type in the PFC that expresses CCR5. Further analysis of microglia in the PFC found that compared to resilient or non-stressed mice, stress-susceptible mice had increased numbers of activated microglia, increased PSD95-positive microglia, and increased number of (micro)vessel-associated microglia. We also found that stress-susceptibility is associated with reduced expression of claudin 5, a tight junction protein indicative of blood-brain barrier (BBB) integrity. We are continuing investigating the interactions between peripheral and central CCL5/CCR5 signaling, microglia activity, neuronal/synaptic structure and function, and stress susceptibility.

Abstract: Chronic stress is a key risk factor for the development of Major Depressive Disorder (MDD), yet it is unknown how stress that is primarily psychological in nature is translated at the level of neurons to produce behavioral dysfunctions associated with MDD. The limbic forebrain region, Bed Nucleus of the Stria Terminalis (BNST), encodes the nature and chronicity of stress to organize behaviorally adaptive responses. Importantly, the Oval Nucleus of the BNST (BNSTov) contains an enriched population of CRF ($BNSTov^{CRF}$) neurons that are stress responsive and thereby may provide the neural link between CRF and depression. Employing a range of behavioral, molecular, and cell-type specific optogenetics and fiber photometry, we unveil a dimension to depression vulnerability that relies upon accumulated stress-exposure. In this study, we seek to elucidate CRF-related neural mechanisms that underlie depression onset that arise from unmitigated exposure to chronic stress. To elicit stress-related depressive behaviors, the Chronic Social Defeat Stress (CSDS) paradigm was administered. Mice underwent behavioral assays that solicit for a range of anxiety and depression related behaviors including social interaction (SI), sucrose preference, and elevated plus maze tests. To manipulate the activity of $BNSTov^{CRF}$ neurons, Crh-Cre mice were injected with viral constructs (DREADDs, opsins, calcium-indicators) and ferrule cannulae implanted. To record electrical activity of $BNSTov^{CRH}$ neurons, Crh-cre::TdTomato reporter mice were used and cell-attached electrophysiology was used to record the spontaneous firing rate. We have discovered a discrete time-window between 7 and 10 days of CSDS, where mice rapidly diverged from baseline behavior to resilient or susceptible phenotypes, unmasking a temporal dimension to stress-susceptibility. Importantly, electrophysiological and fiber photometric studies were conducted to correlate cell-type and circuit level neuroadaptive changes respectively with the behavioral observations. Cell-type specific chemogenetics reveal the necessity and sufficiency for BNSTov CRF neurons in promoting the development of depressive- and anxiety-like behaviors. Altogether, these findings provide evidence of a temporal domain to stress adaptation where alterations in CRF neurotransmission may shift the predisposition of mice toward either stress-induced depressive-like susceptible or resiliency phenotypes. This discrete period of neuroadaptation may present a window of opportunity for targeting molecular mechanisms with the possibility of preventing the onset of depression in stress-susceptible populations.

Title: Investigating the resting-state functional connectivity and microstructural alterations in the brain of Blm-s-knockout moue with depression- and anxiety-like behavior

Authors: S.-M. HUANG[1], W.-C. CHU[2], K.-H. CHO[1], L.-W. KUO[1], *P.-H. HUANG[2]; [1]Inst. of Biomed. Engin. and Nanomedicine, Natl. Hlth. Res. Inst., Miaoli, Taiwan; [2]Grad. Inst. of Pathology, Natl. Taiwan Univer, Taipei, Taiwan

Abstract: *Blm-s* (*Bcl-2*-like molecule, short form), a *Bcl-2* family gene, has been identified and shown to be a key role in regulating the apoptosis of postmitotic immature neurons during corticohistogenesis. How BLM-s expression affects the structural and functional brain network remains unexplored. The present study employed resting-state functional MRI (rs-fMRI) as well as diffusion MRI (dMRI) to investigate the influence of *Blm-s* deletion on brain network in a mouse model because mice with *Blm-s* null present depression- and anxiety-like behaviors. Rs-fMRI is a noninvasive neuroimaging modality in discovering brain functions, which characterizes the intrinsic brain networks under rest condition and can serve as a robust tool in exploring neurobiological disorders both in human and animal studies. dMRI monitors the property of water diffusion and provides the information of fiber orientation, which is valuable to the understanding of structural connectivity as well as local microstructural changes at specific brain regions and axonal pathways. *Blm-s*-knockout mice (KO, n=12) and age-matched wild type (WT, n=14) were scanned under dexmedetomidine anesthesia (0.2 mg/kg) on a 7T animal MRI system (Biospec, Bruker, Germany). Diffusion indices including fractional anisotropy (FA) and diffusivity were reconstructed using the tensor model. Rs-fMRI images were pre-processed and analyzed to assess the brain functional network. Multiple regions of interest were identified to characterize local property as well as the connectivity between each two specific brain regions. Results show that, comparing to WT mice group, KO mice group presents reduced connectivity in the following pairs of regions: left ventral dentate gyrus (vDG) - left caudate putamen (CPu), left insula - right CPu, left insula - left vDG, and right insula - right vDG. The amplitude of low frequency fluctuation (ALFF) was also evaluated to assess regional rs-fMRI activity. Reduced ALFF was found in bilateral dorsal dentate gyrus, while increased ALFF was found in the orbital cortex. From dMRI analysis, elevated FA and reduced radial diffusivity was found in the vDG of KO mice group. Our findings in MRI suggest that microstructures and local rs-fMRI activity in hippocampal area, particularly the vDG region, might be altered in *Blm-s*-null mice. As MRI can provide a neuroimaging insight in mesoscale, the underlying mechanism of the consequence after *Blm-s* deletion can be further uncovered by cytological approaches.

Abstract: The amygdala (AMY) is a key brain region of the limbic system that plays a critical role in emotion processing and stress response. Functional magnetic resonance imaging (fMRI) studies identified abnormal amygdala (AMY) activation in psychiatric illnesses including major depressive disorder (MDD). Stress exposure is a major precipitating factor of MDD episodes which are associated with AMY hyperactivity. We also demonstrated that chronic stress exposure in mice increases AMY volume and synaptic strength which correlate with anxiety- and depressive-like behaviors. Moreover, preclinical studies using pharmacologic, opto- and chemogenetic approaches to activate AMY neurons have consistently demonstrated that acute AMY hyperactivation induces anxiety-like behaviors in mice. However, it remains unknown if chronic amygdala hyperactivation (cAH) is sufficient to induce chronic stress-like deficits or is a susceptibility factor for chronic stress-induced behavioural, volumetric and synaptic deficits. Using *designer receptor exclusively activated by designer drug (DREADD)* approach, basolateral amygdala (BLA) neurons of Camk2a-cre mice infected with AAV2-DOI-GqDREADD were activated with clozapine-N-oxide (in drink water for 5 weeks). Mice were then exposed to chronic restraint stress (CRS; 1X/day for 1hr) for 2 weeks. All mice were behaviorally assessed in the Phenotyper (PT), and sucrose consumption tests (SCT) each week and in the novelty supressed feeding (NSF) test once at the end of the experiment. Animals were then perfused for *ex vivo*-MRI and puncta density analysis. We found that mice with cAH displayed a progressive increase in baseline anxiety-like deficits in the PT test and slightly more marked deficits following CRS compared to controls, but not statistically different from animals subjected to CRS alone. Also, cAH did not exacerbate CRS effect in the NSF. No significant cAH effect was found in the SCT before or after CRS. MRI and synaptic analysis are currently underway. Our results suggest that cAH is sufficient to induce anxiety and may exacerbate CRS effects on

anxiety measures. However, cAH was not sufficient to induce depressive-like behavior and was not a vulnerability factor for stress-induced depressive-like behavior. In conclusion, our findings suggest that although AMY hyperactivity is associated with elevated anxiety, it does not appear to be a predictor or a biomarker of clinical depression.

Title: The interaction of the endocannabinoid system and the serotonergic system and its effect in voluntary wheel running in depression-like behaviors in rats

Authors: *A. P. RAMOS-ROLÓN, W. NORZE, P. A. MUÑOZ-RODRÍGUEZ, A. I. RODRÍGUEZ-LEON, A. I. ACEVEDO-JETTER, V. M. SCHLEIER-ALBINO, K. M. TORRES-MONTERO, M. C. APONTE-REYES, C. S. MALDONADO-VLAAR;
Univ. of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico

Abstract: Depression is one of the most prevalent mental health disorders in the United States. Studies have shown that the endocannabinoid system (eCB) is involved in the pathophysiology of depression. The cannabinoid-1 receptor (CB1) plays a role in depression-like behavior by modulating the serotonergic system. Other studies have revealed that aerobic exercise decreases depression-like behavior by upregulating serotonin (5-HT) release. However, it is still unknown if the eCB system is responsible for modulating the antidepressive properties of exercise through an alteration in 5-HT firing. This project aimed to observe if the manipulation of the CB1 receptor would enhance the therapeutic effect of aerobic exercise in depression. Male Sprague Dawley rats were submitted to an aerobic exercise protocol, while a group remained sedentary. Within the sedentary and exercise group, some rats received intraperitoneal injections of an agonist of the eCB receptors, (+)-WIN 55,212-2, while the others received the vehicle. The rats were divided into four groups: sedentary with the vehicle (Sed/Veh), sedentary with WIN55,212-2 (Sed/WIN), exercise with the vehicle (Ex/Veh), and exercise with WIN55,212-2 (Ex/WIN). We used the forced swim test (FST) paradigm as a depression model. The FST results showed that the Sed/Veh group had significantly less swimming and more floating than Sed/WIN and

Ex/Veh groups, but no the Ex/WIN group. These results suggest that exercise and (+)-WIN 55,212-2 have antidepressive properties, but both treatments simultaneously are not antidepressive. Further studies will be conducted to measure the expression of the CB1 receptor and 5-HT 1A receptors in the hippocampus and medial prefrontal cortex to better understand the neural circuits underlying the depression-like response. Studies like these are essential to better understand the potential molecular antidepressive mechanisms that could help develop new strategies to treat depression.

Title: Cfos expression during stressors significant and non-significant enough to produce stress enhanced fear learning

Authors: *S. Y. MARKOWITZ, L. LAUGHLIN, M. S. FANSELOW;
Dept Psychology, UCLA, Los Angeles, CA

Abstract: Approximately 10% of people who experience a highly stressful event, or trauma, will go on to develop Post-Traumatic Stress Disorder (PTSD). As the majority of people who experience intense stress do not develop PTSD, an important question is what makes a stressful event “significant” enough to cause this disorder to manifest. To investigate this question we used an animal model of stress reactivity called Stress Enhanced Fear Learning (SEFL). Using this model we found that that not all stressors are significant enough to cause SEFL, even if both experiences cause comparable levels of fear. Specifically, rats that experienced 15 presentations (1s, 1mA) of Shock Stress showed future SEFL, while rats that experienced 15 presentations (1s, 120 dB) of Noise Stress did not. Additionally, only Shock Stress animals exhibited a panic-like response to stressor presentations. We concluded that shock is a Significant enough stressor to cause SEFL, while noise was Nonsignificant. The periaqueductal grey (PAG) is a key brain region for defensive responses. It is well established that activity in the PAG is both necessary and sufficient for both fear and panic responses toward external stressors. To understand how the neural signature of significant and nonsignificant stressors differ we examined cFos expression in the PAG following these two types of stressors. Rats were first exposed to either 15

presentations of Shock Stress or 15 presentations of Noise Stress during a 90 minute session. 30-45 minutes after the final stressor presentation, these experimental rats, as well as homecage controls, were perfused. Brain slices from central PAG stained for c-Fos expression showed a significant difference in activity in the lateral PAG (lPAG) and ventral-lateral PAG (vlPAG) between Shock Stress and Noise Stress animals. Thus, we have begun to characterize how activity in specific subregions of the PAG correlate with exposure to "Significant" and "Non Significant" stress, which in turn may better help us understand the underlying neural mechanisms of PTSD.

Title: Post-stress glucose treatment enhances performance on hippocampal-dependent tasks in both humans and rodents

Authors: *N. J. SMITH, D. B. WEATHERILL, M. S. FANSELOW;
Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Post-stress glucose treatment enhances performance on hippocampal-dependent tasks in both humans and rodents
A third of the US population will experience a traumatic event at some point in their life. Posttraumatic stress disorder (PTSD) is a severally debilitating mental disorder affecting up to 20% of that population. It is well established that increased serum levels of glucocorticoids following significant stress impair hippocampal glucose uptake and function, including contextual processing. Without proper hippocampal activity, contextual memory of trauma may not be properly encoded. This deficit in encoding may subsequently contribute to generalization of fear and intrusive memories, hallmark diagnostic criteria for PTSD. We have previously shown, in rats, consumption of glucose within a critical 3-hour window following a significant stressor rescues deficits caused by the stress. The present study provides evidence, in human trauma patients, that post-stress glucose consumption within a 3-hour window of the traumatic event similarly protects hippocampal function. Two main results from this experiment show: (1) glucose following stress benefitted the performance on a hippocampus-dependent task but not a hippocampus-independent task 3-hours, 5-7 days, and 60 days after trauma and (2) the post-stress glucose group recalled significantly more details of the trauma than the placebo group.

Because research on the mechanism(s) by which glucose deficits lead to impaired hippocampal function is presently scarce, we next followed up on our human data by probing performance on a hippocampal-dependent task in rats, using the Object in Place (OIP) task. Both male and female rats were first exposed to either 100 inescapable tail shocks or simple restraint. Animals were then given 24-hour ad libitum access to glucose or a non-caloric sweetener (stevia) before OIP acquisition and test phases, which were separated by a 2-h delay. The post-stress glucose group spent significantly more time investigating the objects in different locations compared to the objects in the same locations. Thus, we have begun to characterize a rodent model to further study the underlying mechanism(s) mediating a potential prophylactic effect of glucose on PTSD/PTSD-like symptom development.

Title: Stressor controllability in Long Evans rats: Comparisons of strains, sex, time-of-day, and regional cFos activation patterns

Authors: *N. BOSNIAN[1], C. SINGH[1], J. GRIZZELL[2], M. SADDORIS[3];
[2]Dept. of Psychology and Neurosci., [1]Univ. of Colorado, Boulder, Boulder, CO; [3]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: The perception of control over the cessation of a string of acute tail shocks has been directly associated with various patterns of resilience to stress in adult, male Sprague Dawley (SD) rats. However, the expression of this behavioral phenomenon in adult, female SD rats is not as readily demonstrated. Here, we present results from a series of studies in our laboratory that demonstrate that the differential expression patterns of behavioral resilience in Sprague Dawley male vs female rats extends to Long Evans (LE) rats. Preliminary results show that following a standard stressor controllability paradigm (ES/IS), adult male LE rats having learned to control tailshock duration (ES) nonetheless fail to demonstrate the male SD-like patterns of behavioral resilience in the juvenile social exploration (JSE) and defensive burial tests (DBT) when stressed and tested during the light phase. Moreover, male LE rats in the ES condition are not statistically differentiable from male counterparts in the inescapable stress (IS) conditions. However, when the stress and behavioral paradigms were presented during the first two hours of the dark cycle,

ES male LE rats approach the social target significantly more than IS male LE rats. In a second study, we found that female LE rats in the ES condition that were stressed during the light cycle similarly approached the same-sexed juvenile in the JSE more than female IS counterparts. These patterns collectively support the notion that strain and sex differences in the expression of behavioral resilience following the stressor controllability paradigm may be linked with ethologically distinct patterns of behavior in a strain-specific manner. Finally, we will present region-specific differences in neuronal activation patterns (cFos) brought on by stressor controllability conditions in age-matched male and female LE and SD rats.

Title: Social experience-dependent influences of stress resilience: Applying a novel paradigm for hierarchy-mediated differences in social stress responses

Authors: *Z. Q. MARSHALL[1], J. GRIZZELL[2], M. SADDORIS[3];
[2]Psychology and Neurosciences, [1]Univ. of Colorado, Boulder, Boulder, CO; [3]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Stressor controllability paradigms demonstrate that rodents having learned to exert control over stressful stimuli display prefrontal cortical mediation of limbic system responses during traumatic stress exposure. Similarly, social experience acts upon these limbic circuits such that acquiring and maintaining a dominant social status promotes a stress resilient phenotype whereas social subordination promotes stress susceptibility. That said, most rodent models of social status-mediated stress resilience/susceptibility rely on heavy bouts of territorialized aggression or food-motivated states to drive social status formation and maintenance. Here, we present results of a novel use of the "Warm Spot" test. Adult, male, Long Evans rats ranging in age from early, middle, and late adulthood were age- and weight-matched into dyads and placed for 10 minutes daily for two weeks into a modified polycarbonate cage that was placed onto a bed of dry ice and contained a heated respite (ave: 36° C) that was large enough for one rat to escape the ice-cold floor (ave: -10° C). 24 hours later, each rat was placed one at a time into a similar cage with the respite removed for a 10-minute "no spot" stressor. Subsequently, rats were tested for social approach/avoid behaviors in either the juvenile social exploration or social interaction test. As in other paradigms, animals demonstrating social

dominance (e.g. greater total durations of warm-spot occupation over 14-day period) showed greater social approach behaviors relative to subordinate counterparts, however this effect was only seen in the social interaction test. We will also present results from preliminary studies demonstrating social status-dependent differences in fear extinction following this novel paradigm, as well as "no spot"-induced expression of cFos in vmPFC, amygdala (BLA and MeA), and dorsal raphe nucleus. Taken together, this paradigm presents a novel opportunity to ascertain social status-dependent differences in stress-induced behavior and neural processing patterns in a naturalistic scenario while minimally driving aggressive behavior and food/water-deprived physiological states.

Title: Enhanced negative feedback of the HPA axis and increased noradrenergic enzyme levels in females exposed to a predator-based psychosocial stress model of PTSD

Authors: *P. R. ZOLADZ[1], C. R. DEL VALLE[1], I. F. SMITH[1], C. S. GOODMAN[1], J. L. DODSON[1], K. M. ELMOUHAWESSE[1], C. D. KASLER[1], B. R. RORABAUGH[2]; [1]Psychology, Ohio Northern Univ., Ada, OH; [2]Pharmaceut. Sci., Marshall Univ., Huntington, WV

Abstract: People with post-traumatic stress disorder (PTSD) exhibit numerous physiological alterations, including lower baseline cortisol levels, enhanced negative feedback of the hypothalamus-pituitary-adrenal (HPA) axis, and increased noradrenergic activity. Male rats exposed to a predator-based psychosocial stress model of PTSD exhibit similar changes in HPA axis function and neurotransmission. Here, we examined whether similar effects would be observed in female rats exposed to this model. Adult female Sprague-Dawley rats were exposed to a cat on two occasions, separated by 10 days, in conjunction with daily social instability. Three weeks following the second cat exposure, we examined rats' anxiety-like behavior on an elevated plus maze (EPM), collected blood samples at baseline and following dexamethasone administration to quantify corticosterone levels, and extracted brains to quantify markers of noradrenergic activity in the hippocampus and prefrontal cortex (PFC). Stressed females did not exhibit heightened anxiety on the EPM, but, relative to controls, they displayed lower corticosterone levels and a greater suppression of corticosterone following dexamethasone

administration. Stressed females also exhibited increased markers of noradrenergic activity in the dorsal hippocampus and PFC. These findings suggest that this model of PTSD may be useful for studying mechanisms underlying trauma-induced changes in female physiology.

