Abstract: Traumatic brain injury (TBI) is defined as an impact to the head by an external force that causes brain alterations and subsequent long-term functional deficits. TBI contributes to an economic burden of $17 billion USD annually and is the leading cause of death and disability for individuals under 45. There are no current treatment(s) for repetitive and mild TBI (rmTBI), therefore, we sought to identify novel signaling molecules/pathways that could contribute to TBI. We employed a clinically relevant (non-surgical) closed-head impact model of engineered rotational acceleration (CHIMERA) that allows free rotation of the head upon impact generated from an air-compressed piston. *Our data suggest a novel role for PRMT7 (*protein arginine methyltransferases) *in the disease progression as indicated by the temporal decrease in protein expression post-rmTBI.* Our central hypothesis is that the loss of PRMT7, due to repetitive and mild TBI, mediates excitotoxicity, increases blood brain barrier (BBB) permeability, and contributes to behavioral deficits. PRMTs are novel targets that catalyze the methylation of arginine residues (a constitutive post-translational modification) involved in transcription, translation, receptor trafficking, and protein stability. There are currently 11 known PRMT isoforms (PRMT1-11), with PRMT7 gene deletion in human patients causing neurological deficits such as intellectual disability, microcephaly, and brachydactyly, along with hyperexcitability and impaired social behaviors in murine *in vivo* models. We measured PRMT7 protein levels post-rmTBI and found that it was decreased in the cortex (p=0.0005) and hippocampus (p=0.0309) 7-days post-rmTBI. Relative PRMT7 mRNA (via real-time qPCR) was enhanced in the cortex (0.040188) 1-day post-rmTBI. Using LC-MS, we measured excitatory neurotransmitters to suggest that glutamate was enhanced (P=0.05) in the hippocampus 3-day post-rmTBI. Tight junction proteins were decreased, such as JAMa (P=0.0023) and occluding

was modulated 1,3,7 days post-rmTBI. These findings were further supported by successively less evans blue dye 1,3 and 7 days post-rmTBI, altogether to suggest blood brain barrier permeability post-rmTBI. Finally, learning, working memory, and locomotor skills were significantly impaired as indicated by decreased alternation ratios (P=0.0271) via T-maze, novel object recognition (P=0.0041) and rotarod assessment (P=0.002103). PRMT7-related neurological deficits have been sparsely described in humans. Our current studies suggest a regulatory role of PRMT7 in TBI, which can also provide novel therapeutic insights into other neurodegenerative diseases.

Title: A distinct population of heterogeneously color tuned neurons in macaque visual cortex

Authors: *S. NIGAM[1], S. POJOGA[2], V. DRAGOI[3];
[1]McGovern Med. Sch., Houston, TX; [2]Univ. of Texas at Houston, Houston, TX; [3]Dept Neurobiol/Anat, Univ. of Texas at Houston Dept. of Neurobio. and Anat., Houston, TX

Abstract: Color constitutes an important property of the visual input to the brain. Color information in the natural environment is processed to guide behaviors such as food gathering, avoiding predators and social interactions that are crucial for the survival of higher vertebrates. An important characteristic of color information in natural scenes is the high degree of spatial diversity i.e., some patches in natural scenes contain a single color (homogeneous) whereas other patches contain multiple colors arranged close to each other. However, whether the receptive fields (RFs) of neurons in the visual cortex are adapted to this diversity in color features in the natural environment is unknown. We reasoned that for the visual cortex to construct an accurate representation of our environment, it should be able to differentiate between homogeneous and heterogeneous color patches. To test our hypothesis, we recorded neuronal populations in mid-level visual area V4 of awake macaques with chronically implanted Utah arrays while stimulating subfields (patches of size ~ 1º x 1º) within the RFs using equiluminant color stimuli (set of 16 colors). We discovered that in addition to neurons that preferred the same color at different spatial locations with their RFs (“homogeneous”), for a significant fraction of neurons,

color preference exhibited spatial variation within the RF ("heterogeneous"), with the most heterogeneous cells preferring up to an average of 6 unique colors. Heterogeneously tuned neurons exhibited higher latencies for peak color tuning compared to homogeneous neurons suggesting a possible role of local recurrent circuits in shaping tuning properties in addition to feedforward connections. Heterogeneous neurons produced significantly higher responses compared to homogeneous neurons when the entire RF was stimulated with a complex color patch containing the preferred colors of each sub-field. On the other hand, a uniform color stimulus covering the RF evoked weaker responses in the heterogeneous compared to homogeneous neurons. Our findings indicate a higher degree of complexity of color encoding mechanisms where homogeneous and heterogeneous neurons could together encode different aspects of chromatic information (uniform vs non-uniform) found in the natural environment.

Title: Modulation of visual contrast sensitivity with individualized transcranial random noise stimulation is time-dependent and specific for the primary visual cortex.

Authors: *W. POTOK[1], A. POST[1], M. BAECHINGER[1], N. WENDEROTH[1,2];
[1]Neural Control of Movement Laboratory, Dept. of Hlth. Sci. and Technology, ETH Zurich, Zurich, Switzerland; [2]Future Hlth. Technologies, Singapore-ETH Centre, Campus for Res. Excellence And Technological Enterprise (CREATE), Singapore, Singapore

Abstract: Transcranial random noise stimulation (tRNS) has been shown to significantly improve visual perception. Previous studies demonstrated that tRNS delivered over cortical areas acutely enhances visual contrast detection of stimuli when tRNS intensity is optimized for the individual. However, it is currently unknown whether tRNS-induced signal enhancement could be achieved within different neural substrates along the retino-cortical pathway and whether the beneficial effect of optimal tRNS intensities can be reproduced across sessions.
In 3 experimental sessions, we tested whether tRNS applied to the primary visual cortex (V1) and to the retina improves visual contrast detection (preregistration: https://osf.io/gacjw). We

first measured visual contrast detection threshold (VCT; N=24, 16 females) during tRNS delivery separately over V1 (no-tRNS, 0.75, 1, 1.5mA) and over the retina (no-tRNS, 0.1, 0.2, 0.3mA), determined the optimal tRNS intensities for each individual (ind-tRNS) and retested the effects of ind-tRNS within the sessions. We further investigated whether we could reproduce the ind-tRNS-induced modulation on a different session (N=18, 13 females). Finally, we tested whether the simultaneous application of ind-tRNS to the retina and V1 causes additive effects. We found that at the group level tRNS of 0.75mA decreases VCT compared to baseline when delivered to the V1 [$F_{(3, 69)}$=4.54, p=0.006]. Beneficial effects of ind-tRNS could be replicated when retested within the same experimental session [$t_{(23)}$=1.72, p=0.049] but not when retested in a separate session [$t_{(17)}$=-0.17, p=0.43]. Applying tRNS to retina did not cause a systematic reduction of VCT irrespective of whether the individually optimized intensity was considered [within $t_{(23)}$=1.05, p=0.15 and between sessions $t_{(17)}$=0.2, p=0.42] or not [$F_{(3, 69)}$=1.69, p=0.18]. We also did not observe consistent additive effects of V1 and retina stimulation [$t_{(17)}$=0.8, p=0.22].
Our findings demonstrate that V1 seems to be more sensitive than retina to tRNS-induced modulation of visual contrast processing. Moreover, the individual optimal tRNS intensity appears to vary across sessions.

Title: Contrast changes on-off dominance in human peripheral vision

Authors: *H. RAHIMI NASRABADI, V. MOORE-STOLL, J. JIN, M. W. DUL, J.-M. ALONSO;
Dept. of Biol. Sci., SUNY Optometry, New York, NY

Abstract: All animals with form vision process light and dark stimuli with ON and OFF visual pathways that originate at the first retinal synapse. Central vision is dominated by the OFF pathway in primates and carnivores and humans are also more accurate at searching dark than light targets with foveal vision. Unlike for central vision, the relative dominance of ON and OFF pathways in peripheral vision remains unclear, which complicates the interpretation of visual deficits measured with traditional white-on-white perimetry in diseases such as glaucoma. To investigate ON-OFF dominance in human peripheral vision, we developed an ONOFF perimetry

test that requires subjects to signal whether a target embedded in noise is presented on the right or left hemifield. The target can be light or dark, be at 90 different positions of the visual field between 5 and 30 degrees eccentricity, and can have eight different luminance contrasts (from 5 to 20%). The targets are presented on a head mounted display equipped with an eye tracker that is fitted to the subjects with the appropriate optical correction (HTC VIVE Pro, refresh rate: 90 Hz, maximum luminance: 110 cd/m^2). All subjects recruited so far were able to perform the task monocularly while fixating on a central dot of the display (a task trial was aborted when the eyes deviated 2.5-3.5 degrees from fixation). Preliminary results from 13 eyes of 13 subjects (age range: 24-61) indicate that dark stimuli are perceived more accurately than light stimuli in peripheral vision (error percentage: 14.2 ± 10.1 for darks versus 22.5 ± 9.3, for lights, $p < 0.0001$, Wilcoxon test), and a significant light-dark difference in accuracy can be also demonstrated at the highest 20-30 degrees eccentricity (error percentage: 18.9 ± 17.7 for darks versus 22.1 ± 17.1 for lights, $p=0.0002$, paired t-test, $p < 0.0001$ normality test). However, decreasing the contrast reduced and sometimes inverted the light-dark difference in accuracy, as would be predicted from the greater contrast-response gain of ON than OFF pathways. For example, reducing the contrast from 20% to 5% made the light-dark difference in accuracy four times smaller (light-dark difference in percent errors: 11.0 ± 3.3 versus 2.7 ± 5.6, $p < 0.0001$, Wilcoxon test) and, at the highest eccentricity (20-30 degrees), it shifted the difference from slightly higher accuracy for darks to slightly higher accuracy for lights (light-dark percentage of errors 4.4 ± 35.7 versus -1.4 ± 68.7, $p= 0.031$, Wilcoxon test). These preliminary results indicate that the OFF pathway dominates human central vision within the central 30 degrees but the OFF dominance decreases and can reverse to ON dominance at low contrast.

Title: Phase specific visual stimulation changes the contrast detection threshold in humans

Authors: *D. BRUEGGER, A. ZIMMERLI, M. ABEGG;
Dept. of Ophthalmology, Inselspital, Bern Univ. Hospital, Univ. of Bern, Bern, Switzerland

Abstract: Introduction: Whether visual perception is continuous or organized in discrete cycles is debated. Recent evidence shows rhythmic changes in perception related to cortical oscillations

at various frequencies. Such rhythmic variations in visual perception open the possibility to influence perceptual performance by using phase-locked visual stimulation.
Methods: We applied phase specific visual stimulation in 20 healthy human participants and measured the contrast detection performance. For this, we briefly (48ms) presented Gabor patches with stripes in one out of four possible orientations close to the detection threshold. We recorded an occipital to frontal EEG signal with active surface electrode. We extracted the theta (4-8 Hz) oscillation to present visual stimuli at one out of four predefined theta phase angles (0°, 90°, 180° 270°). Phase estimation and prediction for the phase-specific stimulation is achieved with a custom developed system based on fitting of sine waves to the raw EEG signal. We tested 18 blocks consisting out of 50 stimuli in each participant. The stimuli within one block were always targeted at the same phase angle. The order of the blocks was randomized and the blocks targeting the positive and negative peaks of the oscillation (90°, 270°) have been shown 5 times each vs 4 times for the blocks at the through (0°, 180°).
Results: We found a significantly higher rate of correctly detected contrast stimuli in trials in which the stimuli were targeted at the 0° phase target ($\chi 2$ Test; p= 0.002; Odds = 2.16 1.87, 1.90, 1.83). In addition, post-hoc modelling showed significant influences of stimulus phase, orientation of Gabor patch, response latency and prestimulus interval on the detection probability.
Conclusion: We provide evidence that contrast detection in humans varies with the phase of theta oscillations. Due to the prospective nature of our experiment with phase-specific stimulation, we can avoid potentially confounding effects associated with retrospective analysis such as artefacts originating from evoked potentials and post-hoc signal processing steps.

Title: Neuronal computations in macaque V2

Authors: *J. D. LIEBER[1], T. D. OLESKIW[2], E. P. SIMONCELLI[3], J. A. MOVSHON[2];
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY; [3]New York Univ. / Simons Fndn., New York, NY

Abstract: The perception of visual form relies on processing within a ventral stream of visual cortical areas. Neurons in the first stage of this pathway, in primary visual cortex (V1), respond selectively to visual stimuli presented at specific locations, orientations, and spatial scales (spatial frequencies). Neurons late in this pathway, in inferotemporal (IT) cortex, respond selectively to complex objects regardless of changes in their location, size, and context. However, the representations of intermediate stages is not well understood. For example, neurons in V2 (but not in V1) are more strongly driven by images containing naturalistic texture than images containing spectrally matched noise, but the computation underlying this selectivity has not been characterized. We mapped receptive fields in areas V1 and V2 using a novel stimulus made of superimposed patches of gratings differing in location, orientation, and spatial scale. Responses of macaque neurons were recorded using two experimental preparations: single units were measured using single electrodes in an awake, fixating animal, and population responses were measured with dense multi-site linear probes (Neuropixels) in anesthetized animals. We used a two-stage model to fit the data. First, we simulated early cortical processing with a large, convolutional bank of filters varying in position, orientation, and scale. The responses of these filters, suitably rectified and pooled, approximate the responses of simple and complex V1 units. Second, we computed a weighted sum of the outputs of these filters and rectified them. We fit the weights and the form of the rectification to maximize likelihood of individual neural responses, using stochastic gradient descent. As expected, V1 neurons had simple receptive field structures, with receptive fields tightly localized in space, orientation, and spatial frequency. In contrast, V2 neurons had larger receptive fields often containing both excitatory and suppressive fields, each localized in the four dimensions of V1 response (spatial position, orientation, spatial frequency). These neurons effectively compute a difference of functionally localized groups of V1 afferents that can represent image features such as spatial gradients of orientation (e.g. curvature) or size (e.g. foreshortening), as well as local texture properties. Simulations of the responses of V2 neuronal ensembles show that such structures are well-suited to produce selectivity for naturalistic image structure relative to spectrally matched noise.

Title: Diverse set of highly exciting images reveals novel spatially localized phase invariance in mouse primary visual cortex

Authors: *Z. DING[1], D. TRAN[1], E. COBOS[1], T. MUHAMMAD[1], S. CADENA[2], A. ECKER[3], A. TOLIAS[1];
[1]Baylor Col. of Med., Houston, TX; [2]Univ. of Tübingen, Tübingen, Germany; [3]Univ. of Göttingen, Göttingen, Germany

Abstract: In order to decipher the algorithm of perception, it is important to characterize neural tuning functions and identify the directions of maximal tuning and invariance to stimulus features. To this end, simple parametric stimuli are typically used, but they make strong assumptions about the stimulus features that neurons are selective and invariant to. Recently, the "inception loop" paradigm was developed which provides a systematic characterization of neural tuning with minimal assumptions. This paradigm combines large-scale neuronal recordings with deep learning models which are trained to predict the responses of neurons to arbitrary stimuli. These models can then be used as *in silico* avatars to perform a large number of experiments and analyses, including ones that are practically impossible to perform in the real brain due to the limited experimental time available and the large space of stimuli and behaviors that must be explored. Inception loops have been used to find the most exciting inputs of neurons (MEIs) in mouse primary visual cortex (V1). These stimuli were verified back *in vivo*. The MEIs exhibited complex spatial features deviating strikingly from the textbook Gabor-like optimal stimuli for V1, challenging the decades-old dogma of V1 representation. Here, our work extends these deep learning optimization methods to study neural tuning invariance. We introduce "diverse exciting inputs" (DEIs), a model-based approach where we synthesize a set of diverse highly activating images. We found that the DEIs of many neurons in mouse V1 exhibited a novel type of invariance. Specifically, these neurons responded invariantly to phase changes of textures localized in only a portion of their receptive field. We propose a local-phase-invariant model that explains single-neuron invariances in mouse V1 which are not accounted for by the traditional Hubel & Wiesel simple-complex cell model. Taken together, our work extends deep learning methods to study sensory processing and reveals a novel type of single-neuron invariance.

Title: Learning a model of shape selectivity in V4 cells reveals shape encoding mechanisms in the brain

Authors: *P. MEHRANI, J. K. TSOTSOS;
Electrical Engin. and Computer Sci., York Univ., Toronto, ON, Canada

Abstract: The mechanisms of local shape information transformation from V1 to more abstract representations in IT are unknown. Studying the selectivities in intermediate stages of transformation suggest plausible mechanisms. For example, findings in Macaque V4 responses suggest that these neurons are selective to convexities and concavities at a specific position in the stimulus (Pasupathy et al., 2001). Although such investigations reveal intermediate shape representations in the brain, they often do not suffice in capturing complex and long-range interactions within the receptive field due to imposing priors on tunings, e.g., fitting a single Gaussian to neuron responses. We propose a learning-based approach that eliminates the need for such strong priors. Specifically, we investigate shape representation in Macaque V4 cells and formulate shape tuning as a sparse coding problem according to previous findings of V4 neurons (Pasupathy et al., 2001). We emphasize that our goal is not to find a mapping from the stimulus to V4 responses but rather to study how V4 neurons combine responses of V2 neurons, in this case, curvature-selective V2 cells, to achieve their reported part-based selectivities. To this end, our proposed model takes responses of simulated curvature-selective V2 cells as input by combining two previously introduced hierarchical models 2DSIL (Rodríguez-Sánchez et al., 2012) and the RBO network (Mehrani et al., 2021). With simulated curvature signal as input, our algorithm learns a sparse mapping to V4 responses that reveals each Macaque V4 cell's tuning and the mechanism by which the tuning is achieved. Our results suggest that V4 cells combine shape parts from the full spatial extent of their receptive field with similar magnitudes of facilitatory and inhibitory contributions. Additionally, our approach suggests a mechanistic model on how object-centered representations in V4 are achieved, providing a better understanding of shape encoding mechanisms in the brain.
Acknowledgments: We perform our experiments on V4 cell responses that were provided by Dr. Anitha Pasupathy for which we are grateful.

Title: High-resolution human recordings demonstrate diverse coding of the shape and category of visual objects

Authors: *V. BOUGOU, M. VANHOYLAND, A. BERTRAND, P. JANSSEN, H. OP DE BEECK, T. THEYS;
KU Leuven, Leuven, Belgium

Abstract: Recent noninvasive imaging studies have revealed multidimensional representations of objects and categories in the human brain. However, it is unknown which tuning curves at the level of single neurons and local neuronal clusters underlie these macroscopic representations at the population level. Invasive human recordings can capture both single-cell activity and the coherent activity of cell assemblies (LFPs - Local Field Potentials), and are therefore a very suitable and high-resolution approach to investigate selectivity for multiple dimensions such as shape and category in different brain areas. We used a combination of invasive recordings in the meso (high-density ECoG, SEEG) and micro (96-channel microelectrode Utah-array) scale in 3 neurosurgical patients, covering a wide range of brain areas (occipital, parietal and frontal cortex). We presented a set of 54 images in which shape and category were dissociated (Bracci et al., 2016). High-gamma power (60-120 Hz) per electrode was computed and averaged over time for 80-300 ms after stimulus onset. Per pair of conditions, we correlated the spatial multi-channel response pattern per grid/microarray. The resulting matrices were converted into dissimilarity matrices (1 - correlation) and were correlated with behavioral dissimilarity matrices for the shape and category dimensions. These multi-channel analyses confirmed previous fMRI data suggesting significant shape-based representations in the Lateral Occipital Complex. In contrast, the activity patterns measured over parietal cortex did not correlate with either of the two dimensions. However, with a further analysis of individual visually-responsive electrodes (two-way ANOVA), we observed significant selectivity for both shape and category. Single electrodes in LOC and in parietal cortex were either category-selective (2.06 % in LOC and 20 % in parietal cortex), shape-selective (13.4 % in LOC and 20 % in parietal cortex), or had interactions between shape and category (11.34 % in LOC). These results show that multichannel analysis offers a general description of the neural representation in an area but fails to capture the underlying neuronal selectivity and its diversity. Thus, invasive recordings in human visual cortex can provide a more detailed view on the shape and category representations, which complements data obtained with functional imaging.

Title: Cognitive spatial representations in posterior parietal cortex

Authors: *J. GAMEZ[1], T. AFLALO[1], K. KADLEC[1], C. GUAN[1], K. W. PEJSA[1], E. ROSARIO[2], N. POURATIAN[3], R. A. ANDERSEN[1];
[1]Div. of Biol. and Biol. Engineering, Caltech, Pasadena, CA; [2]Res. Inst., Casa Colina Hosp. and Centers For Healthcare, Pomona, CA; [3]UCLA, Los angeles, CA

Abstract: The posterior parietal cortex (PPC) has a privileged position in the flow of information through the brain, having access to data from sensory, motor, and association cortical areas. Different regions within PPC transform sensory information into body-centered egocentric representations using gain modulation by eye, head, and limb positions. However, the spatial position of an object can also be described in allocentric coordinates, coding the position with respect to visual landmarks in the visual scene. This representation requires a cognitive process to transform visual information that is initially coded as a retinal position into an abstract spatial representation. It is not known if the neural populations in human PPC and the motor cortex (MC) have access to this cognitive spatial information during visuomotor transformations and action planning and execution. To address this question, we recorded from the cortex of one human tetraplegic participant (N1), implanted with two 96-channel Blackrock arrays, one in PPC and one in MC, as part of a brain-machine interface clinical trial. The recordings were done while N1 performed a task where he had to decide if an object was to the left or the right of his gaze (egocentric condition) or a landmark (allocentric condition). N1 provided his answers using saccades or attempted thumb movements in a staged paradigm to dissociate the spatial decision from this motor response. We found that PPC can code the spatial position of the target object in both egocentric and allocentric coordinates. A population level across-condition analysis showed that egocentric and allocentric reference frames are coded in different neural subspaces with no positive correlation. This spatial coding was distinct during the decision and the motor planning/execution phases. Furthermore, this representation was independent of the effector used to execute the motor action. In contrast, we found no spatial cognitive coding in MC. In one variation of the allocentric condition, we switched the landmark and the object identities. This variation allowed us to establish that different landmarks share a common allocentric spatial representation, and further established that spatial encoding could not be attributed to low-level visual features of the task. These results suggest that PPC contains a neural population representation of cognitive spatial variables in addition to the egocentric variables, and that these cognitive variables are encoded independent of motor planning and execution.

Title: Decoding unfamiliar visual shapes from brain activity in human visual cortices

Authors: F. GUIBERT[1], E. PIRONDINI[3,4], ***D. BAVELIER**[2], I. ALTARELLI[5]; [1]Univ. of Geneva, Geneva, Switzerland; [2]Univ. of Geneva, Geneve, Switzerland; [3]Ecole Polytechnique Fedearale De Lausanne, Geneve, Switzerland; [4]Dept. of physical medicine and rehabilitation, university of Pittsburgh, Pittsburgh, PA; [5]Univ. de Paris, LaPsyDÉ, CNRS,, Paris, France

Abstract: While decoding visual objects from functional brain activity when they fall into known categories, such as faces or places, is well established in humans, the multivariate decoding of novel, unfamiliar shapes is less studied. In order to fill this gap in knowledge, in the current work we presented six unknown shapes drawn from an old, now unused alphabet, to naive adult participants (N=17), performing a 1-back task. In a separate paradigm, the same participants also performed a 1-back task, yet on six distinct well-known visual objects (faces, body parts, places, words, numbers, manufactured objects). Participants performed similarly across these two types of stimuli. Indeed, high accuracy and fast reaction times in both paradigms indicated that participants could discriminate the six novel shapes even without knowing them *a priori*. We then built a multi-voxel pattern analysis (MVPA) decoder in the native space of each participant and for each experimental paradigm, using activation maps extracted from a trial-based general linear model. Our decoder considered the activation maps as input samples and performed supervised classification of the maps with respect to each of the 6 classes. Generalization error was assessed through nested cross validation, with the inner loop selecting the optimal hyper parameters by Tree-Parzen Estimator algorithm. By these means, we were able to decode both familiar (mean ± SEM over subjects: 60% ± 3%) and unfamiliar (46%. ± 3%) shapes with high accuracy, significantly above chance level. As expected, decoder performances were greater for well-known visual objects compared to unknown shapes. Our MVPA procedure started from the entire brain without prior biases towards specific brain regions. To ensure that relevant regions were selected and used by the decoder over the entire population, we computed probability maps, describing the stability of a given cluster of voxels to

perform classification across the whole population. Population-wide probability maps showed that all relevant classification clusters fell into visual areas. Our results demonstrate that novel, unfamiliar shapes can be accurately distinguished in the human visual cortex.

Title: High-density neuronal recording reveals functional domains for shape selectivity across laminae in macaque V4

Authors: *T. NAMIMA[1], P. ZAMARASHKINA[1], N. OWEN[2], A. K. PASUPATHY[1];
[1]Biol. Structure, [2]Univ. Washington, Seattle, WA

Abstract: Previous studies have demonstrated that many neurons in macaque visual area V4 exhibit responses that are selective for the shape of an object; such shape selectivity can be well-described on the basis of the curvature of the object boundary at a specific angular position (APC model; Pasupathy and Connor, 2011). Recent studies using 2 photon calcium imaging and intrinsic optical imaging have reported functional domains for curvature encoding in the superficial layers of macaque V4 (Jiang et al., 2021; Hu et al., 2021). In our present work, we investigated the functional organization along the cortical depth and in high spatial resolution. We performed neuronal recordings in two fixating macaque monkeys as visual shape stimuli (120 two-dimensional shapes) were flashed (200 ms) separated by blank periods (200 ms) in random order, in the near-periphery. Each day we studied tens of well-isolated, nearby neurons using a Neuropixels probe. To quantify the similarity in shape preference for nearby neurons, we constructed a similarity matrix by computing the Pearson's correlation coefficient (r) between the shape responses for all pairs of simultaneously recorded neurons, Across many penetrations in both animals, we saw clear clusters of 5 or more neurons with high similarity in shape preference. These clusters were evident in both the deep and superficial layers. We next asked if the similarity in responses between neurons within the shape domains was based on similar tuning for boundary curvature. We fit an APC model for the responses of each neuron and compared the goodness of fit (GoF:correlation between observed and predicted responses) of the model for neurons within and outside the shape domains. We also compared the similarity matrices for each recording session based on responses predicted by the APC model versus

observed responses. Overall, we found that neurons within shape domains were better fit by the APC model and the responses predicted based on the APC model were also highly similar for neurons within the shape domains. Our preliminary results imply that V4 includes clusters of neurons with similar shape preferences and these neurons within shape domains may play a specialized role in the processing of boundary curvature.

Title: Evidence of Object Based Warping in Retinotopic Cortex

Authors: *G. GURARIY[1], T. J. VICKERY[2], A. S. GREENBERG[1];
[1]Dept. of Biomed. Engin., Med. Col. of Wisconsin, Milwaukee, WI; [2]Dept. of Psychology, Univ. of Delaware, Newark, DE

Abstract: Objects are central to perception and arise from the organization of incoming visual signals. Although visual objects unfold over space, research has demonstrated that objects are capable of "warping" the very space over which they unfold - an effect known as Object-Based Warping (OBW; Vickery & Chun, 2010). This effect can be observed when two items placed within the contours of an object are perceived to be further apart relative to equidistant items viewed in the absence of an object. While numerous studies have quantified this effect behaviorally, the neural correlates of OBW have yet to be explored. In this study, we utilized fMRI to investigate the neural representation of OBW in human retinotopic cortex. First, a distance adjustment task performed outside the scanner was used to replicate previous findings and measure the strength of OBW in 22 participants. Next, a subset of these participants (n=7) who exhibited a behavioral effect of substantial magnitude completed an fMRI study in which they performed a letter discrimination task. The task included 3 conditions: (1) two letters enclosed within an object, (2) two letters without an object at the same spatial distances as in condition 1, and (3) two letters without an object at the "warped" distances (calculated from behavioral data). Separate localizers were used to identify retinotopic regions V1-V3 in addition to a spatial position localizer which was used to map retinotopic coordinates corresponding to the

spatial region in which the letters (real & warped) appeared. To identify the presence of warping, an MVPA classifier was trained on the two no-object conditions (conditions 2 & 3) and tested on the object-present condition (condition 1). Evidence of OBW was found in V1 & V2d, demonstrated by condition 1 (object present) being classified significantly above chance at matching condition 3 (object absent - warped). This warping effect in early visual cortex is likely driven by feedback from higher-level regions and suggests a fundamental change to visual perception caused by the presence of a simple object.

Title: Understanding natural motion encoding in retinal populations

Authors: *S. WANG[1], O. MARRE[2], M. J. BERRY, II[3], S. E. PALMER[1];
[1]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Inst. de la Vision, Paris, France; [3]Princeton Univ., Princeton, NJ

Abstract: Over evolutionary time, the retina has been engineered to encode components of complex, natural environments that are most relevant for the organism. These components are essential for driving effective behavior. In this study, we use data from the salamander retina and a selection of different natural videos to train a deep neural network. We use this framework to explore and visualize what natural motion features are encoded in this early sensory neural population.

Because of sensory delays, whether finding prey, searching for a mate, or escaping from predators, animals must extrapolate natural motion trajectories to make effective interactions with their environment. We focus on the dynamic features of motion in natural scenes, to build on and differentiate from previous work that has mostly focussed on static features in the natural environment. This allows us to ask if the retinal encoding of natural motion reuses static representations.

We build a generative encoder-decoder network combining a cascade reconstruction network and variational autoencoders to reconstruct natural motion from the retinal population spike trains. Using this generative model, we observe that both the natural motion and static scene exhibit low dimensional structures. The low-dimensional structure of natural motion is distinct from the structure encoded by static scenes. Sampling from the low-dimensional structure of

natural motion, we identify features specific for natural motion of different directions (e.g., left to right, up to down), without scene details. Combining these motion features with specific scenes, we are able to synthesize naturalistic dynamic textures that mimic natural movies observed by the retina.