Title: Development of a novel Post Traumatic Stress Disorder (PTSD) model in the rat

Authors: *J. E. FRIEDMAN, K. H. PARK, J. H. LEE, B. Y. LIM, H. PARK, A. LEE, P. J. SWEENEY, P. J. SWEENEY, L. C. PARK;
Naason Sci., Cheongju, Korea, Republic of

Abstract: PTSD is a serious condition that can lead to intense fear, anxiety and depression resulting in social distancing and other behavioral disorders. It has also been found that childhood exposure to highly stressful events increases the likelihood that the adult will be more prone to suffer from PTSD. 8.1M Europeans and 11.4M Americans are actively suffering from PTSD, severely reducing the quality of their lives. Current medication is unspecific, ineffective and has a large number of side effects (sedation, abuse potential, sexual dysfunction). As a result, many people continue to suffer from PTSD in spite of current treatment options, indicating a critical need for new treatments. A limiting factor in the development of treatment for PTSD is the lack of valid, translational models. Naason Science has been developing models of PTSD in the rat and the minipig based on a multi-faceted, prolonged stress paradigm, so as to test the efficacy of new compounds. Animals are stressed as juveniles in order to increase their susceptibility to PTSD as adults. We have used desipramine + methylphenidate or diazepam as controls in the rat. Juvenile SD rats, male and female, n=12/group, are exposed to different stressors over a 2-day period, comprised of restraint (2h), swimming (1m) and submersion (30s) in the Water Associated Zero Maze (WAZM) and queued electric shock (x5). This paradigm is repeated weekly for another 2 weeks. The behavior of the rats is recorded using our Home Cage Activity (HCA) monitoring system, recording the behavior of the mixed group housed animals 24/7. Behavior is automatically assessed using AI computerized systems. After being exposed to the 3-week PTSD paradigm, subjects are treated for 5 days and then exposed to the external track

of the WAZM and subsequently to queued fear conditioning (qFC). This is repeated after another 30 days. Upon terminating the study blood samples are collected. After 60 days, test subjects exhibited signs of anxiety. In the qFC test, normal (non-stressed) rats exhibited freezing for 42sec±17, rats exposed to the PTSD paradigm froze for 125sec±15. Diazepam (1, 3, 10mpk) was not effective in this model. Stressed rats treated with Methylphenidate (2.7mpk) and desipramine (10mpk) exhibited the same freezing time as normal rats (38sec±5). The cortisol levels of normal and treated rats were similar, at 461pg±39/ml, while that of the PTSD/vehicle treated rats was 684pg±66/ml. The model presented here is a simple, robust model of PTSD that should facilitate dissecting out various aspects of this disorder and provides a screening paradigm for new medical treatments.

Abstract: PTSD is a serious condition that can lead to intense fear, anxiety and depression. Childhood exposure to highly stressful events has been found to increase the possibility that the adult will be more prone to suffer from PTSD. The percentage of those affected varies from country to country with 3.5% of Americans and 9.2% of Canadians actively suffering from PTSD. Current medication is not very effective and has a large number of side effects. As a result, many people continue to suffer from PTSD in spite of current treatment options, indicating a critical need for new treatments. One limiting factor in the development of treatment for PTSD is the lack of valid, translational models. Naason Science has been developing models of PTSD in the rat and in a larger animal-the minipig, based on multi-faceted, prolonged stress paradigms, so as to test the efficacy of new compounds. In addition, we expose the animals to stress as juveniles in order to increase their susceptibility to PTSD as adults. Pigs are intelligent animals that not only closely share physiology with humans, such as the cardiovascular system, but demonstrably show emotions, including fear. This is different from many wild animals that do not overtly express fear nor discomfort. This makes them viable candidates for behavioral studies. Jeju minipigs from the same litter, mixed gender, were used for this pilot study, n=3 per group, one group acted as a control for the second group that experienced stressors.
Piglets 1 week old were separated from their mothers for 2 hours/day until weaning. They were restrained in a net for 10 min/day and exposed to predator urine and sound. Both sets of animals appeared to thrive as they experienced similar weight gain. Animal behavior was subsequently tested 2 times/week in an open field from week 6, and for 20 hours in their home cage at week 7. Minipigs were recorded and analyzed using our digitized video recording and AI analysis system. PTSD pigs only moved 64% (55±13m) of the distance that their control littermates moved (86±14m) and over a shorter period of time (2790 vs 3078 seconds). Their speed was also significantly slower by approximately 30% (1.96±0.3cm/s vs. 2.78±0.3cm/s). PTSD pigs experienced longer periods of freezing, by about 55%. In their home cage, PTSD minipigs demonstrated significantly greater social distancing, maintaining 0.608±0.08m distance from their littermates as compared to 0.297±0.02m for the controls.
Whereas the data presented here is a pilot study, it demonstrates how early stress can affect simple behavior in juvenile pigs and can serve as a model system for the development of PTSD in large animals and possibly provide a translational model for humans.

Title: Social status-mediated alterations of stress in a novel social conflict paradigm: comparing male and female Long Evans rats in a repeated, dyadic "Warm Spot" task

Authors: G. KUMAR[1], *J. GRIZZELL[1], M. SADDORIS[2];
[1]Psychology and Neurosciences, Univ. of Colorado, Boulder, Boulder, CO; [2]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Models of social dominance-mediated stress resilience in rodents have shown that dominant social statuses can promote resilience to traumatic stress when compared to subordinate counterparts. However, most models focus only on males due to the paucity of easily quantifiable aggressive behaviors in females. Here, we present results from two studies that compare male and female Long Evans rats that were (1) group-housed until adulthood or (2) socially isolated as juveniles. Upon adulthood, all animals were placed into a modified "warm spot" (WS) task daily for two weeks. For 10 minutes each day, age-, weight-, and sex-matched animals were dyadically paired and exposed to a cage that was placed onto a bed of dry ice but contained a small, warmed respite in a far corner to allow one animal at a time to escape the cold floor. Following the 14th day of pairing in the WS arena, each animal was placed alone in a similar arena but with the respite removed, which we called the "no spot" test and 1 hour afterward, tested in the social interaction test for socially avoidant behavior. 24 hours later, all animals were exposed to a standard cued fear conditioning paradigm and then tested for fear recall, fear extinction, and delayed fear extinction 1, 2, and 9 days afterward, respectively. Social dominance was determined by total WS occupation and greater WS durations were found to be highly correlated with other dominant status-related behaviors such as pushes, resists, attacks, and successful takes of the warm spot. Low WS durations were strongly correlated with yielding the WS to dyadic partner, particularly in females. While most dyads formed predictable hierarchies by day 3, females demonstrated greater WS sharing (i.e. co-occupation) and all animals that had been isolated as juveniles displayed more agonistic behaviors, reduced sharing of WS, and more exchanges of WS occupation. Preliminary results from the fear conditioning/extinction tests indicate that while all animals acquired fear memories at similar levels, socially subordinate males and females displayed greater freezing behavior during fear extinction training and recall, but this effect was attenuated by group housing status during

adolescence. Together, these results indicate that social status in male and female rats may be linked with behavioral markers of resilience.

Title: Behavioral effects of the DA D1R antagonist, SCH-23390, in compulsive methamphetamine taking rats: molecular and biochemical neuroadaptations in the dorsal striatum after long-term withdrawal from methamphetamine self-administration

Authors: *S. JAYANTHI[1], B. LADENHEIM[1], M. T. MCCOY[1], P. SULLIVAN[2], D. S. GOLDSTEIN[2], J. L. CADET[1];
[1]Mol. Neuropsychiatry, NIDA-IRP, Baltimore, MD; [2]Clin. Neurocardiology Section CNP/DIR/NINDS/NIH, NINDS NIH, Bethesda, MD

Abstract: Methamphetamine (METH) use disorder (MUD) remains a persistent public health menace. Perturbations in striatal dopamine (DA) homeostasis are thought to underlie the behavioral and pathobiological consequences of METH exposure in humans and rodents. To identify potential consequences of METH use disorder, we have attempted to mimic DSM criteria for substance use disorders in rats. Towards that end, we trained rats to self-administer METH (9 hours session for 20 days) followed by exposing them to a footshock paradigm to represent adverse consequences. These adverse consequences led to the segregation of METH SA rats into two phenotypes: (*i*) shock-sensitive that drastically decreased their METH-intake and (*ii*) shock- resistant or compulsive drug takers that continued their METH intake despite footshocks. Thereafter, rats were injected intraperitoneally with the DA D1 receptor antagonist, SCH23390. SCH23390 caused substantial reduction of METH taking in a dose-dependent fashion. Stopping SCH23390 administration led to re-emergence of compulsive METH taking in the shock-resistant rats. Moreover, rats that showed compulsive METH taking exhibited greater incubation of METH seeking than non-compulsive rats at withdrawal day 7 and 30, suggesting differential neuroadaptations in the brains of these two phenotypes. Post-mortem analyses of dopamine metabolism revealed non-significant decreases (about 30%) in striatal DA levels in both resistant and sensitive rats. In contrast, striatal contents of the deaminated metabolites, DOPAL, DOPAC, and DOPET, were significantly increased in shock-sensitive rats, suggesting increased DA metabolism in the non-compulsive rats. VMAT2 and DAT protein levels were decreased in both shock-resistant and sensitive animals, suggesting that high levels of METH intake can cause DA terminal degeneration. Interestingly, members of the D2-type DA receptors,

DA D3R and DA D4R but not D2R, showed significant decreased protein expression in the dorsal striatum. These results indicate differential effects of METH SA on DA receptors located on post-synaptic neurons. RNA sequencing studies also revealed substantial differences in the expression of genes between METH-addicted and non-addicted rats. We identified 492 significantly differentially expressed genes that are involved in p13-AKT, cAMP and MAPK signaling pathways. Other differentially expressed genes participate in glutamatergic signaling. Future studies are needed to identify specific roles that genes of interest might play in compulsive METH taking or in suppressing METH self-administration.

Title: Sex-and brain region-specific alterations in dopamine metabolism consequent to methamphetamine self-administration

Authors: *A. P. DAIWILE[1], P. SULLIVAN[2], S. JAYANTHI[1], D. S. GOLDSTEIN[2], J. L. CADET[1];
[1]Mol. Neuropsychiatry Res. Br., NIH, NIDA IRP, Baltimore, MD; [2]Autonomic Med. Section, NIH, NINDS IRP, Bethesda, MD

Abstract: Sex-and brain region-specific alterations in dopamine metabolism consequent to methamphetamine self-administration Atul P. Daiwile*[1], Patricia Sullivan[2], Subramaniam Jayanthi[1], David S Goldstein[2] and Jean Lud Cadet[11]Molecular Neuropsychiatry Research Branch, NIDA IRP, NIH, Baltimore, MD, USA. [2]Autonomic Medicine Section, NINDS IRP, NIH, Bethesda, MD, USA.Methamphetamine use disorder (MUD) is a neuropsychiatric disorder that inflicts significant health burdens throughout the world. Importantly, significant sex differences in use and relapse rates exist among human METH users. Some sex differences have also been reported in animal models of MUD. The biochemical bases for these behavioral differences remain to be determined. We began to address these issues by using a METH self-administration model to identify potential sex differences at biochemical levels. Rats were trained to self-administer METH (0.1 mg/kg/inj, i.v.) using two 3-h daily sessions for 20 days. Rats were then assessed for cue-induced drug seeking on withdrawal days (WD) 3 and 30. Rats were euthanized 24-h after WD30. Dorsal striatum (Dstr), nucleus accumbens (NAc) and prefrontal cortex (PFC) were dissected to measure catecholamine levels. We found that both

female and male rats increased their METH intake during the 4 weeks of the experiment and showed incubation of METH seeking during withdrawal. Male rats compared to female rats had higher levels of 3,4-dihydroxyphenylalanine (DOPA) in the Dstr and PFC; cys-dopamine (DA), a product of dopamine quinone, in the Dstr; and of 3,4-dihydroxyphenylethanol (DOPET) and 3,4-dihydroxyphenylacetic acid (DOPAC) in the NAc in the saline and METH groups. Females showed higher Cys-DOPA levels in the NAc; DA, DOPAL and DOPAC levels in the PFC; and of dihydroxyphenylglycol (DHPG), an oxidative deamination metabolite of norepinephrine (NE) in the Dstr of compared to male controls. Only male showed decreases in DOPA levels in the Dstr after METH SA. Increases were observed only in male low METH takers in the PFC whereas both sexes showed decreased DOPA levels in the NAc. Male high METH takers showed increased cys-DOPA levels in the NAc, whereas female high METH takers showed decreased cys-DOPA levels. Unexpectedly, male high METH takers, but not female rats, exhibited increased DA levels in the NAc. Interestingly, however, both sexes showed decreased levels of cys-DA, DOPAL, DOPET, and DOPAC in the NAc. Our findings further support the importance of understanding the basic sex-specific neurochemical effects of drugs during efforts to develop therapeutic agents against METH use disorder.**Acknowledgement:** This work is supported DHHS/ NIH/ NIDA/ IRP.

Title: Sex-specific alterations in histone deacetylases following methamphetamine self-administration in the rat hippocampus

Authors: *M. T. MCCOY, A. P. DAIWILE, S. JAYANTHI, B. LADENHEIM, J. L. CADET; DHHS/NIH/NIDA/IRP, Baltimore, MD

Abstract: Methamphetamine use disorder (MUD) is a neuropsychiatric disorder that imposes significant health burdens throughout the world. Importantly, significant sex differences in use and relapse rates exist among human METH users. Sex differences in behaviors and biochemical changes have also been reported in preclinical models of MUD. Nevertheless, much remains to be done to clarify the epigenetic bases of METH-induced molecular differences identified in male and female rats. We have been using a METH self-administration model in order to try to further clarify the molecular substrates of behavioral differences between female and male rats. Rats were trained to self-administer METH (0.1 mg/kg/injection, i.v.) using two 3-hours daily

sessions (separated by a 30-minute off interval) for 20 days. Rats were then assessed for cue-induced drug seeking at 3 and 30 withdrawal days (WD). Rats were euthanized 24 hours after WD30. Hippocampi (HIP) were dissected and interrogated for the mRNA expression of histone deacetylases (HDACs). We observed that both female and male rats increased their METH intake during the 4 weeks of the experiment and showed incubation of METH seeking during withdrawal.
Quantitative PCR revealed that male rats had higher basal RNA levels of HDAC1, HDAC2, HDAC3, and HDAC4 in their HIP in comparison to female rats irrespective to treatment conditions. In addition, compared to controls female METH takers exhibited significant increased expression of HIP HDAC4 whereas there were no significant changes in HDAC1, HDAC2, and HDAC3 mRNA levels after exposure to METH SA and withdrawal. Male rats did not show any significant changes in the expression of any of the HDACs after METH SA and withdrawal.
These results identify further evidence for sexual dimorphic responses to METH. These observations support the notion that sex-specific therapeutic approaches to the treatment of METH use disorder may be necessary.

Title: Footshock-induced abstinence from compulsive methamphetamine self-administration is accompanied by increased hippocampal expression of cannabinoid receptors (CB1 and CB2) in the rat

Authors: *J. L. CADET, R. PEESAPATI, S. JAYANTHI;
Mol. Neuropsychiatry, Natl. Inst. On Drug Abuse/ NIH, Baltimore, MD

Abstract: Methamphetamine (METH) use disorder (MUD) is characterized by compulsive and repeated drug intake despite negative life consequences. Large intake of METH in humans and animals is accompanied by dysfunctions in learning and memory processes. The endocannabinoid system (eCB) is known to modulate synaptic plasticity and cognitive functions. The eCB system has also been implicated in the manifestations of substance use disorders (SUDs). We therefore sought to identify potential changes in various enzymes and the receptors

(CB1 and CB2) that are members of the eCB system. Herein, we used a model of METH self-administration (SA) that includes a punishment phase (footshocks) that helps to separate rats into a compulsive METH phenotype (compulsive) that continues to take METH and a non-compulsive METH (abstinent) that suppressed or stopped taking METH in the presence of punishment. Animals were euthanized two hours after the last METH SA session and their hippocampi were used to measure mRNA levels of cannabinoid receptors (*CB/Cnr*), as well as synthetic (*Dagl-a, Dagl-b, Nape-pld*) and metabolizing (*Mgll*, *Faah*, *Ptgs2*) enzymes of the eCB cascade. Non-compulsive rats exhibited significant increased expression of CB1 and CB2 mRNA in the hippocampus. mRNA levels of the synthetic enzyme, *Dagl-a*, and of the metabolic enzymes, *Mgll, and Faah*, were also increased in the hippocampus. Non-compulsive rats also exhibited a significant decrease in Ptgs2 mRNA levels in the hippocampus. Taken together, these observations implicate the hippocampal endocannabinoid system in the suppression of METH intake in the presence of adverse consequences.

Title: The effect of alpha-pinene on methamphetamine-induced conditioned place preference in C57BL/6 mice

Authors: *C. LEE[1], B.-K. DO[2], G. H. PARK[2], J.-H. JANG[1];
[1]Dept. of Pharmacol., Sch. of Medicine, Keimyung Univ., Daegu, Korea, Republic of; [2]Col. of Pharmacy, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Methamphetamine (METH) is a powerful neurotoxic psychostimulant drug affecting dopamine transporter (DAT) activity and leading to blockage of dopamine reuptake, which resulted in continuous excess extracellular dopamine levels between pre- and post-synaptic neurons. In this study, we have tried to elucidate a new molecular regulator involved in METH-induced reward and drug addiction. METH (1 mg/kg/day, *i.p.*) was injected to C57BL/6 mice for four alternative days and locomotor as well as conditioned place preference (CPP) tests were performed as behavior analysis. METH-administered group exhibited and increased sensitivity to place preference compared with saline-treated control group on CPP tests. METH significantly

decreased dopamine-related markers such as dopamine 2 receptor (D2R), and tyrosine hydroxylase (TH). Moreover, METH caused apoptotic cell death by induction of inflammation and oxidative stress. Furthermore we tried to investigate the effect of α-pinene (APN) (3 and 10 mg/kg, i.p) on METH-mediated CPP and elucidate underlying molecular mechanisms. METH-mediated place preference was reduced by pre-treatment of APN. APN restored the levels of D2R and TH in striatum of C57BL/6 mice. APN increased Bcl-2 to Bax ratio and conversely decreased the expression of Iba-1. METH-led to lipid peroxidation was effectively attenuated by APN via augmentation of antioxidant capacity. These findings suggest that APN may be considered as a promising therapeutic agent for METH-induced drug addiction and neuronal damages.

Title: Levamisole as a methamphetamine adulterant in mice: lethal, psychostimulant, and hematological effects

Authors: *Z. P. ESPINOSA-RIQUER[1], A. K. RUIZ-QUIÑONEZ[1], T. BROWNE, Jr.[2], S. L. CRUZ[1];
[1]CINVESTAV, IPN, Mexico City, Mexico; [2]Colombo Plan Secretariat. Drug Advisory Program, Colombo, Sri Lanka

Abstract: Levamisole (Lvm) is an anthelmintic drug commonly found as an adulterant of psychostimulant street drugs such as cocaine. Lvm addition to stimulant drugs seems to potentiate their effects compromise users' health and immunological responses. However, few preclinical studies have addressed the consequences of combining Lvm with psychostimulants. Here, we investigated the lethal, stimulant, and hematological effects of methamphetamine (Meth) combined with Lvm in male Swiss Webster mice. By using independent groups of animals (n=10), we conducted the following experiments: a) mice were i.p. injected with the lethal dose at 10% (LD_{10}) of Meth (5.6 mg/kg), Lvm (31.6 mg/kg), or Meth plus Lvm at the same doses; b) same as in a, but animals received mecamylamine (2.5 mg/kg) 20 min before Lvm or Lvm plus Meth; c) mice received 17.7 mg/kg Lvm twice daily for two weeks. In the third week, animals were divided to receive one of the following treatments: same Lvm treatment, or Lvm plus Meth (0.1 mg/kg; 3x/day until completing 19 administrations). Data were compared

with those obtained from animals treated with 0.1 mg/kg Meth alone (19 administrations) or saline solution (3 weeks). In addition, we evaluated psychostimulant effects by recording locomotion activity on the actimeter in response to 1 mg/kg Meth, alone or in combination with 17.7 mg/kg Lvm. In selected groups, we conducted automated hematological analyses. We found that Lvm increased Meth lethality and this effect was not prevented by 2.5 mg/kg mecamylamine. Lvm also prolonged the hyperlocomotion produced by Meth and worsen leucopenia. By itself, Lvm increased albumin and alanine aminotransferase but did not have additive effects when combined with Meth on other blood chemistry parameters. In conclusion, the addition of Lvm to Meth increases the risk of death and infections, and potentiates the stimulant effects, making them last longer.

Title: Development of CB_2 Receptor Selective Agonists for the Treatment of Stimulant Abuse Disorders

Authors: *A. T. ADAM[1], M. SHAMLOO[3], H. PARK[2], J. S. LIN[2], M. GREEN[2], A. JAHANGIR[2];
[1]Neurosurg., [2]BFNL, Stanford Univ., Palo Alto, CA; [3]Neurosurg., Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: As of 2019, 20.4 million Americans suffered from a substance use disorder. Stimulant abuse is a major contributor to the extension and severity of this social crisis with 1 million suffering from methamphetamine use disorder. Notably, this data is prior to the onset of the COVID-19 pandemic, which threatens a substantial increase in substance use disorders. This increase is anticipated for all age groups due to the stress and isolation caused by the pandemic. Unfortunately, there aren't any FDA-approved pharmacological treatment for stimulant use disorder. This challenge highlights an urgent need to develop non-opioid pharmacological interventions for stimulant addiction, particularly one that does not target the psychoactive opioid receptors. Therefore, it can be prescribed to patients for safe at home use without the risk of developing a dependency. The addiction effects elicited by this methamphetamine is believed to be mediated by cannabinoid receptors in the brain. The cannabinoid receptors 1 and 2 (CB_1R

and CB_2R, respectively) are part of the endocannabinoid system, which play crucial roles in modulating dopamine (DA) levels in the central nervous system (CNS). The inhibition of CB_2 receptor in the brain, in the ventral tegmental area, leads to a decrease in DA release in the nucleus accumbens. This creates new opportunities for targeting this pathway for therapeutic development. We hypothesize that activation of CB_2R is directly linked to the observed anti-addictive properties of the cannabinoids. Currently, our medicinal chemistry and pharmacology efforts focused on the following target profile for selection of the CB_2R agonist: 1) Potent CB_2R agonist; 2) High receptor selectivity (>100-fold over CB_1R and β-arrestin); 3) Good *in vitro* and *in vivo* pharmacokinetics; and 4) High CNS penetration. We have successfully identified a lead series of agonist compounds from extensive SAR, which display functional biased for cyclase over cAMP β-arrestin, highly selective for CB_2R with minimal activity in CB_1R. The lead candidates, CBS-136, CBS-139, CB-149, and CBS-159, are orally bioavailable, brain penetrable, and efficacious in reversing addictive behavior in mice model in nanomolar concentrations. We established 10-250-fold selectivity *in vitro* against closely related receptors, CB_1 and cyclase β-arrestin. We see this biological activity translating into hyperactivity studies in mice stimulated with D-amphetamine. Our goal is to optimize these leads into a preclinical/clinical candidate to treat stimulant use disorder.

Title: The relationship between risk-taking behaviors and methamphetamine-induced conditioned place preference in rats

Authors: *K. TAKAHASHI[1], Y. ICHITANI[1], K. YAMADA[2];
[1]Univ. of Tsukuba, Tsukuba, Japan; [2]Univ. Tsukuba, Tsukuba, Japan

Abstract: It is known that patients with gambling disorder and substance use disorder tend to exhibit maladaptive decision-making. We previously reported that risk-taking rats, which were assessed with a rat version of the Iowa gambling task (rGT) using a radial arm maze, were more likely to be impulsive and more vulnerable to drug dependence (Takahashi et al., 2020). In the present study, we assessed individual differences in risk-taking behavior using operant behavior

(lever press) and investigated the relationship between risk-taking behaviors and vulnerability to drug dependence using methamphetamine (MAP)-induced conditioned place preference (CPP). In the rGT, male Long-Evans rats (7-8 weeks old at the beginning) were trained to choose one of two choice levers (a low-risk/ low reward (L-L) lever and a high-risk/ high reward (H-H) lever). While the choice of the L-L lever stably resulted in frequent (87.5%) small rewards (a 45 mg pellet), the choice of the H-H lever resulted in either infrequent (12.5%) large rewards (four pellets) or intermediate (50 %) large rewards (four pellets) according to auditory cues (white noise or 3 kHz tone). The rGT continued until rats exhibited stable responses to each lever. Rats received 16 forced-choice trials and subsequently 20 free-choice trials in the gambling test. In the CPP, the conditioning sessions were conducted for six consecutive days, and rats received the pairing of MAP (0.5 mg/kg, i.p.) with the unpreferred compartment or saline with the other once a day. The pairing was alternately carried out three times each. During the preference test, rats were allowed to explore the chamber for 15 min, and the time spent in each compartment was recorded. The results demonstrated a significant positive correlation between the percentage of choice for the H-H lever, which resulted in infrequent (12.5%) large rewards, and the preference score for the MAP-paired compartment in the preference test. These findings suggest that risk-taking rats are more vulnerable to drug dependence. In addition, we investigated the effects of an acute MAP treatment on the H-H lever choice in ascending (12.5 % to 50 %) and descending (50 % to 12.5%) conditions). In the ascending condition, rats with acute MAP treatment kept a low percentage of choice for the H-H lever during the intermediate (50 %) large rewards trials, which was the most optimal choice. On the other hand, in the descending condition, they tended to keep a high percentage of choice for the H-H lever during the infrequent (12.5 %) large rewards trials. These results suggest that acute MAP treatment produced an obvious tendency toward response perseveration in the gambling tasks.

Title: Differential effects of ketamine isomers and amphetamine on locomotor sensitization and place conditioning in the rat

Authors: C.-Y. WANG, S.-F. CHEN, C.-C. CHAO, *R.-M. LIAO;
Natl. Cheng Chi Univ., Taipei, Taiwan

Abstract: Ketamine is repurposed in depression therapy, though the underlying neurobehavioral mechanisms remain elusive. One critical concern is the psychotropic effects of ketamine that could link to recreational drug use and resultant abuse. Previous studies frequently used an injectable ketamine solution testing its rewarding effects, whereas comparatively fewer studies have explored ketamine isomer(s) on this issue. We investigated the effects of RS (+/-)-ketamine (RS-KET) and S (-)-ketamine (S-KET) on a behavioral protocol combining conditioned place preference (CPP) and behavioral sensitization (BS) paradigms. Additionally, d-amphetamine (d-AMP) treatment was conducted as a positive control. In a 30-day test, the CPP was conducted by either the unbiased or the biased procedure; and, BS test were run across three phases including a pre-test and a post-test conducted respectively before and after the development phase (7 days of drug injection intermittently separated by saline injects). The drug and saline injections were respectively conducted in two different compartments as applied for the conditioning stage of CPP test. The dose given at the pre- and post-tests was lower (i.e., a half) than that administered in the development phase. For the results, in contrast to that d-AMP (1 mg/kg) significantly produced CPP, neither RS-KET (10 mg/kg) nor S-KET (10 mg/kg) produced CPP via the test with unbiased or biased procedure. However, a CPP was detected in the long-lasting effects test for S-KET treated rats run via biased conditioning procedure. BS appeared markedly to d-AMP treatment which was also profound in the long-lasting test. In RS-KET treated groups, rats run through either the biased or unbiased protocol displayed BS in the development phase and the long-lasting test. However, BS only appeared in the RS-KET treated rats in unbiased but not in biased group. S-KET treatment failed to form BS except that in unbiased group during the development phase. These data indicated that 1) KET isomers differ from d-AMP producing task-dependent effects of drug rewarding, 2) the CPP induced either KET isomers is subtle as compared with d-AMP, and 3) the degrees of BS to KET isomers are lower than d-AMP and varied in different test stages.

Title: Effects of extended-access methamphetamine self-administration on dopamine and cAMP-regulated phosphoprotein (DARPP-32) expression in rat perirhinal cortex and hippocampus

Authors: Y. CAM[1], L. K. CARRICA[3], S. R. WESTBROOK[3], J. M. GULLEY[3,4], *B. A. HEIDENREICH[1,2];
[1]Psychology, [2]Biol. Sci., Illinois State Univ., Normal, IL; [3]Psychology, [4]Neurosci. Program, Univ. of Illinois, Urbana-Champaign, IL

Abstract: Methamphetamine (METH) abuse is a major health concern associated with behavioral disturbances, impaired memory and cognitive deficits. Repeated METH self-administration in rats can produce behavioral tolerance or sensitization and numerous changes in the dopamine (DA) neurotransmitter system. Previously, we investigated the influence of age and sex on the effects of extended access self-administration (6h/day for 14 sessions) of METH or saccharin in Sprague-Dawley rats. Adolescent-onset rats showed a faster escalation of METH intake compared to their adult-onset counterparts, and showed a small decrease in performance on an object-in-place test of recognition memory during a 7-14 day abstinence period. Interestingly, there was no long-lasting effect of METH on dopamine D1 receptor protein levels in nucleus accumbens or prefrontal cortex after 21 days of abstinence.
Dopamine and cAMP-regulated phosphoprotein (DARPP-32) is produced by activation of DA D1 receptors and plays an important role in mediating the short- and potentially long-term effects of drugs of abuse, including dopaminergic stimulants. To further investigate the effects of METH self-administration on DA neurotransmission and the neural substrates of recognition memory, we performed immunohistochemistry for DARPP-32 on the hippocampus and perirhinal cortex of rats from our previous study. Forty micron thick cryostat sections were incubated in primary anti-DARPP-32 antibody, which was then visualized using the avidin-biotin-peroxidase method with 3,3'-diaminobenzadine as the chromogen. DARPP-32 expression in layers V and VI of the perirhinal cortex did not differ between rats that self-administered saccharin or METH. A two-way ANOVA showed a significant main effect ($p = .02$) of the region of the hippocampus examined; the dentate gyrus and CA1 region showed greater intensity of DARPP-32 immunostaining than CA3. There was no main effect of METH vs. saccharin self-administration, suggesting that METH did not cause persistent effects on hippocampal DARPP-32 levels. Together with our previous findings, our results suggest that the effects of METH self-administration on DA D1-mediated neurotransmission do not persist after a 21-day abstinence period.

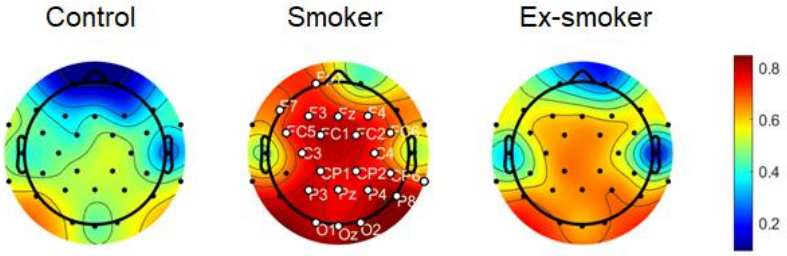
Title: Resting-state EEG in heavy chronic smokers, ex-smokers and non-smokers

Authors: Y. JEON[1], H. LEE[2], J. JEONG[1], C.-I. YOO[3], ***K. BAEK**[1], D. CHUNG[2];
[1]Pusan Natl. Univ., Pusan, Korea, Republic of; [2]Biomed. Engin., UNIST, Ulsan, Korea, Republic of; [3]Dept. of Occup. and Envrn. Med., Univ. of Ulsan, Col. of Med., Ulsan, Korea, Republic of



Abstract: Smoking is a severely chronic addiction. There have been several studies with smokers seeking for the EEG biomarkers, but it is not fully understood how the long-term use of cigarettes alters the resting state EEG and whether such changes can be restored after quitting. Here we examined the resting state EEG from 20 chronic heavy smokers (20 cigarettes per day for more than 20 years), 33 non-smokers and 23 ex-smokers with a long abstinence period (mean: 11.9 years). Resting state EEG was recorded using a cap with high density 31-electrodes using actiCHamp (Brain Products, Germany) for 3 minutes during the eyes-open and the eyes-closed conditions, respectively. EEG data was filtered with the off-line digital bandpass filter (1~50 Hz) after rejecting the artifacts. We compared the relative band power, EEG reactivity (relative change of band power from the eyes-closed to the eyes-open condition) and coherence. As shown in Fig.1, the smokers showed altered resting state EEG band power at the eye-closed condition: decrease in theta power and increase in alpha power when compared to the non-smokers ($p < 0.05$, FDR corrected). The ex-smokers showed decrease in theta power for the frontal and occipital regions but not increase in alpha power. Alpha reactivity, i.e. alpha desynchronization from the eyes-closed to the eyes-open condition, was much strongly manifested in the smokers compared to the non-smokers and the ex-smokers ($p < 0.05$, FDR corrected. See Fig. 1B). In the resting brain network (eyes-closed condition), the smoker exhibited significantly increased alpha coherence compared to the nonsmokers (across the whole brain) and the ex-smokers (primarily with the frontal areas). Increased coherence between left frontal/temporal and the occipital regions were also observed in the ex-smokers. These results suggest that chronic smoking may alter the resting state EEG activity and functional connectivity particularly in alpha band. Increase in alpha reactivity might be associated with changes in cholinergic influence from the basal nucleus of Maynert (Wan et al., Human Brain Map. 2019)

Title: Positron emission tomography (PET) in vivo imaging of 2-[^{18}F]-A85380 trapping in α4β2 receptor-containing acidic vesicles

Authors: C.-M. KAO[1], H. ZHANG[1], ***M. ZAMMIT**[1], N. HOLDERMAN[1], H.-M. TSAI[1], A. GOVIND[1], S. MITCHELL[1], M. BHUIYAN[1], R. FREIFELDER[1], X. ZHUANG[1], J. MUKHERJEE[2], C.-T. CHEN[1], W. GREEN[1];
[1]Univ. of Chicago, Chicago, IL; [2]Univ. of California, Irvine, CA

Abstract: 2-[^{18}F]-A85380 (2-FA) is a weak base PET radioligand that binds with high affinity to α4β2 subtype of nicotinic acetylcholine receptors (nAChRs). Previous work has identified that the smoking cessation drug varenicline (Chantix) becomes trapped in intracellular acidic vesicles containing α4β2Rs and is slowly released over time, whereas nicotine is not trapped. The purpose of this PET study in mice was to evaluate whether the slow in vivo kinetics of 2-FA stems from acidic vesicle ligand trapping, similar to varenicline. 180-minute dynamic 2-FA PET scans were performed on wild type (WT; 5M/5F), β2 nAChR knockout (KO; 8M/3F), acute nicotine-administered (AN; 5M/5F) and chloroquine diphosphate-treated wild type mice (CQWT; 3M/3F) in a β-cube preclinical microPET scanner. Mice were 3-10 months of age, and no sex differences were explored in this study. AN mice were administered 0.5 mg/kg body weight (BW) of nicotine IP 15 minutes before 2-FA injection. CQWT mice were administered 50 mg/kg BW/day of CQ IP for 3 days, with 2-FA PET performed 10 minutes after the final injection. CQ was administered to evaluate whether dissipating the pH gradient across α4β2R-containing acidic vesicles reduced 2-FA binding. Time activity curves were generated using standardized uptake values (SUVs) from the thalamus and midbrain normalized to the cerebellum. Using a cerebellum reference region, distribution volume ratios (DVRs) were determined for each ROI using Logan graphical analysis. Normalized time activity curves revealed reduced binding of 2-FA in the thalamus and midbrain of KO, AN and CQWT mice compared to WT mice. Significant differences in DVRs were observed between groups for the thalamus (ANOVA F(df)=37(3); p<.00001) and midbrain (59(3); p<.00001). Post hoc t-tests revealed that KO, AN, and CQWT mice had significantly reduced DVR compared to the WT mice (all p<.00001 adjusted using Tukey's HSD method). Uptake of 2-FA in KO mice was completely abolished, while AN mice revealed reduced specific binding of 2-FA, indicative of nicotine blocking at the binding sites. CQWT mice revealed significantly reduced uptake of 2-FA, which may indicate that pH neutralization from CQ administration is preventing 2-FA trapping within intracellular acidic vesicles. Together, these findings suggest that the slow in vivo kinetics of 2-FA are influenced by trapping in acidic vesicles containing α4β2Rs similar to our previous results in vitro with varenicline and epibatidine. Our findings highlight the utility of

PET to monitor α4β2R ligand trapping in vivo. All animal procedures were approved by the IACUC of the University of Chicago in accordance with NIH guidelines.

Abstract: Nicotinic agonists play important roles in studying addiction, withdrawal, neuroprotection, cognitive behavior, and neural pharmacology. Previous work with nicotine showed that, in addition to actions on the plasma membrane such as receptor activation and desensitization, pharmacological chaperoning by nicotine begins intracellularly in organelles such as the endoplasmic reticulum (ER). Previous work also showed that nicotine and varenicline enter the ER. We now report genetically encoded fluorescent biosensors for the additional nicotinic agonists dianicline, cytisine, 10-fluorocytisine, and 9-bromo-10-ethylcytisine, which allow comparisons among subcellular pharmacokinetics of nicotinic drugs. Our iDrugSnFRs ("**i**ntensity-based **Drug**-**S**e**n**sing **F**luorescent **R**eporters") utilize mutated OpuBC, a monomeric bacterial periplasmic binding protein (PBP), which features (a) a binding site for amines including a cation-π box, and (b) ligand-induced "Venus flytrap" conformational change invoked by binding of target ligand. We inserted circularly permuted "superfolder" GFP

(cpGFP), flanked by several-residue linkers, near inter-domain hinge regions and applied directed evolution, including X-ray crystallography, to optimize sensing for each drug of interest. Each iDrugSnFR can detect its drug partner with responses of $\Delta F/F0 > 1$ at 1 μM. Using targeting and retention sequences, we directed the constructs to the ER or to the PM of clonal mammalian lines and cultured neurons. Live-cell video imaging (1 - 1000 s) shows that the kinetics of ER entry/exit differ among these nicotinic drugs by > 10-fold. The difference in these subcellular pharmacokinetic properties demonstrates how functional group addition to a parent compound can vastly alter its membrane permeability. With purified proteins in solutions, we examined the thermodynamics and kinetics of biosensor binding/unbinding to their respective drug partner. The biosensor-drug bindings are entropically driven to variable extents among the drug-iDrugSnFR pairs. The kinetics of binding showed several components, suggesting a four-state scheme of biosensor binding, which may extend to other Opu-BC based biosensors. iDrugSnFRs for exogenous molecules provide additional insights into aspects of nicotinic agonists, pharmacokinetics, organellar sequestration of drugs by acid trapping, protein trafficking, and upregulation—all crucial facets in the expanded understanding of "inside-out" neuropharmacology of neural drugs.