Title: Visual proportion sense in untrained deep neural networks

Authors: *H. LEE[1], W. CHOI[1], S.-B. PAIK[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Visual proportion sense - the ability to estimate proportion between two visual magnitudes - is an essential cognitive function in animal survival (i.e. hunting, foraging, and mating), and it is widely observed in animals, humans, and even in infants without any prior knowledge (Jacob, 2012). Neurophysiological and neuroimaging experiments have found that several neurons in rhesus monkeys and voxels in adult humans show selective response to certain visual proportions (Vallentin, 2008; Jacob, 2009). However, how proportion sense can emerge without any learning is elusive, even in theoretical studies. A recent study showed that visual number sense can arise by hierarchical random feedforward connections in an untrained deep neural network (DNN), without any training (Kim, 2021). From this idea, we hypothesized that visual proportion sense can emerge in an untrained network without any training. We designed sets of images consisting of white (W) and black (B) dots, which represent specific proportions (i.e. W/(W+B) = 1/6), and fed these images into a randomly initialized DNN, AlexNet. In the designed images, the total number of dots can vary to 6, 12, or 18 dots, while they can represent the same proportion (i.e. W:(W+B) = 1:6, 2:12, and 3:18 dots = 1/6). In the deep layers of untrained AlexNet (Conv 3-5), we found proportion units in which responses are tuned to specific proportions invariant to the total number of dots in the images. These proportion units selectively and robustly respond to the preferred proportion, when the total number of dots varied from 2 to 30 (invariant to absolute number), and dot size, shape, or total area varied

(invariant to low-level image feature). Next, to examine the emergence mechanism of the proportion units, we tested two possible hypotheses - proportion units selectively receive input from 1) units that encode proportion in a specific total number of dots (i.e. 1/6 = W1 and B5, W2 and B10 ⋯) and 2) units that encode white/black increasing tendency - from the previous layers. From the weight analysis of the untrained network, we found that proportion units in layer 5 receive stronger inputs from white/black increment encoding units than number-specific proportion units in layer 4. In addition, ablation of increment units significantly diminished the emergence of the proportion units, whereas ablating number-specific units did not affect the emergence of the proportion units, supporting the latter hypothesis. In summary, our results suggest that visual proportion sense may arise without training and provide insights into how innate cognitive functions can emerge from a hierarchical network structure.

Title: Development of natural scene processing in primary visual cortex continues after the critical period for ocular dominance plasticity closes

Authors: *T. FUCHS, B. B. JEON, S. J. KUHLMAN;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The development of the visual system is known to be shaped by early-life experience. We recently demonstrated, using decoding methods, that mice raised without visual experience (dark-reared) have a deficit in natural scene processing (Kowalewski et al. 2021, Current Biology). In standard-reared mice, natural scene discriminability increases by 75% between the ages of 4 to 6 weeks. This increase in decoding accuracy is accompanied by a shift in neuronal preference towards natural scenes. Natural scene discriminability, therefore, continues to improve past the peak of the critical period for ocular dominance plasticity at postnatal day (p) 28. It is unknown whether there is a sensitive period for natural scene selectivity to mature, or whether continued visual experience is required for the maintenance of complex scene responses after their development. Here we hypothesize that natural scene representation in primary visual cortex (V1) becomes sparser with visual experience, and that visual experience continues to play a role in shaping natural scene responsiveness past the critical period for ocular dominance plasticity, well into adulthood. A sequential progression in which neurons first prefer simple

stimuli such as oriented bars of light (grating stimuli) prior to the development of selectivity for complex features may help ensure that the spatial organization of receptive fields is maintained as the system becomes refined to represent salient visual cues. We performed 2-photon calcium imaging of excitatory neurons in V1 in awake standard-reared mice at 4, 6 and 8 weeks of age and in an experimental group housed in darkness specifically between 4-6 weeks of age. Mice were presented with two classes of visual stimuli, 60 natural scenes containing complex features, and simple grating stimuli, spanning a range of spatial frequencies. We observed a shift in preference for complex features from 4 to 6 weeks, as well as 6 to 8 weeks in standard-reared mice. Visual deprivation specifically from p28 to p42 interfered with the full development of this preference shift and impaired natural scene decoding accuracy (Mann-Whitney U test, p=0.004). Our results indicate that in contrast to other aspects of visual processing, natural scene response maturation continues beyond the close of the critical periods for ocular dominance plasticity and binocular matching.

Title: Feature representation in the Frontal Eye Field

Authors: *A. SHAHAMATI[1,2], E. REZAYAT[1], J. NOROOZI[1,3], M.-R. A. DEHAQANI[1,4]; [1]Sch. of Cognitive Sci., Inst. for Res. in Fundamental Sci., Tehran, Iran, Islamic Republic of; [2]Dept. of Brain and Cognitive Sci., Royan Inst. for Stem Cell Biol. and Technol., Tehran, Iran, Islamic Republic of; [3]Physiology,, Tarbiat Modares Univ., Tehran, Iran, Islamic Republic of; [4]Sch. of Electrical and Computer Engin., Univ. of Tehran, Tehran, Iran, Islamic Republic of

Abstract: Simultaneous expansion of the visual system and the Prefrontal Cortex in primate's brain can serve as evolution's clue on the link between these two. Given this idea, Prefrontal Cortex may be more involved in mapping the visual world into an internal representation than previously assumed. Frontal Eye Field is a visuomotor area of the Prefrontal Cortex. Since the discovery of FEF, much of the focus has been on its role in producing eye movements. Albeit, FEF's unique position of being extensively interconnected with visual cortical areas in both the dorsal and the ventral streams, along with its role in higher cognitive functions, makes it a probable candidate of an area with the ability to integrate the 'what' and the 'where' visual information. Given this supposition, we recorded the neural activity of FEF neurons of monkeys while they performed a Rapid Serial Visual Presentation task (RSVP). We calculated identity and category information of FEF neurons using a combination of encoding and decoding

methods. Our results suggest FEF neurons are in fact involved in representing both basic and complex features of objects.

Title: Orientation anisotropies in macaque visual areas V1 and V4

Authors: *C. FANG, X. CAI, H. D. LU;
State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China

Abstract: In ferrets and cats, a larger number of neurons in V1 are devoted to cardinal (horizontal and vertical) orientations than those to the oblique orientations ("cardinal bias"). Other studies reported more neurons tended to prefer orientations connecting their RFs and the point of foveal fixation, a phenomenon called "radial bias". However, electrophysiological results from macaque monkey visual cortex were controversial on this aspect. Both isotropic and anisotropic orientation distributions have been reported. It is also unclear whether different visual areas along the visual processing have different orientation anisotropies. To investigate this, we analyzed orientation maps in a large set of existing V1 and V4 intrinsic signal optical imaging (ISOI) data. The stimuli we used were drifting gratings (1-1.5 c/deg) with 4 orientations, fully covered the visual field of the imaged cortex. Pixel-wise responses to 4 orientations were vector summed to obtain the preferred orientation for that pixel. For each case, the distribution of preferred orientation was calculated based on all V1 or V4 pixels in the images. We used a "cardinal + radial" combined model to fit the distributions and evaluated the amplitudes of the orientation anisotropies. We found that both V1 and V4 exhibited significant orientation anisotropies. However, their overrepresented orientations were very different: in V1, both cardinal and radial orientations were overrepresented, while in V4, only cardinal bias was presented. These findings suggest that different cortical areas have evolved to emphasize different features that suitable for their functional purposes, a factor that needs to be considered when efforts are made to explain the relationships between the visual environment and the cortical representation, and between the cortical representation and visual perception.

Title: The Novelty Response induced by visual stimuli in the weakly electric fish Gymnotus omarorum

Authors: *A. CAMARGO[1], A. A. CAPUTI[1], P. A. AGUILERA[2];
[1]Ministerio Educación y Cultgura, IIBCE, Montevideo, Uruguay; [2]Lab. de Plasticidad Sináptica, Ministerio de Educación y Cultura, IIBCE, Montevideo, Uruguay

Abstract: Introduction. Electric fish of the family gymnotidae use self generated electric signals to explore their environment. Due to the uncoupling between fish movements and electrogenesis this is a paradigmatic reafferent sense. In *Gymnotus omarorum* electric organ discharge intervals (EODi) have a skew distribution with a small coefficient of variation. The skewness is due to novel sensory stimuli ('novelty response' NR) triggered by changes in reafferent electric images and also by mechanical, acoustical and electrical exafferent stimuli. These last improve, by means of increasing the sampling rate, the resolution of the main but short range sense of these fish. Here we characterize the effects of light on the EOD rate of *G. omarorum* particularly focusing on photically evoked NRs. **Methods.** In 15 fish EODi were recorded (after 1 hour of adaptation) using a differential amplifier and a Schmitt trigger circuit in a sound isolated cabin in which light was controlled. At noon and midnight (in each fish) the effects of continuous illumination and ligth-dark duty cicles were compared using non parametric statistics.**Results**. We found that: 1) during the day, the median, coefficient of variation and skewness of the EODi was smaller than during the night in both light and dark conditions; 2) continuos illumination decreased the EODi both at noon and midnight; 3) when studied using a 50-50% duty cycle with a 30 second period, on and off transition cause NRs that follow different time courses. Illumination onset were characterized by a decrease of the interval during the next 10 to 20 EODi. Darkening caused a slow decrease of the interval lasting 8 times more than lightening but reaching the same EODi reduction, both responses were followed by a slow relaxation lasting more than 100 EODi; no differences were found between day and night; 4) the amplitude of these NRs increased with the magnitud of the illumination increment; 5) no differences in the magnitude of the NRs were found when the duty stimulation cycle were altered in order to cause shorter or longer stimulation periods in steps of 100 EODs (approximately,4

s).**Conclusions**. Our data indicate variations of the visual sensitivity during the circadian cycle. On and off light transitions cause NRs with typical time courses, graded with the amplitude, but independent of the duty cycle of the stimuli and without day versus night difference suggesting a "wake up" effect.

Title: If a mouse can learn it, maybe a marmoset can, too: cross-species translation of the International Brain Laboratory task

Authors: *P. CHEN[1], D. ROWLEY[1], T. CZUBA[1], C. BADILLO[1], I. NAUHAUS[2], L. K. CORMACK[1], A. C. HUK[1];
[1]Univ. Of Texas At Austin Inst. For Neurosci., Austin, TX; [2]Inst. For Neurosci., Univ. Of Texas At Austin, Austin, TX

Abstract: The marmosets are quickly becoming a leading animal model in neuroscience for studying primate sensory processing and circuitry due to their small size and lissencephalic brains. However, there has been limited success with marmosets training for psychophysics, as they have not responded as well as other primates to strictly regimented tasks. The International Brain Laboratory (IBL) recently introduced a perceptual decision-making task that provides standardized and reproducible measurements of behavior in mice. Here we show that marmosets can learn an adapted version of the task in a controlled head fixed setting, though they require species-specific modifications.
In the IBL training task a Gabor patch with a randomized contrast is presented either on the left or right side of the center of gaze. The animal's task is to turn a wheel to move the visual stimulus from the periphery into the center. After a correct trial, a liquid reward is given, whereas a noise burst and extended intertrial interval follow an incorrect trial. We redesigned the steering-wheel chair used in the IBL task to suit the marmoset, scaling to body size and reorienting them to stand in the chair while holding the wheel.
Two common marmosets (callithrix jacchus) were able to learn the task at full and 50% contrast in only 3 or 4 consecutive training sessions. For habituation, the wheel was manually turned to help the marmosets associate the wheel's rotation with the motion of the stimulus, instead of passively viewing the stimulus jump to the center as in the mice task. A typical training session

was shorter with fewer completed trials and more trial timeouts than a mouse training session. Unlike mice, their performance did not drop when the contrast was lowered to 25%. The task was adapted to include more contrast levels below 6% to fully characterise their task performance.
The most immediate advantage to using this task is the cross-species comparisons that can be made by translating a widely used rodent behaviour task into the primate. These comparisons are key for understanding the degree of relevance that rodent literature has to the primate brain. This head-fixed task is also perfectly suited for use in conjunction with imaging and electrophysiological techniques. Finally, this task will serve as the initial primary training for more sophisticated psychophysical and cognitive tasks in projects to come and ultimately give us key insights into the processing of task-related signals.

Title: The effect of visual feedback and transcranial direct current stimulation (tDCS) on accuracy of ankle motor control

Authors: *M. CUMMINGS, A. DOSHI, F. IHMOUD, L. SHAH, S. MADHAVAN; Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Transcranial direct current stimulation (tDCS), a non-invasive neuromodulatory tool, has been shown to upregulate corticomotor pathways and improve motor learning and function in healthy individuals and those with stroke. Previous studies in adults with no neurological disorders have shown that the variability in ankle motor control is greater in conditions with no visual feedback than with visual feedback. In this study, our objective was to explore if application of tDCS over the primary lower limb motor cortex can enhance proprioceptive feedback and improve accuracy in motor control caused by the absence of visual feedback. We hypothesized that the accuracy of ankle motor control will decrease with lesser visual feedback, and that tDCS application will enhance accuracy in ankle motor control as visual feedback declines. Accuracy was examined by asking participants to perform ankle plantarflexion and dorsiflexion movements to match a computer-generated target sine wave using a custom-built ankle tracking device. The study was divided into two sessions, conducted a week apart, one with visual feedback (VF) and one with visual feedback and tDCS (VF-tDCS). Each session was divided into two blocks containing 3 trials of 4 randomized visual feedback

settings each. The visual feedback settings were: 1) 100% visual feedback: full visual feedback of the ankle position and target, 2) 50% visual feedback: visual feedback of the ankle position for the complete duration of the trial and target for half the time, 3) 0% visual feedback: visual feedback of the ankle position but not the target, and 4) no visual feedback: participants blindfolded with no visual feedback. During the VF-tDCS session, the first block included the application of 1 mA of tDCS for 20 mins. Accuracy was determined as the difference between ankle position and target, measured as the root mean square error, normalized to each participant's range of motion. Preliminary data from six healthy controls (25 participants to be collected) showed that accuracy of the ankle motor control task decreased with a decrease in visual feedback. Accuracy was 92% at 100%VF, 70% at 50%-VF, 62% at 0%-VF, and 61% for no-VF. During 100%, 50% and 0% VF-tDCS conditions, accuracy was demonstrated a trend to be higher than VF only. Accuracy was 93% at 100%VF-tDCS, 76% at 50%VF-tDCS, 65% at 0%VF-tDCS, and 60% at noVF-tDCS. Based on our preliminary results, tDCS may have the potential to improve accuracy of ankle motor control especially when visual feedback is not available. This could have implications in stroke populations where a decline in ankle proprioception maybe enhanced with neuromodulation using tDCS.

Title: M1 V1 - alpha/beta oscillations reflect task performance and movement variability during dynamic isometric pinch task

Authors: *C. HAN[1], L. D. ABRAHAM[2], M. MCMANIS[5], D. M. SCHNYER[3], J. S. SULZER[4], P. FERRARI[6,7,3];
[1]Biomed. engineering, [2]Kinesiology and Hlth. Educ., [3]Psychology Dept., [4]Mechanical Engin., Univ. of Texas at Austin, Austin, TX; [5]Dell Children's Med. Ctr. of Central Texas in Austin, Austin, TX; [6]Pediatric Neurosciences, Helen DeVos Children's Hosp., Grand Rapids, MI; [7]Col. of Human Med., Michigan State Univ., Grand Rapids, MI

Abstract: Chungmin Han, Larry Abraham, David Schnyer, Mark McManis, James Sulzer, Paul Ferrari
Title: M1 V1 - alpha/beta oscillations reflect task performance and movement variability during dynamic isometric pinch task
Visuomotor control for precision pinch and grasp relies on an extensive cortical network for

which research has traditionally focused on frontal and parietal regions subserving executive and visuomotor integration functions, respectively. However, evidence suggests that cortical oscillations within the primary motor and visual cortices can reflect both low and high-level functions. Here we used MEG (MEGIN Oy, Ltd.) to non-invasively measure dynamic oscillatory activity in V1 and M1 to investigate their contribution to performance in an isometric pinch force task. A custom MEG-compatible sensor measured forefinger and thumb forces separately, which controlled the position of a cursor on the screen. The task required subjects to control finger forces normalized to <20% of maximum voluntary contraction (MVC) at increasing and decreasing magnitudes as they tracked a visual target along a 45-degree line. In an 'Independent' condition, forefinger and thumb forces were mapped to the cursor's x and y positions, respectively, in full 2D space. A 'Coupled' task was also performed where the cursor position was constrained along the diagonal task trajectory. A total of 14 subjects (7 females; mean 25.8 yrs) performed 120 trials of each condition. Cortical source activity was analyzed using a beamformer inverse solution using the Matlab toolbox Brainwave. As expected, subjects performed better for the coupled vs the independent condition (RMSE, $p<0.05$). However, force variability was greater in the coupled vs independent condition, creating a dissociation between motor output and visual feedback. We observed strong event-related beta-band desynchronization during the task, with transient beta-rebound synchrony during a change of movement trajectory in both motor and visual cortices. Visual alpha did not show a corresponding transient rebound during trajectory changes, indicating the visual cortex was mapping movement within a motor (beta) oscillation. Furthermore, an analysis of covariation across trials showed that for both M1 and V1, alpha band reflects fluctuations of visual feedback in real-time during the task ($F(1,14)=7.8$, $p=0.015$), while beta band is associated with the level of movement control to achieve high accuracy ($F(1,14)=4.8$, $p=0.047$). Results suggest that cortical oscillations in both M1 and V1 can dissociate task and movement parameters during dynamic pinch tasks and that they may share a common beta network for visuomotor control.

Title: Brain correlates of visuomotor activation due to conscious and unconscious visual perception

Authors: *A. I. TRIGGIANI, S.-J. LEE, M. HALLETT;
Human Motor Control Section, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Subjectively, we have a sense that consciousness has a causal role in our voluntary movements. We do what we have decided to do. However, there is no formal proof that consciousness is causal. By using backwardly masked stimuli in a choice reaction time experiment, subjects made similar movements when they believed the movement was voluntary and when they believed it was a mistake. We explored the brain activity in these two situations.Fifteen healthy adults participated in a variation of a classic backward-masking task with electroencephalographic (EEG) recording. They had to press a button using the right or the left hand, according to an arrow on the screen. Arrows were presented at time S1, 50 ms later at time S2, or both times. When there were two arrows, the first was masked by the second, congruent or incongruent. When incongruent, they might respond to S1 or S2.When responding to S1 but seeing S2, they should believe that it was a mistake, as verified in a separate series of trials after the main experiment.Responses are to S1 for the situation of S1 alone, S1 masked and congruent, and S1 masked, incongruent, but with S1 response. In the first two, the experience is that it is a voluntary response. In the third situation, the experience is that the movement is not in accord with the consciousness of the stimulus, and it is a mistake. Indeed, in this last situation, the EEG confirms the subjectivity of the mistake with a manifestation of error-related negativity (ERN) followed by error-related positivity (ERP).The EEG showed a different cortical activation in all three situations, but, at a parietal level, the electrical activity in response to S1 alone was like S1 masked by a congruent S2. The parietal cortical activity related to the response to S1 in the incongruent condition was different from the other responses to S1. In the incongruent condition, despite similar primary sensory activation, the parietal EEG showed differences when the subject responded to S1 or S2 ($p<0.001$). The former was faster and more persistent, and the latter was higher, but slower and shorter.Results suggest that whether S1 is visible or masked in the congruent condition, the person sees and responds to S1. When S1 is masked in the incongruent condition, it is wiped out before being consciously perceived and replaced by S2. In this case, the S1 motor response is already released. This incompatibility of the motor response and the consciousness is revealed by the ERN/ERP and the behavioral test. Different processing of unseen stimuli seems to lead to the same motor outputs. Relating the brain activity to conscious experience will help answer the question of a causal role of consciousness in the choice of movement.

Title: Terrain complexity and the relationship between gaze and locomotion

Authors: *T. D. WIRTH, S. E. REINHART, R. L. HUYNH, J. S. MATTHIS;
Northeastern Univ., Boston, MA

Abstract: Successful human locomotion over complex terrain relies on interaction between the visual and motor systems. Investigations into recently accumulated datasets of visuo-locomotor behavior in natural environments (Matthis, Yates, & Hayhoe, 2018) demonstrates that the relationship between gaze and foot placement is tied to the complexity of the terrain (e.g. walking across flat ground vs a rocky creek bed). However, because these were quasi-observational experiments in a natural environment, it is unclear which aspects of the terrain were driving the relationship between gaze and locomotion. Examination of how the environment forms synergetic relationships between the visual and locomotor systems is critical in developing a basic-science understanding of visuo-locomotor behavior. Here, we present a newly developed paradigm which allows parametric control over an Augmented Reality Projected Groundplane (ARPG ~2x10m) stimulus, synchronized with full body kinematic motion capture (Qualisys) while binocular gaze data from Pupil Labs was spatiotemporally integrated via post-hoc calibration. Using eye tracking and full body motion capture, we will reconstruct the gaze-ground intersection to find where participants are looking at any given moment. In this experiment, participants (N=5) engage in a stepping stone task where they cross the 10m ARPG while stepping on only target Landolt C's and avoiding distractor O's as well as empty space. We manipulate the visual difficulty of the task by changing the similarity between the C's and O's (6mm vs. 36mm sized C-gap), and we manipulate the mechanical difficulty of the task by changing the ratio of presented targets to distractors (3:1, 1:1 or1:3). Each trial was repeated 20 times for each of the 6 conditions, resulting in 120 trials and 1600 steps per participant. Each condition was presented in randomized blocked order. With this new paradigm, we take our first step towards understanding how visual and mechanical terrain complexities interact to drive the connection between gaze and foot placement during locomotion over natural terrain.

Title: An education-friendly tutorial for visuomotor experiments

Authors: *N. AGHAMOHAMMADI, M. DEMASI, A. ANAND, J. L. PATTON;
Univ. of Illinios, Chicago, Chicago, IL

Abstract: Targeted reaching experimentation is the bread and butter of motor control research, where subjects are typically asked to move the handle of a manipulandum or a robot, allowing analysis of error statistics, variability, adaptation, or other aspects. Despite their widespread use in research, they are not conducive to classroom education as they usually require sophisticated, expensive, and specialty tools such as robots. Such costly hardware dependence restricts widespread adoption and accessibility. Here we describe a proposed educational tool for neuroscience and biomedical engineering classrooms and laboratories. This paper presents a step-by-step visual-rotation adaptation reaching tutorial using open-access code, any computer, and any mouse or pointing device, and the freely accessible Unity® game-engine. By the end of the tutorial, the student will know how to set up a complete visuomotor adaptation experiment that demonstrates neuroplasticity in a hand-eye coordination task. Our work performed on this tool resulted in real evidence of motor learning, with significant after-effects of adaptation. This fundamental building block can be expanded to other experiments and lends itself well to online education, rehabilitation, and computational neuroscience.

Title: Relationship Between Design Parameters of Head-Up Display and Human Visual Information Processing

Authors: *N. YAMADA, K. UEDA, S. TAKADA, M. NAKAO;
Univ. of Tokyo, Tokyo, Japan

Abstract: A head-up display (HUD) is a device that uses the windshield of a vehicle or other mobility device as a screen to display augmented reality images in the traffic environment. This is a type of driver-assistance technology and is expected to contribute to road traffic safety. To design a HUD that allows drivers to safely view images while driving, it is necessary to understand the visual information processing that occurs when humans view images. Visual information processing can be divided into three processes: "visual input" to input images from the eyes to the brain, "cognitive judgment" to understand the content of the images, and "motor output" to execute the actions directed by the images. In this study, we focused on two HUD design parameters, namely the optical image projection method and the image display distance, and investigated the effects of these two parameters on the three processes of visual information processing. Optical image projection methods involve real image projections or imaginary image projections. In the former, the screen was set at the same distance as the image, and in the latter, the screen was set at a closer distance than the image. There were two levels of distance-displaying images: 5 m and 10 m. In the experiment, the HUD image was sometimes displayed while a driving simulator was displayed 20 m away, and the participants answered which of the two patterns the image shape belonged to using two buttons on the steering wheel during driving. For the "visual input," the time required for the eye movement when viewing the HUD image was evaluated via eye movement measurement, and for the "cognitive judgment," the peak latency of P300 when understanding the shape of the HUD image was evaluated by electroencephalogram (EEG) measurement. In addition, the time taken for all the processes including the "motor output" was evaluated by the reaction time of the button press. Participants were divided into two groups: a younger group consisting of men in their 20s and an older group consisting of men in their 40s and 50s. In the younger group, there was no difference in the time required for each process of visual information processing for any of the HUD design parameters; however, in the older group, the time required for visual information processing was

prolonged when the projection method was the imaginary projection. In this presentation, we will discuss and report this difference based on the details of the gaze measurement and EEG data.

Title: Visual circuits modulating aggressive behavior in mice

Authors: *M. WAN[1], M. ARANDA[2], T. M. SCHMIDT[3];
[2]Dept. of Neurobio., [3]Neurobio., [1]Northwestern Univ., Evanston, IL

Abstract: VISUAL CIRCUITS MODULATING AGGRESSIVE BEHAVIOR IN MICE*Mingyu Wan, Marcos L. Aranda, Tiffany M. SchmidtDepartment of Neurobiology, Northwestern University, Evanston, IL*Animals must interact across a range of situations, some of which may lead to social interactions,and others which may lead to aggressive interactions. However, the role of the visual system inmodulating such interactions is not well understood. Intrinsically photosensitive retinal ganglioncells (ipRGCs) express the photopigment melanopsin (encoded by the Opn4 gene) and detectlight directly in absence of rods and cones. Brn3b-positive ipRGCs innervate brain areas involvedin social and aggressive behaviors, suggesting ipRGCs may modulate these types of behavior.The goal of this work was to identify the role of Brn3b-positive ipRGCs in social and aggressivebehaviors. To do this, we used the Resident-Intruder Aggression Test combined with deeplearning to compare social and aggressive behaviors in mice where Brn3b is conditionally deletedspecifically in ipRGCs ($Opn4^{Cre/+}$ $Brn3b^{cKO/cKO}$; referred to as Brn3bcKO). Surprisingly, weobserved a significant increase in aggressive behavior in Brn3bcKO mice compared to controllittermates, but no differences in social behavior. To identify the brain regions via which ipRGCsmay modulate aggression, we next measured expression of the immediate early gene c-Fosfollowing the Resident-Intruder Aggression Test and found greater c-Fos densities in the Dorsal-Medial Hypothalamus(DMH)the Lateral Hypothalamic Area (LHA), the medial amygdala(MEA),and the Basolateral Amygdala(BLA). Viral labeling of ipRGC axons showed that ipRGCs innervateboth the LHA and MEA, suggesting that these regions are candidates for modulation ofaggressive behaviors. Additionally, we observed a significant correlation between c-Fos densityin LHA with aggressive behaviors, suggesting an ipRGC-LHA circuit may modulate aggressivebehaviors. In order to test the sufficiency of LHA-projecting ipRGCs to modulate aggression levels,we chemo genetically excited LHA-projecting ipRGCs in $Opn4^{Cre/+}$ mice. We found that excitationof LHA-

projecting ipRGCs increased the duration of aggressive behaviors. These results suggestthe ipRGC-LHA circuit modulates aggression in mice.

Title: Trial-to-trial variability of multi motor unit activity accounts for worse endpoint control at low force levels

Authors: *S. DELMAS[1], Y. CHOI[1], B. YACOUBI KEYHANI[1], E. A. CHRISTOU[1,2]; [1]Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL; [2]Neurol., Norman Fixel Inst. of Neurolog. Disorders, Univ. of Florida, Gainesville, FL

Abstract: A robust observation in human motor control experiments is that the endpoint control of pre-planned (open loop) contractions is worse at low force levels relative to moderate or high force levels. Despite that the first observations originated in 1892, the underlying neuromuscular control that explains such robust behavioral differences remains unknown. Here, we use the abduction of the index finger, an experimental paradigm that requires control of a single muscle contraction (first dorsal interosseous; FDI), to study the multiple motor unit discharge characteristics that underlie this phenomenon. We recruited 15 young adults who participated in two distinct experiments that used goal-directed pre-planned contractions with the index finger. For both experiments, we quantified endpoint control as the relative endpoint error and variability in force and time and characterized the activity of multiple motor units in the FDI. For each contraction we summated the active motor units and quantified the following across 100 trials: 1) The average of the mean and coefficient of variation (CV) of the discharge rate (DR). 2) The trial-to-trial variability (CV) of the mean and coefficient of variation (CV) of the discharge rate (DR). 3) The average power from 3-8, 8-13, 13-33, and 33-60 Hz. 4) The trial-to-trial variability of power from 3-8, 8-13, 13-33, and 33-60 Hz. In the first experiment, participants aimed to match a force target either at 10% or 40% MVC while attempting to reverse their peak force at 160 ms. The greater force and time endpoint error at 10% relative to 40% MVC associated with greater force and time endpoint variability ($R2 = 0.34$, $p = 0.01$). The increased force ($R2 = 0.34$, $p = 0.01$) and time ($R2 = 0.23$, $p = 0.04$) endpoint variability at 10% relative to 40% associated only with increased trial-to-trial variability of the CV DR, which related to an increase in the variability from 13-33 Hz ($R2 = 0.56$, $p < 0.01$) and 33-60 Hz ($R2 = 0.53$, $p <$

0.01). In the second experiment, we examined if changing the speed of the contraction altered endpoint control and multi motor unit discharge characteristics. Thus, participants aimed to match a 40% MVC force target at either 160 or 280 ms. We found that the endpoint control and motor unit discharge characteristics were similar between the two contraction speeds. In summary, we provide novel findings showing that the worse endpoint control at low force levels relates to an inability to consistently repeat the motor unit discharge across trials.