Title: Age and sex differences in the effects of nicotine on tyrosine hydroxylase protein levels and DARPP-32 phosphorylation at Ser130 in mice

Authors: T. L. PROFFITT[1], A. D. HUDSON[2], *K. J. FRYXELL[1];
[1]Sch. of Systems Biol., George Mason Univ., Manassas, VA; [2]Dept. of Reproductive Med., Univ. of California at San Diego, La Jolla, CA

Abstract: Nicotine and other drugs of abuse can cause dysregulation of the dopaminergic system. Tyrosine hydroxylase (TH) and Dopamine-and-cAMP-regulated phosphoprotein (DARPP-32) play important roles in dopamine synthesis, and dopamine signaling, respectively.

Nicotine acts directly on nicotinic acetylcholine receptors (nACHRs) in the brain and indirectly stimulates TH gene transcription, as well as stimulating dopamine release from mesocorticolimbic neurons. TH is the rate-limiting enzyme for the synthesis of catecholamines (including dopamine). Ca^{2+} currents that are stimulated by nAChR tend to increase TH gene expression. DARPP-32 integrates both glutamatergic and dopaminergic signaling via phosphorylation events at distinct sites within the DARPP-32 protein. In particular, nAChR signaling affects DARPP-32 (via glutamatergic and dopaminergic signaling), in part by stimulating protein phosphatase-2b (PP2b) activity, which indirectly activates casein kinase 1 (CK1); and also by stimulating inositol triphosphate (IP3) signaling, which increases CK1 gene expression. CK1 phosphorylates DARPP-32 at Ser130. In this study, TH protein levels and phosphorylation of DARPP-32 at Ser130 were measured in the ventral tegmentum (VT), ventral striatum (VS), and medial prefrontal cortex (mPFC) of adolescent and adult mice after subcutaneous nicotine injections. In the VT, we found a highly-significant nicotine-induced decrease in TH in adult males, but not in adult females. These findings were presumably influenced by the suppressive effect of androgens on tyrosine hydroxylase expression in the VT. DARPP-32 phospho-Ser130 decreased in the VT of both sexes of adolescent mice (but not adults) after repeated nicotine injections. This age-specific, nicotine-induced decrease in phospho-Ser-130 is likely to make adolescents more vulnerable to nicotine dependence. In the mPFC, nicotine injections decreased TH protein in adolescent females (prior to puberty), but increased TH protein in adult females, possibly due to the effects of estrogen levels on TH expression. In the mPFC, nicotine injections decreased DARPP-32 phospho-Ser130 in adult males, but increased it in adult females. Several precedents suggest that estrogen signaling may have intensified the nicotine-induced glutamatergic signal, and thus increased the net effects of nicotine on both TH and DARPP-32 phospho-Ser130 in adult female mice. If so, this may provide a novel basis for the vulnerability of females to nicotine dependence after puberty.

Title: Lynx2 modulates neuronal activation in the VTA and the IPN

Authors: *M. BAUTISTA[1], J. P. FOWLER[2], C. D. FOWLER[3];

Abstract: Tobacco-use results in damage to several major organs in the body and remains the highest cause of preventable death and disease in the United States. However, currently available methods for nicotine cessation are only moderately efficacious, thereby creating a need for new therapeutics with endogenous allosteric modulators emerging as targets of interest for drug development. The lynx2 protein is a negative allosteric modulator of the nicotinic acetylcholine receptor (nAChR) and regulates cellular activity within the cholinergic system. Here, we used *lynx2* knockout mice and their wildtype littermates to explore the role of lynx2 in cellular activation, following acute nicotine administration. We quantified c-fos positive cells using unbiased stereology in the ventral tegmental area (VTA) and the interpeduncular nucleus (IPN), which are associated with nicotine reward and nicotine aversion, respectively. Our data show that Lynx2 knockout mice have altered cellular activation in both the VTA and IPN in comparison to their wildtype littermates following acute nicotine administration. Together, these findings demonstrate that Lynx2 contributes to mediating nicotine's actions in both the VTA and IPN, thereby illustrating its potential role in nicotine-related behaviors.

Title: An investigation of the associative rewarding aspects of nicotine in a novel heritable model of drug abuse vulnerability.

Authors: *L. D. PEETERS[1], L. J. WILLS[2], *S. E. TURNEY[1], L. P. BULLOCK[1], W. GILL[1], C. VIED[3], J. T. GASS[1], R. W. BROWN[1];
[1]Biomed. Sci., [2]Psychology, East Tennessee State Univ., Johnson City, TN; [3]Florida State University, Col. of Med., Tallahassee, FL

Abstract: Our laboratory established that neonatal treatment of the dopamine (DA)D_2-like receptor agonist quinpirole (NQ) to rats induces an increase in DAD_2 receptor sensitivity throughout the animal's lifetime, which has validity to a number of clinical conditions which

have high rates of substance abuse comorbidity. Based on this permanent change in DAD_2 sensitivity, we bred adult F0 generation NQ-treated male and female rats with their NQ-treated or neonatal saline (NS)-treated counterparts to determine whether increases in DAD_2 sensitivity were passed to the next generation. Results revealed that offspring of these animals also demonstrated increased DAD_2 signaling on both a yawning behavioral test, which is a behavioral profile of DAD_2 signaling, and produced changes in analyses of DAD_2 signaling proteins β-arrestin-2 and phospho-AKT consistent with increased DAD_2 activity. Based on these data, we analyzed genetic changes using RNASeq, and found that the F1 offspring of two NQ-treated rats demonstrated dramatic increases in cortisol synthesis and release, suggesting these animals demonstrate an enhanced sensitivity to stress, consistent with a model of drug abuse vulnerability. Therefore, we analyzed behavioral responses to nicotine on the conditioned place preference (CPP) task in these F1 offspring. Interestingly, F1 offspring of both NQ-treated rats or a male NQ- and female NS-treated pair demonstrated enhanced nicotine CPP in adolescence. Finally, we investigated two novel pharmacological targets to reduce enhanced adolescent nicotine CPP in F1 generation rats. DAD_2 receptors are known to form functional heteromers with several other classes of G protein-coupled receptors (GPCRs), including the adenosine A(2A) and metabotropic glutamate type 5 receptor (mGlu5). Stimulation of A(2A) or mGlu5 has been shown to reduce the affinity of the DAD_2 receptor for its endogenous agonist in striatal membrane preparations. Therefore, we administered the A(2A) agonist CGS 21680 (0.03 or 0.09 mg/kg) or the positive allosteric modulator to mGlu5, CDPPB (10 or 30 mg/kg) before nicotine during conditioning. Results revealed that both of these drugs alleviated enhanced CPP as well as nicotine CPP in F1 generation animals, and CDPPB alleviated nicotine CPP in controls. These results are the first to show that increased DAD_2 sensitivity is passed to the next generation, and this model is a viable heritable model of drug abuse vulnerability. In addition, we revealed two novel pharmacological treatment targets to reduce rewarding aspects of nicotine.

Title: Acute nicotine intake alters metabolism and brain circuitry in nicotine-dependent rats

Authors: *K. SHANKAR[1,2], O. GEORGE[2];
[1]The Scripps Res. Inst., La Jolla, CA; [2]UC San Diego Hlth., San Diego, CA

Abstract: Nicotine consumption in both human and animal studies has been strongly associated with changes in feeding-related behaviors and metabolism. The current dogma is that nicotine is an anorectic agent that decreases food intake and increases metabolism, leading to decreased body weight gain. However, we have found that acute intake of nicotine in rats through multiple administration models produces a short-term increase in feeding behavior, contrary to long-term anorexigenic effects of nicotine. To elucidate the mechanisms producing this phenomenon, we studied both changes in metabolic signaling as well as brain circuitry following acute nicotine intake. Adult male and female Wistar rats were subcutaneously implanted with nicotine osmotic minipumps and given acute subcutaneous nicotine injection at different timepoints. Plasma samples were collected from these animals at multiple timepoints for downstream metabolic analysis. Another group of animals was subjected to intravenous nicotine self-administration, and following completion of the paradigm, brains were collected for circuit analysis. As our primary behavioral results show differences between non-dependent and dependent animals, our studies focused on comparisons of acute nicotine intake in dependent *vs*. non-dependent rats. Our results challenge the notion that nicotine *per se* is an anorexigenic drug and suggest that nicotine's physiological dysregulation contributes to acute anti-anorectic effects that may lead to long-term anorexigenic effects of nicotine.

Title: Laterodorsal tegmental nucleus mediates negative nicotine withdrawal affective symptoms

Authors: *A. MONICAL, D. S. MCGEHEE;
The Univ. of Chicago, Chicago, IL

Abstract: Tobacco dependence is the leading cause of preventable death worldwide. Understanding how nicotine withdrawal alters excitability of key brain areas associated with addiction is important for developing effective therapeutic interventions and identifying risk factors. Dopamine (DA) release from ventral tegmental area (VTA) projections to the nucleus accumbens (NAc) is important in the induction, progression, and maintenance of addiction. Suppression of VTA DA signaling is one consequence of withdrawal from chronic nicotine use. One of the key presynaptic regulators of VTA DA neuron activity is the laterodorsal tegmental nucleus (LDTg). Previous research has shown GABAergic drive from the interpeducular nucleus

(IPN) to the LDTg is important in the aversive effects of acute high-dose nicotine exposure. While it is known that nicotine withdrawal also activates IPN GABA neurons, the role of the projections from the IPN to the LDTg in nicotine withdrawal has not been tested. We hypothesize that suppression of LDTg projections to VTA mediates aspects of the aversive withdrawal symptoms. Using real-time preference testing with optogenetic inhibition of the GABAergic neurons synapsing within the LDTg, we observed a decrease in the negative affective state associated with nicotine withdrawal, as mice experiencing mecamylamine-precipitated nicotine withdrawal chose to spend more time in the environment paired with this inhibition. This preference persists over three days of testing, after which, animals were assessed for conditioned responses to the previously light-paired and unpaired chambers. Conditioned place testing revealed that preference was state-dependent, as the animals preferred the previously light-paired chamber only when they were experiencing nicotine withdrawal. In addition, we are exploring the impact of IPN GABAergic projections to LDTg in nicotine withdrawal-associated behaviors, including affective state and somatic signs. During optogenetic inhibition of IPN GABAergic terminals in LDTg, we observed a normalization of exploratory behavior that is typically reduced during the withdrawal state, as measured by open field test. As these tests were not associated with a change in locomotor behavior, this suggests that IPN projections to LDTg may contribute to withdrawal associated anxiety.

Abstract: Tobacco smoking is a leading cause of preventable disease, disability, and death. Relapse is common and existing cessation aids are far from curative for many smokers, underscoring the need to develop a deeper understanding of the underlying neurobiology. While the roots of nicotine addiction are clearly complex, an emerging body of research suggests that,

once established, negative reinforcement mechanisms (smoking to alleviate/avoid anxiety) play a central role in continued nicotine use and relapse. Indeed, heightened signs and symptoms of anxiety are a hallmark of nicotine withdrawal, manifesting in the laboratory as potentiated defensive responses to threat, particularly when threat is uncertain in timing, intensity, or likelihood. Although it is widely believed that withdrawal-related anxiety reflects sensitization of the central extended amygdala (EAc)—including the central nucleus of the amygdala (Ce) and bed nucleus of the stria terminalis (BST)—this hypothesis has yet to be rigorously addressed in humans. Here we used fMRI and the Maryland Threat Countdown paradigm to test this hypothesis in 78 daily tobacco smokers randomized to either smoke as usual or abstain for 24 hours prior to neuroimaging. A multiband pulse sequence, best-practice data processing techniques, spatially unsmoothed data, and anatomically defined Ce and BST regions-of-interest enabled unbiased testing with enhanced anatomical resolution. Results demonstrated that acute abstinence increased anxious distress (in-scanner ratings) and arousal (skin conductance) during the anticipation of aversive stimulation (noxious shock, visual, and auditory stimuli; ps<.01). Abstinence was also associated with heightened EAc activation during the anticipation of aversive stimulation with certain timing (p=.02). Other effects were not significant. These findings prompt further exploration on how acute nicotine withdrawal may interfere with orchestrating appropriate responses to threat and elucidate our understanding of how nicotine addiction may interact with anxiety responses to make smoking cessation challenging. Broadly, this work contributes to building a neurobiological framework of addiction processes in humans.

Title: Nicotine Self-Administration Induces Plastic Changes to Nicotinic Receptors in Medial Habenula

Authors: *X.-T. JIN[1], B. R. TUCKER[2], R. M. DRENAN[2];
[2]Dept. of Physiol. and Pharmacol., [1]Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: Nicotine Self-Administration Induces Plastic Changes to Nicotinic Receptors in Medial HabenulaXiao-Tao Jin , Brenton R Tucker , Ryan M Drenan

Chronic nicotine upregulates nicotinic acetylcholine receptors (nAChRs) throughout the brain, and reducing their activity may promote somatic and affective states that lead to nicotine seeking. nAChRs are functionally upregulated in animal models using passive nicotine administration, but whether/how it occurs in response to volitional nicotine intake is unknown. The distinction is critical, as drug self-administration (SA) can induce neurotransmission and cellular excitability changes that passive drug administration does not. In this study, we probed the question of whether medial habenula (MHb) nAChRs are functionally augmented by nicotine SA. Male rats were implanted with an indwelling jugular catheter and trained to nose poke for nicotine infusions. A saline SA group controlled for non-specific responding and nicotine-associated visual cues. Using patch-clamp whole-cell recordings and local application of acetylcholine, we observed robust functional enhancement of nAChRs in MHb neurons from rats with a history of nicotine SA. To determine whether upregulated receptors are generally enhanced or directed to specific cellular compartments, we imaged neurons during recordings using two-photon laser scanning microscopy (2PLSM). nAChR activity at the cell soma and on proximal and distal dendrites was examined by local nicotine uncaging using a photoactivatable nicotine (PA-Nic) probe and focal laser flash photolysis. Results from this experiment revealed strong nAChR enhancement at all examined cellular locations. Our study demonstrates nAChR functional enhancement by nicotine SA, confirming that volitional nicotine intake sensitizes cholinergic systems in the brain. This may be a critical plasticity change supporting nicotine addiction.

Title: Activation of accumbens microglia and adenosine A2a receptors contributes to nicotine self-administration and cue-induced-reinstatement

Authors: *E. O. BONDY, S. N. KHATRI, E. MAHER, C. D. GIPSON;
Dept. of Family and Community Med., Univ. of Kentucky, Lexington, KY

Abstract: Neuroimmune mechanisms within the nucleus accumbens core (NAcore) are involved in nicotine seeking behavior. Further, microglia are activated following withdrawal from experimenter-delivered nicotine, and this is a critical neuroimmunological response in the

nicotine-induced cellular signaling cascade. Adenosine 2 receptors (A2aRs) regulate the proliferation and survival of microglia, and have been found to trigger microglial activation and inflammatory cytokine release. Systemically agonizing A2aRs effectively reduces ethanol self-administration and cocaine reinstatement, but these receptors have not been thoroughly studied for their role in nicotine-motivated behaviors. In the current studies, Long Evans male and female rats underwent nicotine self-administration (0.06 mg/kg/infusion) followed by extinction training in which rats were administered with A2a agonist (CGS 21680, 0.4 mg/kg i.p.), A2a antagonist (SCH 58261, 0.4 mg/kg i.p.), or vehicle. One cohort of animals were used to quantify NAcore microglia morphology following nicotine self-administration while a second cohort received A2a agonist/antagonist treatments through extinction and prior to cue-induced reinstatement. Results show altered morphology indicative of microglia activation, and an increase in A2a expression within the NAcore following chronic nicotine-self administration. Pretreatment with systemic injections of CGS 21680 resulted in the significant decrease of cue-induced nicotine seeking compared to SCH 58261-treated animals. These results indicate that A2a activation counteracts nicotine seeking behavior. Ongoing studies are determining if this is mediated by microglia.

Title: cIBS: an ideal Bayesian observer for visual search in natural scenes

Authors: M. SCLAR[1], ***G. BUJIA**[1,2], S. VITA[1], G. RUARTE[1], F. TRAVI[1], G. SOLOVEY[2], J. KAMIENKOWSKI[1,3];
[1]Lab. de Inteligencia Artificial Aplicada, Inst. de Ciencias de la Computación, Univ. de Buenos Aires - CONICET, Ciudad Autónoma de Buenos Aires, Argentina; [2]Inst. del Cálculo, Univ. de Buenos Aires - CONICET, Ciudad Autónoma de Buenos Aires, Argentina; [3]Maestría de explotación de datos y descubrimiento del conocimiento, Univ. de Buenos Aires, Ciudad Autónoma de Buenos Aires, Argentina

Abstract: Visual search is a vital task that humans perform systematically on an everyday basis. In the last decades, thanks to the advance of deep neural networks, there was a large

development of models that predict the most likely gaze fixation locations when observing a scene (saliency maps). Today, one of the biggest challenges in the field is to go beyond these saliency maps to predict the exact sequence of fixations and tasks different from simple observation. In visual search tasks, Bayesian observers have been proposed to model the visual search behavior as an active sampling process. In this process, during each fixation, humans incorporate new information and update the probability of finding a target at every location. Here, we combine these approaches for visual search in natural images and propose a model to predict the whole scanpath. Our Ideal Bayesian Searcher (IBS) uses a saliency map as prior and computes the most likely next location given all the previous fixations, considering visual properties of the target and the scene. We collected eye-movement visual search data (N=57) in 134 natural indoor scenes and compared different variants of the model and its parameters. Firstly, different state-of-the-art saliency maps performed similarly to previous reports only on the first fixations. After the third fixation, their performance rapidly decayed to almost chance. This suggests that saliency maps are not able to capture fixations distributions when top-down information is critical. Secondly, we introduced different variants of the IBS model to deal with natural scenes, as the priors and measure of similarity between the target and the whole scene. We showed that IBS models using saliency-based priors produced scanpaths that were more similar to humans than using simpler priors, both in the percentage of target found as a function of the fixation rank and the scanpath similarity, reproducing the entire sequence of eye movements. Thirdly, the IBS model presented here behaves more similarly to humans than other state-of-the-art scanpath prediction models based on deep neural networks in the present dataset with scenes of interiors with multiple distractors. Overall, our results and others showed that the Bayesian observer is a natural framework to model the top-down processes, such as the integration of information and predictions, that influence visual search and also guide eye movements beyond the saliency models.

Title: Discovering the temporal correlation between physiological states and risk preferences

Authors: *Z.-Y. YAN[1], P. W. GLIMCHER[2];
[1]New York Univ., New York, NY; [2]Neurosci. Inst., NYU Med. Sch., New York, NY

Abstract: Economics has traditionally viewed preferences, for example risk attitude, as immutable features of the chooser that lie outside of models. There is, however, some evidence that preferences are impacted by both biological and environmental variables. Both human and animal experiments have shown that internal metabolic states can impact risk preferences. (Symmonds et al., 2010; Levy, Thavikulwat & Glimcher 2013; Yamada et al., 2013). Less work has focused on predicting risk attitudes from combinations of behavioral, physiological, and environmental measurements. We longitudinally measured daily behavioral activities, emotional states, environmental variables and risk preferences at the within-subject level to determine of any of correlated with risk attitudes. Our goal was to identify state variables that regulate, and ultimately allow prediction of, the temporal dynamics of risk preferences. We recruited 123 subjects residing in the US using CraigsList and an NYU subject recruitment system for an 8-week experiment. Over the 8-weeks subjects completed between 2 and 3 behavioral instruments per day for a total of 112 behavioral instruments. We employed a mobile smartphone-based experimental platform (Linkt) for delivering daily behavioral instruments. Each participant was asked to complete a weekly time use diary and the following instruments at least once every week: a risky choice task (Levy et al. 2010), the self-report affect. In the time use diary, we asked subjects to fill out a timeline of everything they did on that day, and we categorized these activities into Sleep, Work, Home, Leisure, and Social times. We also gathered 13 personality inventories, one time each, throughout the study from the following domains: attitude toward uncertainty, temporal discounting tendency, impulsivity, and the level of psychological distresses to better understand the individual difference of the risk attitude. Here we present data showing how the amount of a particular activity spent last week correlates with risk attitude, as measured using a Principal Component Analysis (PCA) that allowed us to collapse our many risk-related measures to a single vector. We used a Granger-Causality-style approach to relate this PCA vector weekly behavioral assessments. We found that Sleep time can predict significant changes in risk attitude in the coming week. With more sleep time, our subjects became more risk-tolerant. In future work we will expand the scope of our analyses and the scope of the data we will gather from additional subjects. Our results, however, do suggest that changes in a simple bio-behavioral variable can influence risk attitude from week to week.

Title: Identifying unique neurocognitive mechanisms of food addiction and binge eating using longitudinal study design and computational modeling

Authors: *M. KWON[1], J.-H. LEE[1], J. YANG[1], R. S. CHANG[1], W.-Y. AHN[1,2];
[1]Dept. of Psychology, [2]Dept. of Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Strong evidence indicates that dietary restraint and excessive body image concerns are ironically associated with pathological overeating. Overeating is present in both food addiction and binge eating disorder (BED) but the role of dietary restraint and body image concerns in food addiction and BED still remains unclear. Furthermore, decision-making processes associated with food addiction and BED are yet to be identified. To address this gap, we designed a longitudinal study to investigate whether improved body image concerns by liposuction surgery would play a different role in food addiction and BED. We also investigated their decision-making under uncertainty using novel weight-related decision-making paradigms and computational modeling. In Study 1 (N=93), we validated the novel weight-related decision-making tasks in the community samples and found that measures from weight-related decision-making tasks are more related to body image concerns than those from tasks involving monetary decisions. In Study 2, we recruited obese individuals who registered for liposuction surgery (N = 54, body mass > 25), and longitudinally tracked their food addiction symptoms, binge eating behaviors, dietary restraint, body image concerns, and model parameters (e.g., loss aversion, risk-seeking, and ambiguity tolerance) before and after the surgery. The results showed that 1) changes in body image concerns are significantly associated with binge eating behavior but not with food addiction, and 2) binge eating was positively associated with risk-seeking in pursuing weight loss while food addiction showed the opposite pattern. Our results suggest differential decision-making mechanisms in food addiction and BED, providing novel insights into their constructs.

Title: A confirmation bias during the active seeking of new perceptual evidence across saccades

Authors: *A. CHATTORAJ[1], S. SHIVKUMAR[1], Y. S. RA[2], R. M. HAEFNER[1];
[1]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY; [2]Dept. of Bio and Brain Engin., KAIST, Daejeon, Korea, Republic of

Abstract: Human decision-making is often biased, and few biases are as ubiquitous as the confirmation bias (Nickerson 1998; Michel and Peters 2020). Two major components contribute to the confirmation bias: first, a biased seeking of new information to support one's belief, and second, a biased interpretation of the observed information in agreement with one's existing belief. In a previous study, we have shown under what circumstances a confirmation bias of the second kind arises as the result of approximate hierarchical inference, and shown it to induce a primacy effect during perceptual evidence integration (Lange et al. 2020). However, the seeking of new sensory evidence, most notably by eye-movements, has so far mostly been found to be close to optimal (Najemnik and Geisler 2005; Yang et al. 2016).
Here, we describe a new psychophysical task that requires collecting sensory information by making multiple saccades in the context of a two-choice coarse orientation discrimination task. Using a gaze-contingent display, our task allows us tight control over the information received by an observer both in the fovea and in the periphery. Importantly, it allows us to estimate the observer's subjective belief about the correct choice before each saccade. We find that eye-movements of 13/16 participants exhibit a confirmation bias in that they are more likely to saccade to a peripheral stimulus that is expected to provide new information in agreement with the current belief than to a stimulus of the opposite orientation. Interestingly, such a confirmatory strategy is also favored by an ideal observer who tries to maximize the gain in task-relevant information with every saccade. However, we also find that 9/13 observers are significantly more biased than the ideal observer. We show that this can be explained by a computational model that starts with a Bayesian active sensing strategy (Yang et al. 2016) but assumes that the computations are implemented approximately. Interestingly, the biased strategy arises when the part of the computations that only involves sensory information is performed with higher accuracy than the part that also involves task-specific (cognitive) information. Such a difference is compatible with previous observations on the difference in information capacity comparing sensory periphery and central processing, and suggestions that lower sensory areas act as a "high-resolution buffer" for higher-level computations (Lee and Mumford 2003). Fitting our model to trial-by-trial choices and eye-movements allows us to infer the degree of approximation, here measured in number of samples, for the cognitive component of each observer.

Title: Pupil size reflects computational complexity of decisions in humans

Authors: *E. A. BOWMAN[1], K. ROTARU[2], J. FRANCO[1], C. MURAWSKI[3];
[1]The Brain, Mind and Markets Laboratory, Dept. of Finance, Univ. of Melbourne, Parkville, Australia; [2]Monash Business Sch., Monash Univ., Caulfield, Australia; [3]The Brain, Mind and Markets Laboratory, Dept. of Finance, The Univ. of Melbourne, Parkville, Australia

Abstract: This project examined how computational complexity and cognitive load affect pupil response during complex decisions.
73 participants aged between 18 and 35 years (mean age 22.7, 52 female, 21 male) completed 72 trials of the decision knapsack task. Before each trial, participants were required to memorise either a 1-digit or a 6-digit number displayed for 5 seconds. Each trial consisted of a 5- to 7-second grey fixation screen, followed by the knapsack decision task where participants were given up to 25 seconds to decide if a combination of any of the six items displayed on the screen could be found to satisfy a both minimum value and maximum weight constraint. After the knapsack decision screen, participants were required to enter the number they were asked to memorise at the start of the trial. Participants were paid according to the number of trials in which they both correctly recalled the memorised number and made the correct knapsack decision.
Knapsack task instances varied in computational complexity (as measured by a control parameter defined by the ratio of normalised capacity and normalised profit), but the number of satisfiable and unsatisfiable instances was the same. Gaze and pupil recordings were performed during the task, sampling at 300Hz with Tobii Pro Spectrum video eye trackers. Pupil recordings were de-blinked, interpolated, smoothed, and downsampled into 1000ms bins for modelling using Growth Curve Analysis (GCA).
Mixed-effects modelling of participant responses found a strong effect of instance complexity, and of satisfiability, on trial performance. However, only an inconsistent effect of memory load was found. Participants also spent significantly less time solving knapsack trials of lower instance complexity, and the relationship between instance complexity and time taken significantly predicted performance on a trial. Pupil diameter change was correlated with instance complexity. This difference in pupil response to trials of different instance complexity was detectable up to 15 seconds before the decision point at the end of the (maximum 25-second) trial, and was greatest in incorrect trials.
These results demonstrate that the computational complexity of a task is detected by the

participant, and reflected in the effort-related pupil response, well before the decision is signalled through behaviour.

Title: Perceptual Decision Making in Tree Shrews

Authors: *C. LI[1], K. M. MCHANEY[2], P. B. SEDERBERG[1], J. CANG[2,1];
[1]Psychology, [2]Biol., Univ. of Virginia, Charlottesville, VA

Abstract: Studying decision making and its underlying neural mechanisms can benefit our understanding of how the brain computes goal-related variables with the information it receives. Recently, there has been growing interest in the role of time pressure on the decision-making process, the effects of which are often more profound in animals than in humans, likely complicating the interpretation of the underlying processes. To test the plausibility of different theories of decision-making, it is often required to combine behavioral data with high-resolution neural data and experimental manipulations that can most easily be acquired from animals. Here we present a new animal model - tree shrews (*Tupaia belangeri*) - for decision studies. Tree shrews are evolutionarily closer to primates and have a well-developed visual system that is more ideal for visual decision making tasks compared to mice or rats. In this study, we aim to 1) develop a visual decision paradigm for tree shrews, and 2) test different computational models of perceptual decision-making with and without processes that affect the decision based on the passage of time in each trial with the tree shrew behavioral data. We successfully trained 5 freely moving tree shrews (M=4, F=1) to perform a two-alternative-forced-choice (2AFC) contrast discrimination task, and collected both choice and reaction time (RT) data. All animals produced standard sigmoidal psychometric curves, showing increased proportion correct with higher contrast difference between the choices, along with a plateau effect at the lower levels of difficulty. The choice-RT data were then fitted with a variety of sequential sampling models with and without a timing mechanism that could interrupt evidence accumulation and force an immediate decision. Tests within a Bayesian framework demonstrated strong evidence in favor of models with the timing mechanism. This work establishes tree shrews as a new animal model for studying perceptual decision-making tasks, and also suggests tree shrews exhibit choice behavior similar to other animals, relying in part on a subjective expectation for trial durations to

guide when to make decisions. Future work will explore alternative mechanisms for the timing mechanism, including both urgency gating and collapsing bounds, as well as augmenting the analysis with physiology data to map the decision-making processes to different neural substrates.

Title: Simultaneous evidence evaluation over different timescales revealed in change point detection task with multiple alternatives

Authors: *T. STEVENSON, T. HANKS;
UC Davis, Davis, CA

Abstract: To interact appropriately with a dynamic environment, individuals must be able to detect when aspects of their environment change, however the space of potential changes with behavioral significance is often large. In this study, we used an auditory change point detection task to investigate how knowledge about the direction of potential changes affects subjects' abilities to detect when they occur. Nine human subjects listened to a series of clicks that were randomly generated from a Poisson process with an underlying generative rate that either increased or decreased at a random point in the trial, which subjects were instructed to detect. Prior to each click train, subjects were either informed of the direction of the change or not. From the behavioral data, we characterized the subjects' decision-making process using both model-free and model-based methods. When fitting the data to a sequential sampling model parameterized as an Ornstein-Uhlenbeck process, we found that subjects simultaneously applied distinct timescales of evidence evaluation to the same stream of stimuli when there were multiple potential changes. Additionally, subjects had worse task performance when unsure of the change direction, which can be explained by sub-optimal evaluation timescales and decision bounds in our behavioral model. When subjects were informed of the change direction, they were able to improve their performance by optimizing their decision bound on trials with an increase in click rate, or by optimizing both the timescale of evidence evaluation and the decision bound on trials with a decrease in click rate. One outstanding question of this work is whether this asymmetry in parameter tuning is robust to the behavioral model employed. Additionally, the traditional integration-to-bound behavioral model assumes that subjects respond when the estimated click rate reaches a learned criterion level, however it is also possible that subjects first estimate the baseline click rate on a trial-by-trial basis to compare with their estimate of the current click rate.

To investigate both of these questions, we are currently developing a new behavioral model that allows us to determine whether subjects used prior stimulus history to inform their decision on a per-trial basis. The results of this study establish three important capacities of information processing within any proposed neural mechanism of decision making: the ability to simultaneously employ multiple timescales of evidence evaluation, the ability to rapidly adjust those timescales to task demands, and the ability to modify the amount of information required to make a decision in the context of flexible timescales.

Title: Characterizing individual difference in decision-making strategy by normative solution from the Markov decision process for a non-stationary Bernoulli bandit task

Authors: S. KOTANI[1], K. NAKANISHI[1], S. HIROSE[1], Y. YAMASHITA[2], K. KATAHIRA[3], S. SUZUKI[4], *M. FUKUSHIMA[1];
[1]Deloitte Analytics, Deloitte Touche Tohmatsu LLC, Tokyo, Japan; [2]Natl. Inst. of Neuroscience, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [3]Dept. of Psychological and Cognitive Sciences, Grad. Sch. of Informatics, Nagoya Univ., Nagoya, Japan; [4]Dept. of Finance, Brain, Mind and Markets Lab., The Univ. of Melbourne, Parkville, Australia

Abstract: There is growing interest in elucidating individual characteristics of computations ("computational phenotypes") underlying decision-making for complementing traditional trait and symptom measures. A normative solution in Markov decision process (MDP) corresponds to optimal behavior in a decision-making task under the assumption that the current choice influences the outcome in the distant future. Humans often deviate from the normative solution, and there is individual difference in the degree to which one deviates from the solution. Here we develop a method to describe the difference in individual decision strategy parametrically as deviations from the normative solution. In particular, we derived the normative solution for a three-armed bandit task with time-varying reward probabilities (a non-stationary Bernoulli bandit task). This task has been used to investigate the relationship between decision-making performance and psychiatric symptoms. Our MDP framework uses the Volatile Kalman Filter (VKF) to estimate the information state that is updated as the task progresses. The VKF is an extended Kalman filter algorithm appropriate for a volatile environment as in the bandit task. Thus, we obtained a normative solution from the utility for every state calculated by a value iterative algorithm. The parameters of a normative solution determine the behavioral

characteristics of the solution in the task. An example of such parameters is the discount parameter that controls the degree of explore-exploit trade-off. We confirmed that the discount parameter controlled the behavior as expected in our numerical simulation. The agent with a larger discount parameter value tends to choose an arm recently not selected (i.e., exploration). In contrast, the agent with a smaller value is more likely to stay choosing an arm rewarded recently (i.e., exploitation). Next, we use multiple normative solutions with different parameter settings as reference strategies to characterize individuals. For each reference strategy, we calculate the likelihood of each decision-making history on the bandit task so that the likelihoods collectively represent the decision-making tendency for each individual. This set of likelihoods could characterize the individual difference in performing the task. We plan to apply this to the data obtained from 1,900 non-diagnostic participants performing the bandit task (Suzuki et al. 2021). Our approach with the normative solutions has the potential to uncover a novel computational phenotype for decision-making in a broad range of normal and psychiatric populations.

Title: Neuronal mechanism for decision-making under dynamic belief states

Authors: *C. XUE, L. E. KRAMER, M. R. COHEN;
Dept. of Neurosci. and Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Decisions in natural environments consist of two conceptually separable cognitive processes: flexibly adapting to the changes in the task-demands under a dynamic environment (task-switching), and performing the believed-relevant decision task (perceptual decision-making), both extensively studied individually for their impacts in science and translation. But

do our brains make decisions under dynamic and uncertain environments in these two separable steps? We trained macaque monkeys and artificial neural networks to make perceptual decisions while keeping track of implicitly evolving task demands at the same time. In contrast to their conceptual separability, we demonstrated inextricable neuronal interactions between the flexible belief about the task-demand (or task-belief) and perceptual decision-making. These specific neuronal interactions are associated with behavioral interactions between decision-making performance and task-switching strategy on a trial-by-trial basis, which is not predicted by artificial neural networks trained to perform the same task. Specifically, by analyzing task- and perception-related signals from simultaneously recorded neuronal populations in monkey cortical areas 7a and V1, we demonstrated that stronger task-belief is correlated with better perception, and in turn, response fluctuations in visual neurons affect the updating of task-beliefs. Meanwhile, the behavioral and neuronal effects of interaction are not observed with recurrent neural networks trained to perform this task. These results revealed a specific and inextricable link between the neuronal mechanisms for task-belief and perceptual decisions in the brain, which is not a necessary feature for any network trained to make decisions under dynamic environments. This suggests that studying task-belief and decision-making as an integrated system would reveal unknown neuronal constraints and lead to more holistic understanding of task-switching and decision-making in ways that treating either as a standalone function cannot. Our findings demonstrate how multiple brain areas interact to perform seemingly separable components of complex behavior and provides a path toward therapies for neuropsychiatric disorders that affect multiple brain systems.

Title: In search of motor-independent evidence accumulation signals in monkey EEG

Authors: *K. KALOU[1], R. O'CONNELL[1], S. KELLY[2], T. TEICHERT[3];
[1]Sch. of Psychology, Trinity Col. Neurosci. Program, Dublin, Ireland; [2]Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland; [3]Dept of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Neural signals that accumulate evidence for perceptual decisions have been identified in a variety of species and brain regions. Thus far, studies of non-human electrophysiology have

exclusively observed such signals in effector-selective brain regions that play a role in preparing the decision-reporting actions. In parallel, investigations of human electroencephalogram (EEG) data have identified a new class of decision signal over centro-parietal scalp sites (the Centro-Parietal Positivity, CPP) that has the unique characteristic of tracing evidence accumulation irrespective of the sensory or motor demands of the task. Such a signal has not yet been observed in non-human animals, raising the question of whether it is a uniquely human process or simply one that has been overlooked by intracranial investigations. In the present study, we collected EEG data from both human and macaque subjects while they performed the same auditory oddball task. We collected EEG data from 6 human participants, while they were asked to discriminate a frequency deviant tone among a number of identical standard tones. A response was considered as valid only if it was given between 100 and 700 ms after target onset. The frequency difference between each standard and target tone (dF) was varied to define 5 different levels of sensory difficulty. The stimulus onset asynchrony (SOA) was varied between 0.25 and 12 seconds to manipulate the short-term memory demands of the task. For our human participants, target detection probability increased with frequency separation (dF) and decreased with SOA. Human EEG data highlight a slowly building positive CPP component following target tones, peaking between 400ms and 700ms, that is absent following standard tones. Furthermore, there was a significant effect of dF on the amplitude reached by the CPP by the time of response. To test for the existence of a similar signal in monkey EEG, we conducted a re-analysis of 32-channel cranial EEG data collected from macaques performing the same auditory oddball task (Teichert 2017). The behavioral results indicate a rise in accuracy with dF and vice versa with SOA. In the EEG we observed a slowly building positivity over central electrodes rising 300ms after target tone presentation and peaking close to response execution, whose slope is modulated by dF, SOA and RT and reaches higher amplitudes for target than standard tones. This presents a potential monkey homolog of the CPP that further analysis will be needed to substantiate.