Title: Motor unit firing rate trajectories in agonist muscles during elbow extension movements

Authors: *E. A. KIRK, C. L. RICE;
Western Univ., London, ON, Canada

Abstract: Voluntary movements ultimately are controlled by skeletal muscle contractions that create force in response to neural inputs from the spinal cord or brainstem. These inputs originate from lower motor neuron discharges that synapse onto innervated muscle fibres, defined as a motor unit (MU). Despite extensive experimental evidence during sustained isometric contractions, how the MU firing rate trajectory controls movement remains elusive. Our purpose was to measure MU firings rates as a function of time comparing firing rate trajectories of MU trains during sustained isometric contractions and elbow extension movements. In awake human participants, single MU activity was recorded by intramuscular electromyography from the anconeus (n = 15) and lateral head of the triceps brachii (n = 6) muscles during elbow extension contractions at various intensities, up to maximum efforts. From single MU trains, the change of firing rate was measured as a function of contraction time course using simple linear regression and was adjusted based on firing rate variance explained by elbow extension torque. For comparisons between contraction conditions, MU trains were unpaired. We hypothesized that MU firing rates would have greater changes (increase or decrease) during elbow extension movements that have greater effects of muscle shortening, as compared to sustained isometric contractions. Altogether, 42 MU trains during sustained isometric contractions (fixed 90 deg) and 222 MU trains during elbow extension movements (120 deg range of motion) were

measured. During increasing torque of isometric contractions, the firing rate trajectory was positive in 88% of measured MU trains. In contrast, the firing rate trajectory was significantly different (likelihood ratio test, chi-squared = 32±9.5; $p < 0.001$) and negative in 88% of measured MU trains during elbow extension movements at different targeted velocities. Through correlation analysis, the magnitude of the decreasing firing rate trajectory was related to both the targeted velocity (rho = -0.43, $p < 0.01$) and the MU recruitment threshold of related torque ($r = -0.35$, $p < 0.01$), that were different than during isometric contractions. These findings show that neural drive to the shortening muscle during voluntary movements decreases with contraction time course, suggesting a different pattern of motor command as compared to sustained isometric contraction. Title: Firing rate responses of human motor units during muscle potentiation

Authors: *A. M. ZERO, E. A. KIRK, C. L. RICE;
Univ. of Western Ontario, London, ON, Canada

Abstract: Post-activation potentiation (PAP) is the acute enhancement of submaximal contractile properties following a short duration high intensity contraction. During this enhanced contractile state (PAP) submaximal MUFRs are depressed, but the mechanisms or relationship for this response is unknown. Persistent inward currents (PICs) are long-lasting depolarizing intrinsic currents of the motoneuron and contribute to the net excitatory synaptic input of the motoneuron pool directly altering motor unit (MU) firing rate (FR) patterns. During small increments of voluntary isometric torque (proxy of increasing extrinsic synaptic input) MUs exhibit initial FR acceleration followed by saturation demonstrating non-linear responses to linear torque increases. PICs amplify synaptic input up to ~fivefold and thus during graded isometric contractions MUFRs will briefly accelerate following recruitment and then saturate. If there is a minimal PIC response or intrinsic synaptic amplification MUFRs will increase linearly. The purpose was to explore and compare the occurrence of MUFR saturation during isometric ramp contractions when the target muscle is either potentiated (PAP) or non-potentiated (control). We hypothesized that with PAP, MUFRs will be lower and will increase linearly, but under control conditions will briefly accelerate and then saturate. During dorsiflexion, graded

isometric ramp contractions up to 10% of maximal voluntary contraction (MVC) occurred over 10 seconds, with single MU potentials followed using two pairs of bipolar fine-wire electrodes inserted into the tibialis anterior muscle. The control condition consisted of only slow ramp contractions from rest, whereas the PAP condition was induced by a 5s ramp to MVC followed by a 5s hold, that was immediately followed by slow ramp contractions. To characterize the firing rate trajectory, each MUFR was fit to competing functions of linear regression and a negative exponential (i.e. saturation) in response to isometric torque (Fuglevand et al. 2015). From the 5 MUs obtained so far from 3 participants there was a significant decrease of 13% ($p<0.05$) in MUFRs during PAP (11.5 ± 2.7 Hz) compared to control (13 Hz ± 2.9 Hz). During the control condition MUs were better fit to the exponential (saturation) function (5/5; $p<0.05$), but under the PAP condition the same MUs were better fit to the linear function (5/5; $p<0.05$). These initial results indicate a smaller PIC or intrinsic motoneuron amplification response during PAP may contribute to the decrease of MUFRs. Supported by NSERC

Title: Neural representation of hindlimb muscle synergies in the mouse spinal cord revealed by spike-triggered averages of optogenetically elicited electromyographic activities

Authors: *B. HE[1], P. SALMAS[1], J. ZHANG[2], X. DUAN[3], V. C.-K. CHEUNG[1,4];
[1]The Chinese Univ. of Hong Kong, Hong Kong, China; [2]The James Franck Inst., Chicago, IL; [3]Col. of Future Technol., Peking, China; [4]The Chinese Univ. of Hong Kong and Kunming Inst. of Zoology of The Chinese Acad. of Sci., Hong Kong, China

Abstract: Movement execution requires the motor system to coordinate a large number of neuro-musculoskeletal elements. To simplify motor control, it has been proposed that spinal interneurons are organized into functional motor modules which activate different muscles concurrently as muscle synergies, and are recruited with distinct temporal activation profiles. Though previous studies using electrical micro-stimulation of the spinal cord delivered during electromyographic (EMG) and neural recordings have found that the spinal premotor interneurons underlie the muscle synergies, less is known about the specific interneuronal types that contribute to their organization. Here, we use optogenetics to selectively stimulate excitatory spinal interneurons in the anesthetized Thy1-ChR2 transgenic mice while simultaneously

recording intramuscular EMG (6 hindlimb muscles) and neural spike trains of spinal interneurons. Neural activities were recorded using soft carbon nanotube (CNT) electrodes. Since their shapes are not rigid, CNT electrodes do not require any holder for mechanical support at the recording sites, thus leaving the exposed spinal cord surface free of obstacles. This in turn allowed us to stimulate the lumbosacral spinal cord comprehensively by moving the laser in steps of 200-μm increment along the spinal surface. Using spike-triggered averages of EMG, the post-spike effect of a spinal interneuron on the recorded muscles was quantified as a muscle field. We found that the muscle fields of the recorded interneurons matched the muscle synergies extracted from EMG by nonnegative matrix factorization; the temporal activities of the interneurons also correlated highly with the synergies' activation coefficients. We argue that during locomotion, the hindlimb muscles are activated not randomly, but through recruitment of the muscle synergies with their temporal activities modified by the spinal interneurons. Furthermore, different synergies may result from different combinations of interneurons with distinct muscle fields. Nevertheless, the synergies' activation coefficients may be specified by a few specific interneurons responsible for precise temporal control of the muscle synergies.

Title: Stimulated disruption of cortical or spinal activity during voluntary movement preparation

Authors: *A. D. PAISH[1], E. A. KIRK[1], C. L. RICE[1,2];
[1]Sch. of Kinesiology, Fac. of Hlth. Sci., [2]Dept. of Anat. and Cell Biology, Schulich Sch. of Med. and Dent., The Univ. of Western Ontario, London, ON, Canada

Abstract: Motor planning involves complex interactions of neural pathways to execute muscle contractions. In humans, transcranial magnetic stimulation (TMS) and cervicomedullary evoked potentials (CMEPs) are techniques used to investigate the neural contributions from supraspinal (cortical) and spinal portions, respectively. Moreover, these techniques can also be used to disrupt the timing of voluntary motor outputs, as prior studies have shown that supraspinal disruption using TMS results in delayed movement onset, while movement kinematics (i.e., torque, velocity and position) are otherwise unhindered. However, pre-movement disruption at

the spinal level (i.e., CMEP), or supraspinal levels (i.e., TMS) during maximal voluntary efforts have not been tested. Thusly, we assessed the electromyographical (EMG) and kinematic responses throughout reaction based elbow extension movements, with and without suprathreshold TMS or CMEP delivered during the preparatory time of voluntary movement. We hypothesized that a single TMS pulse to the primary motor cortex will both delay reaction time and decrease movement kinematic potency during maximal voluntary efforts, whereas, evoked CMEPs at the spinal level will have minimal effect. In five participants, muscle activity was recorded through surface and intramuscular EMG electrodes from the anconeus, triceps brachii and biceps brachii muscles. Before a visual go-cue, the contraction condition was randomized between submaximal and maximal elbow extension movements in an arm dynamometer. Prior to EMG activity, one of three stimulation conditions was randomly executed: TMS, CMEP or control (no stimulation). Each condition was repeated at least three times per participant. We found that the reaction time (triceps brachii EMG onset) was significantly increased ($\bar{x}\approx$107ms; +48%) with TMS compared to control, whereas the CMEP reduced the reaction time ($\bar{x}\approx$50ms; -18%). Peak torque and velocity, as well as, time to peak torque, velocity, and position were significantly lower with TMS (10%, 6%, 9%, 11%, and 6%, respectively), whereas the time to peak torque and velocity were quickened (11% and 6%, respectively) with a CMEP compared to control. These results indicate an inability to fully recover motor execution following cortical disruption (TMS) during maximal voluntary elbow extension movements. Yet, disruption at the spinal cord (CMEP), and presumably the motor unit pool, quickened movement outcomes.

Abstract: The diversity of voluntary movement originates from control mechanisms in the central nervous system (CNS). Previous studies have suggested that the CNS generates movement by translating motor intentions into commands for a small number of motor output units called muscle synergies that activate muscle groups involved in different behaviors. However, physiological evidence for the existence of muscle synergies in humans is lacking, and thus synergy-based movement generation has not been broadly accepted. Here, we aim to provide evidence to support the existence of lower-limb muscle synergies in the human CNS by applying focal, noninvasive transcranial magnetic stimulation (TMS) to the primary motor cortex (M1). Surface electromyographic signals (EMGs) were recorded from 16 lower-limb and trunk muscles of 3 healthy subjects during multiple voluntary locomotor tasks, and during the neuro-navigated TMS stimulations which were delivered with a double cone coil applied over the subject's scalp along with a grid corresponding to the leg region of M1. Muscle synergies were extracted from the behavioral EMGs and TMS-derived motor evoked potentials using nonnegative matrix factorization. The TMS-derived muscle synergies were then matched to the behavioral synergies. For each TMS synergy, its representation over M1 was reconstructed by mapping its activities to the spatial locations of the stimulated M1 loci. The blood-oxygen-level-dependent signals during motor imagery of locomotor tasks were also acquired through functional magnetic resonance imaging to build an activity map that could be compared with the muscle-synergy representation map from TMS. We found that across all subjects, 9 of 16 behavioral muscle synergies could be well matched to the TMS-derived synergies elicited from the same subject (scalar product >0.8). The topographic representations of different TMS-derived synergies overlapped substantially with each other over M1. Our result demonstrates that it is possible to access and map out muscle synergies with TMS, thereby revealing how muscle synergies for locomotion may be encoded in M1. The unmatched behavioral synergies may arise from spinal circuits. Our data provide direct evidence for the existence of at least a subset of locomotor muscle synergies in humans.

Title: Fatigue-related changes in intermuscular coherence of rotator cuff and deltoid muscles

Authors: *X. YU[1], L. HAMMOND[2], H. ZHU[2], Z. WANG[3], L. GRIFFIN[4];
[1]Kinesiology and Hlth. Educ., Univ. of Texas, Austin, Austin, TX; [2]Kinesiology and Hlth. Educ., The Univ. of Texas at Austin, Austin, TX; [3]Physiol., Northwestern Univ., Chicago, IL; [4]Kinesiol & Hlth. Edu, Univ. Texas Austin, Austin, TX

Abstract: Maintaining shoulder joint stability requires coordination of the rotator cuff and deltoid muscles, neuromuscular fatigue may change these coordination patterns. EMG coherence between two muscles indicates that they have a common descending input, this common drive is important because it maintains joint stability. However, it has not been investigated during fatigue. Eight healthy individuals (mean age ± SD = 19.13 ± 0.99 years, 6 females, 2 males) participated in this study. Surface EMG activity was recorded from the anterior deltoid (AD), middle deltoid (MD), supraspinatus (SS) and infraspinatus (IS). Participants performed an isometric fatiguing contraction at 30° scaption at 25% maximal voluntary contraction (MVC) until endurance limit (the time at which the force deviated from the target by ± 5% MVC). Performance time was divided into 3 phases: initial, middle and final. As fatigue progressed, the EMG RMS amplitude of all muscles significantly increased, slopes of EMG median frequency of all muscles were significantly less than zero, with AD exhibiting the highest fatigue rate (-0.33 ± 0.02 %/phase, p=0.00). EMG coherence of each muscle pair (SS-IS, SS-AD, SS-MD, IS-AD, IS-MD) in the common drive (0-5 Hz), physiological force tremor (5-12 Hz), beta band (15-35 Hz), Piper band (35-60 Hz) and gamma band (60-90 Hz) in each fatigue phase were measured. A Friedman's and Wilcoxon signed-rank test revealed that coherence of SS-MD significantly increased with fatigue in all frequency bands except for the common drive band. SS-AD coherence exhibited a significant increase in the tremor and beta bands. Coherence of IS-MD and IS-AD also significantly increased in the tremor, beta and Piper bands. However, there were significantly lower SS-IS coherent oscillations in all frequency bands except the tremor band as the fatigue level increased. Thus, neuromuscular fatigue induced less common drive within the rotator cuff muscles than between rotator cuff and deltoid muscles. Greater coherence between rotator cuff and deltoid muscles allows these two muscle groups to contract in a more synergistic manner to maintain force output during neuromuscular fatigue.

Abstract: Aging is a natural process that causes alterations in the neuromuscular system, which contribute to weakness and reduced quality of life. Reduced firing rates of individual motor units (MUs) likely contribute to weakness, but the mechanisms underlying reduced firing rates are not clear. Persistent inward currents (PICs) are crucial for the initiation, gain control, and maintenance of motoneuron firing, and are directly proportional to the level of monoaminergic input. Since the concentration of monoamines (i.e. serotonin and norepinephrine) are reduced with age, we sought to determine if estimates of PICs are reduced in older (>60 years old) compared to younger adults (<35 years old). We decomposed MU spike trains from high-density surface electromyography over the biceps brachii and triceps brachii during isometric ramp contractions to 20% of maximum. Estimates of PICs (i.e. ΔF) were computed using the paired MU analysis technique. Regardless of the muscle, peak firing rates of older adults were reduced by ~1.6 pulses per second (pps) ($P = 0.0292$), and ΔF was reduced by ~1.9 pps ($P < 0.0001$), compared to younger adults. We further found that age predicted ΔF in older adults ($P = 0.0261$), resulting in a reduction of ~1pps per decade, but there was no relationship in younger adults ($P = 0.9637$). These findings suggest that PICs are reduced in older adults, and, further, age is a significant predictor of estimates of PICs in older adults. Reduced PIC magnitude represents one plausible mechanism for reduced firing rates, weakness, and reduced function in older individuals.

Title: Estimates of persistent inward currents are increased at short muscle lengths

Authors: S. T. JENZ[1,2], J. A. BEAUCHAMP[1,4], O. U. KHURRAM[1,4], C. J. HECKMAN[1,2,3,5], G. E. PEARCEY[1,2,3,5];

Abstract: Voluntary motor commands are comprised of excitation, inhibition, and neuromodulation. Persistent inward currents (PICs), which depend on the level of neuromodulatory drive, alter the intrinsic excitability of motoneurons and lead to amplification and prolongation of motoneuron discharge. PICs are reduced by antagonist muscle stretch, and changes in muscle length can impact an individual's maximum voluntary torque (MVT) due to mechanical properties of the muscle. It is not clear whether motoneuron excitability is altered with changes in static joint angle in humans, or whether reduced PICs contribute to reductions in MVT at short muscle lengths. To address these questions, we investigated whether changes in joint angle altered estimates of PICs and hypothesized that Ia input from the lengthening of the antagonist muscle would reduce estimates of PICs. High density surface electromyography was used to decompose individual motor unit (MU) spike trains from the tibalis anterior, soleus, and medial gastrocnemius. Participants (n = 13; 25.9 ± 3.09 years) performed isometric plantarflexion and dorsiflexion triangular ramp shaped contractions to a peak of 30% MVT. Contractions were performed at varying ankle joint angles (70° and 110°), representing short and long muscle lengths. PICs were estimated using the well-validated paired-MU analysis technique, which quantifies discharge rate hysteresis (ΔF) by comparing the discharge rate of a lower-threshold MU at the onset and offset of a higher-threshold MU. In agreement with previous studies, MVTs were lowest at joint angles that shortened the agonist muscle. A linear mixed effects model found that joint angle was a significant predictor of ΔF ($\chi 2$ (3) = 27.904, $p < 0.0001$). However, contrary to our hypothesis, ΔF was greater at short, compared to long, agonist muscle lengths for all muscles tested. These results suggest that motoneuron excitability is greater at short muscle lengths, despite the reduced force generating capacity at such angles. This may be due to altered monoaminergic input to motoneurons in order to compensate for biomechanically disadvantageous muscle lengths. These findings add to our basic understanding of neural control of movement at various muscle lengths and could shed light on remaining questions such as the source of muscle cramps at short muscle lengths.

Title: The sombrero contraction: a novel task that highlights the prolongation of motoneuron discharge from persistent inward currents and their potential impediments in force control

Authors: *J. A. BEAUCHAMP[1,2], G. E. PEARCEY[2,3,4,5], O. U. KHURRAM[2,3], J. P. DEWALD[1,2,4], C. J. HECKMAN[3,2,4,5];

Abstract: A central feature of normal motor function is the persistent inward currents (PICs) of motoneurons, the amplitude of which correlate with descending monoaminergic input. These PICs are important for amplifying and prolonging excitatory synaptic input to motoneurons and often manifest in their firing patterns, allowing for quantification. Here, we explored a novel isometric contraction paradigm that exploits the phenomenon of PIC induced prolongation, where PICs allow motoneurons to discharge at a lower level of excitatory input than was required at recruitment. Specifically, we asked human participants to perform isometric joint torques in the shape of a hat (i.e. a sombrero hat), comprised of a triangular contraction superimposed upon a steady low-level contraction. This joint torque profile demands two plateau regions of identical motor output before and after a triangular contraction, which allows for characterization of the motoneurons that are recruited by additional synaptic input in the triangular region and sustain discharge into the second plateau. To investigate this contraction profile, we asked participants (n = 7) to perform isometric plantarflexion and dorsiflexion tasks consisting of a slow increase to and hold at 10% of their maximum voluntary torque (MVT) for 10 s, a slow increase to 30% MVT, a decrease back to 10% MVT, another hold at 10% MVT for 10 s, and a slow decrease to rest. We collected high density surface electromyography from the tibialis anterior, medial gastrocnemius, and soleus for all contractions and decomposed signals into individual motor unit (MU) spike trains using convolutive blind source separation. To examine the effects of higher threshold MUs firing into the second plateau, we quantified the percentage of MUs recruited in the triangular region that sustained discharge into the second plateau and the variability in torque during the two plateau regions. Initial analysis revealed sustained discharge in all muscles, with ~50% of MUs recruited in the triangular region firing to the end of the second plateau phase. Furthermore, torque variability was highest during the second plateau, with the coefficient of variation in torque exhibiting a 1.5 fold increase from the first to the second plateau. This suggests that, once activated, PICs may be a hindrance to static precision tasks, and points to a potential limitation in human static torque control introduced by PICs.

Title: Augmented motor unit discharge rates underlie acute intermittent hypoxia-induced increases in volitional elbow strength in persons with chronic incomplete spinal cord injury

Authors: *G. PEARCEY[1], B. AFSHARIPOUR[2], A. HOLOBAR[3], W. Z. RYMER[4], M. S. SANDHU[5];
[1]Northwestern Univ., Chicago, IL; [2]Univ. of Alberta, Edmonton, AB, Canada; [3]Univ. of Maribor, Maribor, Slovenia; [4]Shirley Ryan AbilityLab, Chicago, IL; [5]Sensory Motor Performance Program, ShirleyRyan Ability Lab., Chicago, IL

Abstract: Acute intermittent hypoxia (AIH) is an emerging technique for facilitating neural plasticity in individuals with neurological deficits. It utilizes a brief, rapid reduction of oxygen concentration in the inspired air, which stimulates the serotonergic system, a potent neuromodulator of α-motoneurons. In humans with incomplete spinal cord injury (iSCI), a single 15 dose sequence of AIH enhances ankle, hand grip, and elbow strength for up to 90 minutes. We have recently observed that changes in torque are associated with an increased spatial distribution of muscle activation over the muscle surface and an overall increase in root mean squared EMG amplitude of the biceps and triceps brachii, but mechanisms underlying the altered EMG maps are not clear. Herein, we examined how AIH contributes to improved muscle strength by decomposing individual motor unit spike trains from high-density surface electromyography during maximal elbow flexion and extension torques, recorded prior to and 60 minutes after AIH. Seven individuals with chronic iSCI at the cervical level visited the laboratory on two different occasions, at least a week apart, and received AIH and Sham AIH interventions in a randomized order. Participants performed maximal voluntary isometric elbow flexion and extension contractions prior to and 60 minutes after either intervention. AIH consisted of 15 brief (~60s) periods of low oxygen (fraction of inspired O_2 = 0.09) interspersed with 60s periods of normoxia, whereas Sham AIH consisted of repeated exposures to normoxia. After AIH, elbow flexion and extension torque increased by 104.1 ± 30.56% ($p = 0.016$) and 71.7 ± 30.34% ($p = 0.031$) from baseline, respectively, whereas there was no change (i.e. < 10% change) after Sham AIH ($p > 0.2$ in both cases). We were able to track individual motor units pre-to-60 minutes post intervention and found that the discharge rates during maximal contraction increased by ~20% following AIH. These findings show that a single session of AIH

enhances elbow flexion and extension strength in individuals with chronic iSCI. Furthermore, our preliminary motor unit analysis suggests that excitability and/or the activation of spinal motoneurons are augmented after AIH, providing an underlying mechanism to explain the observed strength increases induced by AIH.

Title: Characterization and creation of a linear Hill-type muscle model of the Aplysia californica I1/I3 retractor muscle complex

Authors: Q. CHEN[1], R. SUKHNANDAN[2], S. PAO[1], J. P. GILL[1], H. J. CHIEL[3], *V. A. WEBSTER-WOOD[2];

Abstract: Understanding and predicting how neural patterns generate behavior requires both neural and biomechanical models. One model of interest to study multifunctionality is feeding behavior in the marine mollusk *Aplysia californica* [1] which generates (1) biting, an unsuccessful attempt to grasp food, (2) swallowing, successfully grasping and ingesting food, and (3) rejection, egestion of inedible food. Although many neurons involved have been identified, a Hill muscle model has only been reported for the I2 protractor muscle [2]. In all three behaviors, the I3 retractor muscle plays a critical role. This study aimed to characterize the I1/I3 retractor muscle complex and create a linear Hill muscle model. Half sections of the cylindrical I1/I3 complex were isolated from fully anesthetized adult *Aplysia*, maintaining innervation by Buccal Nerve 2 (BN2). Isolated muscles were mounted to a length-controlled servo-motor along the I3 contraction direction. A stimulation suction electrode was applied to BN2, and a recording hook electrode was applied proximally along the nerve. Muscles were maintained at 14-20 °C in an aerated mixture of 50% *Aplysia* saline and 50% low calcium, high cobalt saline containing glucose to reduce spontaneous firing. Three experiments were performed as follows. **Force-Frequency:** Muscles were held at rest length and stimulated for 5 seconds at increasing stimulation frequencies (2-50 Hz, in 4 Hz increments) once every three minutes. The

optimal stimulation frequency was used in subsequent experiments. **Force Stability:** Muscles were held at rest length and stimulated 5 seconds every three minutes to test force stability over time. **Length-Tension:** Length-tension characterization was performed using three-minute episodes in increments of 0.5 mm. Active tension was determined by stimulating the muscle for 5 seconds at each length following passive force relaxation. **Linear Hill Muscle Model:** To create a muscle model, force-frequency and length-tension results were normalized to the maximum active tension in the length-tension study. Normalized force-frequency was fit to a saturating exponential model [2]. Normalized passive force was fit to a piecewise quadratic model and active force to a Gaussian function [3,4], resulting in a linear Hill-type muscle model. In the future, we will use this model in neuromechanical models of *Aplysia* feeding and expand our characterization to include muscle force-velocity.

Title: Early changes in ultrastructure of NMJs in Soleus and Tibialis Anterior muscles after spinal cord transection and spinal AAV-BDNF overexpression in adult rat

Authors: *A. GLOWACKA[1], A. A. SZCZEPANKIEWICZ[2], B. JI[3], M. H. SKUP[3]; [1]Group of Restorative Neurobio., [2]Lab. of Electron Microscopy, Nencki Inst. of Exptl. Biol., Warszawa, Poland; [3]Group of Restorative Neurobio., Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Overexpression of brain-derived neurotrophic factor (BDNF) in rats with spinal cord transection (SCT) was shown by us and others to increase function of the lumbar spinal network associated with improvements in assisted locomotor performance detectable as early as 1-2 weeks postlesion, but led also to functional deterioration in time (Boyce et al., 2012, Ziemlinska et al., 2014). Elevated neurotransmitter markers and symptoms of hyperexcitability in BDNF-treated rats prompted us to search for their consequences at the level of peripheral synapse. We

used transmission electron microscopy (TEM) imaging to examine the neuromuscular junctions (NMJs) of motoneurons controlling extensor (Soleus) and flexor (Tibialis anterior) muscles of the ankle joint. We hypothesized that their ultrastructure is changed to different extent, because denervation of extensor and flexor motoneurons (MNs) develops to varying degrees in time after spinalization (Skup et al., 2012, Grycz et al., 2019).Three groups of adult male Wistar rats were used: intact control (n=3), spinalized at Th10, with intraspinal injection of phosphate-buffered saline (SCT-PBS, n=3), and spinalized, with intraspinal injection of AAV-BDNF (SCT-BDNF, n=3) at lumbar L1-2 segments. At 2 weeks postlesion rats were perfused with 4% PFA, and single muscle fibers were isolated from Soleus and Tibialis anterior muscles. NMJs were identified using nicotinic ACh receptor binding of fluorescent conjugate of alpha-bungarotoxin. Areas of fibers containing labeled NMJs were localized under the microscope (obj. 20x), 1-2 mm long blocks were cut out and post-fixed in 2.5% glutaraldehyde. Six NMJs per group were analyzed.TEM imaging showed differences in NMJs ultrastructure between groups, but not muscle types. Control junctions had MN boutons tightly packed with vesicles, pre- and postsynaptic areas almost devoid of loose filaments, regularly arranged myofibers with repeating dublets of mitochondria assisting the majority of sarcomeres. In NMJs from SCT-PBS rats less mitochondria and synaptic vesicles were present in MN terminals, perijunctional area and axoplasm were rich in filaments, and myofiber structure was loose. In SCT-BDNF rats, mitochondria located between motor endplate and myofibers revealed regular arrangement, and the structure of myofibers was tighter and more regular than in SCT-PBS rats. Clearly higher abundance of mitochondria in the perijunctional area in SCT-BDNF group might be connected to increased activity of motor units.

Title: Use It or Lose It? Maybe Not: Enhanced excitability and maintenance of force output in breathing muscle after a month-long apnea in frogs

Authors: *S. KIHUWA-MANI, J. SANTIN;
Univ. of North Carolina at Greensboro, Greensboro, NC

Abstract: Skeletal muscle requires ongoing activity to maintain healthy physiological properties. This is clear in several clinical scenarios, such as mechanical ventilation, spinal cord injury, and bedrest, whereby muscle structure and function degrades due to muscle disuse. The motor system that produces breathing in American Bullfrogs is interesting because breathing muscles are inactive during underwater hibernation. In contrast to other animals, frogs do not experience observable changes to breathing behavior after months of inactivity, which is surprising because highly active skeletal muscles typically atrophy rapidly in most other vertebrate animals. Using *in vitro* muscle force assessments, we tested the hypothesis that skeletal muscle involved in breathing from hibernating frogs resists atrophy. To test this hypothesis, we measured function of a breathing muscle of the lower jaw (*m. intermandibularis*) in control (n=5) and hibernating frogs (n=6). Using direct muscle stimulation, we found that specific twitch force, tetanic force, and recovery from fatigue are maintained despite 1 month of disuse during hibernation ($p>0.05$). In addition, the time between stimulus and twitch force development (twitch latency) was reduced, indicative of enhanced muscle excitability($p=0.01$; two-tailed t-test). Finally, twitch relaxation time was reduced relative to controls ($p=0.008$; two-tailed t-test), suggesting improved sarcoplasmic Ca^{2+} handling following hibernation. These results indicating maintained or improved function are remarkable since this muscle is typically highly active but was unused for one month..These results suggest a diverse set of physiological and biochemical compensatory mechanisms which act to ensure breathing resumes appropriately when animals emerge from hibernation. Ongoing follow-up studies aim to repeat these experiments using nerve stimulation to infer function of the neuromuscular junction, as well as quantitative PCR to measure the expression of candidate genes that may contribute to enhanced muscle excitability and Ca^{2+} handling. Uncovering the mechanisms that allow this muscle to maintain function despite inactivity, which may uncover new insights for muscle disorders in humans.

Title: Retrograde signaling at the neuromuscular junction: The MuSK-BMP pathway regulates Collagen XIII expression and synapse stability

Authors: *L. A. FISH[1,2], M. EWING[3], D. JAIME[4], L. A. MADIGAN[4], J. R. FALLON[3,2]; [1]Neurosci. Grad. Program, [2]Carney Inst. for Brain Sci., [3]Dept. of Neurosci., [4]Mol. Biology, Cell Biol. & Biochem. Grad. Program, Brown Univ., Providence, RI

Abstract: Synaptic stability is essential for information processing and storage. The neuromuscular junction (NMJ) is a genetically and structurally accessible synapse that is amenable to precise mechanistic dissection of synapse stability. We recently reported that postsynaptic NMJ component muscle-specific kinase (MuSK), in addition to its role as an agrin-LRP4 receptor, is a bone morphogenetic protein (BMP) co-receptor. MuSK binds BMPs and their Type I receptors and regulates BMP-mediated transcription (Yilmaz et al, 2016). To investigate the role of the MuSK-BMP pathway at the NMJ, we created a ΔIg3-MuSK mouse model and cell lines that lack the BMP-binding MuSK Ig3 domain. MuSK-BMP signaling is attenuated in ΔIg3-MuSK cells as assessed by BMP-induced Smad1/5/8 phosphorylation and transcriptional output, but agrin-induced AChR clustering is preserved. To probe the role of the MuSK-BMP pathway in NMJ development and stability across different synapse types, we first conducted a morphological analysis of NMJs in the fast sternomastoid (STM) and slow soleus (SOL) muscles, which show differential susceptibility to denervation in ALS and other disorders. Analysis of the STM showed that NMJs in ΔIg3-MuSK mice form normally but are unstable as indicated by endplate fragmentation, which is observed as early as P21. Interestingly, when compared to WT, NMJ areas in ΔIg3-MuSK muscle are larger in immature, but smaller in mature animals. Preliminary ultrastructural analysis indicated that ΔIg3-MuSK NMJs have sparser and shallower junctional folds that are more variable in spacing and depth than WT. In SOL, NMJ area is also reduced in mature ΔIg3-MuSK animals. However, the axonal branches at the SOL NMJ are strikingly thicker compared to WT or to ΔIg3-MuSK STM. To gain insight into the mechanisms by which the MuSK-BMP pathway regulates NMJ structure, we performed RNA-seq analysis of ΔIg3-MuSK SOL. Notably, we observed a reduction in the expression of Collagen XIII, a component of the synaptic basal lamina known to be required for NMJ stability and structure. Multiple transcripts involved in glutamatergic and GABAergic synaptic signaling are also upregulated. Unexpectedly, we also observed increased expression of transcripts encoding the presynaptic components snap25, synaptotagmin-1 and piccolo. Together, our data support a model in which postsynaptic MuSK-BMP signaling regulates the expression of Collagen XIII, which in turn acts as a retrograde signal that is required for synaptic stability, normal pre- and postsynaptic structure, and branch size. The MuSK-BMP pathway could present new therapeutic targets to promote synaptic resiliency in neuromuscular disorders.

Title: Sex differences in intrinsic hand muscle size and echo intensity measured by ultrasonography

Authors: *C. S. KLEIN, H. LUI, C. ZHAO, Z. MENG;
Guangdong Work Injury Rehabil. Ctr., Guangzhou, China

Abstract: It is generally accepted that the average female has smaller muscles than the average male adult. However, this may not necessarily be the case in the intrinsic hand muscles given the conflicting, albeit limited, findings in previous studies. [1, 2] The intrinsic hand muscles are a unique and convenient model for the study of sex differences in muscle morphology as they are free of the confounding effects of weight bearing. In the present study we used ultrasound imaging to quantify sex differences in muscle cross-sectional area (CSA), muscle thickness, and echo intensity (EI, an indicator of fat and connective tissue in muscle). Height, weight, and various hand and digit dimensions (i.e., finger and thumb length, diameter) were recorded to assess whether any sex differences in muscle morphology are entirely explained by anthropometric (body size) differences. Ultrasonography of the flexor pollicis brevis (FPB), abductor pollicis brevis (APB), opponens pollicis (OP), abductor digiti minimi (ADM), and first dorsal interosseous (FDI) was completed in 15 healthy females (28.1 ± 6.9 y, mean ±SD) and 14 males (31.1 ± 5.4 y). We found that the mean female FPB, APB, OP, ADM and FDI thickness was 86%, 73%, 84%, 80% and 81% of the male means , and APB, ADM, and FDI CSA were 71%, 64%, and 71% ($P < 0.01$). EI was about 5-10% higher in some female than male muscles ($P < 0.05$). Total CSA (APB+ADM+FDI CSA) was correlated with body height in females ($r = 0.79$) and males ($r = 0.69$), and was stronger than the correlations with hand or digit dimensions. After accounting for differences in height, about 80% of the sex difference in total CSA can be attributed to factors other than body size. Intra-rater and inter-rater reliability of thickness and CSA was high; intraclass correlation coefficient (ICC) > 0.8. These results indicate that intrinsic hand muscles are 20-30% smaller in females than males. The findings suggest that factors other than body dimensions, such as neural or systemic factors, may account for much of the sex differences in muscle morphology. 1. Title: Als-associated kif5a mutation causes delayed and decreased recovery following sciatic nerve crush.

Authors: *K. A. RICH, H. HARRIS, A. FOX, M. G. PINO, M. L. JONES, W. ARNOLD, M. YALVAC, S. J. KOLB;
Neurol., The Ohio State Univ., Columbus, OH

Abstract: Background: *KIF5A* encodes kinesin protein KIF5A, which is involved in anterograde transport of cargos in eukaryotic cells. C-terminal mutations in *KIF5A* have been identified in patients with amyotrophic lateral sclerosis (ALS). The mechanism linking *KIF5A* mutations and ALS pathogenesis is unknown. Peripheral nerve injury (PNI) is an established paradigm to study mechanisms of axon repair, including axon transport, in rodent models. Complete recovery is observed in young mice, though recovery diminishes with age. Following PNI, electrophysiology can be used to monitor recovery *in vivo* and is a clinically relevant measure of motor unit integrity. Degradation of the motor unit is a primary biological feature of ALS. To investigate this, we created a novel mouse with an ALS-associated C-terminal *Kif5a* mutation (c.3005+1G>A).
Methods: PNI was induced via sciatic nerve crush (wildtype, *Kif5a*$^{+/c.3005+1G>A}$ and *Kif5a*$^{c.3005+1G>A/c.3005+1G>A}$) at 14 weeks or 35 weeks. Before crush and throughout recovery, mice were monitored via weekly assessments of electrophysiology (compound muscle action potential [CMAP] and estimation of motor unit number [MUNE]). At 16 weeks post-recovery, Nissl staining of the L3-L4 region of the lumbar spinal cord was used for motor neuron analysis (motor neuron area and number). Cross-sectional electrophysiological evaluations were also performed in uninjured mice.
Results: *Kif5a*$^{+/c.3005+1G>A}$ mice demonstrated delayed and incomplete recovery of MUNE compared to wildtype, and recovery was further impaired in *Kif5a*$^{c.3005+1G>A/c.3005+1G>A}$ mice. CMAP did not differ between genotypes. Pathologically, motor neuron area was reduced in mutants on the injured side of the spinal cord. There appeared to be an influence of age on latency to recover, as mice with PNI at 35 weeks had an even more delayed and incomplete electrophysiological recovery compared to those injured at 14 weeks.
Conclusions: Our findings suggest that *Kif5a* C-terminal mutations result in a loss of normal KIF5A function, impacting motor unit recovery. Decreases in nerve crush recovery in older mice suggests age-related nerve degeneration may lead to a more severe phenotype. This work

establishes a model system to develop disease-modifying therapies and understand basic principles of *KIF5A* biology.

Abstract: Introduction: The Hoffmann reflex is obtained by the electrical stimulation of afferent fibers Ia that innervate the muscle spindles of a muscle under study. The excitability of the spinal cord is in correlation with the Hoffmann reflex amplitude. Spinal manipulation can modify the spinal cord excitability, in this work, we made ten spinal manipulations with the activator IV as part of a treatment to solve biomechanical problems of the spine, it was to seek to reduce sub-dislocations in patients. After complete therapy of ten sessions, we analyzed the amplitude of Hoffmann reflex. **Objective:** Measure the amplitude of the Hoffmann reflexes recorded on soleus muscles of subjects who practice regional dance and compare them with the records obtained in control subjects, before and after spinal manipulation using the IV activator. **Method:** we had a sample of 7 regional dance subjects, as well as 7 control subjects. The protocol was approved by the local ethics committee. Participants underwent medical history, they were asked to sign an informed consent form, they were taken radiographs. Then we applied current constant stimuli with DS5 and DS7 Digitimer stimulators to record Hoffmann reflexes on bilateral soleus muscles of both groups. **Results:** The ratios H_{max}/M_{max} for control subjects were 0.56±0.15 before and 0.55±0.19 after (p=0.47), on the dancers were 0.43±0.35 before and

0.31±0.23 after (p=0.27). **Conclusion:** A complete chiropractic therapy of 10 sessions using activator IV does not produce differential effects on spinal excitability on dancers neither control subjects.

Title: Vasti Motor Units are Less Synchronized in Adults with Patellofemoral Pain

Authors: *Z. WANG[1,2], A. JOHNSON[3], L. GRIFFIN[2];
[1]Dept. of Neurosci., Northwestern Univ., Chicago, IL; [3]Dept. of Surgery and Perioperative Care, [2]The Univ. of Texas at Austin, Austin, TX

Abstract: The vastus medialis oblique (VMO) and vastus lateralis (VL) are important patellar stabilizers. Imbalanced activation of these muscles can lead to knee injury and pain. The purpose of this study was to investigate differences in the correlations of the motor unit firing rates of the two muscles between healthy adults and adults with patellofemoral pain (PFP). Twenty healthy participants (10 females and 10 males) and 21 participants with PFP (11 females and 10 males) performed a sustained isometric knee extension of 20% maximal voluntary contraction until task failure. Intramuscular fine-wire electrodes were used to record single motor unit discharge rates. Fifty-four motor units of the VMO and 51 motor units of the VL were recorded. VMO motor unit firing rates were significantly higher in healthy males (11.2 ± 0.6 Hz) than in healthy females (8.7 ± 0.7 Hz, $p = 0.006$), males with PFP (8.9 ± 0.6 Hz, $p = 0.011$) and females with PFP (7.5 ± 0.6 Hz, $p < 0.001$); whereas VL motor unit firing rates were similar across the four groups (healthy females: 9.6 ± 0.5 Hz; healthy males: 9.2 ± 0.6 Hz; PFP females: 9.1 ± 0.5 Hz; PFP males: 10.3 ± 0.6 Hz). Motor unit firing rates were higher in the VMO than in the VL only in healthy males ($p = 0.011$). VMO motor unit firing rates were lower than the VL in females with PFP ($p = 0.002$) and similar to the VL in healthy females and males with PFP. Motor unit firing rate synchronization within motor unit pairs was calculated using spike cross-correlograms from 106 motor unit pairs across the VMO and VL of both the healthy and PFP groups. VMO-VL motor unit firing rate synchronization was highest in healthy males (0.457 ± 0.027 Hz) compared to healthy females (0.350 ± 0.029 Hz, $p = 0.043$), males with PFP (0.322 ± 0.029 Hz, $p = 0.006$) and females with PFP (0.273 ± 0.031 Hz, $p < 0.001$). Only healthy males exhibited fatigue-induced increases in VMO-VL synchronization ($p = 0.031$). This study shows that the reduction of VMO motor unit firing rates and weak common drive among motor unit pairs of

vasti synergists in individuals with PFP may be neural mechanisms underlying patellofemoral degeneration.

Title: Characterisation of neurovascular function in old mice

Authors: K. SHAW[1,2], L. LEE[3], L. W. BOORMAN[3], P. S. SHARP[3], J. BERWICK[3], ***C. HOWARTH**[3];

Abstract: Neurovascular coupling (NVC) enables increasing neuronal energy demands to be met by local increases in cerebral blood flow. This mechanism is not only important for normal brain function but also underlies functional imaging techniques, which are commonly used as surrogate measures of neural activity in humans. NVC dysfunction has been previously reported in aging, and such changes in NVC may be associated with age-related cognitive and motor impairments[1]. As the global population is aging, it is therefore of growing importance to characterise how neurovascular function may be altered during aging. Therefore, in adult (6-8 months old) and old (18 -25 months old) mice, we applied 2-dimensional optical imaging spectroscopy (2D-OIS), with and without electrophysiology, to assess the effect of age on cortical haemodynamic responses to whisker stimulation and hypercapnia in anaesthetised mice. Hypercapnia-evoked responses were reduced in old mice as compared to adult mice. However, in contrast to previous studies[2], the amplitude of sensory-evoked haemodynamic responses were unaltered with age. As these experiments were performed using non-invasive procedures, differences between our and previous findings may reflect differences in experimental procedures[3]. In separate experiments, electrophysiological recordings suggested that neural activity evoked by whisker stimulation was similar in adult and old mice. In these experiments, insertion of the electrode caused a cortical spreading depolarisation (CSD), which affects NVC. We hypothesise that the effects of trauma associated with acute procedures differs with age. The characterisation of different aspects of neurovascular function in old mice will not only elucidate how aging affects NVC but may also highlight neurovascular biomarkers of aging. 1.Tarantini S,

Title: A cellular substrate for ultra-slow bilateral hemodynamic correlations

Authors: *K. L. TURNER[1], M. HOSSAIN[1], Q. ZHANG[2], K. W. GHERES[3], P. J. DREW[2]; [1]Dept. of Biomed. Engin., [2]Dept. of Engin. Sci. and Mechanics, Pennsylvania State Univ., University Park, PA; [3]Huck Inst. of the Life Sci., Pennsylvania State Univ. Univ. Park, University Park, PA

Abstract: Hemodynamic signals in the brain are routinely used to infer local neural activity through a relationship referred to as neurovascular coupling (NVC). Understanding which neurons modulate the arousal-state-dependent strength of NVC and functional correlations in the hemodynamic signals between brain regions is of fundamental importance. Previous work has shown that the activity of neuronal nitric oxide synthase (nNOS) expressing neurons play an important role in NVC and setting the basal diameter of arterioles. To explore the role of these neurons in NVC and bilateral hemodynamic correlations, we selectively removed a subset of neuronal nitric oxide (nNOS) interneurons, known as type-I nNOS neurons, from the whisker-related region of somatosensory cortex of mice using a targeted ablation technique. We concurrently measured cerebral blood volume and neural activity in these mice during sleep and wake states. We also measured the dynamics of pial and penetrating arteriole diameter changes using 2-photon microscopy. Ablation of these neurons had no effect on sensory-evoked and fidgeting-evoked neural and hemodynamic responses, but did decrease the bilateral correlations in gamma-band power and blood volume in the somatosensory cortex at ultra-low frequencies (~0.003-0.1 Hz). Additionally, ablation of type-I nNOS neurons reduced the coherence between gamma-band power and hemodynamic signals in the ultra-low frequency band. Our results suggest that type-I interneurons may play a role in synchronizing neural and vascular signals across hemispheres at ultra-low frequencies.

Title: The role of nitric oxide in nNOS interneuron and sensory-evoked neurovascular coupling

Authors: *L. LEE[1,2], O. SHABIR[2,3], J. BERWICK[1,2], C. HOWARTH[1,2];
[1]Dept. of Psychology, [2]Neurosci. Inst., [3]Dept. of Infection, Immunity & Cardiovasc. Dis., Univ. of Sheffield, Sheffield, United Kingdom

Abstract: To meet the resultant demand for oxygen and glucose, changes in neural activity are tightly coupled with local cerebral blood flow (CBF), through a process termed neurovascular coupling (NVC). NVC relies on different populations of neural and glial cells mediating CBF through several vasoactive messengers, including K^+, prostaglandin E2 and nitric oxide (NO)[1]. Of these molecules, NO has been suggested to contribute up to 64% of the NVC response[1]. We have recently shown that activation of cortical neuronal nitric oxide synthase (nNOS)-expressing interneurons evokes localised haemodynamic responses[2]. While such evidence points to NO having a primary involvement in NVC, it's role remains unresolved, with recent studies suggesting that NVC is NO-independent[3]. Therefore, we combined optogenetic and pharmacological approaches to investigate the contribution of NO in the haemodynamic responses to sensory stimulation and direct activation of nNOS-interneurons. Using two-dimensional optical imaging spectroscopy (2D-OIS) and electrophysiology, we recorded the cortical surface haemodynamics in response to interleaved 2s photostimulation (473nm LED) and 2s mechanical stimulation of whiskers in lightly anaesthetised nNOS-CreERT x ChR2-EYFP mice (n=12, 6 male 6 female, 5-10 months old, [Jax 014541[4] x Jax 024109[5]]). Experiments were performed in the absence and presence of the nonspecific NOS inhibitor, N(ω)-nitro-L-arginine methyl ester (LNAME), to block the production of NO. We demonstrate that, when NOS is inhibited, the initial haemodynamic response to a mechanical whisker stimulation is unaltered. Conversely, specific activation of nNOS-expressing interneurons evokes an initial reduction in blood volume followed by a delayed increase. Inhibition of NOS affected the haemodynamic return to baseline regardless of type of stimulation. These results indicate that, unlike those evoked by nNOS-interneuron activation, the initiation of sensory-evoked haemodynamic responses is NO-independent. Thus, different vasoactive pathways may be

involved in sensory and nNOS-interneuron evoked NVC. Experiments in which photo- and whisker- stimulation were simultaneously applied further support this idea. In summary, we demonstrate that NO is not involved in the initiation of sensory-evoked NVC, suggesting that the role of NO in NVC is more complex than simply as a direct mediator.

Title: The participation of local field potentials and single neuronal activity in the regulation of brain tissue oxygen

Authors: *D. P. AKSENOV[1], E. D. DOUBOVIKOV[1], A. V. DMITRIEV[2], N. A. SERDYUKOVA[2], A. DROBYSHEVSKY[1], D. A. GASCOIGNE[1], R. A. LINSENMEIER[2]; [1]NorthShore Univ. HealthSystem, Evanston, IL; [2]Northwestern Univ., Evanston, IL

Abstract: The brain is a metabolically demanding organ, and sufficient oxygen must be delivered to brain regions to prevent global or local hypoxia. As the many pathological consequences of hypoxia have become better understood, the need to characterize the relationship between neuronal oxygen supply and demand has grown. Several distinct systems regulate brain tissue oxygen (PO_2). Oxygen levels throughout the brain are maintained by cerebrovascular autoregulation in response to fluctuations in arterial pressure. Local increases in oxygen demand, in response to sensory signals, motor output, etc., are supported by transient increases in cerebral blood flow via the hemodynamic response (i.e., functional hyperemia). In the resting state, PO_2 oscillations are generated by changes of vascular tone (i.e., vasomotion) at the level of arterioles. PO_2 is therefore the product of oxygen delivery through local blood flow and oxygen consumption, primarily by neurons. Presently, the exact underlying mechanisms of PO_2 regulation remain a point of contention. Previous studies have primarily used acute recording of vasomotion and neuronal activity (e.g., local field potentials). Instead, to address the hypothesis that chronic implantation of both oxygen electrodes and neuronal activity electrodes

for simultaneous recordings can characterize their relationship in a novel manner, we implanted rabbits and recorded these signals from awake subjects. For PO_2 recordings, electrodes were polarized and connected to an ammeter to record current. The current was then converted to voltage, notch and low-pass filtered (30 or 50 Hz), and lastly amplified. For neuronal activity recordings, the signals from the microwires were fed through a miniature preamplifier to a multichannel differential amplifier system (Neuralynx Inc., Bozeman, MT, USA). The signals were then amplified, band-pass-filtered (300Hz to 3 kHz for single units and 1Hz-100Hz for local field potentials), and digitized (32 kHz/channel) using a Neuralynx data acquisition system. Our results confirmed previous observations that vasomotion follows a specific band (gamma) of local field potentials. Beyond this, we expanded the results to characterize the interaction between changes in the behavior of individual neurons and PO_2, which in turn, will help to further the understanding of the physiological basis for fMRI techniques. Our study suffered an obvious limitation; due to the limited number of electrodes used, we were not able to interrogate the relationship between PO_2 and the entire local neuronal network.

Abstract: We have recently shown that effectiveness of the neuroprotection strategies used to improve the focal ischemia outcome is circadian rhythm dependent. While understanding the cerebral blood flow regulation is critically important to improve the treatment strategies, a significant gap remains in our understanding of how circadian rhythm influences both global and microvascular blood flow across brain regions. In this work, we applied two-photon microscopic imaging to investigate the circadian rhythm associated changes in the microvascular blood flow and intravascular oxygenation in both middle-cerebral-artery (MCA) and adjacent watershed cortical territories in head-restrained C57BL/6 mice, through a sealed chronic cranial window. The same group of mice was imaged in the awake state, at rest, during the night (mice active phase) and the daytime (mice inactive phase). The results showed that both the baseline capillary red-blood-cell (RBC) flux and blood flow in the surfacing venules were higher during the inactive phase than during the active phase. Importantly, the relative decrease of both capillary RBC flux and venular blood flow between the inactive and the active phase was larger in the watershed region than in the adjacent MCA territory. Finally, whisker stimulation revealed the difference in the transient blood flow response between the active and inactive phase. Our preliminary results imply that both resting-state blood flow and its response to functional activation are circadian cycle dependent, and that effect of the circadian rhythm may be larger in the more vulnerable watershed territories. These results will pave the way towards better understanding of the blood flow regulation and neuroprotective treatment strategies.

Sci. and Mechanics, The Pennsylvania State Univ., University Park, PA; [6]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The cerebrovascular network and its mural cells must meet the dynamic energy demands of different neuronal cell types across the brain, but their spatial relationship among these cells is largely unknown. Here, we apply brain-wide mapping methods to create a comprehensive cellular-resolution resource comprising the distribution of and quantitative relationship between microvessels, pericytes, and glutamatergic and GABAergic neurons including neuronal nitric oxide synthase-positive (nNOS+) neurons and their subtypes in mice. Leveraging these data, we discovered region-specific signatures of vasculature and cell type compositions across cortical and subcortical areas, including strikingly contrasting correlations between the density of vasculature, pericytes, glutamatergic neurons and parvalbumin-positive interneurons versus nNOS+ neurons in the isocortex. We also found surprisingly low vasculature and pericyte density in the hippocampus, and distinctly high pericyte to vasculature ratio in the hypothalamus. These findings suggest that vascular density and mural cell composition is finely tuned to maintain regional energy homeostasis.

Title: Exposure to dim light at night during recovery from cardiac arrest affects behavior and brain vasculature

Authors: *O. MELÉNDEZ-FERNÁNDEZ[1,3], J. C. WALTON[1,3], W. H. WALKER, II[1,3], J. R. BUMGARNER[1,3], J. A. LIU[1,3], N. ZHANG[1,3], A. DEVRIES[1,3,2], R. J. NELSON[1,3];
[1]Neurosci., [2]Medicince, Div. of Oncology/Hematology, West Virginia Univ., Morgantown, WV; [3]Rockefeller Neurosci. Inst., Morgantown, WV

Abstract: Electrical lighting and devices are now ubiquitous, but the negative effects of exposure to light at night (LAN) is becoming uncovered. Exposure to LAN disrupts endogenous circadian biological clocks, and consequently, has many downstream effects. Mice exposed to dim LAN (dLAN) decrease expression of vascular endothelial growth factor-A (VEGF), increased microglial expression, and reduced brain derived neurotrophic factor. These results suggest that LAN alters brain physiology and behavior. In the present study, the effects of dLAN on mouse behavior and neurovasculature after cardiac arrest (CA) were examined. We hypothesized that exposure to dLAN after CA impairs behavior and hippocampal vascularization in mice. Male and female Swiss Webster mice (8 wks of age; n=160) underwent a cardiac arrest/cardiopulmonary resuscitation (CA/CPR) or sham procedure and were exposed to either dark nights [14 h light 125 lux):10 h dark (0 lux) n=40m/40f)] or dim white LAN conditions [14 h light (125 lux):10h dim light (5 lux) (n=40m/40f)] for one week. Following that week, all mice were returned to dark night conditions for 1 week. Behavioral testing and tissue collection were conducted at the end of this week. Anxiety-like behaviors were assessed using the elevated plus maze (EPM). Prior to euthanasia, mice were administered tomato lectin via a tail vein injection to visualize and quantify vasculature. Females that underwent CA and were exposed to dLAN reduced anxiety-like behaviors in the EPM compared to their counterparts in dark nights. Males exposed to dLAN reduced their latency to enter open arms in the EPM compared to their counterparts, however, no differences in total open arm entries were observed. In the hippocampus, females exposed to dLAN reduced vascularization in the CA2 and dentate gyrus regions of the hippocampus, which was exacerbated by CA; however, dLAN elevated vascularization in the CA1 and CA3 regions of Sham females. In males, dLAN elevated vascularization in the dentate gyrus regardless of procedure. Overall, we observed sex differences in vascularization across all regions assayed. These data suggest that re-exposure to dark nights following one week of recovery from CA while exposed to dLAN may not be sufficient to reverse the effects of dLAN. Moreover, these effects may occur in a sex-dependent manner.

Abstract: We recently identified a novel millihertz modulation of the EEG of very young pediatric patients with acquired brain injuries, which we termed macroperiodic oscillations (MOs). During MOs the EEG power attenuates in a gradual and cyclic manner with a periodicity of 2-5 minutes. The mechanisms underlying this phenomenology remain unknown. However, we observed that during periods of MOs, fluctuations in ICP and HR occurred with the same 2-5 minute periodicity, synchronized with the EEG modulation. Prior studies of ICP oscillations in critically ill patients have not shown a relationship with brain electrical activity and HR. The multi-modal synchronization we observed is suggestive of a broader physiological mechanism underlying MOs. To investigate this mechanism, we generated and characterized a computational model of the relationship between cerebral hemodynamics, ICP, and electrophysiology.
We augmented existing models of ICP biophysics and integrated these with novel biophysical models of cerebral hemodynamics, by coupling a chemoreceptor modulation coefficient to the mechanosensitive autoregulation and cerebral blood flow dynamics. We then coupled equations modeling electrical activity in the brain to hemodynamic autoregulation, wherein partial pressures of CO_2 and O_2 were a proxy for substrate availability, similar to BOLD hemodynamic response functions. Feedback between substrate availability and hemodynamics were governed by the chemoreceptor modulation coefficient. Physiological parameters were initialized based on documented measurements. Our developed model recapitulates ICP oscillations and demonstrates their ability to impact electrophysiology and in certain parameter regimes, induce coupled slow modulation commensurate with MOs. The modulation factor modeling physiological autoregulation through partial pressures in cerebral blood is the key mechanistic mediator linking the three different physiological processes (ICP, hemodynamics, and electrophysiology).
We generated a model with physiological correlates for key parameters to study MOs, a regime of aberrant hemodynamic and electrophysiological oscillations observed in patients with brain injuries. The brain is not a closed system, and this work reveals ways in which physiological processes interact with brain electrical activity during injuries with aberrant autoregulation, building on existing modeling of metabolic processes and neural activity. Our findings suggest a possible mechanism for MOs, paving the way for analysis of potential interventions at various feedback points within the system.

Title: Impairments in vascular function in a mouse model of cerebral amyloid angiopathy

Authors: *M. G. KOZBERG, L. P. MUNTING, B. J. BACSKAI, S. M. GREENBERG, S. J. VAN VELUW;
Massachusetts Gen. Hosp., Boston, MA

Abstract: Cerebral amyloid angiopathy (CAA) is a small vessel disease in which amyloid-β is deposited in the walls of leptomeningeal and cortical blood vessels. CAA leads to several hemorrhagic and ischemic pathologies and is a leading cause of intraparenchymal hemorrhage in the elderly. The mechanisms leading to vascular amyloid-β deposition and subsequent vascular injury in CAA remain largely unknown, but it has been suggested that impairments in the clearance of amyloid-β may play an important role in CAA pathogenesis. Prior work from our group has shown that spontaneous vasomotion, slow oscillations (~0.1 Hz) in vessel diameter, can aid in paravascular waste clearance and is impaired in advanced CAA (van Veluw, Neuron 2020). In this study, using longitudinal, awake two-photon microscopy, we tracked changes in vascular structure and function in the APP23 mouse model of CAA preceding and immediately following initial amyloid-β deposition. This model was chosen given its propensity for spontaneous macro and microbleeds, similar to human CAA. Chronic cranial windows and headposts were implanted in transgenic mice (n = 4) and wildtype littermates (n = 4) and individual vessels in each mouse were imaged monthly from 7 - 12 months of age. We observed amyloid-β deposition in the walls of pial arteries starting at ~8-10 months of age in transgenic mice. Spontaneous vasomotion significantly declined with age in transgenic mice but remained intact in wildtype littermates. Vessel pulsatility, i.e. low-amplitude fluctuations in vessel diameter corresponding to each heartbeat, was observed to increase with age in transgenic mice. Additionally, coinciding with amyloid-β accumulation, pial arteries were observed to increase in diameter by 12 months of age in transgenic mice. Given the importance of smooth muscle cells to maintaining vascular tone and mediating larger changes in vessel diameter as in vasomotion, we hypothesize that impairments in smooth muscle cell function occurring with initial amyloid-β deposition may drive these changes in vascular function. Further work is underway to assess smooth muscle cell function in detail over this age range in the APP23 mouse model. Early impairments in vasomotion (and potentially underlying loss of smooth muscle cell function) may be an important therapeutic target in CAA; reduced vasomotion may lead to a feed-forward

mechanism in which vessels with amyloid-β deposits are less able to clear soluble amyloid-β, leading to extension of the pathology.

Abstract: Assessing neuronal ciliary localization of melanin concentrating hormone receptor 1 (MCHR1) *in vivo*Kathryn M. Brewer[1], Tisianna K. Kamba[1], Staci E. Engle[1], Ruchi Bansal[1], and Nicolas F. Berbari[1,2,31]Department of Biology, Indiana University-Purdue University Indianapolis, Indianapolis, IN USA.[2]Stark Neurosciences Research Institute, Indiana University, Indianapolis IN, USA.[3]Center for Diabetes and Metabolic Diseases, Indiana University School of Medicine, Indianapolis, IN, USA.
Dysfunctional primary cilia are associated with a broad range of clinical features, including an array of neural developmental and behavioral phenotypes. Primary cilia on neurons throughout the central nervous system localize a diverse set of G protein-coupled receptors. Several of these receptors dynamically localize to cilia in heterologous expression *in vitro* approaches. Here, we sought to investigate whether a ciliary GPCR, melanin concentrating hormone receptor 1 (MCHR1), dynamically localizes to cilia *in vivo* under physiological conditions in which MCHR1 signaling has been implicated such as feeding behavior, obesity, and circadian rhythm. Cilia were detected in images of several mouse brain regions using artificial intelligence driven software followed by analysis of MCHR1 positive cilia frequency as well as cilia length and fluorescence intensity. We found significantly different ciliary lengths across brain regions. However, the percentage of MCHR1 positive cilia, cilia length, and intensity did not change. Further analysis of MCHR1 localization in relation to other ciliary markers as well as a detailed

analysis of MCHR1 localization outside of cilia is ongoing. While these results suggest that MCHR1 does not dynamically localize, it does not rule out the possibility that dynamic ciliary localization could occur *in vivo* under other conditions or for other GPCRs. A better understanding of the subcellular localization dynamics of ciliary GPCRs could reveal mechanisms regulating behavior and potential opportunities to therapeutically target these ciliary receptors.