Title: Neuronal encoding of rapid categorical decisions across the primate oculomotor network

Authors: *O. ZHU[1], V. SHIRHATTI[1], S. DAVID[1], S. CHANG[1], A. MEDOFF[1], A. A. SILVA[1], D. J. FREEDMAN[2];
[2]Neurobio. and Computat. Neurosci., [1]Univ. of Chicago, Chicago, IL

Abstract: Our ability to rapidly categorize incoming stimuli is an essential cognitive process that imbues our world with meaning and guides our behavior. Previous studies have examined the oculomotor system's role in categorical decisions, but few have explored this process when ongoing motor plans are rapidly modulated and updated by incoming sensory information. In this study, we designed an urgent saccade-based, motion categorization task that utilizes a compelled-saccade paradigm to systematically limit the viewing time of the motion stimuli. This task structure exploits the animal's natural variability in reaction times across trials to quantify the psychophysical impact of categorical information towards ongoing motor plans with millisecond resolution. During task performance, we recorded populations of neurons using up to six linear microelectrode arrays (Plexon V-Probes) simultaneously targeting the lateral intraparietal area (LIP), frontal eye field (FEF), and superior colliculus (SC). On average, each session yielded around 50 well-isolated single units from each area. We quantified category selectivity in each area using linear support vector machine (SVM) classifiers trained from population activity from each area in individual sessions and found that SVMs for each area achieved >90% decoding accuracies and, on average, exhibited latencies that were not significantly different from each other (~120ms after stimulus onset; $p>0.05$). In particular, SVMs for SC populations surprisingly achieved >95% decoding accuracy at a similar latency to LIP and FEF. We also quantified the saccade selectivity of each area with linear SVMs and found that all areas achieved >95% decoding accuracies, though FEF and SC exhibited slightly shorter latencies than LIP ($p<0.05$). The similar latencies and high decoding performance for each area support a distributed model of categorical decision making in which brain areas operate as a collective network rather than discrete modules for perception and motor control. In particular, our results demonstrate that SC is engaged in cognitive functions such as categorization and decision making beyond its traditionally understood role in saccade execution and orienting behaviors. Ongoing experiments will reversibly inactivate each individual area while simultaneously recording the other areas to investigate the causal relationships between brain areas during rapid categorical decision making.

Title: Neural network dynamics underlying the adjustment of temporal evidence weighting in perceptual decisions

Authors: *C. VIVAR[1,2], G. MOCHOL[1,2], A. J. LEVI[3], A. C. HUK[3], K. WIMMER[1,2];
[1]Ctr. De Recerca Matematica, Bellaterra (Barcelona), Spain; [2]Barcelona graduate school of mathematics, Barcelona, Spain; [3]Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: During perceptual decision making, sensory information can be accumulated using distinct strategies; weighting some stimulus epochs more heavily than others. A recent study has shown that primates can flexibly adapt their temporal weighting strategy to the stimulus statistics (Levi et al., Eneuro 2018). Sensory stimuli with more information at the beginning of the trial produced early weighting, while stronger sensory evidence in later stimulus epochs caused a switch to a late weighting strategy.
To shed light on how this flexible adjustment can be mechanistically implemented at a neuronal level, we used a two-area firing rate model composed of a sensory and a decision circuit with bottom-up and top-down connectivity (Wimmer et al., Nat. Commun. 2015). We included the time-varying MT activity as a constraint to the sensory circuit as well as a time-varying modulation signal, ("choice commitment" signal), that altered the attractor dynamics of the decision circuit. This modulation signal affected the decision circuit in two ways. Firstly, it initiated the decision process by pushing the network into a competition regime. Secondly, it changed the decision dynamics by accelerating or delaying the choice, similar to an urgency signal.
The model could reproduce the experimentally observed primacy weighting for early and flat stimulus statistics and late weighting for late stimulus conditions. We reasoned that the modulation signal may be related to the subject's task engagement, which we measured as the time needed to execute a successful fixation at the start of the trial. Consistent with the model, we found that the subject's engagement was higher (faster fixation) in the early weighting condition and lower (slower fixation) for the late condition.
Preliminary analysis of neural data recorded from areas MT and LIP indicated that the neurons' pre-stimulus activity was correlated with task engagement, providing further evidence for the modulation signal.

Title: Neuronal economic utility arising from the heterogeneous coding of reward magnitude and probability in orbitofrontal neurons, elicited through the continuity axiom of Expected Utility Theory.

Authors: *S. FERRARI-TONIOLO, W. SCHULTZ;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Introduction. Utility is a fundamental economic concept which defines subjective values. Expected Utility Theory (EUT) describes choices as a utility-maximization process: we assign a numerical utility to each option and choose the option with the largest utility. Crucially, this "as if" framework (we make choices "as if" maximizing utility) makes no assumption on the underlying brain mechanism and on the existence of a neuronal utility signal, which remains undetermined. We investigated whether single neurons and neuronal populations in the macaque orbitofrontal cortex (OFC) encode a utility signal compatible with the axiomatic economic theory.
Methods. We first identified a quantitative utility measure based on the continuity axiom of EUT, a test for robustness of magnitude-probability integration into a scalar utility value, across multiple settings. This showed that utility maximization can reliably describe risky choices in macaques (Ferrari-Toniolo et al, 2021). We then recorded the activity of single OFC neurons using the same paradigm, to infer a corresponding neuronal utility measure. Both behavioral and neural procedures considered the non-linear contribution of magnitudes and probabilities to the formation of utility values, in line with modern economic theories (e.g. Prospect Theory).
Results. Within the neurons responding to both reward magnitude and probability, we found that: 1) Neurons complied with the continuity axiom, allowing us to define a neuronal utility measure; 2) Such neuronal measure corresponded with the behavioral one in a minority of neurons, while most units predicted risk attitudes significantly different from the behavioral ones; 3) A reliable utility code was reconstructed from this mixed population, which included cells with diverse non-linear magnitude and probability coding patterns.
Conclusions. Our data showed that, while many reward-modulated neurons encoded utility values incompatible with the animal's choices, a neuronal utility signal able to reliably describe

choices was reconstructed from a population of such neurons. The variability with which single units represented magnitude and probability non-linearly, resembling a distributional code, suggested a population scheme able to flexibly accommodate a broad pattern of risk attitudes. These results represent an insight into the process for value computation, proposing a mechanism for the neuronal counterpart of economic utility. The existence of a neuronal utility signal supports a neural implementation of the utility-maximization principle and provides a basis for understanding the origin of risk attitudes and choice biases.

Title: Examining neural dynamics of motivational decisions using large-scale array recordings in macaque prefrontal cortex

Authors: *S. WANG, R. FALCONE, B. J. RICHMOND, B. B. AVERBECK;
NIMH/NIH, Bethesda, MD

Abstract: Animals naturally balance the tradeoff between effort and reward. Some rewards are worth the effort while others are not. The more valuable the reward is, the more motivated the animal is to get it**.** In this work, we studied neural dynamics in prefrontal cortex that underlie motivational decisions on whether to accept or reject an offer. Offers were defined by the magnitude and delay-to-reward. We investigated population dynamics of prefrontal neurons using large-scale Utah-array recordings.
Two macaques were trained to either reject or accept (by either releasing or holding a bar) an instrumental trial (a sequential red-purple color discrimination). Accept or reject decisions were based on a visual cue that indicated the reward size (2, 4 or 6 drops) and delay-to-reward (1,5 or 10s). The monkeys almost always accepted the offer for some cues (high reward, short delay), and almost always rejected the offer for other cues (low reward, high delay). For other cues which signaled intermediate value offers, the monkeys had intermediate probabilities of rejecting vs accepting.
Prefrontal neurons encoded the cue information. Using a KNN based population decoding analysis, we were able to decode the 9 cues (3 reward sizes by 3 delay-to-reward times) at an accuracy of 50% (significantly above the chance level of 11.1%) using cross validation. The decoding accuracy peaked between 400ms and 700ms after cue onset. Using a linear SVM

classifier, we were able to predict monkey's choice to accept or reject at an accuracy of 80-85% from 500-1000ms after cue onset.
We further examined the neural dynamics of motivational decisions in a low dimensional neural subspace. We projected the neural dynamics onto the 1-dimensional space perpendicular to the separating hyperplane in the SVM classifier to maximize the information about choices. We investigated how the landscape of the neural manifold in this 1-dimensional space varied between different offers of reward sizes and delay-to-reward times. Preliminary data suggests that the manifolds have a steeper attractor basin following presentation of cues that have clear motivational preferences (high reward low delay, or low reward high delay), and have shallower attractor basins following cues that have ambiguous preferences. This suggests that the landscape of the neural manifolds shape how motivational decisions are made in macaque prefrontal cortices.

Title: Causal role of midbrain dopamine neurons and ventral striatum circuit in economic decision-making in macaque monkeys

Authors: *M. NEJIME[1], M. YUN[1], T. KAWAI[1], H. YAMADA[1], K.-I. INOUE[2], M. TAKADA[2], M. MATSUMOTO[1];
[1]Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan; [2]Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: The brain reward system, consisting of midbrain dopamine (DA) neurons and their target (i.e., the ventral striatum (VS)), is involved in economic decision-making. However, how these structures cooperate with each other to make appropriate decisions remains poorly understood. To address this issue, we conducted single-unit recordings therefrom in macaque monkeys performing an economic decision-making task. The monkey was required to decide whether to choose an option based on its value. We analyzed how neuronal activity varied over time as the economic decision-making process progressed, and found that DA and VS neurons showed different activity dynamics. These neurons represented four decision-making variables,

the value of option (value), the value of the option that the monkey would choose (chosen value), the value of the option that the monkey would not choose (unchosen value), and whether to choose the option (choice). The DA neurons exhibited a short-latency phasic activity signaling these variables just after the option was offered, and their largest population represented the chosen value. By contrast, many of the VS neurons displayed a long-latency ramping activity signaling the choice. These results suggest that DA and VS neurons may be involved mainly in an earlier or a later stage, respectively, of the economic decision-making process. From the difference of their signal dynamics, we hypothesized that the DA signals in the VS will affect the choice behavior in the economic decision-making. To verify this hypothesis, we next examined the causal relationship between DA signals transmitted to the VS and monkey's choice behavior using an optogenetic technique applicable to the monkey brain. We optically stimulated axon terminals of DA neurons in the VS when the option was offered in the economic decision-making task. Of all stimulation sites, 12% produced a significant increase in the monkey's choice rate of the option, while none generated a significant decrease in the choice rate. Our findings have confirmed and expanded the current knowledge as to how DA and VS neurons regulate economic decision-making by highlighting their distinct signal dynamics and causal roles in monkey's choice behavior based on the signal interactions.

Title: Evidence accumulation and suppression of trial history-related influence by dorsomedial frontal cortex

Authors: *T. Z. LUO[1], A. G. BONDY[1], D. GUPTA[1], V. A. ELLIOTT[1], C. D. KOPEC[1], C. D. BRODY[2];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst., HHMI/Princeton Univ., Princeton, NJ

Abstract: Perceptual decisions depend on multiple processes, including the gradual integration of noisy sensory evidence over time. A related process involves the incorporation of prior

knowledge of the environment into the present decision and depends on the integration, over a longer timescale, of past choices and their outcomes. In trial-based tasks in which the rewarded choice is solely determined by the present sensory stimulus, the influence of priors manifests in a history-dependent choice bias that can be observed even in expert subjects. It remains unclear how these two processes interact during the formation of perceptual choices. The dorsomedial frontal cortex (dmFC) has been implicated in decisions that depend on behavioral history and also in decisions that depend on sensory evidence. To understand the interaction between evidence integration and the influence of behavioral history, we studied the causal roles of dmFC in rats performing a task that requires the gradual accumulation of pulsatile auditory evidence. Neuronal populations in dmFC and interconnected frontal brain areas were recorded using Neuropixels probes, and neurons in dmFC were silenced using pharmacology, photoinactivation, and chronic lesion. Population activity in dmFC showed a robust representation of evidence. Compared to several frontal areas interconnected with dmFC, including medial prefrontal cortex, striatum, and primary motor cortex (M1), this evidence signal was stronger and emerged earlier in dmFC. Silencing of dmFC through different methods consistently decreased sensitivity to the sensory evidence while increasing bias to the rewarded option of the previous trial. Optogenetic silencing randomly interleaved across trials increased history-dependence on the same trial as the photoinactivation, but not on the subsequent trial. This indicates that the increase in history-related bias occurred before or during, but not after, choice formation. The behavioral consequences of dmFC inactivation can be reproduced in simulations of a bounded drift-diffusion process by biasing the initial point toward the rewarded option of the previous trial, but not by increasing sensory or accumulation noise. Consistent with these simulations, dmFC silencing resulted in an additive bias toward the previous rewarded option in the evidence signal in the neural activity of striatum and M1. These results indicate that during perceptual decisions, dmFC is causally involved in the gradual accumulation of evidence and also the suppression of history-dependent choice bias. A competition between evidence- and history-related signals may underpin the formation of perceptual choices.

Title: A mechanistic account of how trial history biases give rise to lapses in perceptual decisions

Authors: *D. GUPTA[1], B. DEPASQUALE[1], C. D. KOPEC[1], C. D. BRODY[1,2];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Experienced subjects in perceptual tasks often deviate from the predictions of optimal decision theory, displaying several suboptimalities. Among the most pervasive of these are history biases or the inappropriate influence of past trials on perceptual evidence, and lapses or evidence independent errors. History biases and lapses are often assumed to arise from independent processes, since the former seems to interact with evidence while the latter does not. However, numerous recent observations suggest that they may share a common origin. For instance, the prevalence of history biases and lapses covaries (Gold ‘08, Busse ‘11), lapse trends are modulated by trial history (Scott ‘15, Ashwood ‘20, Pisupati ‘21) and their proposed neural substrates overlap (Erlich ‘15, Siniscalchi ‘19, Sindreu ‘21). What cognitive process could underlie the links between these suboptimalities? Here, we demonstrate that history biases and lapses can both emerge from normative accumulation of evidence under the incorrect belief that the environment is non-stationary. This corresponds to an accumulation to bound process whose initial state undergoes history dependent updates. While small deviations in the initial state result in largely additive biases to the evidence, larger deviations also decrease the effective sensitivity to evidence. Therefore trial to trial deviations in the initial state produce history-biased choices which have varying degrees of attenuation in evidence dependence, resembling the evidence independence of lapses. In this model, the parameters governing evidence accumulation and initial state updating impose constraints on the relative strengths of history biases and apparent lapses. We test this proposal by fitting a trial-by-trial model to a large dataset of 6.4M choices from 160 rats trained on an evidence accumulation task (Brunton ‘13). We show that the constraints posited by the model are obeyed in this dataset, despite the heterogeneity in history biases and lapse rates in this population. Finally, because variations in the initial state modulate the time to reach decision bounds, reaction times offer a strong test of our proposal. Hence we apply our model to rats trained on a similar task with reaction time reports and show that it explains detailed patterns of choices, reaction times and their history dependence. Our model offers a unified explanation for two common suboptimalities in perceptual decisions, and enhances our ability to predict the precise dynamics of decision variables both within and across trials. This mechanistic account has the potential to improve our understanding of neural correlates of the decision making process.

Title: Sensory priors, choice and outcome history in service of optimal behavior in noisy environments

Authors: *E. MENICHINI, V. PEDROSA, V. PLATTNER, R. LOW, A. AKRAMI;
Univ. Col. London, London, United Kingdom

Abstract: While navigating the world, we constantly make decisions under uncertainty which can originate from ambiguous sensory inputs or unknown action outcomes. In face of noisy perceptions, we build and continuously update our priors and expectations about future events, in order to efficiently estimate sensory information. Via learned policies, agents then have to map the relevant sensory information onto appropriate behavioral responses in order to maximize reward. In a non-stationary environment where action values may change, the rules mapping stimuli to outcomes may not be fixed and exploratory behavior represents an optimal strategy to identify the most rewarded contingencies at any given context. How do animals integrate knowledge about the statistical context and action policy of the environment into an overall model of the world? In this work, we investigate how previous experience (sensory priors, choice and outcome history) can inform such models during decision-making in a perceptual categorization task. Combining behaviors in rats and humans with computational models, we show agents' sensitivity to history of sensory and action events as a mechanism to constantly update policies. By performing large-scale electrophysiological recordings, we will identify neuronal dynamics in key brain areas involved in learning and utilization of priors, in conjunction with policy updates.

Abstract: To select and initiate appropriate actions in complex decision-making tasks requires information to be aggregated and exploited within and across trials. We know little about the brain mechanisms for computation and storage of across-trial information, such as prior probabilities of stimuli or rewarded actions. We examine neural correlates of this information using neural activity recorded in the international brain lab (IBL) task: 583 neuropixel penetrations covering 361 brain regions in the Allen atlas. In the IBL task, mice maximize rewards by exploiting a blockwise prior probability governing the appearance of stimuli. Behavioural modeling has revealed the (usually approximate) way in which the mice are sensitive to the identity of the block. We therefore use a combination of encoding and decoding to localize which brain regions contain either the best estimate of the stimulus prior taken from behavioral modeling or other related quantities such as the true Bayesian posterior over the block.For encoding, we use a Generalized Linear Model (GLM) with a linear link function to express neural activity as a function of numerous task-related variables such as stimulus onset time, contrast, licking, reward delivery, and wheel movement. We incorporate either the block probability or our approximate prior estimate into this model as well, and are examining the variance explained by each regressor.Our decoding approach includes the use of linear decoders, linear discriminant analysis, and a reduced-dimensional representation of the PSTH of neural activity by region to examine how neural activity changes as a function of block probability, stimulus side, or prior estimate and how information is tied together between successive trials.Combining these approaches, we hope to gain insight into the distribution of information about the prior across the brain, as well as clues as to where and how it is computed and updated across trials and how it is brought to bear upon within-trial information processing.Preliminary results indicate substantial variability in the encoding and decodability of prior information across all of: subjects, sessions and brain regions. Despite this, we identify a set of brain regions which still show information content beyond what we expect from said variability. Cortical (retrosplenial) and subcortical (MRN) areas offer some particular promise for investigation, with evidence for distinct sub-populations in the latter integrating prior and stimulus information across different timescales.

Brain Lab., London, United Kingdom

Abstract: Understanding whole-brain-scale electrophysiological recordings relies on the collective work of multiple labs. Because two labs recording from the same brain area often reach different conclusions, it is critical to quantify and control for features that decrease reproducibility. We addressed this by repeatedly inserting Neuropixels probes in the same location in the mouse brain, via a joint effort of 8 labs in 3 countries. Here, we report results for 66 total insertions. First, we screened probe insertion accuracy via standardized histological reconstruction of probe tracts. Mean displacement on the brain's surface was 398 μm from the planned site, and 532 μm from the experimenter's intended position (read from the micro-manipulator). Probe insertion angle showed small mean perturbations from the planned angle: 3.3° (coronal) and 5.7° (sagittal). As a result of these displacements, 10/66 insertions failed to target the repeated site, and were excluded. Next, for successful insertions, we compared response properties of recorded neurons across labs. We restricted the analysis to labs with at least 4 successful insertions. Firing rate and LFP power were reproducible across 4 labs: within-lab variability (though considerable) exceeded across-lab variability. Further, neural responses to task events were reproducible across labs up until movement initiation. In most brain regions, the observed variability in neural activity, within or among labs, did not arise from spatial position or lab ID. Finally, we trained a multi-task neural network to quantify variance in neural activity explained by task variables (e.g., stimulus onset time), behavioral variables (timing of licks/paw movements), and other variables (e.g., spatial location in the brain or the lab ID). The model extends common, simpler regression approaches by allowing nonlinear interactions between

variables. We found that within-lab random effects were comparable to between-lab random effects. Taken together, these results suggest that across-lab standardization of electrophysiological procedures can lead to reproducible results across labs. Failures of reproducibility are often driven by deviations from planned insertion locations, and may be ameliorated by refinements in stereotaxic procedures.