Title: Marmite, a new conserved neuropeptide mediates protein-specific satiety

Authors: *A. P. FRANCISCO[1], I. TASTEKIN[1], G. EZRA-NEVO[1], B. DEPLANCKE[2], A. M. GONTIJO[3], C. RIBEIRO[1];

Abstract: Neuropeptides are a diverse class of signaling molecules produced in the nervous system, with different spatial and temporal scales of action, ranging from local to systemic effects. They are involved in almost all aspects of animal's physiology and behavior, from metabolism to feeding. While we know that animals can modify their food choices in response to the lack of specific nutrients, how that is done is still not clear. *Drosophila melanogaster* is an attractive model to explore the role of neuropeptides in feeding and metabolism due to its molecular similarities to vertebrate systems as well as its genetic toolkit and its complex behavioral repertoire. We have identified *marmite*, an uncharacterized gene whose expression is upregulated in amino acid-rich diets, and downregulated in amino acid-poor diets. This gene is

predicted to encode a secreted peptide with unknown function in *Drosophila*. Bioinformatic analyses suggest that the encoded peptide is a possible orthologue of vertebrate neuropeptides which have previously been proposed to affect feeding behavior. To characterize the role of *marmite* in mediating feeding decisions, we used the flyPAD technology, an automated capacitance-based setup that enables the quantitative analysis of feeding in flies choosing to eat from either yeast (protein-rich source) or sucrose. Using this technology, we found that *marmite* knockdown in the nervous system changes feeding decisions, leading to an increase in yeast intake in satiated flies. We have also used a CRISPR-based approach to generate mutants and knock-in driver lines for this gene. *marmite* mutants also showed an increase in yeast but not sucrose intake, confirming the knockdown results, and suggesting a role in protein homeostasis. A *marmite*-specific Gal4 line driving GFP showed expression in only one neuron in each brain hemisphere and neuronal silencing of *marmite*-expressing neurons also leads to an increase in yeast feeding, recapitulating the loss of function phenotype. Moreover, activation of these neurons is sufficient to decrease yeast feeding in a *marmite*-dependent manner, suggesting that *marmite* acts as a satiety signal. To better understand the evolution of this new family of peptides, we are also exploring the functional conservation of *marmite* orthologues. Our experiments show that neuronal expression of the human orthologue is sufficient to modulate feeding in flies. Thus, we have identified a novel class of conserved neuropeptides that play a key role in nutritional homeostasis and feeding decisions across phyla.

Title: Glp-1 signaling regulates energy homeostasis in the paraventricular-dorsal vagal complex circuit

Authors: *L. WANG, M. BERNABUCCI, I. SINGH, A. E. OUAAMARI, Z. P. PANG; Neurosci., Child Hlth. Inst. of New Jersey and Dept. of Neurosci. and Cell Biol., NEW BRUNSWICK, NJ

Abstract: Glucagon-like Peptide-1 (GLP-1) controls feeding and influences glucose homeostasis. GLP-1 Receptor (GLP-1R)-expressing neurons in paraventricular nucleus of the hypothalamus (PVN) mediate food intake suppression induced by GLP-1. The PVN downstream

circuit mechanisms remain unclear. Here we define a PVN-to-dorsal vagal complex (DVC) circuit as an essential pathway that the PVN GLP-1R neurons mediate signaling in regulating feeding and glucose homeostasis. We found that the PVN GLP-1R-expressing neurons send robust projections to the DVC, composed of the nucleus tractus solitarius (NTS), the dorsal motor nucleus of the vagus nerve (DMX), and the area postrema (AP), and release glutamate. The release of glutamate from the PVN GLP-1R neurons is enhanced by GLP-1 signaling, suggesting GLP-1 regulates energy homeostasis, at least partially via this circuit. Inactivation of the PVN-to-DVC projecting neurons causes overeating, obesity, and diabetes. Activation of this neuronal pathway suppresses food intake. These data suggest that the PVN GLP-1R neurons projecting to the DVC play a pivotal role in regulating energy metabolism.

Hosp., Tao-Yuan, Taiwan

Abstract: Neuropeptide FF (NPFF) belongs to a FMRF-NH2 peptide family and is recognized as an opioid modulating peptide. NPFF involves in different physiological functions including the regulation of analgesic effect of opioids, and controls food consumption and cardiovascular function through its interaction with two cognate receptors, NPFFR1 and NPFFR2. NPFFR2 has higher binding affinity towards NPFF than NPFFR1. Central control of food intake is mainly regulated in the hypothalamus through the arcuate nucleus (ARC), which regulates the feeding behaviors by receiving the peripheral signals, which including insulin and leptin. NPFF is highly expressed in the hypothalamus and has been reported to regulate feeding behavior. However, its downstream cellular mechanism remains unclear. In the current study, we explore the role NPFFR2 in food intake through regulating the hypothalamic insulin downstream signals. Our

evidences suggest that the activation of hypothalamic NPFFR2 inhibit the insulin-regulated satiety signals. The knockdown of NPFFR2 in mice is benefic to metabolic health.

Abstract: Sex differences in metabolism and physiology depend heavily on estrogen receptor alpha (ERα) in hypothalamic neurons that control energy expenditure and intake. In response to changes in circulating estrogens, such as 17β-estradiol (E2), these neurons shift homeostasis to prioritize energy utilization and thereby meet the metabolic demands and behavioral outputs required for mating and reproduction. In both humans and rodent models, loss of ERα signaling promotes a hypometabolic state that includes physical inactivity, unhealthy adipose accumulation, and increased risk of metabolic and cardiovascular disease. The ventrolateral division of the ventromedial hypothalamic nucleus (VMHvl) contains a key module of ERα-expressing neurons that promotes energy expenditure by increasing spontaneous physical activity; however, the mechanisms and exact VMHvl neurons that carry out this function remain unclear. Here, we identified the melanocortin-4 receptor (MC4R) as a direct ERα target gene that

is upregulated in the VMHvl by endogenous or exogenous E2. Chemogenetic activation of this MC4R-VMHvl module in mice greatly increases spontaneous activity and is sufficient to decrease sedentary behavior following ovariectomy. Consistent with E2-dependent *Mc4r* transcription, specifically restoring the functional *Mc4r* allele to the VMH of otherwise null mice improves hypoactivity and body weight phenotypes only in females. In contrast, increasing *Mc4r* expression in the VMHvl of adult wild type mice using CRISPR-mediated activation (CRISPRa) sidesteps the E2 requirement and results in a long-lasting increase in physical activity levels in both sexes.
Collectively, our data indicate that VMHvl neurons integrate steroid hormone and central metabolic signals to optimize energy mobilization across the reproductive cycle. That both chemogenetic stimulation of MC4R-VMHvl neurons and CRISPRa augmentation of *Mc4r* expression increases activity in males suggests that the organization of this hormone-sensitive behavioral module is conserved in both sexes. Our findings now explain the pre-ovulatory surge in spontaneous activity observed in ruminants and in rodents first reported nearly a century ago. We suggest that the central intersection of ERα and MC4R signaling accounts for the stronger phenotypes noted in both female rodent/human MC4R mutants. Finally, we predict that age-related decline in circulating estrogens limits MC4R signaling in the VMHvl, and potentially other brain regions, which negatively impact physical activity behaviors and metabolism.

Abstract: Introduction: Starch is the main source of carbohydrates in human diet, it allows many innovations in food industry due to its functional properties, however, modifications are done with the purpose of improving its functionality. Pyrodextrinization, is one of them and confers the property of being almost or totally indigestible, so allows it to reach the colon to be fermented by microbiota (resistant starch, RS), consequently, affect some other functions of the central nervous system though its ability to produce short-chain fatty acids, which can act by triggering a series of physiological mechanisms regulated by the hypothalamus involving appetite and satiety neurotransmitters. Obesity have developed around the world, which is related to chronic non transmissible diseases, however, RS consumption has been associated with a risk reduction of developing them. Several studies remark that starch is found in most food products because it has a low production cost and high acceptance by most of the population, due to its mixed with other ingredients facility. Cassava (C) and sweet potato (SP) are tubers with considerable starch yields, more profitable than corn plus have an important production in south of Mexico. **Objective:** To modify cassava and sweet potato starch and to evaluate their metabolic effects by consumption in a rat model with a high sucrose diet (HSD). **Methods:** This study consisted of two steps, starting with the modification of cassava and sweet potato starch by pyrodextrinization. For the evaluation of the metabolic effect of pyrodextrins intake, the experiment was divided in two periods: HSD induction (24 weeks) and treatment period (4 weeks). 7 groups were formed CN (normal diet, control), CP (control), HM (hi-maize, 1 g/kg), PY1 (C pyrodextrin, 1 g/kg), PY2 (C pyrodextrin, 1.5 g/kg), PC1 (SP pyrodextrin, 1 g/kg) and PC2 (SP pyrodextrin, 1.5 g/kg). **Results:** C pyrodextrin have 24.42 % RS and SP pyrodextrin 47.15 %. After 20 weeks of HSD, glycemia of CP was (96.50 ± 3.756 mg/dL), CN (71 ± 3.076 mg/dL), HM (66.13 ± 2.69 mg/dL), PY1 (80.63 ± 2.95 mg/dL), PY2 (86.38 ± 11.89 mg/dL), PC1 (97.86 ± 3.52 mg/dL) and PC2 (94.13 ± 1.40 mg/dL). After treatments, glycemia of CN was 72.38 ± 1.91 mg/dL), HM (78.25 ± 3.63 mg/dL), PY1 (81.63 ± 2.40), PY2 (85 ± 2.29 mg/dL), PC1 (65.86 ± 2.91 mg/dL) and PC2 (69 ± 2.84 mg/dL) ($p<0.05$). **Conclusion:** Cassava pyrodextrins may not be able to decrease glycemia due its lower content of RS, on the contrary, sweet potato pyrodextrins show decrease of glycemia, it may be due its higher content of RS.

Title: Identification of Ixodes Neuropeptides and GPCRs Related to Feeding

Authors: *C. A. KNOX[1], L. L. KYLE[1], L. M. SZCZESNIAK[2], R. J. H. WOJCIKIEWICZ[2], B. E. KNOX[1];
[1]Ophthalmology and Visual Sci., [2]Pharmacol., Upstate Med. Univ., Syracuse, NY

Abstract: Identification of *Ixodes* Neuropeptides and GPCRs Related to FeedingHard ticks transmit a wide variety of pathogenic microorganisms during hematophagy. Central tothe regulation of feeding and seeking are neuropeptide (NP) systems. A major gap in Ixodidneurobiology is knowledge about the NP-GPCR receptors that control feeding behaviors. Thereare many arthropods GPCRs that impact feeding, with three well-studied examples being theshort NPF, CCHamide and sulfakinin receptors. To address this problem, we have characterizedthese NP-GPCRs and their related preproneuropeptides from *Ixodes scapularis*.**Methods**: Phylogeny and comparative sequence analysis were used to identify potential NP-GPCRs and preproneuropeptides cDNAs. RNA was isolated from adult ticks and RT-PCR orcommercial DNA synthesis was used to obtain full length cDNAs. *I. scapularis* G-protein alphasubunits were identified and full-length cDNAs were synthesized commercially. Peptidesencoding putative *Ixodes* neuropeptides were synthesized commercially. Full-length cDNAs forthe NP-GPCRs were expressed in human 293T and GNAQ/GNA12 mutant 293T (Alvarez-Curto*et al*., (2016) J. Biol. Chem. 291, 27147-27159) cells by transient transfection. Activation of NP-GPCRs coupled to the endogenous Gαq/PLCβ signaling pathway was monitored by a calciumrelease fluorescence-based assay with a FlexStation3 Multimode Plate Reader.**Results:** *Ixodes* CCHamide receptor was activated by a CCHamide containing an internaldisulfide bond with an EC50 of 12 pM (CI: 11, 14). However, a scrambled CCHamide peptide withan internal disulfide bond weakly activated the receptor with an EC50 >>1 x 10^{-6} M. TheCCHamide receptor did not elicit calcium changes in 293 cells with GNAQ/GNA12 disruptions.Human but not *Ixodes* GNAQ could restore the peptide responsiveness when co-transfected withthe CCHamide receptor into GNAQ/GNA12 mutant 293 cells. One of the *Ixodes* NPY-likereceptors (1A, Dinglasan et al., (2013) PLoS Negl Trop Dis 7, e2486) responded to the *Ixodes*sNPF peptide with an EC50 of 1.9 nM (CI: 1.7, 2.1) while the other (1B) did not respond, evenwith concentrations up to 0.1 mM. The *Ixodes* sulfakinin receptor was activated by a sulfatedsulfakinin peptide with an EC50 of 220 pM (CI: 191, 260) but not with the non-sulfated peptide.**Conclusion:** The preproneuropeptides and their receptors for CCHamide, sNPF, and Sulfakininhave been isolated from *Ixodes scapularis.* All three receptors are able to activate a Gq pathwayin 293T cells when exposed to peptides in the pM to nM range. Our experiments open the wayfor *in vivo* characterization of their function.

Title: Regulation of motivation for sucrose by orexin and dynorphin peptides: Analysis using an open-source operant lickometer

Authors: C. SANDOVAL[1], L. LUARTE[1], J. TESKE[2], ***C. PEREZ-LEIGHTON**[1];
[1]Dept. de Fisiología, Facultad de Ciencias Biológicas, Pontificia Univ. Catolica de Chile, Santiago, Chile; [2]Dept. of Nutritional Sci., Univ. of Arizona, Tucson, AZ

Abstract: The orexin and dynorphin (DYN) peptides regulate motivated behaviors, including intake of palatable foods. In the paraventricular nucleus (PVN), the opioid peptide DYN-A_{1-13} increase intake of palatable foods, an effect blocked by co-treatment with the orexin-A peptide (Nutritional Neuroscience 5:1-10). However, whether orexin and DYN-A_{1-13} in the PVN regulate motivation to work for palatable food remains unknown. To answer this question, we built an open-source operant lickometer using 3D printing with open-source electronics and software. Our device is low cost, easily constructed and can provide operant access to two different liquids. We validated this device in male C57BL/6J mice. First, we successfully measured the circadian rhythm of water intake (n = 3, licks/h active period: 216.5 ± 83.8; inactive period: 83.8 ± 1.8; $P<0.01$). Next, we trained mice to work for a solution of sucrose 5% w/v (~10 μL sucrose/delivery event) in two reinforcement schedules (1 h daily sessions during their active period): a fixed ratio 5 (FR5, 5 licks / delivery event) or a progressive ratio (PR, exponential increase in licks/delivery) and access to water in a FR5 schedule in both schedules of sucrose access. After 6 sessions of FR5, mice worked significantly more for sucrose compared to water (n = 6; delivery events; sucrose: 21.2 ± 4.8; water: 4.5 ± 1.4; $P=0.01$) and after 7 sessions of PR, mice reached 1,000 ± 202 licks for sucrose compared to 24.7 ± 8.5 licks for water ($P<0.01$). Next, a different set of mice (n=10) were cannulated aiming at the right PVN and trained to work for sucrose in the same FR5 and PR schedules (1 h, 7 sessions each). Next, mice were injected with DYN-A_{1-13} (0, 1, 3, 6 nmol) into PVN before PR tests using a repeated measures design. Compared to vehicle, DYN-A_{1-13} (3 nmol) significantly increased sucrose but not water licks during the first 30 min (sucrose: 225 ± 78.9; water: ± 2.3; $P<0.05$) without differences in the second half of the session ($P=0.69$). These data suggest that in the PVN, DYN-A_{1-13} increases motivation for sucrose. Ongoing experiments will determine whether this effect is blocked by orexin-A or the kappa opioid receptor antagonist norBNI. The operant lickometer device and these data open new avenues of research to determine the contribution of orexin and opioid DYN peptides to motivated behavior.

Title: Paraventricular hypothalamic melanin-concentrating hormone signaling and food intake control

Authors: M. SPAULDING, J. HOFFMAN, M. LORD, *E. NOBLE;
Univ. of Georgia, Athens, GA

Abstract: Melanin concentrating hormone (MCH) is a neuropeptide produced in the lateral hypothalamic area (LHA) and zona incerta (ZI) that promotes weight gain by both elevating food intake and reducing energy expenditure. The receptor for MCH (MCH1R) is expressed throughout the brain and is a target for novel obesity pharmacotherapy development, however, the site(s) of action for MCH-mediated alterations in energy balance are largely unknown. We first set out to determine putative sites of action for MCH-mediated feeding effects by injecting MCH or vehicle (CTL) into the lateral ventricle of rats either given a meal of 5 grams of standard chow or in the absence of food (4 groups: MCH with food, MCH without food, VEH with food, VEH without food). At 60 or 90 minutes post injection, animals were sacrificed for immunohistochemical analyses of cFOS expression. Results revealed elevated levels of cFOS in the paraventricular hypothalamus (PVH) of animals injected with MCH in the presence of food. The PVH is a critical orchestrator of energy homeostasis, and MCH1R is expressed in several neuronal populations in the PVH known to regulate body weight. Therefore, we investigated whether MCH signaling in the PVH impacts eating behavior. Male and female Sprague Dawley rats were implanted with chronic indwelling cannula bilaterally targeting the PVH. MCH (0, 0.25 µg, 0.5µg) was injected in a within-subjects design and food intake was monitored. Results revealed that MCH injection into the PVH increases food intake at one hour post injection in both male and female rats. We further investigated whether MCH in the PVH impacts food motivated behavior using a progressive ratio task. MCH injection into the PVH had no effect on motivated responding for palatable sucrose pellets. Given that MCH alters both food intake and energy expenditure, we next investigated whether chronic MCH 1R knockdown in the PVH affects energy balance in rodents using shRNA targeting MCH1R gene expression. Bilateral injection of an AAV1-GFP-U6-r-Mchr1-shRNA, or AAV1-GFP-U6-r-scram-shRNA (control) were injected into the PVH of a small pilot cohort of male rats (n=6 per group), and daily food intake and body weight were monitored. MCH1R knockdown had no impact on food intake but tended to reduce body weight gain on an obesogenic high fat/ high sugar diet. We conclude that the PVH is a brain region in which MCH signaling modulates food intake and possibly energy balance. Future experiments will build on these findings to determine the endogenous relevance

of PVH MCH1R signaling to energy balance regulation and susceptibility to diet induced obesity in both male and female rodents.

Title: The influence of CRF on evoked calcium influx in the optic tectum of the South African clawed frog, Xenopus laevis.

Authors: *C. WANG, P. KEYEL, J. CARR;
Texas Tech. Univ., lubbock, TX

Abstract: As the primary visual center of the non-mammalian vertebrate brain, optic tectum contains CRFR1 receptors that modulate feeding and predator avoidance in part. Tectal CRF neurons respond to stressors and food deprivation, using an intrinsic CRF signaling system, but the signaling pathway is poorly understood. Since gamma-aminobutyric acid (GABA) is one major inhibitory neurotransmitter in the optic tectum, GABAergic neurons might act downstream of CRFR1. This study tested the hypothesis that CRF acts on tectal CRFR1 to inhibit basal and K^+-evoked calcium flux in tectal neurons via GABAergic signaling. We performed three sets of experiments using in-vitro tectal slices from *Xenopus laevis* adults. We tested the following questions: 1) Does CRF dose-dependently inhibit evoked calcium influx in tectal neurons? 2) Do any inhibitory effects of CRF on evoked calcium influx require CRFR1? 3) Does GABA inhibit evoked calcium influx in tectal neurons? These questions were tested using 300 μm brain slices perfused with artificial cerebrospinal fluid containing 2.5 mM K^+ (basal) or 30-60 mM K^+ (depolarization). Peak evoked calcium influx, the latency to peak influx, and the decay in evoked influx were measured as dependent variables. We found subtle but unreproducible effects of CRF at single doses on peak and latency to peak evoked calcium. The water-soluble and selective CRFR1 antagonist NBI 35965 hydrochloride did not change evoked calcium influx. Importantly, there were no substantial inhibitory effects of GABA on calcium influx evoked with either 30 or 60 mM K^+. These findings suggest that peak calcium influx evoked with high K^+ primarily reflects the rapid opening of voltage-gated calcium channels in presynaptic nerve endings upstream of tectal GABA-responsive cells. Whether these findings reflect a lack of CRF-mediated presynaptic inhibition needs to be confirmed using electrophysiological methods.

Title: Fear Devaluation and Extinction Rely on Distinct Molecular Mechanisms but Produce a Similar Behavioral Outcome

Authors: ***S. TRASK**[1], J. NELSEN[2], S. ORSI[2], H. DURAISWAMY[2], K. GRISALES[1], T. J. JAROME[3], F. J. HELMSTETTER[4];

Abstract: Exposure to weak shock following contextual fear conditioning with a strong shock can have opposing effects on fear behavior depending on the number of weak-shock exposures. While 2 context-weak shock pairings will increase fear responding, 10 context-weak shock pairings reduces responding. While we hypothesized that the 10-shock procedure worked by modifying and weakening the original UCS memory, the 10-shock group received more chamber exposure than other groups suggesting this might instead be an extinction-like effect which relies on creation of a new inhibitory memory. The current experiments aimed to directly compare devaluation to a more straightforward extinction procedure. Following contextual fear conditioning with a strong (1.0mA) shock, animals were given one of three interference procedures: updating (2x .3mA shocks), devaluation (10x .3mA shocks), or extinction. Updating increased fear relative to both the devaluation and extinction groups who did not differ from each other. While devaluation and extinction both reduced spontaneous recovery, only devaluation reduced reinstatement. We also found that, like extinction, the effects of devaluation are context specific. In separate animals, brain tissue was collected 60-min following updating, devaluation, or extinction. Phosphorylated CREB was upregulated in the lateral amygdala following devaluation, but downregulated following extinction. Only devaluation produced an upregulation

of K48 polyubiquitination in the synapse, a marker of plasticity associated with memory reconsolidation and modification. Together, these results suggest that devaluation represents a unique interference paradigm that weakens fear responding by targeting the original acquisition memory rather than through the creation of a new memory, as is the case in extinction. Further work will need to examine the circuit-level mechanisms of devaluation as it compares to extinction, which is heavily dependent on cortical regions like the infralimbic cortex for expression.

Title: Habituation and disruption of memory with the use of a sedative in Physarum polycephalum

Authors: *E. MULLER, A. DUSKIC, G. GOTTHARD;
Muhlenberg Col., Allentown, PA

Abstract: Memory has typically been reserved for multicellular organisms with a central nervous system, and yet *Physarum polycephalum*, which is a unicellular, non-neuronal organism, can hold some form of memory. Two experiments were conducted to test the strength of *Physarum*'s memory. In Experiment 1A, *Physarum* was exposed to 5% white vinegar, which is a known mold killer yet unstudied in a lab setting, to assess the organism's ability to habituate to the deterrent (from 3-5 days). *Physarum* was placed at one end of a 1 cm x 2 cm vinegar/agar bridge (experimental group; n=35) or an agar only bridge (control group; n=36), with its food source at the opposite end of the bridge (adapted from Boisseau et al., 2016). The speed of *Physarum* to traverse the bridge and reach the food source (i.e., oats) was recorded using infrared cameras. In Experiment 1B, disruption of *Physarum*'s habituation memory was tested. Once habituation was established, the *Physarum*'s speed to cross the vinegar/agar bridge (experimental group; n=28) or the agar only bridge (control; n=29) was challenged using a sedative, Valerian root extract (300µL), which was confirmed by Adamatzky et al. (2011) to slow down the oscillation and, potentially, the movement and transfer of information throughout the organism, which may disrupt the organism's ability to "remember" what it learned. For Experiment 1A, repeated measures ANOVA revealed a significant main effect of trial showing time to cross

significantly decreased from the first to the last habituation trial [$F(3,207)=17.382$, $p<0.001$, $\eta p^2=0.201$]. There was a significant interaction between groups for speed to cross and showed that the slime exposed to the vinegar took longer to cross than the control [$F(3,207)=2.586$, $p=0.054$, $\eta p^2= 0.036$]. In Experiment 1B, a significant main effect of Valerian was observed, with all *Physarum* crossing at a decreased speed [$F(1,55)=43.986$, $p<0.0001$, $\eta p^2=0.444$]. Additionally, a significant interaction was observed; Valerian disrupted vinegar-habituated "memory" resulting in increased speed to cross the bridge when compared to controls [$F(1,55=8.243$, $p=0.036$, $\eta p^2= 0.078$]. Although the mechanism underlying *Physarum* "memory" is still unknown, our findings provide support for memory disruption via Valerian root in an organism without a brain.

Title: Optogenetic photo-stimulation of basolateral amygdala neurons activated during fear memory formation promotes anxiety-like behaviors

Authors: *R. HAMMACK, N. CLAUSS, L. C. DAWS, G. M. TONEY;
Dept. of Cell. & Integrative Physiol., Univ. of Texas Hlth. Sci. Center, San Antonio, San Antonio, TX

Abstract: Fear-related neuropsychiatric disorders such as posttraumatic stress disorder (PTSD) often present with symptoms of anxiety. Although fear and anxiety are often considered distinct both in their behavioral manifestations and their mediating neuronal pathways, to what extent re-activation of neurons activated during fear memory formation elicit anxiety-like behaviors is unknown. Since activity of basolateral amygdala (BLA) neurons is key to formation of fear and anxiety, we hypothesized that photo-stimulated re-activation of neurons activated during fear memory formation will elicit anxiety-like behaviors. To test this hypothesis, we used the 2nd generation of Targeted Recombination in Active Populations (TRAP2) transgenic mice injected bilaterally with adeno-associated virus encoding Cre-dependent enhanced channelrhodopsin (ChR2) in BLA. Mice were instrumented with fiber optic cannulae above the injection sites. Nine days later mice were habituated to the fear conditioning chamber for 5 days (3 min/day) to decrease novel exploration induced BLA activation. The following day, mice underwent fear conditioning (5, 0.75 mA foot shocks in 6 min) and immediately (<1 min) after were fear-

TRAPed with 4-hydroxytamoxifen (4-OHT) to induce Cre recombinase expression of ChR2 driven by *c-fos* promoter/enhancer elements. Three weeks post TRAPing, we validated functional ChR2 expression using brain slice electrophysiology. At this same time point, mice (n=4/group) underwent an open field test (OFT) while being photo-stimulated either with dummy (no light) or blue light (473 nm, 20 Hz, 5 ms) for 5 min. One hour following this test, mice underwent elevated plus maze (EPM) testing, again with or without photo-stimulation. Compared to dummy pulses, photo-stimulation of fear-TRAPed BLA neurons increased time that mice spent around the edges of the open field (blue light: 268 ± 9 s, no light: 132 ± 28 s, unpaired t test P=0.0040) and decreased time spent in the open arms of the EPM (blue light: 43 ± 16 s, no light: 206 ± 12 s, unpaired t test P=0.0018). Findings indicate that optogenetic re-activation of BLA neurons that were *c-fos* activated (TRAPed) during fear memory formation promotes anxiety-like behaviors in two test paradigms. We conclude that fear-related BLA neurons could contribute to subsequent anxiety-like behaviors. Further investigation into cellular and circuit mechanisms underlying these observations is warranted.

Title: Manipulations of fear memory induced by a non-invasive activation of dopamine neurons

Authors: *Y. JO[1], G. PYEON[1], L. S. ZWEIFEL[2];
[1]Sch. of Psychology, Korea Univ., Seoul, Korea, Republic of; [2]Pharmacol., Univ. of Washington, Seattle, WA

Abstract: Recent evidence indicates that optogenetic stimulation of dopamine cells during fear conditioning significantly decreases fear generalization. The optical dopamine manipulation during extinction training also facilitates fear extinction. Here we tested that instead of the optogenetic intervention, whether a non-invasive activation of dopamine cells induced such effects on fear memory. *Slc6a3*-cre mice (DAT-cre) first underwent a Pavlovian reinforcement learning where an auditory conditioned stimulus (CS) was associated with the delivery of a food pellet (rewarding CS; re-CS) and the other CS was not (nonrewarding CS; nonre-CS). Electrophysiological results showed that dopamine cells preferentially responded to re-CS over 8 days of Pavlovian learning. Then the mice received a probabilistic version of fear conditioning in which a high-probability CS (highCS) was paired with a footshock 7 out of 10 trials, whereas a

low-probability CS (lowCS) was paired with the other three trials. When highCS was presented during fear conditioning, either re- or nonre-CS was also played as a compound cue to excite dopamine cells for 1 s. Mice with nonre-CS failed to discriminate between highCS and lowCS as they exhibited comparable levels of freezing to both CSs. However, mice with re-CS showed an improvement in discriminatory freezing behavior. To demonstrate that the better performance requires dopamine activation by re-CS, another group of DAT-cre mice expressing Jaws, an inhibitory opsin, in dopamine cells was included. The Jaws group went through the same behavioral procedures, except that dopamine neurons were inhibited by red light (1 s) during the presentation of re-CS. Dopamine inactivation prevented discriminatory fear memory. Next, we examined whether the non-invasive excitation of dopamine neurons facilitated the extinction of fear memory. Mice received Pavlovian reward association for 8 days, followed by fear conditioning where a CS was paired with a footshock 4 times. During the training of fear extinction, CS-alone trials were presented 40 times. In each trial, either re-CS or nonre-CS was turned on for 1 s at the end of the fear-associated CS. Compared to mice with nonre-CS, mice with re-CS showed significantly less freezing behavior during the extinction training. Overall, these results indicate that dopamine activation evoked by a reward-predicting cue can facilitate fear discrimination and extinction as effectively as optical dopamine activation. The present study also suggests a possibility that fear- and reward-related compound cues can help to diminish generalized fear responses in human patients suffering anxiety-related disorders.

Title: Hippocampal somatostatin interneurons mediate fear extinction retrieval

Authors: *A. F. LACAGNINA, S. KHAN, R. L. CLEM;
Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Fear extinction is a process where defensive responses to a conditioned stimulus diminish when the stimulus no longer predicts a threat. While plasticity in prefrontal-hippocampal-amygdala circuits has been implicated in extinction learning, much less is known about the mechanisms of extinction retrieval. We first identified brain regions associated with

extinction retrieval by mapping expression of the activity-related gene c-Fos in mice retrieving a contextual fear extinction memory. We found that extinction retrieval was associated with elevated c-Fos expression in the stratum oriens layer of ventral hippocampal area CA1 (vCA1) predominantly in interneurons co-expressing somatostatin (SST-INs) compared to fear retrieval or in unshocked mice. An extinction-specific recruitment of SST-INs in vCA1 was confirmed using an intersectional genetic strategy to fluorescently tag SST-INs active during fear conditioning or extinction retrieval. Optogenetically activating the extinction-tagged SST-INs attenuated fear relapse but did not affect extinction retrieval or context discrimination. Additionally, silencing excitatory projections from vCA1 to prelimbic medial prefrontal cortex did not affect fear retrieval but prevented extinction retrieval. Our results suggest extinction retrieval is mediated by activity of vCA1 SST-INs, which we hypothesize regulate the output of hippocampal ensembles to promote extinction-related behaviors in part through projections to the prefrontal cortex.

Title: Social buffering extinguishes fear by oxytocin triggering sustained changes in neuronal activity in the central amygdala

Authors: C. HEGOBURU[1], S. GHOSH[2], R. TRIANA DEL RIO[2], I. SALGADO[2], M. ABATIS[2], R. NIU[2], E. H. VAN DEN BURG[2], C. GRUNDSCHOBER[3], ***R. STOOP**[4];

Lausanne, Prilly, Lausanne, Switzerland; [3]Roche Pharma Res. and Early Develop., Roche Innovation Ctr. Basel, Basel, Switzerland; [4]Univ. of Lausanne, Prilly, Lausanne, Switzerland

Abstract: Background: In fear extinction therapy, social interaction can help to realize successful and long-lasting decrease of fear. In rat models of fear-conditioning, the presence of a conspecific during the recall can attenuate fear responses. The mechanism underlying this social buffering of fear (SBF) is not fully understood. One candidate to mediate SBF is oxytocin (OT),

a neuropeptide produced by the paraventricular nucleus of the hypothalamus (PVN) and known for its anxiolytic effects in the central amygdala (CeA). We hypothesize that OT, through its projections from the PVN to the CeA, plays a role in socially-induced acute and long-lasting decrease (extinction) of fear.
Methods: We developed a fear conditioning paradigm for rats, in which the recall of a threat was delivered in the presence of a conspecific. Using pharmacological, optogenetic, chemogenetic and electrophysiological approaches, we assessed the role of OT signaling in the PVN to CeA pathway during SBF.
Results: We found that social interaction reduced the freezing responses immediately and long-lastingly and that OT release from the PVN into CeA plays a crucial role in this process. Multi-unit *in vivo* electrophysiological recordings in the CeA in combination with optogenetic stimulation showed that these behavioral responses were accompanied by acute and long-lasting changes in spiking patterns in OTergic neurons in the PVN and three different types of fear-conditioned responding neurons in the CeA.
Conclusion: Our findings provide insight in the neurobiological mechanisms of OT-signaling underlying the short, and long-lasting effects of social buffering of fear.

Title: Fear Extinction Training Suppresses Reactivation of Fear Ensembles Throughout the Hippocampus and Induces Specific Single-Cell Transcriptomes

Authors: *A. ZUNIGA[1], J. HAN[2], I. MILLER-CREWS[1], C. ROSSMEISSL[2], H. A. HOFMANN[1], *M. R. DREW[1];
[1]Univ. of Texas At Austin, Austin, TX; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Learned fear often relapses after extinction, suggesting that extinction training generates a new memory that coexists with the original fear memory. Recent work from our lab has identified the hippocampal dentate gyrus (DG) as a region where such fear and extinction memories are generated. Specifically, using activity-dependent neural tagging in mice, we

discovered that extinction training suppresses reactivation of contextual fear engram cells in DG while activating a second ensemble, a putative extinction engram. Here we investigate (1) whether these effects of extinction training on fear ensembles are limited to the DG or exist in other regions of the hippocampus and parahippocampal cortex, and (2) whether fear and extinction ensembles in DG exhibit distinct patterns of gene expression. ArcCreErt2-eYFPflx mice injected with tamoxifen immediately after contextual fear conditioning, thereby inducing expression of eYFP in neurons active during fear acquisition. Mice then received extinction training or were left undisturbed in their home cages. After a test of conditioned fear in the training context, we first assessed reactivation of eYFP-tagged fear acquisition neurons using immunohistochemistry against Arc and Fos proteins. Although the total number of eYFP+, Fos+ and Arc+ neurons in the dorsal DG did not differ between Extinction and No-Extinction groups, extinction training suppressed reactivation of YFP-tagged fear acquisition neurons in the DG, replicating results of Lacagnina et al. (2019). This extinction-induced suppression of reactivation of eYFP+ fear acquisition neurons was observed in dorsal and ventral DG, dorsal CA1, and dorsal and ventral lateral entorhinal cortex. In DG there was considerable overlap between Arc and c-Fos expression, and expression of both immediate-early genes in DG was suppressed by extinction training. Next we used single-nuclei RNA Sequencing (snRNA-seq) to characterize gene expression profiles in eYFP+ and eYFP- cells in the dorsal DG of mice from Extinction and No-Extinction groups. We recovered the canonical DG cell types, examined how the transcriptomes of eYFP+, Fos+ and Arc+ fear acquisition neurons changed after extinction training, and identified the transcriptomes of extinction-activated neurons. Our findings show that extinction training has anatomically and molecularly robust effects on hippocampal fear representations.

Title: The dynamic nature of a fear engram in extinction and reconsolidation memories

Authors: *J. GRIEBLER LUFT, L. DE OLIVEIRA ALVARES;
Univ. Federal do Rio Grande do Sul (UFRGS), Porto Alegre, Brazil

Abstract: Neurons active in memory formation will be re-engaged again during retrieval. Those cells are called engrams or neuronal ensembles. However, an important question about engrams remains unknown: Does the fear engram remain the same after extinction or memory reconsolidation in Basolateral Amygdala (BLA)? Using Fos-LacZ transgenic rats, we aimed to investigate if the reconsolidation and extinction of memories would maintain the same pattern of neurons that were active during its consolidation. With this technique, we can silence neurons that express the immediate early gene c-fos at the moment of the infusion of the drug Daun02. We first tested the role of the BLA engram in the reconsolidation of an aversive memory and demonstrated that silencing the neurons active during reconsolidation caused an impairment of the fear memory. However, silencing BLA neurons active during an extinction memory recall did not disrupt the extinction memory as seen by the low fear expression presented by the animals during the test. Our findings suggest that reconsolidation and extinction memory engrams have distinct dynamics in BLA, meaning that reconsolidation memories use the same subset of neurons, while extinction memories do not.

Title: Synaptic correlates of associative fear memory in the lateral amygdala

Authors: *D. CHOI, J. KIM, H. LEE, J.-I. KIM, Y. SUNG, J. CHOI, P. PARK, H. JUNG, B.-K. KAANG;
Sch. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Successful adaptation to the environment requires accurate responding to external threats by recalling specific memories. Memory formation and recall requires engram cell activity and synaptic strengthening among activated neuronal ensembles. However, elucidating the underlying neural substrates of associative fear memory remained limited without a direct interrogation of extinction-induced changes of specific synapses that encode a specific auditory fear memory. Using dual-eGRASP (enhanced Green Fluorescent Protein Reconstitution Across Synaptic Partners), we found synapses among activated neuronal ensembles or activated synaptic ensembles showed a significantly larger spine morphology at auditory cortex (AC) to lateral amygdala (LA) projections after auditory fear conditioning in mice. Fear extinction reversed these enhanced synaptic ensemble spines while re-conditioning with the same tone and shock restored the spine size of the synaptic ensemble. Taken together, we suggest that synaptic ensembles encode and represent different fear memory states.

Abstract: Multiple studies have tried to interfere with the consolidation of fearful memories by pharmacological means, however this has proven difficult in humans. The matrix metalloproteinase (MMP) inhibitor doxycycline has been shown to attenuate the consolidation of aversive memory in delay fear conditioning when ingested before the acquisition phase (Bach et al., 2018). Delay fear conditioning, where a conditioned stimulus (CS) co-terminates with an unconditioned stimulus (US), is widely used to model traumatic memory; however, in real-life memory cues that elicit trauma often are not present during the trauma but separated in time. To model this situation, we sought to replicate the previous finding in a trace fear conditioning paradigm. Crucially, this difference in experimental timing leads to additional involvement of hippocampus, but currently it is unclear whether doxycycline can block memory consolidation when it is hippocampus dependent. We tested the impact of Doxycycline on trace fear memory consolidation in a randomised double-blind placebo-controlled study with 97 participants: n = 49 (25 females) received placebo, n = 48 (24 females) received doxycycline 3.5 hours before conditioning. We used two visual CS and electric shock as US with 100% reinforcement of the CS+ and a 15-s trace interval. The first acquisition session (day 0) encompassed 40 trials (20 CS+ and 20 CS-). A recall session (day +7) included 30 trials (15 CS+, 15CS-) without reinforcement. We used startle-eye blink responses (SEBR) - elicited by a white noise burst - to measure memory retention. Beforehand, we ensured in two independent samples trace fear memory retention in this paradigm can be measured after 7 days. We found that the placebo group retained fear memory indicated by a significant CS+/CS- difference, while the Doxycycline group showed no memory retention. However, we did not observe a significant group difference. As a side finding it is worth noting that, within the placebo group, only females but not males retained fear memory.

Title: Infralimbic prefrontal glutamate projection in extinction of methamphetamine conditioned place preference

Authors: *J.-C. CHEN, T.-Y. WU, H.-C. CHANG, Y.-T. LIN;
Grad. Inst. of Biomed. Sci., Chang Gung Univ., Tao-Yuan, Taiwan

Abstract: Exposure to contextual cues frequently triggers relapse of addictive drug use, even after prolonged abstinence. To eliminate this drug-cue association, strengthening the extinction process would be a practical manner to effectively suppress the devastating drug relapse. Cortical glutamate efferent projects to many midbrain regions and this projection pathway has been demonstrated to play a critical role in the extinction of fear conditioning (aversive). Whether prefrontal glutamate plays a similar role in appetitive conditioning remains unclear. To delineate if infralimbic mPFC (IL-mPFC) glutamate, via activation of inhibitory GABA neurons in the VTA, would modulate the METH-CPP extinction process, we adopted optogenetics along with specific Cre mice to unwire this neural circuitry. We found photo-inactivation (AAV5/Efla-DIO-eNpHR3.0-mCherry) of IL-mPFC glutamate projection in the VTA of vGluT2::Cre mice during the extinction training suppresses the METH-CPP extinction. Photo-inactivation of GABA interneurons in the VTA of Parvalbumin::Cre mice during the extinction training also blocks the METH-CPP extinction. Nevertheless, photo-inactivation of GABA projection neuron, with NpHR delivered in the NAc-shell but optical fiber implanted in the VTA of GAD2::Cre mice, displayed normal METH-CPP extinction after CPP re-test. In addition, animals that received mutant GluR1/S831A/S845A or GluR1/S845A exhibited normal acquisition of METH-CPP but could not extinguish the CPP, suggesting that disrupts the glutamate response at VTA GluR1 level prevents the formation of METH-CPP extinction. In addition, extinction of METH-CPP could also be blocked by systemic pretreatment of AMPA-R antagonist, NBQX during METH-CPP extinction training. These data suggest that disrupts the glutamate response at VTA GluR1 level prevents the formation of METH-CPP extinction. Overall, we hypothesize that during extinction training of METH-CPP, IL-PFC consistently sends an excitatory signal to the VTA GABA interneuron, in turn, suppresses VTA dopamine activity hence results in a suppression of METH-CPP. Thus, photo-inactivation of IL-PFC glutamate during this critical extinction

training stage would totally disrupt the memory extinction process and animals remain in the acquisition stage of METH-CPP.

Title: Coding of social odors in the hippocampal CA2 region as a substrate for social memory

Authors: *S. I. HASSAN, S. BIGLER, S. A. SIEGELBAUM;
Neurosci., Zuckerman Institute, Columbia Univ., New York, NY

Abstract: The ability to store, recall, and update social information about individuals is critical for lasting social relationships. The computational demands for the brain to support those features are challenging as multiple parallel streams of information have to be woven into a coherent representation, which at the same time has to be flexible enough to cope with the dynamic nature of social behavior. Research over the last decades established a crucial role of the hippocampus in the formation of social recognition memory, however, the underlying computations are unknown. Here we took inspiration from scent marking as a crucial feature for individual recognition in many mammalian species and paired the presentation of the volatile fraction of urine from individual mice via a custom-built olfactometer with large-scale, high-resolution calcium imaging in the hippocampus of awake head fixed mice. We focused on area CA2, whose crucial role in social recognition memory is well established on a behavioral level, and report network computation features underlying social as well as non-social odor representation. We show found that during passive experience of individual novel social odors, CA2 uses a sparse code to form specific and robust neural representations that allow for stimulus decoding with high accuracy. Moreover, these representations are highly associative and incorporate valence in a flexible manner when tested in an associative reward learning task. Optogenetic silencing of CA2 impairs the learning of odor-reward associations, supporting a causal role of CA2 in social odor discrimination. To further explore the logic by which CA2 encodes odor stimuli, we trained mice in the reward learning task using two novel social odors and two non-social odors, in which one each of the social and non-social odors was rewarded. After learning, we found that CA2 activity can distinguish all four odors in a manner consistent with a geometry of neural representations allowing for it providing abstract representations of

social versus non-social odors. Together these results argue strongly that CA2 forms a hub that classifies and distinguishes multiple forms of olfactory stimuli, which both enhances the learning of olfactory-reward associations and is poised to contribute to social memory storage.

Title: Viral inhibition of HDAC3 in the infralimbic cortex during Pavlovian extinction eliminates Pavlovian-to-instrumental transfer

Authors: *R. C. DERMAN[1], D. P. MATHEOS[2], M. LATTAL[1], M. A. WOOD[2];

Abstract: The extinction of learned (conditioned) behaviors is an essential process for functioning adaptively in an ever changing environment. In the context of Pavlovian processes, extinction of conditioned responses (CRs) occurs when an unconditioned stimulus (US) is omitted from presentations of an acquired conditional stimulus (CS). Although extinction results in the disappearance CRs, the original associative CS-US memory is preserved and can be revealed with several experimental procedures. Most of the approaches that test the preservation of the original association focus on the return of CRs themselves (e.g., spontaneous recovery, reinstatement, and contextual renewal), however one particularly powerful approach is a test for Pavlovian-to-instrumental transfer (PIT). In this approach presentation of an acquired CS invigorates an independently acquired instrumental behavior (e.g, lever pressing for a US). Although extremely useful for understanding behavioral mechanisms of extinction, PIT has been underutilized for the purposes of studying the extent and efficacy of extinction training. Here we evaluate the effects of viral manipulation of histone deacetylase 3 (HDAC3) in the infralimbic (IL) cortex of male Long Evans rats on Pavlovian extinction. Normally functioning HDAC3 keeps chromatin in a repressive state and reduces transcription; in contrast, inhibition of HDAC3 shifts chromatin to a permissive state, facilitating transcription and enhancing learning and memory. The IL has been identified as a key structure meditating the preservation of associative memories in the face of extinction training. In this study, following initial instrumental training and Pavlovian conditioning, rats received IL injections of a point mutant HDAC3 virus to

interfere with HDAC3 function, a wild type HDAC3 to enhance HDAC3 activity, or null virus to serve as control. After recovery rats underwent Pavlovian extinction followed by PIT testing. During extinction training CRs (food cup entries) disappeared with only subtle differences in the rate of extinction among groups. However, during PIT testing only null and wild type transduced groups demonstrated PIT, pointing to a preservation of the original CS-US association. In contrast, PIT was notably absent in the point mutant transduced group, suggesting a degradation of the original CS-US association. In a final tests for contextual renewal of CRs, testing in a new context revived conditioned food cup entries only in the null transduced group. These data identify HDAC3 as one underlying mechanism by which the IL acts to preserve original memories.

Title: Repeated morphine exposure alters prelimbic cortex activity and induces risk-taking behavior in rats

Authors: *A. M. VASQUEZ[1], C. B. QUAVE[1], E. P. BORA[1], C. L. CHIDOMERE[1,2], G. AQUINO-MIRANDA[1], D. S. ENGELKE[1], F. H. DO MONTE[1];

Abstract: Opioid addiction is associated with impaired risk-related decision-making. However, it remains unclear how the brain processes risk in the pursuit of opioid use to alter motivated behavior during conflict situations. The prelimbic area of the medial prefrontal cortex (PL) has been associated with executive functioning and behavioral responses to rewarding and aversive stimuli. We therefore hypothesized that repeated opioid exposure would suppress activity in PL and increase risk-taking behavior. To test this hypothesis, we designed an approach-avoidance conflict model that involves the presentation of an innate fear-inducing predator odor. Using a biased opioid conditioned place preference (CPP) model, we injected adult male Long-Evans rats with saline (n = 36) or morphine (n = 24) and exposed them to their least-preferred side of the

chamber on alternating days over a 10-day period. After 72 h of forced abstinence, morphine-treated rats showed a higher preference for the drug-paired side when compared to the saline group ($p < 0.001$). Immediately after preference testing, we added predator odor (cat saliva) to the previously drug-paired side to produce a motivational conflict. While the saline group showed avoidance to the cat odor during the conflict test, the morphine group continued to enter the drug-paired side, demonstrating that morphine conditioning induces an increase in risk-taking behavior. Single-unit recordings from PL neurons revealed a significant number of cells with suppressed firing rates after acute administration of morphine (22 %, 19/86), but not saline (6 %, 5/64; Fisher exact test, $p = 0.011$). On the last conditioning day, morphine administration did not induce changes in PL firing rates as compared to saline ($p = 0.397$), suggesting that PL neurons adapt to the effects of repeated morphine over time. During the conflict test, distinct populations of PL neurons were either excited ($n = 28$ neurons, $p = 0.011$) or inhibited ($n = 14$ neurons, $p = 0.0061$) when saline rats entered the cat odor-paired side as compared to when they entered the same side during the preference test. Interestingly, this change in neural activity was not observed in the morphine group during the conflict test. Taken together, our results demonstrate that opioid-induced CPP is associated with reduced inhibition of PL activity following repeated administrations of morphine. In addition, after repeated opioid exposure, PL neurons failed to respond to threat stimuli, and this pattern of neuronal activity occurred alongside increased risk-taking behavior during approach-avoidance conflict.

Title: Dynamics of prelimbic cortex activity encode the predictive value of reward-associated cues.

Authors: *C. B. QUAVE[1], G. AQUINO-MIRANDA[1], R. ALBERT[1,2], C. L. CHIDOMERE[1,3], E. BORA[1], M. CATTANI[1,4], J. A. FERNANDEZ-LEON[1], D. S. ENGELKE[1], F. H. DO MONTE[1];

Abstract: Behavioral adaptation to shifts in food availability is critical for maintaining efficiency during foraging. Neurons in the prelimbic prefrontal cortex (PL) display changes in firing rates in response to food-associated cues. However, it is unknown whether PL activity encodes fast changes in food availability (e.g. reward omission). We hypothesized that PL neurons show modified responses to reward availability and associated cues according to variations in reward predictability**.** Male Long-Evans rats implanted with a single-unit electrode in PL were trained to press a lever to obtain a reward (single sucrose pellet) in a nearby dish. Reward availability was limited to the duration of 15-second audiovisual cues. Rats were then subjected to an intercalated omission session (20 rewarded and 20 omitted trials semi-randomly interspersed) followed by a repeated omission session (18 rewarded followed by 20 omitted trials) to compare the neuronal correlates of unexpected vs. expected reward omission, respectively. PL firing rates were analyzed during both the onset of cues and when the animal's head entered the dish after cued lever presses. During unexpected reward omission, rats exhibited "frustrative behaviors" characterized by higher lever press rate, greater number of burst presses, and increased locomotion speed (ANY-Maze automated video tracking system). However, these behaviors were not observed when reward omission was expected. Recordings from PL neurons (n = 233 cells from 16 rats) revealed a subset of cells that altered their firing rates (16% excited, 14% inhibited) when rats detected the presence of reward in the dish. Interestingly, 58% of these cells did not respond when reward was omitted, suggesting that PL neurons encode loss of a previously available reward. During expected reward omission, a subset of cells emerged exhibiting increased firing rates exclusively upon repeated detection of reward omission (8%), indicating that some PL neurons are recruited when reward omission becomes predictable. In addition, 13% of PL cells showed reductions in firing rates upon repeated reward cue presentation, half of which did not respond to repeated omission cues. It is possible that this progressive loss of inhibition in PL neurons may encode the reduced predictive value of cues when reward omission becomes an expected outcome. Together, our findings suggest that separate populations of PL neurons signal immediate vs. persistent reward loss and that real-time updating of PL activity is associated with dynamic changes in the predictive value of reward cues.

Title: Activity in the prelimbic prefrontal cortex encodes individual differences in approach-avoidance conflict in rats

Authors: *G. AQUINO-MIRANDA[1], J. A. FERNANDEZ-LEON[1], D. S. ENGELKE[1], A. GODSON[2], F. H. DO MONTE[1];
[1]Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [2]Rice Univ., Houston, TX

Abstract: Neurons in the prelimbic subregion of the prefrontal cortex (PL) respond to both reward- and threat-associated cues. However, whether PL activity regulates the animals' decision to approach or avoid such cues as remains unknown. To address this question, male Long-Evans rats with single-unit recording electrodes implanted in PL were initially trained to press a bar for sucrose during the presentation of audiovisual cues. Next, rats were fear conditioned by pairing a neutral odor with electrical footshocks. During the test session, rats were placed in an arena and exposed to three phases: only audiovisual cues (reward), only odor cues (fear), or both simultaneously (conflict). During the reward phase, animals pressed the bar immediately after the onset of the food cues. In the fear phase, animals showed robust defensive behaviors characterized by high levels of freezing, avoidance, and risk-assessment responses. Interestingly, two different behavioral phenotypes emerged during the conflict phase: rats that continued searching for food (*pressers)* vs. rats that remained in the hidden area and showed suppression of food-seeking responses (*non-pressers*). PL recordings during the reward phase revealed a greater number of reward-cue responses in *pressers* (~33% of 237 neurons), when compared to *non-pressers* (~21% of 89 neurons; Fisher Exact Test, $p = 0.042$*)*. Notably, the magnitude of reward-cue responses observed during the conflict phase was similar to the reward phase for *pressers,* but was drastically reduced for *non-pressers*. Using a combination of recordings and optogenetics for photoidentification of distinct subtypes of PL neurons in *pressers*, we found that ~31% of PL glutamatergic (PL^{GLUT}) neurons inhibited their spontaneous firing rate during the reward phase, when compared to baseline. Presentation of the conditioned odor during the fear phase disinhibited ~67% of these PL^{GLUT} neurons, whereas the introduction of reward cues during the conflict phase restored the inhibition to the same levels as the reward phase. In contrast, changes in spontaneous firing rate of PL GABAergic neurons were similar across the different phases. Moreover, photoactivation of PL^{GLUT} neurons during the onset of the reward cues reduced reward-seeking responses in *pressers,* whereas photoinhibition of PL^{GLUT} neurons in non-pressers reduced defensive responses and biased animals' behavior toward the food area during conflict (Wilcoxon test, all p values < 0.05). Together, our results establish a role for PL in the regulation of approach-avoidance conflict by demonstrating that reduced activity in PL^{GLUT} neurons is associated with increased risky sucrose-seeking behavior.

Title: Shifts in the activity of prelimbic cortex and paraventricular thalamic neurons correlate with changes in food-seeking strategies in a predator-associated context

Authors: *D. S. ENGELKE[1], G. AQUINO-MIRANDA[1], M. CATTANI[2], F. H. DO MONTE[1]; [1]Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [2]Tufts Univ., Medford-Somerville, MA

Abstract: In nature, animals live in dynamic environments where availability of food and risk of predation constantly change. Updating a contextual memory is important to resume foraging behavior when a threatening environment becomes safe again, but which neural circuits regulate this dynamic process remains unclear. Rats exposed to predator odor form a contextual fear memory and express defensive behaviors when returned to the same environment. Here, we designed a contextual fear conflict model in which rats have to forage for food in a context previously associated with predator odor (cat saliva). Adult male Long-Evans rats were initially trained to press a lever for food during the presentation of audiovisual cues. Next, rats were exposed to a context with cat odor and in the following day reexposed to the same chamber for a contextual fear conflict test. To investigate whether foraging behavior changed across the session, we compared food-seeking responses during the first 18 food cues (early) vs. the last 18 food cues (late). Although cued lever presses remained the same across the session, the latency to press reduced from early to late cues, suggesting behavioral flexibility over time. Recently, we demonstrated that cat odor exposure suppresses food-seeking responses, and this effect is mediated by increased neuronal activity in the paraventricular nucleus of the thalamus (PVT). The PVT is reciprocally interconnected with the prelimbic cortex (PL), a region directly involved with behavioral flexibility and contextual information. To test whether shifts in the activity of PL and PVT neurons correlate with the dynamic changes in lever-press latency observed during the test, we performed single-unit recordings from PL (223 cells, 14 rats) and PVT (161 cells, 13 rats) neurons in two different cohorts. We observed that a higher number of PL neurons changed

their spontaneous activity from early to late session (37 % excited, 42 % inhibited) when compared to PVT neurons (16 % excited, 20 % inhibited, $p < 0.001$). When we time-locked neuronal activity with the onset of the food cues, both PL and PVT neurons showed fast excitatory food cue responses at the early phase, with sustained excitatory food cue responses emerging only at the late phase when rats exhibited shorter latencies to press the lever. In contrast, fast inhibitory food cue responses in PL and PVT neurons were observed at both phases, but sustained inhibitory responses were exclusively observed in PVT neurons at the early phase. Dynamic shifts in PL and PVT activity may serve to update information about the predator context and food cues, thereby allowing changes in foraging strategies in a conflicting environment.

Title: Computational-designed training protocols enhance associative learning in rats

Authors: *X. O. ZHANG[1], Y. ZHANG[1], D. S. ENGELKE[1], C. E. CHO[2], P. D. SMOLEN[1], J. H. BYRNE[1], F. H. DO MONTE[1];
[1]Dept. of Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [2]Rice Univ., Houston, TX

Abstract: Associative learning requires the activation of protein kinases with distinct temporal dynamics. Learning protocols with computationally designed inter-trial intervals (ITIs) that maximize the interaction between fast-activated protein kinase A (PKA) and slow-activated extracellular signal-regulated kinase (ERK) enhance memory acquisition in *Aplysia*. Here, we tested whether an optimized learning protocol, predicted computationally to increase the overlap between PKA and ERK signaling in rat hippocampus, would enhance memory formation. On day 1, male adult Long-Evans rats were exposed to an auditory fear conditioning session (Context A) with multiple trials of a conditioned stimulus (CS, 3 kHz tone, 30 s) that co-

terminated with an unconditioned stimulus (US, footshock, 0.7 mA, 0.5 s). Rats were randomly assigned to 3 groups: i) full conditioning (FC, n = 7), which received 8 CS-US pairings with 4.5 min ITIs; ii) partial conditioning (PC, n = 6), which received only 4 CS-US pairings with 4.5 min ITIs; and iii) enhanced partial conditioning (EPC, n = 7), which received only 4 CS-US pairings, but with ITIs of 8, 8 and 16 min. After conditioning, all groups exhibited high levels of freezing (~70 %) and reduced locomotion. On day 2, rats were exposed to a retrieval test consisting of two CS presentations in a novel context (Context B). Rats in the FC and EPC groups showed reduced locomotion speed when compared to the PC group, suggesting stronger memory retrieval. On day 3, rats were returned to Context A for extinction training (12 CS presentations only). Interestingly, EPC and FC groups showed impaired extinction learning characterized by sustained freezing levels within the session, compared to the PC group which showed successful extinction as indicated by reduced freezing and increased locomotion. Next, we tested whether the same optimized ITIs would enhance fear extinction. A separate group of rats that were previously trained to press a lever for sucrose were fear conditioned, and then randomly assigned to three groups: i) full extinction (FE, n = 12), which received 12 CS presentations with 2.5 min ITIs; ii) partial extinction (PE, n = 13), which received only 4 CS presentations with 2.5 min ITIs; and iii) enhanced partial extinction (EPE, n = 11), which received only 4 CS presentations, but with ITIs of 8, 8 and 16 min. Compared to FE and PE groups, the EPE group showed higher lever press motivation during a spontaneous recovery test on day 28, suggesting an enhancement in the extinction of contextual fear memory. Together, these results demonstrate that computationally designed learning protocols based on PKA and ERK dynamics may enhance associative learning in mammals.

Title: Sex differences in reward processing: A focus on incentive contrast

Authors: *K. M. THOMPSON[1], E. L. STEWART[2], A. K. QUINN[2], H. C. CROMWELL[3]; [1]Neuropsychology, [2]Psychology, [3]Bowling Green State Univ., Bowling Green, OH

Abstract: Research on sex differences for preferences of reward outcomes, such as flavors, show mixed results between male and female rats. Some consumption studies suggest that sexual dimorphism of the brain is contributing to female's consistent performance at higher rates for sucrose concentrations than males; however, these finding are not reliably shown between

studies. The current study examined sex difference in motivation for sucrose reward and focused on relative reward effects as they interact with basic motivation. Inducing hunger through food restriction is a method that is used in the present study to examine its influence on reward processing. This study uses three levels of sucrose solution concentrations as rewards between 12 male and 12 female Sprague-Dawley rats. This study is focused on determining if sexual dimorphism of the brain is reflected by performance differences of processing reward information. Specifically, we are examining the differences between the sexes on their ability to change performance on the original concentration (control) given when an up-shift or down-shift occurs. If differences in responses to the same outcome occurs, then it is labeled as an incentive contrast (IC). MED-PC IV software was used to record nose-pokes, licking rates, and latency data, while consumptions were taken directly from sucrose syringes (ml) after trials. Results support few to no sex differences in reward discrimination or IC, but large sex differences in sucrose consumption. Moreover, significant effects were found for the influence of motivational state and behavioral context. Animals expressed incentive contrast when food restricted and in the context of their home cage. These effects were diminished to absent when animals ate freely or were tested in an operant task for relative reward effects. Overall, the findings point to diverse influences on sexual dimorphism for reward processing. Other implications include brain behavior relations such as memory consolidation, motivation, and drug and alcohol use/abuse.

Title: Impact of social isolation on the prefrontal-nucleus accumbens circuit critical for social recognition in mice

Authors: *G. PARK[1], C. RYU[2], S. KIM[1], S. KIM[3], Y.-S. LEE[4];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Physiol., Seoul Natl. Univ. Col. of Med., Jongno-Gu, Seoul, Korea, Republic of; [4]Dept. of Physiol., [3]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: It is known that social isolation in early life causes prolonged deficit in cognitive functions. Previous studies have shown that social isolation in the postnatal critical period altered functions of various medial prefrontal cortical (mPFC) within a variety of related behaviors including social preference in mice. However, it is still elusive how other aspects of social functions and which downstream targets for the mPFC are affected by the insubstantial social experience in young age. In this study, we observed that socially isolated mice in their postnatal developmental period showing an impairment in social behavior which was not rescued by following re-socialization period. Interestingly, we found that the functional connectivity between mPFC and the shell part of nucleus accumbens (NAc shell) is altered after the social isolation in both electrophysiology and c-fos immunohistochemistry. Consistently, *in vivo* Ca^{2+} imaging using fiber photometry also revealed an increased activity of NAcSh-projecting IL neurons when the subject mouse encountered a familiar mouse only in normal mice, but not in singly housed mice. Chemogenetic inhibition of NAcSh-projecting IL neurons caused a significant impairment in the social recognition while activation of such neuron in single isolated mice exhibited a rescued social recognition. This result suggests that early social experience of mice can have a lifelong-lasting impact on their social behavior, which is critically modulated by mPFC-NAc shell circuit.