Title: Coordinated prefrontal activity during choice behavior revealed by intracranial recordings

Authors: *J. OVERTON[1], M. STICKLE[1], T. DEVESETTI[1], K. A. MOXON[1], I. SAEZ[1,2]; [1]Univ. of California Davis, Davis, CA; [2]Neurosci. & Neurol., Mount Sinai, New York, NY

Abstract: Risky decision-making involves coordinated activity across multiple brain regions involved in evaluation and comparison of options, cognitive control, and action selection. Contrary to notions that assign compartmentalized and sequential roles for individual brain regions, the associated neural activity is likely represented across multiple brain regions in a parallel and distributed fashion (e.g., Hunt & Hayden, 2017; Hunt et al. 2018). Understanding these complex inter-regional dynamics requires simultaneous recordings across multiple brain regions with both high spatial and temporal resolution, which are limited in non-invasive studies of human cognition. In this study, we examine the invasive recordings of multiple brain areas implicated in reward behavior in a large dataset of human neurosurgical patients (n=20) using intracranial electroencephalography (iEEG) while they played a gambling game designed to probe value-based decisions. On each trial, participants chose between a certain reward and a risky gamble of varying win probability. Electrode coverage was determined clinically and therefore varied per subject, but consistently included orbitofrontal cortex (OFC), lateral prefrontal cortex (LPFC), pre- and post-central gyri, cingulate cortex (CC), amygdala, and hippocampus. We analyzed iEEG local field potential (LFP) data in six power bands across all

regions, at multiple time epochs. Here, we focused on the deliberation period (1s prior to choice) and examined power modulation across frequencies and regions by comparing pre-choice activity to a pre-stimulus baseline. We found significant task-related power modulations across all power bands: in general, lower frequency activity (delta, alpha, theta) decreased in frontal and limbic regions, and increased in pre- and post-central gyri and parietal regions. In contrast, higher frequencies (beta, gamma, and high gamma) were more likely to show both increases and decreases in power modulation across electrodes in LPFC, OFC and CC. We compared power across trials between safe bets and gambles and found that task-related modulations related to subsequent choice (gamble or safebet) existed in multiple regions and frequencies. Multivariate regression analyses relating powerband data to task regressors suggest a role of beta and high gamma across OFC, LPFC, and precentral gyrus in choice. These results describe critical components of neural activity underlying human decision-making and have broad implications for neuropsychiatric disorders that involve maladaptive decision-making such as in addiction and obsessive-compulsive disorders.

Title: Single-trial choice decoding from distributed intracranial recordings

Authors: *M. STICKLE[1], J. OVERTON[1], T. DEVESETTI[1], I. SAEZ[1,2], K. MOXON[1];
[1]Univ. of California, Davis, Davis, CA; [2]Neurosci. & Neurol., Mount Sinai, New York, NY

Abstract: Risky decision-making involves coordinated activity across multiple brain regions for evaluation and comparison of options, cognitive control, and action selection. Intracranial recordings from distributed brain regions provide a high spatial and temporal resolution representation of inter-regional neuronal dynamics, and a unique substrate to carry out single-trial decoding of choice behavior. Machine learning tools have been applied to movement-related neural data to gain similar insight into brain dynamics controlling movement. Here, we compare the effectiveness of classification techniques to predict the decision outcome of neurosurgical patients undergoing invasive monitoring (intracranial electroencephalography, iEEG) while

performing a gambling task. In this task, patients chose between a safe bet (fixed, small amount of money) or a risky gamble of varying probabilities. Electrode coverage was determined clinically and therefore varied per subject, but consistently included orbitofrontal cortex (OFC), lateral prefrontal cortex (LPFC), cingulate cortex, and hippocampus. We analyzed iEEG local field potential (LFP) data in six power bands (delta, alpha, theta, beta, low gamma, and high gamma) across all regions, at multiple time epochs. Our aim was to construct a method for classifying subject's choice (gamble or safe bet) on a given trial using neural power features alone (time bin x frequency bands x regions) as inputs. We used Principal Component Analysis (PCA) to determine the main axis of variance of neural data, and found that the first principal component (PC) was a good representation of average power in each frequency band. Subsequently, we used a linear classifier (Euclidean distance classifier) to determine what neural features predicted overt trial-by-trial choice. Classification was carried out on both representations of neural activation: raw power and neural PCs. We found that the raw power classifier tended to outperform the PC classifier, obtaining upwards of 70% performance in some patients using a leave-one-out cross validation procedure. Finally, we examined which features of the analysis influenced variance observed in model performance across patients and found that behavioral performance as well as electrode count and localization had a significant impact on decoder performance. Specifically, higher decoding accuracy was achieved in patients with better behavioral performance and a higher number of electrodes in LPFC. These results demonstrate a promising approach for decoding of high-order cognitive states (i.e. choices) from multi-regional, multi-frequency invasive iEEG recordings.

Title: The effect on sensory statistics and serial dependency on sound categorization behaviour

Authors: *V. PEDROSA[1], L. ZHOU[2], E. MENICHINI[1], P. E. LATHAM[2], A. AKRAMI[1];
[1]Sainsbury Wellcome Ctr., [2]Gatsby Computat. Neurosci. Unit, Univ. Col. London, London, United Kingdom

Abstract: Animals integrate evidence to infer the statistics of sensory stimuli. The appropriate use of these statistics is essential to optimise rewards when making decisions. It is not fully understood, however, how stimulus statistics affect decision making in humans and animals. In particular, it is not clear how stimulus temporal and spatial dependency guide decision making. Here, we investigate how humans integrate sensory evidence and use previous experiences to inform their decision in a perceptual categorisation task. We analyse the decisions performed by subjects based on overall sensory statistics and preceding choices, outcomes, and stimuli. Depending on the overall statistics of sensory stimuli, subjects adapt their perceptual responses. To unravel the potential underlying mechanisms of this decision-making process, we then compare subjects' performances with computational simulations and behavioural outcomes in a similar task performed by rats. Computational models simulate normative agents behaving based on different first principles. Since sensory perception is inherently limited, our results indicate that the observed adaptation in animal psychometric curves leads to an improvement in performance conditioned on certain constraints. Our combined behavioural and computational analyses unravel further details of specific aspects of sensory information taken into consideration by humans and rats when performing decision-making tasks.

Title: Distinct causal contributions of FEF and LIP to rapid categorical decisions in primates

Authors: *V. SHIRHATTI, O. ZHU, S. DAVID, S. CHANG, A. MEDOFF, D. J. FREEDMAN;
Univ. of Chicago, Chicago, IL

Abstract: The ability to make rapid categorical decisions about incoming sensory stimuli is a behavioral capacity of fundamental importance. To study the neuronal mechanisms spanning multiple primate brain areas underlying rapid categorical decisions, we designed a novel rapid visual motion categorization paradigm that compels the subject to make rapid decisions about the abstract category membership of a visual motion stimulus, and allows independent assessment of the visual, cognitive, and motor aspects of the monkey's decisions. The lateral intraparietal (LIP) and frontal eye field (FEF) cortical areas are involved in an array of functions including visual categorization, target selection, saccade planning and execution. To delineate their contributions to rapid categorical decisions we reversibly inactivated local populations in these regions with a $GABA^A$ agonist, muscimol, during a saccade-based categorization task. We used two different stimulus-target spatial configurations, such that either the category stimulus or one of the targets was placed in the inactivated visual field to separately test the impact of inactivation of visual and motor aspects of behavior. The category stimuli transitioned from 100% noise to fully coherent motion (in 1 out of 6 different motion directions) at a variable gap time, relative to presentation of the response target (go cue for the saccade response). The monkey was required to rapidly categorize the direction of motion under variable durations of coherent motion on each trial, referred to as the processing time (PT). The tachometric curve plots the relation between this PT and accuracy, and reveals how long the monkey needs to view the stimulus in order perform the task with reliable accuracy. Inactivating FEF caused a marked decrease in accuracy for both spatial configurations, for nearly all processing times and motion directions. Furthermore, FEF inactivation resulted in longer processing times and slower cognitive processing to reach peak performance across all conditions, as evidenced from the tachometric curves. In contrast, LIP inactivation impaired accuracy and produced longer processing times only when the motion stimulus, but not saccade target, was placed in the inactivated visual field. The deficits from LIP inactivation were stronger for more difficult stimuli (i.e. near the category boundary). Our results suggest a causal role for FEF across oculomotor and perceptual-cognitive components of rapid visual categorical decisions, whereas LIP appears to be more engaged in the cognitive evaluation of sensory stimuli rather than saccade plan during this task.

Title: Goal and context embeddings of the lateral prefrontal cortex during reinforcement learning

Authors: *Y. SUNG, S. LEE;
Bio and Brain engineering, Korea Advanced Inst. in Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Humans flexibly control their behavior to adapt to context changes in the environment. The inferior lateral prefrontal cortex (ilPFC) is known to guide goal-directed learning by choosing the optimal strategy for the given context. However, it is still unclear how the neural representations of goal and context reflect the context-dependent control in ilPFC. We investigated the neural embedding structure of goal and context during reinforcement learning and their effects on choice behavior. We performed multi-voxel pattern analysis on twenty participants' fMRI data collected with a sequential two-stage Markov decision task (Lee et al., 2014). Participants make two sequential choices to obtain a reward in the goal state. There are two types of contexts: goal condition (specific goal and flexible goal) and uncertainty condition (high uncertainty with state-transition probability (0.5, 0.5) and low uncertainty with probability (0.9, 0.1)). We estimated the representational dimensionality of neural embedding by averaging accuracies of all binary classifiers across the contexts and goal states (Bernardi et al., 2020). First, we found that the context dimensionality of the ilPFC is significantly higher than that of other brain areas, including the hippocampus, primary visual cortex, and ventral striatum (paired t-test, all pairwise comparison with $p<0.05$). To further explore the nature of the context embeddings, we subdivided the combination of contexts into two cases: linearly separable embedding, in which the goal and uncertainty are represented independently, and nonlinear mixed embedding, which represents their interactions. Unlike other brain areas, we found that the ilPFC represents both types of embeddings, demonstrating its capacity for multiplexed context representations. This nonlinearly multiplexed context representation might support ilPFC's flexible control in the complex environment. We also investigated the goal state embedding of brain regions. We found that the goal state representational dimensionality of the ilPFC is high (0.538, significantly higher than the chance level 0.5 with $p<1e-3$), comparable to that of the primary visual cortex (0.54). Notably, the ilPFC's goal state dimensionality is seemingly a unique predictor of task performance in terms of average reward (Pearson's correlation, $R=0.502$, $p<0.05$) and choice optimality ($R=0.641$, $p<0.01$). Our study elucidates the critical role of goal and context embeddings of the ilPFC in guiding goal-directed behavior.

Title: Neuronal encoding of ranked items in primate prefrontal cortex during different phases of transitive inference task

Authors: *S. RAMAWAT[1,2], V. MIONE[1], F. DI BELLO[1], P. PANI[1], S. FERRAINA[1], E. BRUNAMONTI[1];
[1]Dept. of Physiol. and Pharmacol., [2]PhD Program in Behavioral Neurosci., Sapienza Univ., Rome, Italy

Abstract: Problem solving based on deduction using logical reasoning is one of the aspects of intelligence in humans and non-human primates. Provided with the knowledge that A > B and B > C, the subject is able to infer that A > C. This ability to link the partially overlapping information and extend it to deduce a novel relationship is the basis of a Transitive Inference (TI) capability. Previous neurophysiological studies have described the pattern of neuronal activity from the Prefrontal Cortex being modulated while an abstract mental schema of ranked items is accessed during the inferential reasoning test phase. However, the question of how the neuronal encoding of the individual items subtending this representation is shaped by the learning of higher reciprocal relationships is relatively unexplored. In this study, we aimed to answer this question by investigating the single-neuron activity recorded from the dorsolateral PFC of 2 monkeys that learned the rank ordered series of items as (A>B>C>D>E>F) for solving TI problems. Each session was organized around two consequential Learning phases, where the relationship between the adjacent items (e.g. A>B, B>C) of the series were first learned separately and then intermingled, and a Test phase where inferential pairs were included. In each of the experimental sessions, we first searched for a signature of the acquisition of the mental schema in the monkey's performance during Inference. This was behaviorally assessed by observing a symbolic distance effect in each session, which characterizes the comparisons between items with greater rank difference as easier, than the ones with smaller rank differences, subtending a comparison between their positions on the mental schema. Then, we studied the neuronal activity of 80 neurons recorded in these sessions while the monkeys fixated each item of the series to define a tuning curve of activity of these neurons during the Test Phase. The tuning activity from the same neurons was then observed during the different Learning phases of the task to study if and how the changed with the acquisition of the items rank order. We observed that the progression of the task from Learning to Inference led to significantly different activity patterns in 50% of the studied neurons. A greater majority (43%) exhibited different tuning preferences for the series items, while only about 7% cells mirrored the previous tuning preferences but with different magnitudes of activity. These results emphasize the involvement of PFC neurons in the learning phases of the TI task by reorganization of rank ordered activity.

Title: Self-control signals in dorsolateral prefrontal cortex of monkeys during a multi-effector temptation task

Authors: *J. G. ELSEY[1,2], V. STUPHORN[2,3];
[1]Psychological and Brain Sci., [2]The Zanvyl Krieger Mind/Brain Inst., [3]Dept. of Neurosci., The Johns Hopkins Univ., Baltimore, MD

Abstract: Self-control is the ability to resist rewards that are tempting but lead to suboptimal or negative long-term outcomes. We developed a new temptation task that allows to identify states of low and high self-control. General self-control signals should be effector independent. To probe the generalizability of self-control signals, we trained a monkey on a temptation task where they were had to control either an eye or arm movement to indicate and maintain their choice.

To initiate a trial, the monkey fixated a central point and centered a joystick. The central point then changed into a horizontal or vertical bar cue indicating that the trial would require either an eye or an arm movement to indicate the preferred option. The eye- and arm-response trials were randomly interleaved. Following the cue fixation period, two annulus-shaped targets representing the smaller-sooner (SS) and larger-later (LL) options were presented. Each annulus had a colored section, whose length and color indicated the delay and amount of rewards, respectively. The monkeys made an eye or arm movement to one of the targets and maintained fixation/directional joystick position, until they received the indicated reward amount. On no-temptation trials, the unchosen target disappeared upon choice of either target. However, on temptation trials, the unchosen target did not disappear, and the monkeys were allowed to change their initial choice as long as the time of the chosen target did not run out. Since temptation trials were randomly interleaved and rare, the monkeys' initial choice functions were identical in both conditions and indicated their true preferences. Nevertheless, the monkeys sometimes switched targets in temptation trials. This typically involved a switch from an initial delayed LL target to an immediate SS target (LL-SS switch). The opposite switch (SS-LL switch) occurred almost never. These results indicate that an LL-SS switch is the result of a failure in resisting temptation of the immediate reward and not the correction of a mistake in the initial choice.

We found that monkeys were able to reliably switch between selecting options with either eye or

arm movements. Response times on arm movement trials were longer than eye movement trials. However, monkeys showed a greater willingness to delay reward on arm than on eye movement trials. This indicates that controlling eye position is more effortful than controlling arm position. To investigate the effector-dependence of the neural correlates of self-control, we will record single-unit activity from the dorsolateral prefrontal cortex while monkeys perform the multi-effector temptation task.

Title: Human and non-human primates show similar sampling and choice behavior during multi-attribute decision making

Authors: *Y.-P. YANG[1], A. SAMPSON[1], E. NIEBUR[1,2], V. STUPHORN[1,2];
[1]Mind/Brain Inst., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: In the real-world, we make many complex multi-attribute decisions that require the integration and comparison of multiple pieces of information. This complexity is thought to tax limited cognitive resources, since an agent can only pay attention to a limited set of information and then use it to dynamically construct preferences. Previous evidence supports the role of attention in constructing subjective value and guiding choice. However, the cognitive and neural processes that are at the heart of preference formation are still poorly understood. An animal model that allows the tracking of attention during the decision process is of critical importance. Here, we developed a novel multi-attribute decision-making task in both human and non-human primates. This task allows us to observe the focus of attention of subjects as they sequentially inspect the individual attributes (amount, probability) determining the value of reward options and select one of them. Two important aspects make it well suited to investigate dynamic preference formation of risky choices. First, our task is a free-viewing task. Thus, the subject's eye movements directly indicate which decision-related variable is attended, and in what order. Second, the information about the value of the two functionally different attributes is parametrically encoded using two different symbolic cues. The cue shape explicitly indicates the attribute types. We observed behavior in the task in both humans (n=34) and macaques (n=2). Monkeys choice behavior indicates that they understand the meaning of the attribute cues. They can integrate this information into a single subjective value estimate for each option and compare

the value of each option before choosing. Risk attitude of individual subjects can be explained by their relative weighing of the two attributes. On most trials, both humans and monkeys inspected all available information before making a choice, and first fully inspect one option, before inspecting the other. Late fixations are strongly correlated with choice. Our new attention-guided sequential sampling task will allow the study of option value computation and comparison in a primate model of multi-attribute choice.

Title: Direct representation of a Bayesian posterior in the prearcuate gyrus

Authors: *J. A. CHARLTON, R. L. T. GORIS;
Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: When sensory information is ambiguous, perceptual inference is guided by prior knowledge of statistical regularities of the environment, in accordance with Bayesian theory. The neural mechanisms that integrate sensory signals with context-specific priors likely reside in a network of association areas. However, the nature of the neural representation that supports Bayesian-like inference is not known. Ideal Bayesian decision-makers interpret the world on the basis of a posterior stimulus belief. There may exist neurons whose firing rate *directly* represents this statistic. Alternatively, Bayesian-like choice behavior may arise from an *indirect* neural representation of the posterior. To distinguish between these hypotheses, we used multi-electrode arrays to record neural population activity in the prearcuate gyrus (PAG) of a macaque monkey while the animal performed Bayesian-like perceptual inference in a 2-AFC discrimination task. The observer judged the orientation of a stimulus presented in the near-periphery and communicated its judgment by means of a saccadic eye movement towards one of two choice targets. The meaning of the response options was not derived from their spatial position (one was placed within the neurons' motor response field, the other on the opposite side of the fixation mark), but from a visual feature (one was oriented clockwise, the other counterclockwise), enabling us to distinguish the neural correlates of perceptual inference from those of action selection. The animal performed the task under two contexts, each associated with a different stimulus distribution, and under conditions of low and high stimulus uncertainty. His choice behavior exhibited the key signatures of Bayesian inference. To gain insight into the neural correlate of this behavior, we built a population decoder optimized to predict the monkey's perceptual choice and corresponding motor action. The resulting decision variable trajectories

exhibited an initial excursion along the perceptual dimension, followed by an excursion along the motor dimension. This suggests that choice formation takes place in an abstract perceptual space, and is then mapped onto a motor response. During the putative deliberation epoch, firing rate of individual PAG units appeared to directly represent a posterior stimulus estimate. Specifically, when stimulus uncertainty was low, firing rate only depended on stimulus orientation. But when stimulus uncertainty was high, firing rates were additionally modulated by task context. These results clarify the nature of the neural representation that supports Bayesian-like perceptual inference.

Title: Investigating prefrontal markers of action control and the effects of theta-burst deep brain stimulation in Parkinson's disease

Authors: *N. BENTLEY[1], Z. T. IRWIN[1], S. BLACK[1], A. ROLLER[1], C. L. GONZALEZ[2], K. M. VISSCHER[3], R. T. KNIGHT[4], B. L. GUTHRIE[1], H. C. WALKER[2];

Abstract: Dysfunction in the ability to control behavioral responses with changing environmental demands is a prominent feature in many neurodegenerative disorders such as Parkinson’s disease (PD). This dysfunction is associated with decreased local field potential (LFP) activity in brain areas underlying cognitive control. Our study aimed to investigate LFP changes in dorsolateral prefrontal cortex (DLPFC) during an action control task (Go/No-go). The task includes rest, a motor block consisting of simple button presses, and a cognitive block of 50% "No-go" trials. We investigated whether intermittent theta-burst deep brain stimulation (iTBS) is associated with increased theta power in the DLPFC and led to faster response times.We recorded LFPs from DLPFC using acute electrocorticography during awake deep brain stimulation surgery in PD (n=3) or essential tremor (n=2) participants. A 6-contact strip

electrode was inserted over DLPFC. We measured rest- and task-evoked LFP, then delivered iTBS, measuring changes in LFP and response times. Resting power spectra in both PD and ET participants demonstrated peaks both in the theta (3-8 Hz) and beta (13-30 Hz) range, with highest theta amplitudes in rostral and caudal DLPFC (Fig. 1A). iTBS increased cortical theta-power more when delivered in the globus pallidus interna in comparison to the subthalamic nucleus or to the ventral intermediate thalamic nucleus. Theta-power increased specifically during "No-go" trials requiring response inhibition for ET, but not PD, participants (Fig. 1B). However, delivery of iTBS enhanced theta-power in PD patients during "No-go" trials (Fig. 1B). Finally, we found a trend towards faster reaction times during task performance during iTBS compared to off stimulation. These exploratory preliminary results suggest that the Go/No-go task engages theta activity in the DLPFC, and iTBS may speed response times and increase theta power.

Title: Anodal tDCS over the dorsolateral prefrontal cortex modulates the balance between Pavlovian and instrumental systems in the punishment domain

Authors: *H. KIM[1], J. HUR[1], M. KWON[1], S. KIM[1], Y. ZOH[1,3], W.-Y. AHN[1,2];
[1]Dept. of Psychology, [2]Dept. of Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: Literature suggests that the brain has multiple systems for decision-making, and the balance between Pavlovian and instrumental systems is critical for optimal decision-making. Pavlovian bias refers to a coupling of action and valence, for example, approach toward reward-predictive stimuli and avoidance of punishment-predictive stimuli, which is often against instrumental response. Recent neuroimaging studies have identified brain regions implicated with Pavlovian bias including the dorsolateral prefrontal cortex (dlPFC). However, it is unclear whether Pavlovian bias can be influenced by an exogenous method such as brain stimulation. Here, we investigated whether up-regulating the dlPFC using transcranial current direct stimulation (tDCS) would modulate Pavlovian bias. In our double-blind study, participants were assigned to either the anodal or the sham group and received stimulation over the right dlPFC for three successive days. On the last day, participants performed a reinforcement learning task called the orthogonalized Go-Nogo task which allows us to assess participants' degree of Pavlovian bias in both reward and punishment domains. We used computational modeling and hierarchical Bayesian analysis to estimate model parameters reflecting latent cognitive processes. Several competing computational models were tested using model comparison methods and we found that a model with separate Pavlovian bias parameters for reward and punishment domains showed the best model fit. The results showed that (1) when using a behavioral index of Pavlovian bias, the anodal group showed significantly reduced Pavlovian bias in the punishment domain, but not in the reward domain compared to the sham group. (2) The Pavlovian bias parameter in the punishment domain from computational modeling was also lower in the anodal group compared to the sham group, which is consistent with behavioral findings. In addition, the anodal group showed a lower go bias parameter than the sham group. These results remained significant even after controlling for age and sex. Together, these findings suggest that anodal tDCS may lead to behavioral suppression or change in Pavlovian bias and shed light on the neural basis of Pavlovian bias.

Title: Electrophysiological evidence for alternative value encoding in macaque frontopolar cortex

Authors: *M. AINSWORTH[1], J. M. GALEAZZI[1], C. PEDREIRA[1], F. A. MANSOURI[2], M. J. BUCKLEY[1];
[1]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [2]Monash Univ., Melbourne, Australia

Abstract: Although the importance of prefrontal cortical regions in decision making is well established, the exact contribution of frontopolar cortex (FPC) has remained elusive. A number of recent studies have suggested that FPC is essential for representing the value of unchosen, alternative stimuli and rules with the cortex (Mansouri 2017). However, this hypothesis relies primarily or the neuroimaging in humans and combined behavioural (Boorman 2009) and lesion studies in non-human primates (NHPs) and there remains little electrophysiological evidence supporting the encoding of alternative/unchosen stimuli within the neuronal circuits in FPC.Here we use a combination of reinforcement learning (RL) models, local field potential recordings, and electrical micro-stimulation in two NHPs implanted chronically with Utah microelectrode arrays to explore local circuit activity in FPC whilst they performed a WCST analogue. In this task animals were required to match one of three targets with a sample stimuli. The correct target was determined by either shape or colour, on a block-by-block basis. To determine how animals learnt the correct rule we fit RL models to the animals choices. This modelling suggested that both animals attempted to estimate the value of both the current and the alternative rule throughout the task. Examination of LFP activity recorded from FPC revealed increased gamma frequency activity (60-120Hz) after animals made a choice, but not on presentation of sample stimuli or choice targets. This choice-aligned LFP activity corresponded both to whether animals received a reward, and to an RL derived value attached to the alternative rule. Electrical micro-stimulation of FPC did not impact the animals performance within a block. However it did decrease their ability to switch rules following a block change. These data directly link local circuit output from FPC, with the valuation of alternative choices and stimuli in decision making, and should motivate future research involving single unit recordings from FPC.

Title: Stimulating Visual Cortex Reactivates Latent Visual Working Memories

Authors: *Z. XIE[1], J. SAMAHA[2], N. S. ROSE[1];
[1]Dept. of Psychology, Univ. of Notre Dame, Notre Dame, IN; [2]Dept. of Psychology, Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: In this experiment we elucidate the neurocognitive processes that enable items to be held in working memory in different states of accessibility (actively- or passively-retained, or deleted). On each trial, healthy young-adult humans retained two line-orientations in WM, actively-retained the cued item and passively retained the uncued item until it was deleted when it was no longer relevant on the trial while delay-period transcranial magnetic stimulation (TMS) was applied to the retinotopically localized areas of visual cortex where the items were processed with simultaneously recorded EEG. Inverted encoding modeling (IEM) of the EEG data showed that TMS could reactivate both the actively- and passively-retained items, but TMS after the second retro-cue could no longer reactivate the item that was deleted. The findings are consistent with the sensorimotor recruitment hypothesis -- that features of items retained in WM are represented via “activity-silent” mechanisms in the sensory cortex.

Title: Dual-task walking in older adults - the influence of cognitive task constraints on task interference

Authors: *M. MACK[1], R. STOJAN[1,2], O. L. BOCK[3,2], C. VOELCKER-REHAGE[1,2];
[1]Univ. of Muenster, Münster, Germany; [2]Chemnitz Univ. of Technol., Chemnitz, Germany;
[3]German Sport Univ., Cologne, Germany

Abstract: Performing a cognitive task while walking typically leads to task interference. These dual-task effects (DTEs) are particularly pronounced in older adults and occur in either the walking task or the cognitive task, or both. However, it is unclear how constraints of the cognitive task affect DTEs. Therefore, this study investigated how DTEs of the walking and the cognitive task differ when response intervals are fixed (Stroop task) versus self-paced (Serial 3's). We expected lower cognitive DTEs but higher walking DTEs with fixed compared to self-paced response intervals. Data of 38 healthy older adults (age: 68.64 ±4.09; 20 females) were analyzed. Participants completed a virtual dual-task walking scenario on a motorized treadmill with a fixed walking speed of 1 m/s. The scenario comprised two different dual-tasks (Walking + Stroop, Walking + Serial 3's) and three different single tasks (Walking, Stroop, Serial 3's). All tasks were carried out in a pseudorandomized order (5 trials per task, 30 s per trial), that was identic for all participants. Outcomes were relative DTEs in % for walking, calculated for Step Cadence and Step Time Variability, and relative DTEs in % for cognition, calculated for Response Speed and Accuracy. All DTEs were analyzed by Bonferroni corrected two-sided t-tests, comparing DTEs to zero. Further, Bonferroni corrected dependent t-tests were conducted to compare DTEs for Stroop and Serial 3's. Significant DTEs emerged for Step Cadence in Walking + Stroop ($t = 6.48$, $p < .001$), and for Response Speed in Walking + Stroop ($t = -3.46$, $p = .001$) and in Walking + Serial 3's ($t = 12.67$, $p < .001$). DTEs for Step Cadence were significantly higher ($t = 8.52$, $p < .001$) and DTEs for Response Speed were significantly lower ($t = 11.78$, $p < .001$) for Walking + Stroop compared to Walking + Serial 3's. No significant task differences were found for Step Time Variability ($t = 1.81$, $p = .078$) and Accuracy ($t = 1.06$, $p = .298$). Results suggest that task interference depends on task pacing. A fixed presentation mode (Stroop), seems to shift task priority towards the cognitive task, if compared to self-paced presentation mode (Serial 3's). As low postural variability might facilitate the achievement of the cognitive task, Step Time Variability may be not affected.

Title: Significant influence of task-irrelevant stimuli on task performance

Authors: *A. MATANI;
Hiroshima Univ., Hiroshima, Japan

Abstract: The Stroop, Stroop-like, and Simon effects are conflict effects where the congruency between two factors in a stimulus modulates response performances to the stimulus (e.g., reaction time (RT) and correct answer ratio). When analyzing data by repeated measures analysis of variance (rANOVA), significant effects are often observed besides the conflict effect between two factors, e.g., the main effect and interactions (primings) including the task-relevant stimulus. We performed a Stroop-like experiment, in which the stimulus was a left-or-right moving left-or-right pointing triangle and the task was assigned to the moving or pointing direction. Let the condition (2 levels: left or right) of the pointing and moving directions in the current trial be denoted by Pnt and Mov, respectively and those in the previous trial by pnt and mov, respectively. When task was on Pnt, the Pnt-Mov Stroop and Pnt-mov priming (often called negative priming) effects were strongly observed in RT ($p < 0.001$, $N = 47$). It is reasonable that one cannot make decision of left or right of Pnt before resolving conflicts including Pnt. However, the Mov-mov priming effect was weak but significant ($p < 0.05$) although Mov and mov were totally task-irrelevant. It may be interesting but we do not identify the specific reason so far. Such a task-irrelevant influence is sometimes found in emotional priming experiments, in which an emotional cue is given first and then an unemotional task is presented, and the emotional processing slows RTs. As a first reason, the Mov-mov priming may be due to the same kind of phenomenon. Second, the rANOVA ('r' is not important here) may have multiple problems to apply such RT analyses. The rANOVA employed a generalized linear model (Pnt×Mov×pnt×mov = 2×2×2×2): RT = aMeanRT + bPnt + cMov + ⋯ + dPnt*Mov + ePnt*mov + fMov*mov + ⋯, meaning that each brain process (e.g., to Pnt*Mov and Pnt*Mov) run serially, not parallel at all, because of the additions. If parallel, only the slowest process determines the RT. It has another problem; the model does not express that the task is assigned to Pnt and does treat all terms equally. We eliminated the invalid trials (e.g., wrong responses) from the rANOVA and it might have been an implicit reflection of the task. The model may be valid if there is one left-and-right integrator has four ports accepting the left-or-right signals from Pnt, Mov, pnt, and mov without knowing each port connection (Mov, pnt, and mov are inhibited in advance for correct response). As another problem, if the Pnt-Mov Stroop and Pnt-mov priming has an interaction, the Mov-mov priming is possibly observed as an apparent, or confounding phenomenon because of Pnt*Mov*Pnt*mov = Mov*mov.

Title: Functional connectivity models track fluctuations in attention and working memory

Authors: *N. HAKIM[1], E. AWH[2], E. K. VOGEL[1], M. D. ROSENBERG[3];
[1]Univ. of Chicago, Chicago, IL; [2]Psychology, Univ. of Chicago Dept. of Radiology, Chicago, IL;
[3]Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: Attention and working memory are deeply intertwined constructs that fluctuate synchronously - when attention lapses, participants are less likely to hold information in working memory (deBettencourt et al., 2019). At the same time, however, there is growing evidence to suggest that these two processes are neurally dissociable (Hakim et al., 2019). Here, we used fMRI functional connectivity to further delineate the relationship between attention and working memory. To do this, we re-analyzed a previously published dataset in which 8 participants each performed 2-6 runs of a spatial attention task and a working memory precision task using the same stimuli (Sprague & Serences, 2013). We then applied two open source pre-trained functional connectivity models to predict performance in each of these tasks. For each participant, we calculated functional connectivity matrices within each task by concatenating trial-wise BOLD activity from correct and incorrect trials separately. First, we applied an attention-based model that was trained to predict individual differences in performance on a gradual-onset performance task (gradCPT) and has been shown to track within-subject fluctuations in sustained attention (Rosenberg et al., 2020). We found that strength in this sustained attention network during the spatial attention task distinguished participants' correct vs. incorrect attention task trials. However, sustained attention network strength during the working memory precision task did not distinguish high vs. low working memory precision task trials. Next, we applied a working memory-based model defined to predict individual differences in 2-back task performance (Avery et al., 2020). Interestingly, strength in this working memory network during the working memory task distinguished high vs. low working memory precision task trials. However, this working memory network did not predict attention task performance. These results suggest that there is a double dissociation between attention and working memory in these two task contexts, and they provide further evidence that attention and working memory processes are neutrally dissociable.

Title: Adult functional connectivity models differentially predict sustained attention and working memory in youth

Authors: *O. KARDAN[1], A. J. STIER[1], C. CARDENAS-INIGUEZ[1], J. C. PRUIN[1], K. E. SCHERTZ[1], Y. DENG[1], T. CHAMBERLAIN[1], W. J. MEREDITH[2], X. ZHANG[1], J. E. BOWMAN[1], T. LAKHTAKIA[1], L. TINDEL[1], E. AVERY[3], Q. LIN[3], K. YOO[3], M. M. CHUN[3], M. G. BERMAN[1], M. D. ROSENBERG[1];
[1]Univ. of Chicago, Chicago, IL; [2]UCLA, Los Angeles, CA; [3]Psychology, Yale Univ., New Haven, CT

Abstract: Sustained attention (SA) and working memory (WM) are central cognitive processes that vary between individuals and change over time. These abilities are impactful in development because of their consequences for life outcomes. Here, we characterize the functional brain architecture of SA and WM in children age 9-11 using models based on functional connectivity measured with functional magnetic resonance imaging. We analyzed data from the Adolescent Brain Cognitive Development (ABCD) Study dataset (*n*=1545) to ask whether connectome-based predictive models (CPMs) built to predict SA and WM in adults generalize to capture inter- and intra-individual differences in SA and WM task performance in youth.
We found that a predefined CPM of SA (Rosenberg et al., 2016) predicted individual differences (r=.18, p <.001) and block-to-block fluctuations (β=.07, p<.001) in children's performance on the 0-back task, an attentionally taxing low-WM-load task. A predefined CPM of WM (Avery et al., 2020), on the other hand, predicted individual differences (r=.14, p <.001) and block-to-block fluctuations (β=.04, p<.001) in performance on the 2-back task, an attentionally taxing high-WM-load task, in addition to the 0-back task (r=.15, p <.001).
We further assessed the degree to which the adult-defined models captured the functional architecture of SA and WM in youth in two ways. First, we compared the SA and WM models' predictive power to that of a CPM of general cognitive abilities defined in the ABCD sample itself. Although this sample-specific CPM outperformed the WM model for predicting 2-back performance, it did not outperform the SA model for predicting 0-back performance. Second, we tested whether the SA model showed worse predictive power in the ABCD sample that it did in the adult Human Connectome Project sample (HCP; *n*=754). We did not test the WM model because it was defined in HCP. We did not find evidence for reduced predictive power in youth relative to adults. Rather, the SA model showed comparable predictive power for inter- and intra-individual differences in 0-back task performance in the ABCD and HCP samples.
Finally, we evaluated the consequences of SA and working WM expression for long-term

memory in children and found that the WM model predicted children's later recognition memory for *n*-back task stimuli ($r = .12$, $p < .001$). Together these results demonstrate that functional connectivity models of SA and WM defined in adults generalize to youth. Whereas a network predicting SA specifically captures individual differences and fluctuations in attention in the developing brain, a network predicting WM model captures general aspects of memory and attention at this age.

Title: Connectome stability as a marker of cognitive performance

Authors: *A. CORRIVEAU[1], K. R. YOO[2], Y. KWON[3], M. M. CHUN[2], M. D. ROSENBERG[1]; [1]Psychology, Univ. of Chicago, Chicago, IL; [2]Psychology, Yale Univ., New Haven, CT; [3]Psychology, Yale Univ., East Haven, CT

Abstract: Although sustained attention and working memory are essential to daily life, individual abilities vary. Whole-brain fMRI functional connectivity (FC) is a useful tool for building brain-based markers of cognition and has been used to identify network models of sustained attention [1] and working memory [2]. Further, features of an individual's FC pattern, or connectome, may provide additional predictive utility for cognition. In particular, connectome stability, or the similarity of an individual's FC pattern across repeated fMRI runs, increases across development and is related to social function [3,4]. The current study investigates whether connectome stability predicts sustained attention and working memory, critical cognitive abilities, in adults.

We identified three independent datasets that included repeated fMRI runs of working memory and/or sustained attention tasks. Sustained attention was assessed with the gradual-onset continuous performance task (gradCPT) in Datasets 1 and 2 [1,5]. Dataset 1 (*n*=25) contained 3 gradCPT runs collected in the same scan session and Dataset 2 (*n*=94) included 2 gradCPT runs collected ~2 weeks apart. Dataset 3 included 316 participants from the Human Connectome

Project sample [6,7]. We assessed attention using performance on 0-back blocks of two *n*-back task runs collected in the same scan session. Working memory was measured in Dataset 2 as performance on a visual short term memory task and in Dataset 3 as performance on 2-back blocks of the *n*-back task. Datasets also included other cognitive tasks (DS 2&3), movie viewing (DS 2), and rest runs (DS 1,2&3). We defined run-specific FC patterns using a 268-node brain atlas [8]. Connectome stability was defined as the Pearson correlation between vectorized connectomes and was calculated for all pairs of fMRI runs within a dataset.
Connectome stability was correlated with sustained attention and working memory performance in all three datasets (partial r_s value range = .16-.41, $p = 1.2*10^{-4}$-.09). Relationships were specific to stability within sustained attention and working memory task runs, respectively, and relied on stability of the whole connectome rather than specific brain networks. Furthermore, connectome stability improved the generalizability of behavioral prediction from previously published sustained attention and working memory connectome-based models [1,2]. These results demonstrate connectome stability's utility as a marker of cognitive performance.