Title: Dopamine release in nucleus accumbens core during social behaviors in mice

Authors: *B. DAI[1], F. SUN[2], A. KUANG[1], X. TONG[1], Y. LI[2], D. LIN[1];
[1]New York Univ. Sch. of Med., Neurosci. Inst., New York, NY; [2]Peking Univ., Beijing, China

Abstract: Social behaviors are among the most important and rewarding motivational behaviors. How dopamine, a “reward” signal, releases in the nucleus accumbens (NAc) during social behaviors has become a topic of interest for decades. However, due to limitations in temporal resolution, long-term stability and sensitivity of early recording methods, a complete understanding of moment-to-moment dopamine responses during social behaviors remains lacking. Here, we employ a genetically encoded dopamine sensor, $GRAB_{DA2h}$, to record dopamine activity in the NAc core in mice and find acute changes in extracellular dopamine

levels during all three phases of social behaviors: approach, investigation and consummation. We find that dopamine releases during approach and investigation correlate with animal's motivation and familiarity towards the social target respectively whereas its release during consummatory phase signals the valence of the experience. Negative and positive social experiences evokes opposite dopamine release patterns at both the onset and offset of the experience. Furthermore, dopamine release during sexual and aggressive behaviors are sexually dimorphic with an overall higher level in males than in females. Taken together, our results reveal complex information encoded by NAc dopamine activity during social behaviors and beyond.

Biol. of Polish Acad. of Sciences, Warsaw, Poland, Warsaw, Poland; [2]Lab. of Neuroinformatics, Nencki Inst. of Exptl. Biol. of Polish Acad. of Sciences, Warsaw, Poland, Warsaw, Poland

Abstract: Classifying individuals as members of an in-group, that is social circles with whom we identify, is a rapid and unconscious process. Consequently, very little is required to discriminate against the ones we identify as out-group, which happens on a similarly prompt and arbitrary basis, and oftentimes results in an unconscious bias. Arguably, it is because classifying individuals as either "us" or "them" is a hard-wired neuronal mechanism present in many mammalian species**.** Now more than ever, understanding brain mechanisms underlying the formation of attachment and resulting social bonding, seems crucial for our ability to address aggravating health and societal issues. As studies indicate a crucial role of the prefrontal cortex in social bonding, we studied the effects of the cell-specific inhibition in its prelimbic part (PL). To investigate various aspects of social behavior group-housed mice were tested in both, automated, ecologically relevant assays, which closely follow murine ethology, and standard

tests of social affiliation. Specifically, we used Eco-HAB, a system measuring spontaneous social interactions to assess sociability and exploration of social scents, and IntelliCage, a system measuring cognition to investigate animals' ability to socially learn from their conspecifics about aversive and appetitive stimuli. Additionally, standard social familiarity assays were used to assess the propensity to spend time with cagemates after separation. Using genetically modified mice and the Pharmacologically Selective Actuator Module-based chemogenetic approach, we performed time-constrained manipulation of the PV-expressing neurons in the PL and tested subjects' behavior. We show that activation of the PV-expressing neurons in the PL impairs animals' sociability expressed towards familiar conspecifics. Specifically, it reduces spontaneous social interactions with cagemates, diminishes animals' interest in familiar social olfactory stimuli, and decreases the propensity to spend time with a recently separated cagemate. On the other hand, such manipulation of neuronal activity does not influence the exploration of novel social stimuli. Moreover, it has no impact on social learning. Taken together, our findings indicate distinctive neural mechanisms influencing bonding with familiar conspecifics, but not other forms of social behavior. Our research reveals a specific role of the PV-expressing cells in the PL in the maintenance of the social structure and in sustaining ongoing interest in familiar conspecifics. Thus, presented data lays the foundation for understanding the neural underpinnings of social attachment.

Title: Opposite activity dynamics of two midbrain circuits encodes social novelty

Authors: *S. MOLAS, T. G. FREELS, R. ZHAO-SHEA, A. R. TAPPER;
Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Social investigations represent innate motivational drives critical for species survival and community wellbeing. Individuals engage social contacts to fulfill needs of internal states and these contacts are strongly associated with the overall salience of the social stimuli. For instance, novel (or unfamiliar) social cues are more attractive than familiar ones and lead to higher levels of arousal/attention. This enhanced response to social novelty is necessary to assess

the potential benefits of sociability, as well as its threatening aspects such as aggression. Social novelty responses are significantly disrupted in numerous neurodevelopmental and neuropsychiatric disorders including autism and schizophrenia, although to date, the neurobiological substrates underlying novel social investigations in a healthy brain, and how they are affected in neuropathological conditions remain unclear. Accumulating evidence indicates that dopaminergic (DAergic) midbrain circuits, including the mesolimbic pathway, promote exploratory assessment and guide approach/avoidance behavior to novel social stimuli. In addition, we previously demonstrated that the interpeduncular nucleus (IPN) of the midbrain represents a neuroanatomical substrate for familiarity signaling and the preference for novelty. The IPN is a major component of the habenulo-interpeduncular pathway that connects the limbic forebrain with midbrain/hindbrain areas, integrating cognitive with emotional and sensory processing. However, how DA responses habituate as novel stimuli become familiar and the interplay between DAergic ventral tegmental area (VTA) and IPN GABAergic neuron activity during these transitions is poorly understood. Here, we have implemented fiber photometry combined with biosensors to record activity dynamics from VTA DAergic neurons, IPN GABAergic neurons, and striatal DA release in awake behaving mice during social novelty tests and during novel social stimuli transitions to familiarity. Fiber photometry recordings reveal that activity dynamics of IPN GABAergic subpopulations inversely correlates with the DA response to novelty. In addition, we have mapped activity and functional connectivity of IPN GABAergic--hindbrain projecting neurons that convey social novelty information. The present study unravels a new circuitry within the novelty network that may be key in understanding disrupted social novelty response observed in numerous neurological disorders.

Abstract: Anxiety is a negative emotional state that is overly displayed in anxiety disorders and depression. Although anxiety is known to be controlled by distributed brain networks, key components for its initiation, maintenance and coordination with behavioral state remain poorly understood. Here, we report that anxiogenic stressors elicit acute and prolonged responses in glutamatergic neurons of the mouse medial preoptic area (mPOA). These neurons encode extremely negative valence and mediate the induction and expression of anxiety-like behaviors. Conversely, mPOA GABA-containing neurons encode positive valence and produce anxiolytic effects. Such opposing roles are mediated by competing local interactions and long-range projections of neurons to the periaqueductal gray. The two neuronal populations antagonistically regulate anxiety-like and parental behaviors: anxiety is reduced, while parenting is enhanced and vice versa. Thus, by evaluating negative and positive valences through distinct but interacting circuits, the mPOA coordinates emotional state and social behavior.

Title: Neural control of prosocial touch in comforting behavior

Authors: Y. WU, J. DANG, L. KINGSBURY, M. ZHANG, F. SUN, R. HU, *W. HONG; UCLA, Los Angeles, CA

Abstract: The ability to help and care for others fosters social cohesiveness and is vital to the physical and emotional well-being of social species including humans. Affiliative social touch, such as allogrooming, is a major type of prosocial behavior that provides comfort to others. It serves to establish and strengthen social bonds throughout a wide range of social species, such as birds, bats, rodents, canids, equids, and primates, and can help console distressed conspecifics.

However, neural circuits that promote prosocial touch have remained elusive. Here, we show that mice exhibit affiliative allogrooming behavior toward distressed partners, providing a consoling effect. This phenomenon occurs in response to different types of stressors and can be evoked by olfactory cues from distressed partners. We record neural activity of the medial amygdala (MeA) and find that single-neuron and ensemble activity in the MeA respond differentially to stressed vs. unstressed animals and encode allogrooming behavior. Through functional manipulations and intersectional genetic targeting, we establish a direct causal role of a select subpopulation of MeA neurons in controlling affiliative allogrooming. Our study uncovers a crucial node that controls affiliative social touch during prosocial interaction and opens up new avenues for interrogating the neural basis of prosocial behavior.

Title: Leptin enhances social motivation and reverses chronic stress-induced social anhedonia during adolescence

Authors: Y. LEI[1], D. WANG[2], Y. BAI[1], J. NOUGAISSE[1], N. L. WEINTRAUB[1], M. GUO[2], X.-Y. LU[1];

Abstract: Social anhedonia, a loss of interest and pleasure in social interactions, is a common symptom of depression as well as other psychiatric disorders. Depression can occur at any age, but typically emerges in adolescence or early adulthood, which represents a sensitive period for social interaction that is vulnerable to stress. In this study, we evaluated social interaction reward using a conditioned place preference (CPP) paradigm in adolescent male and female mice. Adolescent mice of both sexes exhibited a preference for the social interaction-associated context. Chronic unpredictable stress (CUS) impaired the development of CPP for social interaction, mimicking social anhedonia in depressed adolescents. Conversely, administration of

leptin, an adipocyte-derived hormone with antidepressant-like properties, enhanced social interaction-induced CPP in non-stressed control mice and reversed social anhedonia in CUS mice. By dissecting the motivational processes of social CPP into social approach and isolation avoidance components, we demonstrated that leptin treatment increased isolation aversion without an overt social reward effect. Further mechanistic exploration revealed that leptin stimulated oxytocin transcription in the paraventricular nucleus of the hypothalamus, while blockade of oxytocin receptors abolished the leptin enhancement of socially-induced CPP. These results establish a behavioral model to study social anhedonia in adolescent mice and provide evidence that leptin's effects on social motivation are mediated by oxytocin.

Abstract: The worldwide obesity rate in adolescents has been on the rise in recent years. Previous research has reported that the consumption of high calorie diets can affect the proper development of structures in the brain during adolescence. As a result, cognitive alterations, mood, personality and eating disorders can manifest. On the other hand, it has been widely established that physical exercise is beneficial for various cognitive functions and has a positive

influence on certain social behaviors under stress conditions, which could counteract the effect of high-fat diets (HFD). In this study, we evaluated the effect of voluntary physical exercise in c57BL6 mice exposed to a HFD (consisting of 45% of fat) for a period of 24 weeks, a running wheel was added after 3 months of diet exposure. Four groups of animals were used: normal chow (NC), normal chow + running wheel (NC-R), high-fat diet (HFD) and high-fat diet + running wheel (HFD-R). After 24 weeks of diet exposure, behavioral tasks were evaluated: memory recognition (Novel Object Recognition Task [NOR]), spatial memory (object location memory [OLM]) and social memory (three-chamber test [3CT]). Glucose tolerance test and the body weight of all groups of animals were measured.We observed that HFD animals are not able to recognize between two objects previously presented, and we observed an improvement in the recognition index of HFD-R animals when we compare normal and treated groups. Results of OLM test indicated an impairment in the spatial memory on HFD fed animals which could not discriminate between the displaced and non-displaced object. However physical activity improved this memory in the HFD-R group.. 3CT test showed and impairment in the social memory in the HFD animals, that could not recognize the conspecific that were in contact with previously. Voluntary physical activity also improves recognition of a previously known conspecific. These results suggest a palliative effect of exercise when HFD exposure has affected brain function, restoring both metabolic profile and cognitive performance even after a long exposure started at weaning.

Title: Altered social behavior following conditional genetic deletion of the mu opioid receptor (Oprm1) from nucleus accumbens neurons

Authors: *C. TODDES[1], C. RETZLAFF[1], E. LEFEVRE[1], B. L. KIEFFER[2], P. E. ROTHWELL[1];
[1]Univ. of Minneosta, Minneapolis, MN; [2]McGill Univ. Psychiatry, Douglas Hosp. Res. Ctr., Verdun, QC, Canada

Abstract: The mu opioid receptor regulates naturally rewarding behaviors, including social interaction and drug reward. The constituitive mu opioid receptor knockout mouse has been shown to display impaired reciprocal social interaction and social reward alongside an attenuation in response to the rewarding aspects of opioid drugs. Our group recently identified changes within the microcircuit of the nucleus accumbens following constitutive mu opioid receptor deletion that specifically affected perisomatic inhibitory connections onto D2 receptor expressing medium spiny neurons (Toddes et al., *J Neurosci*, in press). The current study sought to expand upon these findings by conditionally deleting mu opioid receptors from targeted cell types within the nucleus accumbens microcircuit and evaluating the resultant effect upon social related behaviors. We deleted mu opioid receptors from cells within the nucleus accumbens by injecting AAVdj-hsyn-cre-GFP, AAV2retro-hSyn-Cre-P2A-tdTomato, or AAV8-mdlx-icre-tdTomato into equal numbers of male and female mice with a floxed OPRM1 gene, or by crossing our floxed mouse line with a line expressing Cre in either the D1 receptor expressing or D2 receptor expressing medium spiny neurons. We found a significant attenuation in reciprocal social behaviors of male and female mice injected with either local or retro-Cre and thus focused our attention on neurons specifically within the nucleus accumbens. Interestingly, mice lacking mu opioid receptors in either D1- or D2-medium spiny neurons displayed no changes in reciprocal social behaviors. However, male and female mice with a conditional deletion of mu opioid receptors from only GABAergic interneurons (AAV8-mdlx-icre-tdTomato) demonstrated a robust attenuation of reciprocal social interactions that recapitulated the phenotype seen in the constitutive knockout model. Responses to the analgesic, hyperlocomotive, and rewarding properties of opioid drugs were also tested in these mouse models with a change in response only demonstrated in mice lacking mu opioid receptors on both D1- and D2-medium spiny neurons where there was a significant attenuation of hyperlocomotion. These results indicate that inhibitory interneurons within the nucleus accumbens may be a key target for mu opioid receptor modulation of social interaction in male and female mice.

Title: An fMRI study of grandmaternal neural responses to grandchild stimuli

Authors: *J. RILLING, A. GONZALEZ, M. LEE;
Dept. of Anthropology, Emory Univ., Atlanta, GA

Abstract: In many societies, grandmothers are important caregivers, and grandmaternal investment is often associated with improved grandchild well-being. Here, we present the first study to examine grandmaternal brain function. We recruited 50 grandmothers with at least one biological grandchild between 3 and 12 years old. Brain function was measured with fMRI as grandmothers viewed pictures of their grandchild, an unknown child, the same-sex parent of the grandchild, and an unknown adult. Grandmothers also completed questionnaires to measure their degree of involvement with and attachment to their grandchild. After controlling for age and familiarity, viewing grandchild pictures activated areas involved with emotional empathy (insula and secondary somatosensory cortex) and movement (motor cortex and supplementary motor area). Grandmothers who more strongly activated areas involved with cognitive empathy (temporo-parietal junction and dorsomedial prefrontal cortex) when viewing pictures of the grandchild desired greater involvement in caring for the grandchild. Finally, compared with results from an earlier study of fathers, grandmothers more strongly activated regions involved with emotional empathy (dorsal anterior cingulate cortex, insula, and secondary somatosensory cortex), and motivation (NAc, ventral pallidum and caudate nucleus). All in all, our findings suggest that emotional empathy may be a key component of grandmaternal responses to their grandchildren.

Title: Sex differences in the creative brain

Authors: *J.-Y. YANG, Y.-C. CHAN;
Natl. Tsing Hua Univ., Hsinchu City, Taiwan

Abstract: Creative thought relies on an associative mode of processing, which involves novelty and usefulness. Executive control network (ECN) and default-mode network (DMN) are involved in creative processes when generating and evaluating ideas (Beaty et al., 2015; Kleinmintz et al., 2019). The present study employed a fMRI paradigm to explore sex differences in appreciating alternative uses production. Forty healthy participants (20 males and 20 females) were right-handed and no history of neurological or psychiatric disease. The stimuli were presented across conditions for the 32 creative objects and 32 common objects (baselines).

The present study used a 2 × 2 mixed factorial design with sex (males and females) and stimulus type (creativity and common) as factors. Imaging was performed using a 3 T Siemens Magnetom Prisma scanner using a standard 20-channel head coil at the Imaging Center for Integrated Body, Mind and Culture. The fMRI images were pre-processed and analyzed using Statistical Parametric Mapping (SPM12) implemented in Matlab. A flexible factorial analysis was performed for brain activations. Creative appreciation elicited greater activation in males than females in the left precuneus, left middle frontal gyrus (MFG), left middle temporal gyrus (MTG), and right posterior cingulate gyrus (PCC), while females showed greater activation than males in the left midbrain, left MTG, right superior frontal gyrus (SFG), right temporoparietal junction (TPJ), left dorsal anterior cingulate gyrus, right precuneus, left PCC, left MFG, right insula, and left inferior parietal lobule (IPL) associated creative appreciation. These finding provide the mechanisms underlying the processing of creative appreciation for the sex differences in cognitive control, attention, evaluative processes, and feelings of pleasure.

Title: Idiosyncratic emotional responses evoked by music

Authors: S. SPIVACK[1], A. POINCOT[2], G. IENNER[2], *P. WALLISCH[1];
[1]Data Sci., [2]Psychology, New York Univ., New York, NY

Abstract: We are interested in emotional responses evoked by music. Specifically, we wondered whether these responses are idiosyncratic or whether they can be predicted by the sonic qualities of the music. To investigate this question, we exposed a large sample of research participants to a diverse musical selection and recorded their emotional responses as well as subjective appraisal and arousal. We then related these emotional responses to the sonic characteristics of the music as well as to each other, between participants. We found that music evokes strong emotional responses, but that appraisal and emotional responses are highly idiosyncratic and not well determined by sonic properties of the music, in contrast to arousal. We model these responses and conclude that personal features of the individual are reflected in their “emotional fingerprint” in response to music.

Title: How do I love thee?: Using psychophysiology to validate a relationship satisfaction theory.

Authors: *E. LEAVER[1], D. PHILLIPS[2], A. MIANO-BURKHARDT[1], S. CURTIS[1], M. P. W. DONELLY[3], S. FURMAN[1];
[1]Salisbury Univ., Salisbury, MD; [2]Psychology, Univ. of South Carolina Aiken, Aiken, SC; [3]Menomie, Menomie, WI

Abstract: This is the first study that has used psychophysiological measures to investigate the validity of Gary Chapman's (1992) relationship satisfaction theory, *The Five Love Languages.* This theory proposes that individuals have a preferred means of communicating love. Heart rate, skin conductance, and respiration rate were recorded while 89 college students listened to guided imagery scripts representing one of the five love languages (LL). Using a within-subjects design, a repeated-measures ANOVA was run on each physiological measure. A composite score of the physiological responses indicated a significant increase in arousal for when participants listened to their primary LL as compared to their non-preferred LL ($t(88)=-2.3$, $p=.02$, $d=.37$). For skin conductance ($t(88)=-2.03$, $p<.05$, $d=.35$) and heart rate ($t(88)=-2.15$, $p=.03$, $d=.35$), we observed a significant difference in physiological response found for the preferred versus non-preferred LL. This study gives the first evidence that Chapman's five love languages may be reflected in human physiology, suggesting some degree of construct validity for this relationship typology theory. Interestingly, whether an individual received their preferred love language from their significant other or not had no impact on their relationship satisfaction nor their commitment. Unresolved questions include the nature of the relationship between LLs, relationship satisfaction, and commitment.

Title: Subjective Well-Being Predicts Foraging Behavior in Humans

Authors: *V. U. LUDWIG[1,2], V. GUPTA[6], D. L. CRONE[3], A. RAMAKRISHNAN[6], M. L. PLATT[1,2,4,5];
[1]Dept. of Neurosci., [2]Wharton Neurosci. Initiative, [3]Positive Psychology Ctr., [4]Marketing Department, Wharton Sch. of Business, [5]Dept. of Psychology, Sch. of Arts and Sci., Univ. of Pennsylvania, Philadelphia, PA; [6]Indian Inst. of Technol., Kanpur, India

Abstract: Foraging is a fundamental behavioral challenge all brains evolved to solve. The marginal value theorem (MVT) specifies the optimal solution to determining when to abandon a depleting resource and search for a new one: leave the current patch when the instantaneous return rate falls below the environmental average. Although all animals tested thus far conform on average to the MVT, systematic differences are observed across species adapted to rich or poor environments as well as in mental health disorders including anxiety (Ramakrishnan et al., SFN 2018, 2019), problem gambling (Addicott et al. 2015), and Parkinson's disease (Rutledge et al., 2009). These observations suggest that conditions characterized by altered patterns of decision making may reflect systematic variation in the function of circuits that collectively carry out MVT computations.

Although variation in foraging behavior, as well as its underlying neural mechanisms, have been clearly linked with mental health disorders, we know little about how they vary with positive mental states such as well-being. Here we tested whether individual differences in satisfaction with life (SWL) and positive emotion (PE) are linked to individual variation in foraging behavior. Participants played a virtual foraging game in which they collected berries, which were redeemable for money at the end of the game. Harvest rates per patch declined over time within a patch, and participants could choose to travel to a new patch at any time. The time needed to travel between patches varied across blocks (3 or 10 sec). Participants also completed a series of questionnaires, including Diener's SWL Scale and the PE subscale of the PERMA-profiler by Butler and Kern (2015).

Study 1 tested a cross-cultural sample (N = 416; 214 in India, 42 female; 202 in the US, 85 female) using the MTurk online platform. Study 2 was pre-registered and tested a representative US sample using the Prolific online platform (N = 488, 247 female).

We used binomial regression to model trial-by-trial choices and found significant effects of SWL and PE. Participants scoring high in SWL, as well as PE, persisted significantly longer in patches

than participants scoring low in SWL or PE. One potential explanation for these differences is that people who have high well-being experience higher subjective reward rates within patches thus diminishing motivation to explore. These findings connect well-being to well-described, mathematically formalized mechanisms regulating the trade-off between exploitation and exploration, and suggest people manage these decisions along a computational continuum systematically set by both internal and external conditions.

Title: Anger, Exuberance and Incentive Reward

Authors: *T. L. WHITE[1], M. A. GONSALVES[2], C. ZIMMERMAN[2], H. JOYCE[3]; [1]Behavioral and Social Sci., [2]Neurosci. Grad. Program, [3]Undergraduate Program in Cognitive Neurosci., Brown Univ., Providence, RI

Abstract: Anger is a powerful, negatively valenced emotion with significant impact on human health and well-being. As such, there is potentially great value in better understanding the behavioral phenotypes associated with anger and their underlying neural substrates. We present a novel incentive theory of anger derived from assessments of emotion, personality, task-based functional magnetic resonance imaging (fMRI), and pharmacological challenge in healthy young adults. Two experiments were conducted to evaluate tiered hypothesis regarding the relationship between anger, exuberance, reward and approach. Experiment I found self-reports of anger to frustrative non-reward and exuberance to success events rose jointly in an incentive challenge task (*N*=39). Anger and exuberance responses were also positively associated with scores on the personality trait of social potency (SP), a measure of agentic extraversion that relates to the sensitivity to reward. Experiment II used task-based fMRI and found anger was positively related to (a) task-induced exuberance, (b) trait SP and (c) fMRI BOLD response in right nucleus

accumbens to *d*-amphetamine, a psychostimulant with dopaminergic and neurometabolic effects (*N*=10). Our findings are consistent with mechanistic contributions of dopamine to anger, indicating anger is an incentive state that facilitates the approach and acquisition of rewards that entail risk. Implications for neural mechanisms of anger, exuberance and its relevance to reward-motivated action and risk-taking are discussed.

Title: Emergence of emotion selectivity in deep neural networks trained to recognize visual objects

Authors: P. LIU[1], K. BO[3], L. CUI[1], Y. CHEN[1], C. T. TRAN[2], M. DING[1], ***R. FANG**[1]; [1]Dept. of Biomed. Engin., [2]Dept. of Electrical and Computer Engin., Univ. of Florida, Gainesville, FL; [3]Dept. of Physiol. and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Affective images with pleasant, unpleasant, and neutral content are differentially represented in the human visual cortex. How these emotion-specific neural representations arise is debated. Here we show that emotion selectivity can arise spontaneously in a deep neural network (DNN) model of the visual cortex trained to recognize visual objects. Adopting a VGG16 network pre-trained on the ImageNet data, the 1000 neurons in the last object recognition layer were replaced by 2 neurons, which were trained to perform binary emotion recognition: pleasant versus non-pleasant, neutral versus non-neutral, or unpleasant versus non-unpleasant. Affective images from two datasets: the International Affective Picture System (IAPS) and the Nencki Affective Picture System (NAPS) were used for training and testing. The emotion selectivity of each neuron was defined according to the largest normalized mean response among the three emotion types. The functionality of these neurons was tested using lesion and attention enhancement methods. The results showed that (1) in all layers of the DNN model, there were artificial neurons that responded consistently and selectively to neutral, pleasant, or unpleasant images, with later layers showing higher selectivity than earlier layers

and (2) lesioning the emotion selective neurons leads to decrease in emotion recognition performance whereas implementing feature attention in these neurons leads to increase in emotion recognition performance. These results suggest that emotion selectivity can arise intrinsically in the visual cortex and the functional importance of emotion selective neurons in emotion perception.

Title: Taste and emotion semantics are linked by the shared attribute of valence across human languages

Authors: *J. A. AVERY, A. G. LIU, M. CARRINGTON, A. MARTIN;
Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: ‘Parting is such sweet sorrow’. Sensory metaphors, particularly from the sense of taste, provide a rich vocabulary for describing emotional experience. This may be partly due to the common neural substrates shared by taste and emotion processing, such as the insular cortex and amygdala. With such a close functional connection in the human brain, we might expect that these cognitive domains are tightly linked within the conceptual structure of human thought. One way we can explore this is by examining the semantic similarity of concepts revealed in the structure of language. To do this, we used a behavioral ‘odd-one-out’ task (Hebart et al., 2020) in an online sample of 1059 participants on Amazon Mechanical Turk whom we asked to compare concepts related to emotion, taste, and color. Using the data from this task, we generated a semantic similarity matrix of these concepts. We then compared the similarity of emotion and taste concepts to the similarity of emotion and color concepts, another rich source of sensory metaphors. Consistent with our brain-based prediction, we found that the semantic similarity of emotion and taste concepts was greater than the similarity of emotion and color concepts ($t = 7.0$, $p < 0.001$). Importantly, the similarity of taste and emotion concepts was related to the similarity in hedonic valence between these concepts ($r = 0.55$, $p < 0.001$), mirroring a recent finding about valence as a source of universal structure of emotion semantics (Jackson et al., *Science*, 2019). As in this previous study, we also looked at patterns of colexification - where semantically related concepts are named with the same word - using a concept database containing cross-

linguistic polysemies aggregated from over 2400 languages (Rzymski et al, *Scientific Data*, 2020). Interestingly, we also observed that the similarity of colexification patterns between taste and emotion concepts across world languages was significantly greater, and thus less variable, than the colexification patterns within emotion concepts themselves ($t = 4.9$, $p < 0.001$). These findings suggest that, across human cultures, we use hedonic valence as a way of bridging the divide between concepts about our shared sensory environment and concepts which relate to our internal emotional experience.

Title: Interaction of the semantic and action observation networks in the brain underlies subjective understanding of actions and emotions

Authors: *M. ZHAN[1], R. GOEBEL[2], B. DE GELDER[3];
[1]NeuroSpin, Gif sur Yvette, France; [2]Fac. of Psychology and Neurosci., Maastricht, Netherlands; [3]Maastricht Univ., Maastricht, Netherlands

Abstract: Studies on the brain basis of action and emotion perception use predefined categories. How we subjectively generate an understanding of other people's bodily actions and emotions is not well understood. In this 7T fMRI study with a large stimulus set, alongside conventional univariate/multivariate analyses with predefined categories, we examined the representational geometry of bodily action- and emotion-understanding by mapping individual subjective reports with word embeddings. For the behavioral reports, dimensionality reduction (principle component analysis) revealed that the representations for perceived action and emotion were high dimensional, each correlated to but were not reducible to the predefined action and emotion categories. For brain activity, searchlight representational similarity analysis showed that the left middle superior temporal sulcus and left dorsal premotor cortex showed systematic correspondence with the subjective action and emotion representations. Furthermore, using task-residual functional connectivity and hierarchical clustering, we found that areas in the action observation network and the semantic/default-mode network were functionally connected to

these two seed regions and showed similar representations. Our study illustrates the feasibility of subjective report analyses and provides direct evidence that both networks were concurrently involved in subjective action and emotion understanding.

Title: Effects of Emotional Distractors on the Processing of Motion Stimuli

Authors: *C. XIONG[1], K. BO[2], N. M. PETRO[1], A. KEIL[3], M. DING[3];
[1]Univ. of Florida, Gainesville, FL; [2]Dartmouth college, Hanover, NH; [3]Univ. Florida, Gainesville, FL

Abstract: Images containing affective scenes are thought to be highly potent distractors. We tested the behavioral and neural effects of three categories of affective images from the International Affective Picture System (IAPS): pleasant (erotic couples), neutral (workplace people), and unpleasant (bodily mutilations) on task-relevant visual processing. Functional magnetic resonance imaging (fMRI) were recorded while participants detected instances of coherent motion in a random dot kinematogram (primary task) overlayed on IAPS pictures (distractors). Applying support vector machines to multivariate BOLD response patterns in the ventral visual cortex (VVC) and MT we found the following results. First, the behavioral accuracy on the primary task was not significantly different whether the distracting scenes were pleasant, neutral, or unpleasant, all being ~60%. Second, in VVC and MT, the decoding accuracy of pleasant vs neutral scenes and unpleasant vs neutral scenes were significantly higher than chance level, suggesting that distractor information was represented in the motion processing regions of the brain. Third, the aforementioned decoding accuracy and the behavioral accuracy on the primary task were significantly negatively correlated, suggesting that stronger neural representations of distractor information are more detrimental for task-relevant visual processing. These results reveal that valence is a not crucial factor in determining distractor potency and the competition between the primary task and distractors underlies the behavioral outcome on the primary task.

Title: Classification of Self-Reported Stress Levels from fMRI data in Veterans with Posttraumatic Stress Disorder

Authors: *T. TSE[1], R. GOEL[2], B. NAYLOR[3], L. SMITH[5,6], D. RESS[3], W. WILLIAMS[6], R. SALAS[3,4,6,7];
[1]SBHSE, Arizona State Univ., Tempe, AZ; [2]Psychology, San Jose State Univ., San Jose, CA; [3]Neurosci., [4]Psychiatry and Behavioral Sci., Baylor Col. of Med., Houston, TX; [5]Psychology, Univ. of Houston, Houston, TX; [6]Michael E DeBakey VA Med. Ctr., Houston, TX; [7]The Menninger Clin., Houston, TX

Abstract: *Objective:* Posttraumatic stress disorder (PTSD) is a significant burden among combat Veterans returning from active warzones in Iraq and Afghanistan. While empirically supported treatments such as exposure therapy have demonstrated reductions in PTSD symptomatology, many Veterans still meet clinical definitions of PTSD after treatment and there remains a need to improve treatment effectiveness. Real-time functional magnetic resonance imaging (fMRI) neurofeedback has emerged as an innovative treatment to ameliorate PTSD symptom severity. Virtual reality (VR) approaches have also shown promise as a means of exposing patients with trauma-related events to controlled stimuli, thus hopefully increasing desensitization, treatment compliance, and outcomes. To facilitate fMRI neurofeedback-associated therapies, it would be advantageous to be able to accurately and quickly classify internal brain stress levels while Veterans are exposed to trauma-associated VR imagery. *Methods:* Initially, male combat Veterans with PTSD symptoms (N = 8) were screened to ascertain their stress responses to various video stimuli, enabling design of audiovisual stimuli designed to evoke variable amounts of stress; stimuli were created using a VR tool called “BraveMind” that was specifically designed to provide VR exposure therapy to Veterans. Next, we use two sessions of fMRI to collect neural responses to the VR stimuli. Veterans reported their self-perceived stress level on a scale from 1-8 every 15 seconds throughout the fMRI sessions. In our proposed framework, we precisely sample the fMRI data on cortical gray matter at the 2x2x2-mm fMRI spatial resolution, blurring the data along the gray-matter manifold to reduce noise and dimensionality while preserving maximum information. Then, three machine learning (ML) algorithms were independently applied to these fMRI data collected across two sessions, separately for each Veteran, to build individualized ML models that predicted their internal brain states (self-reported stress responses). *Results:* We were able to classify the 8-class self-reported stress responses accurately with a mean (± standard error) root mean square error of 0.6 (± 0.1) across

all Veterans using the best ML approach. *Conclusion:* The findings demonstrate the predictive ability of ML algorithms applied to cortical fMRI data collected during individual Veteran sessions. *Significance:* The framework we have developed to pre-process cortical fMRI data and train ML models across sessions should provide a valuable tool to enable individualized real-time fMRI neurofeedback during VR exposure therapy for PTSD.

Title: Resting state functional connectivity predicts postconcussive symptoms in trauma-exposed veterans

Authors: *M. MARVIN[1], J. BOMYEA[1,2,3], A. SPADONI[1,2,3], A. SIMMONS[1,2,3];
[1]VA San Diego Healthcare Syst., San Diego, CA; [2]Ctr. of Excellence for Stress and Mental Hlth., San Diego, CA; [3]Dept. of Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: Post-Traumatic Stress Disorder (PTSD), mild traumatic brain injury (mTBI), and depression are commonly diagnosed in veterans exposed to combat stress. These conditions are difficult to diagnose accurately due to the overlap in diagnostic criteria. Previous neuroimaging research suggests there may be overlapping and distinct functional connectivity which may aid in distinguishing PTSD, mTBI, and depression. The present study utilized a data driven approach to investigate a longitudinal dataset of combat veterans' resting state functional connectivity and its utility as a predictor of clinical outcomes. Seventy-six Veterans with combat-related trauma exposure (mean age = 33.7, SD = 7.6) completed questionnaires and a resting state functional magnetic resonance imaging (fMRI) scan at three time points over 18 months. Participants completed the self-report PTSD checklist (PCL), Neurobehavioral Symptom Inventory (NSI), and Patient Health Questionnaire-9 (PHQ-9), to assess PTSD, postconcussive, and depression symptom severity, respectively. Based on a recent meta-analysis of areas often associated with PTSD, twelve regions of interest (ROIs) were defined to be used in the Subgroup Group Iterative Multiple Model Estimation (S-GIMME) algorithm. S-GIMME is a data driven approach that estimates the directed functional connectivity of fMRI BOLD signal between predefined brain ROIs at the individual, group, and subgroup level. The unsupervised S-GIMME produced two subgroups. Subgroup 1 (n-48) had fewer connections, including the right insula to right medal

prefrontal cortex and right inferior frontal gyrus to left supramarginal gyrus. Subgroup 2 (n=28) had connections between the left supramarginal to right IFG and right insula, right Heschl's gyrus to right caudate and right calcarine gyrus, right fusiform gyrus to left supramarginal gyrus, right calcarine gyrus, and right Heschl's gyrus. Associations between the neural subgroups and symptom trajectories revealed no associations between subgroup and PTSD or depression severity, but there was a significant association between subgroup and postconcussive symptom severity over time. Subgroup 2's postconcussive symptoms increased over time whereas Subgroup 1's symptoms began higher but were relatively stable. Results indicate that S-GIMME could effectively identify data-driven subgroups of veterans with heterogeneous networks of functional connectivity during a resting state fMRI scan. The brain-derived patterns and subgroup membership may be predictive of the clinical course of mTBI and indicative of the mechanisms that underlie postconcussive symptoms.

Title: Ayahuasca-based psychedelic therapy for PTSD and its effects on the microbiome: a discovery cohort

Authors: *L. R. KESSLER[1], L. M. DAWUD[1], J. D. STERRETT[1], A. I. ELSAYED[1], B. WEISS[2], J. GOULD[3], K. PATE[3], C. A. LOWRY[1];
[1]Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO; [2]Dept. of Psychology, Univ. of Georgia, Athens, GA; [3]Heroic Hearts Project, New York, NY

Abstract: Posttraumatic stress disorder (PTSD) is a mental health condition triggered by a traumatic event, associated with symptoms such as flashbacks, nightmares, depression, and anxiety, which can persist for years after the trauma experience. Although prolonged exposure therapy is an effective first-line treatment for PTSD, approximately 20-30% of individuals who complete treatment continue to have a PTSD diagnosis. An even smaller number of individuals respond to first-line pharmacological treatments, such as selective serotonin reuptake inhibitors (SSRIs), highlighting a need for novel interventions. Recent studies have evaluated the therapeutic potential of psychedelics for treatment of various mental health conditions. In this study, we investigated how the ceremonial use of ayahuasca to treat PTSD in United States Veterans can affect the microbiome. Ayahuasca is a decoction of plants such as *Psychotria viridis* which contains *N,N*-dimethyltryptamine (DMT), and the *Banisteropsis caapi* ayahuasca vine, which contains monoamine oxidase inhibitors (MAOIs) required for DMT to be orally

active. This brew has a long history of ceremonial use among indigenous peoples of Brazil and the Amazonian basin of South America. Participants of the current study included 14 US Veterans, 12 male, who attended one of two different week-long retreats where they participated in traditional ayahuasca ceremonies. While previous analysis of psychological survey data from this cohort revealed a healing experience among participants, little is known of the effects on the microbiome. This is of particular interest since the microbiome has been implicated in the etiology of other mental health conditions such as depression and anxiety. Additionally, ingestion of the brew is known to cause emesis and other gastric distress during the ceremony, a potential cause of instability in the host microbiome. Fecal samples were collected from participants at two timepoints, before and after ayahuasca-based treatment. Two retreats (n=9, n=5) were processed using 16S rRNA gene sequencing. Changes in personality traits conceived by the Five-Factor Model (FFM) were observed, with a significant decrease in neuroticism (a trait characterized by emotional instability in the FFM). Analysis revealed a trend toward lower alpha diversity in post-treatment samples. Overall, while there was a decrease in neuroticism, we did not detect changes in diversity of the microbiome in this cohort.

Ctr., New York, NY

Abstract: Patterns of resting-state functional connectivity (rsFC) following a traumatic event might reflect underlying neurobiological processes that play a role in the pathogenesis of and recovery from posttraumatic stress disorder (PTSD). In the current study, we examined rsFC in recent trauma survivors who either developed sustained PTSD symptomology or showed recovery from early acute stress symptoms. Specifically, we tested the association between rsFC and PTSD symptoms (both absolute severity and relative change in severity) at one, six and 14 months following trauma exposure (T1, T2 and T3, respectively). Functional MRI (fMRI) and clinical data were collected from n=158 adult civilians recruited from the emergency department of Tel-Aviv Sourasky Medical Center at T1 (50% male; mean age = 33.5 years), n=119 at T2 (47.05% male; mean age = 34.6 years) and n=109 at T3 (44.9% male; mean age = 34.4 years). PTSD severity was assessed by Clinician-Administered PTSD Scale for DSM-5 (CAPS-5) and intrinsic connectivity during a resting-state scan was examined using a seed-based whole-brain approach. We focused on seed regions of Default-Mode Network (DMN; hippocampus, ventromedial prefrontal cortex and posterior cingulate cortex) and Salience Network (SN; anterior insula, amygdala and dorsal anterior cingulate (dACC)), which have been reported to be altered in PTSD. Results showed that functional connectivities between insula and hippocampus, between insula and temporal gyrus, as well as between amygdala and inferior frontal gyrus at T1 were associated with PTSD symptoms at T3. We also found that connectivities between amygdala and insula, between hippocampus and insula and between hippocampus and dACC at T1 were associated with change in symptoms from T1 to T3. Lastly, connectivity between insula and dACC at T3 was associated with symptom severity at T3 (all $p < .050$, FWE corrected). Overall, this study suggests that specific connectivity patterns between SN and DMN, within SN and between SN and attention networks early after trauma, could potentially be used as biomarkers to predict PTSD symptom severity and recovery following a traumatic event. (YL and JS contributed equally to this work.)

Abstract: About 8 million Americans suffer from PTSD annually and the lifetime prevalence of the disorder is 8%. Drug therapies for PTSD are repurposed antidepressants and anxiolytics, which are minimally effective and produce undesirable side effects. The CNS vasopressin system, through the V1a receptor subtype, represents a novel target for pharmacological intervention. Preclinical imaging studies in a conditioned fear paradigm in rats showed that treatment with a V1a antagonist blocked hyperarousal to the memory of fear. In a human experimental medicine imaging study, V1a antagonist treatment significantly and selectively reduced BOLD signal in fear/threat response circuitry. We tested the primary hypothesis that treatment with a V1a antagonist, SRX246 (from Azevan Pharmaceuticals, Inc.), would result in a clinically meaningful 10-point reduction in mean CAPS score compared to placebo. Secondary hypotheses included testing for tolerability and safety as well as changes in other well-known scales (e.g., PTSD Symptom Checklist, Beck Depression Inventory-II, Pittsburgh Sleep Quality Index, Sheehan Disability Scale). The study was approved by the Weill Cornell IRB and the DoD Human Research Protection Office. Participation was open to 18-65 year-olds with a primary diagnosis of PTSD as defined by DSM-V for at least 3 months and a minimum CAPS-5 score of 32. All participants received SRX246 (160 mg BID) for 8 weeks and placebo for 8 weeks in an 18-week proof-of-concept randomized crossover clinical trial. Participants were reassessed every 2 weeks. Two hundred sixty-three subjects were screened, 89 were consented and assessed, and 33 were randomized. Substance abuse was the primary rule-out criterion during the baseline assessment. Randomization was balanced by sex and comorbid major depression. The primary outcome, CAPS-5 Severity, decreased significantly over the course of the study regardless of treatment order. Although the mixed effects model did not show significant treatment differences, examination of effect sizes adjusted by covariates suggested superiority for SRX246, with an effect about 30% higher than placebo. SRX246 was safe and well tolerated; the type and number of AEs did not differ from placebo; there were no SAEs. Regarding secondary endpoint scales, the PSQI findings suggest that SRX246 may show some stabilizing effects on sleep quality; no other effects or trends were found. These preliminary findings suggest SRX246 may be an effective treatment for PTSD. If confirmed through additional clinical studies, SRX246 would represent a breakthrough in pharmacotherapy for PTSD.

Abstract: The search for pathophysiological changes in PTSD has been facilitated by the establishment of the National PTSD Brain Bank (NPTSDBB). In the first postmortem anatomical study of PTSD, we described deficits in dendritic spine density in PTSD frontal cortex (FCTX) which were associated with increased transcript levels of the chaperone FKBP5 (PMID: 26844242). In a larger cohort, our NPTSDBB research group recently reported higher levels of FKBP5 and alterations in both neuronal and glial transcripts (PMID: 33349712). Among the most robustly affected were transcripts selectively expressed in interneurons.

Interestingly, a deconvolution analysis found that the proportion of interneuron cells was not altered in PTSD, suggesting that the affected transcripts in PTSD were down-regulated. In the present re-analysis of the combined sex data, we examine the distribution of interneuron-specific transcripts in WGCNA modules. Interneuron-specific transcripts were enriched in the Blue module (VIP, CRH, DLX1, DLX2) and in a small module (Coral2) composed almost entirely of interneuron transcripts (SST, CORT, GAD1, GAD2, PNOC, RELN, ELFN1, OSTN, TAC1). All of the above transcripts were at least nominally down-regulated in PTSD dlPFC. We generated signed p-value ranked GSEA lists of the Blue and Gray (unassigned transcripts) modules and probed these with the Hallmark gene sets, designed to investigate cellular stress responses. In the Gray analysis, no Hallmark sets were significantly enriched, while the Blue module recapitulated almost all of the up-regulated associations found in the entire dlPFC dataset. Up-regulated enriched sets in the Blue module (FDRq<0.01) included HYPOXIA, TNFA_SIGNALING_VIA_ NFKB, IL6_ JAK_ STAT3_ SIGNALING, EPITHELIAL_ MESENCHYMAL_ TRANSITION (FDRq<0.05), IL2_STAT5_SIGNALING, COAGULATION, INTERFERON_ GAMMA_ RESPONSE, INFLAMMATORY_RESPONSE, MTORC1_ SIGNALING, XENOBIOTIC_METABOLISM and APOPTOSIS. When we repeated the analysis in the sgACC, stress response signals such as HYPOXIA were less robust and interneuron-specific transcripts were less consistently down-regulated than in the dlPFC. These data support the presence of significant modulators of cell stress such as hypoxia in PTSD cortex, with the effect(s) being especially prominent in the dlPFC. A subset of interneuron transcripts (VIP, CRH) were co-regulated with cellular stress modules, but others (SST, CORT, GAD1, GAD2) were not. Investigation into the forces driving these transcriptomic changes have the opportunity to provide insight into how they may be reversed, potentially contributing to the development of novel treatments for chronic PTSD.

Abstract: There has been a growing emphasis on the relationship between inflammatory responses, gut microbiota and the immune system, and their influence on mental health outcomes. Stress can influence the composition of gut microbiota which, in turn, influences the central nervous systems response to future stressors. C-Reactive Protein (CRP) is a biomarker for inflammation that has been linked to depression, anxiety disorders and PTSD that is released in response to pro-inflammatory cytokines. The goal of this study was to test a direct association between behavior profiles such as anxiety and depression, the composition of the gut microbiota, basal levels of CRP and cytokines, cortisol and genetic predisposition. Measures of anxiety, depression, PTSD, substance use and overall health were obtained from adults with no recent illness or surgery, or exposure to antibiotics. Biological measures focused on pro- and anti-inflammatory cytokines from plasma, cortisol levels from hair, and gut microbiome; as well as single nucleotide polymorphisms (SNPs) were assayed. Using factor analysis we determined a shared mental health panel including depression, anxiety and PTSD measures that was negatively correlated to related cytokines. Regression modeling was used to related quantitative traits to demographic and genetic factors, revealing significant relationships between inflammatory markers and mental health. Understanding these relationships will help to determine direct future research in assessing causal direction between all of these factors that can promote mental well-being, and could in the future be used as biomarkers for vulnerability to mental illness, and even help re-think how we treat mental health disorders.

Ctr., Jerusalem, Israel; [4]bMolecular Psychiatry Lab. - Dept. of Psychiatry, Jerusalem, Israel

Abstract: Background and Aim: Long term neuroendocrine immune alterations have been proposed to play a mechanistic role in Post-Traumatic Stress Disorder (PTSD) as well as in its associated increase in physical morbidity and mortality. Better characterization of altered immune function may help identify diagnostic and prognostic biomarkers and potentially targets for preventive intervention. **Methods:** As part of a prospective cohort ongoing study, we conducted a preliminary case control comparison of resting mononuclear cell profile between terror victims treated in childhood at the Hadassah Medical Center emergency department over the previous decade, who developed chronic PTSD upon long term follow up or recovered, and healthy non traumatized controls. **Results:** Our results point to childhood trauma related childhood long term alterations in the expression of genes related to cortisol reactivity, including the glucocorticoid receptor as well as its trans-activator Spindle And Kinetochore Associated Complex Subunit 2 (SKA2) among resting mononuclear cells in young adults. **Conclusion:** Chronic resetting of the neuroendocrine reactivity of immune cells may participate in inflammatory activation, as well as modulate immune - neuro-endocrine feedback. Better characterization and understanding of these findings may point to diagnostic and prognostic biomarkers and potentially elucidate mechanistic involvement of immune activation in childhood trauma related chronic PTSD.

Title: Translating a novel neuromodulation therapy to treat PTSD

Authors: *D. PRUITT[1], H. L. CAREY[2], J. D. EPPERSON[2], N. BLEKER[2], S. A. HAYS[3], R. L. RENNAKER[5], J. WIGGINTON[6], M. POWERS[7], M. P. KILGARD[4];

Abstract: Prolonged exposure therapy (PE) is a powerful treatment for PTSD. However, roughly 15% of patients do not respond, 20% dropout of treatment, and 60% are not fully recovered (remission/loss of diagnosis). Preclinical studies suggest vagus nerve stimulation (VNS) augmentation of extinction may enhance efficacy and tolerability by enhancing synaptic plasticity in brain networks (efficacy) and engaging parasympathetic activation (tolerability). Based on these promising preclinical studies, we have begun a first-in-human clinical trial to evaluate the ability of VNS paired with prolonged exposure therapy to reduce symptoms in patients with PTSD. This study is funded by the DARPA ElectRx program. Here, we present the initial findings from this ongoing clinical study. Participants with a diagnosis of PTSD were enrolled and implanted with a VNS device on the left vagus nerve. All participants then underwent six weeks of prolonged exposure therapy with a licensed therapist. During in-office sessions, the therapist used a software app to record the session and trigger brief bursts of VNS coincident with prolonged exposure therapy exercises. Participants then used the software app to perform homework sessions, during which VNS bursts were automatically triggered matching the timing of the in-office session. Safety was assessed throughout the course of the study. Functional outcome measures were assessed prior to and after the conclusion of therapy. Enrollment commenced in early March 2021 and the initial implantations occurred in late March 2021. Findings from the initial participants indicate that the therapy, including implantation and stimulation, is safe and can be feasibly delivered. We expect to have completed up to 10 subjects by the end of summer 2021. We will present up-to-date data on safety and functional outcome measures at the meeting. Together, these preclinical and initial clinical findings demonstrate that VNS paired with extinction training represents a novel strategy to enhance prolonged exposure therapy for patients with PTSD. Pending successful results of the first-in-human study, VNS therapy should be evaluated in a larger double-blind, multi-site study.

Title: Blockade of CRF_1 receptors in the infralimbic cortex prevents stress-induced reinstatement of alcohol seeking in male Wistar rats: Evidence of CRF/orexin interaction.

Authors: *F. J. FLORES-RAMIREZ[1], A. MATZEU[2], L. SANCHEZ-MARIN[4], R. MARTIN-FARDON[3];
[1]Mol. Med., [3]Neurosci., [2]The Scripps Res. Inst., La Jolla, CA; [4]Unidad Gestion Clinica de Salud Mental, Inst. de Investigacion Biomedica de Malaga-IBIMA, Hosp. Regional Universitario de Malaga/Universidad de Malaga, Malaga, Spain

Abstract: Alcohol use disorder (AUD) remains one of the most treatment-elusive medical conditions globally. Although major advances have been made in the management of other health conditions, few pharmacological therapies have emerged for AUD. Indeed, a major problem in the management of AUD is the high vulnerability to relapse, even after long periods of abstinence. One explanation for this phenomenon is that chronic alcohol use dysregulates responsivity to stress, which is mediated by corticotropin-releasing factor (CRF). Thus, with repeated cycles of alcohol use, the hypothalamic-pituitary-adrenal axis becomes hyporesponsive, rendering individuals vulnerable to relapse during stressful episodes. Orexin (Orx) plays a well-established role in regulating diverse physiological processes, including stress, and interacts with CRF. The present study tested the CRF/Orx interaction in the infralimbic cortex (IL). We administered the CRF_1 receptor antagonist CP154,526, dual Orx-A/Orx-B receptor antagonist TCS1102, and their combination before testing the stress-induced reinstatement of alcohol-seeking behavior. Male Wistar rats were trained to self-administer 10% alcohol (w/v) for 3 weeks. The rats then underwent 2 weeks of extinction training (identical to the alcohol self-administration sessions, but alcohol was withheld). The day after the last extinction session, the rats received an intra-IL injection of CP154,526 (0.6 µg/0.5 µl/side), TCS1102 (15 µg/0.5µl/side), or their combination and then tested for the footshock stress-induced reinstatement of alcohol-seeking behavior. CP154,526 significantly prevented reinstatement, but TCS1102 did not produce any effect. Interestingly, the co-administration of TCS1102 with CP154,526 reversed the effect of CP154,526 alone, thus demonstrating a functional interaction between Orx receptor and CRF_1 receptor signaling and suggesting that CRF_1 receptor antagonism may ameliorate stress-induced alcohol craving and relapse.

Title: Is the dopamine D4 receptor a pharmacotherapeutic target for alcohol use disorder?

Authors: C. DONEGAN[1], S. URIBE[1], H. BUECHLER[1], M. SUMI[1], F. DIGIORGIO, Jr.[1], E. DIDOMENICO[1], A. ANTONIO JUAREZ[1], C. SIDE[1], Y. TAPIA[1], J. CONVISER[1], R. NAMBIAR[1], A. ACOSTA[1], I. MITHRA MADHURANTHAKAM[1], C. A. BOATENG[2], B. D. FISCHER[3], ***T. M. KECK**[1];

Abstract: Alcohol use disorder (AUD) affects more than 15 million people in the United States. Current pharmacotherapeutic treatments for AUD are only modestly effective, necessitating the identification of new targets for medications development. The dopamine D4 receptor (D4R) is a target of interest in the development of medications for psychostimulant addiction, but has been largely unexplored for AUDs. In this study, we investigated the effects of the classic D4R antagonist L-745,870 and the novel, high-affinity D4R-selective antagonist CAB01-019 in rodent models of alcohol use disorder using adult male CD-1 mice. L-745,870 and CAB01-019 were tested for effects in operant food and ethanol self-administration tasks. Food-restricted mice were trained to nose poke for delivery of palatable food (vanilla Ensure) or alcohol rewards (8% w/v in water). L-745,870 (1.5 and 3.0 mg/kg, i.p.) did not significantly attenuate ethanol or food self-administration compared to vehicle. Additional testing with L-745,870 pretreatment during conditioned place preference (CPP) training did not affect the rewarding value of 2.0 g/kg ethanol using a three-compartment CPP apparatus. Similar tests with CAB01-019 are ongoing. These results, and future studies exploring whether D4R antagonism affects relapse-like responding in reinstatement models, will provide a comprehensive analysis of whether D4R antagonism affects alcohol-taking and -seeking behaviors.

Title: Lysergic acid diethylamide acutely reduces intermittent ethanol intake without effects on sucrose consumption or intracranial stimulation reward in mice

Authors: L. V. ELSILÄ, J. HARKKI, E. ENBERG, A. MARTTI, A.-M. LINDEN, ***E. R. KORPI**;
Dept. of Pharmacol., Univ. of Helsinki, Helsinki, Finland

Abstract: Small clinical studies have raised great expectations for the treatment of alcohol use disorders using psychedelics, such as lysergic acid diethylamide (LSD). To get more mechanistic insight, we studied the action of LSD on alcohol drinking and reward in male C57BL/6J mice. We aimed to test if a single dose of LSD decreases binge-like ethanol drinking in mice, both acutely and in a prolonged fashion, and if the observed acute effects are due to reward attenuation and generalized to a more natural reinforcer, sucrose. The ethanol consumption was monitored using intermittent two-bottle choice design (n=27) with ethanol available for 2 h on 4 consecutive days a week. The drug treatment was given on the fourth drinking day. The same design was used with sucrose (n=29). Effects on reward were tested using discrete-trial current threshold method of intracranial self-stimulation (ICSS) with electrodes in the medial forebrain bundle (n=9). In all experiments, LSD was administered i.p. immediately before the start of the measured behaviour. LSD doses of 0.05 and 0.1 mg/kg were tested in the drinking experiments, and additional doses of 0.2 mg/kg LSD and 3.0 mg/kg D-amphetamine were used in the ICSS. Statistical significance was tested using either one-way or repeated measures ANOVA and Bonferroni-corrected multiple comparisons with alpha level 0.05, as appropriate. Both tested LSD doses induced a decrease in 2-h ethanol drinking relative to control during the day of administration (0.05 -32%, $p>0.05$; 0.1 -83%, $p<0.05$), but the drinking returned to the control level in the next session. No changes in water consumption were observed. In the sucrose consumption experiment, minor, non-significant reductions were observed with both LSD doses (0.05 -12%, $p=0.4$; 0.1 -8%, $p=0.2$, relative to control). In the ICSS, the LSD doses tested failed to affect the response threshold acutely ($p=0.2$) or at 24 h after the treatment ($p=0.4$). When administered together with 3.0 mg/kg D-amphetamine, 0.1 mg/kg LSD did not modify the amphetamine-induced decrease in the threshold (-20% from the baseline) to either direction (sal vs. amph: $p=0.03$, sal vs. amph-LSD: $p=0.02$). LSD acutely decreased intermittent ethanol self-administration in mice but failed to induce prolonged effects. The present results imply that the decrease does not stem from effects on the animals' ability to drink as the mice continued to drink water. The ICSS results imply that the decrease is not due to LSD being aversive, nor does LSD cause any general attenuation of reward by an addictive drug. Further studies on LSD effects on consummatory behaviour are warranted.

Title: Exposure to a Ketogenic Diet Alters Metabolic Brain Activity, Alcohol Intake and Withdrawal in Rats

Authors: *J. L. GOMEZ, S. K. ELVIG, L. F. VENDRUSCOLO, M. MICHAELIDES; Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: A ketogenic diet (KD) is comprised of a high-fat, adequate-protein, low-carbohydrate diet. In contrast to typical Western diets, individuals on a KD utilize more fatty acids and ketone bodies for energy metabolism and less glucose. Current studies have examined the effects of the diet on various disease models, such as diabetes, cancer, Alzheimer's, and alcohol misuse. Specific to alcohol misuse, individuals acutely intoxicated metabolize less glucose and heavy alcohol drinkers switch from using glucose to ketones as the main energy source in the brain. Using positron emission tomography (PET), we examined whole brain metabolic uptake of [^{18}F]Fluorodeoxyglucose (FDG) following exposure to a KD, alcohol exposure, and withdrawal. Rats on a KD for 5-weeks showed a global reduction in FDG uptake compared to regular chow diet. After alcohol exposure, rats on a KD had fewer changes in FDG uptake and rats on a regular chow diet had increased metabolic activity during acute withdrawal. These changes persisted after 6-weeks of protracted withdrawal from alcohol in rats on the chow diet. Here, we show the potential neural circuitry that may be involved in the beneficial effects of a KD on treating alcohol use disorders. In conclusion, the advantageous effects previously reported on KD reducing alcohol craving and intake, while ameliorating negative withdrawal symptoms during detoxification are reflected in the metabolic brain activity seen in this study.

Title: Reducing Alcohol and/or Cocaine-induced Reward and Toxicity via an Epidermal Stem Cell-Based Gene Delivery Platform

Authors: *Q. KONG[1], L. RIEDY[1], Y. LI[2], J. YUE[2], X. WU[2], M. XU[1];
[1]Dept. of Anesthesia and Critical Care, [2]Ben May Dept. for Cancer Res., The university of Chicago, CHICAGO, IL

Abstract: Alcohol use disorder (AUD) is one of the foremost public health problems. Alcohol is also frequently co-abused with cocaine. There is a huge unmet need for the treatment of AUD and/or cocaine co-abuse. We recently demonstrated that skin grafts generated from mouse epidermal stem cells that had been engineered by CRISPR-mediated genome editing could be transplanted onto mice as a gene delivery platform. Here, we show that expression of the glucagon-like peptide-1 (GLP1) gene delivered by epidermal stem cells attenuated development and reinstatement of alcohol-induced drug-taking and seeking as well as voluntary oral alcohol consumption. GLP1 derived from the skin grafts decreased alcohol-induced increase in dopamine levels in the nucleus accumbens. In exploring the potential of this platform in reducing concurrent use of drugs, we developed a novel co-grafting procedure for both modified human butyrylcholinesterase (hBChE)- and GLP1-expressing cells. Epidermal stem cell-derived hBChE and GLP1 reduced acquisition of drug-taking and toxicity induced by alcohol and cocaine co-administration. These results imply that cutaneous gene delivery through skin transplants may add a new option to treat drug abuse and co-abuse.

Title: Adolescent intermittent ethanol exposure followed by free-choice drinking in adulthood: with and without environmental enrichment

Authors: *J. I. WOODEN, J. MELBOURNE, K. NIXON;
Pharmacol. & Toxicology, The Univ. of Texas at Austin, Austin, TX

Abstract: Binge drinking in adolescence increases likelihood of problematic alcohol use in adulthood. In rats, this has been modeled with intermittent ethanol (AIE) exposure in adolescence followed by testing 2-bottle free-choice (2BC) alcohol drinking in adulthood. Rats are single-housed during 2BC, although single housing can enhance development of some addictive-like behaviors. Environmental enrichment (EE) in the home cage of single-housed rats is often used to prevent stress from isolation. Here, we conducted 2 experiments that utilized AIE vs. adolescent intermittent saline (AIS) in male Sprague-Dawley rats, followed by 2BC. AIE was 8 *i.p.* injections of 2 g/kg EtOH (20% w/v or 0.9% saline for AIS) in a 2 days on/2 days off manner during PND 30-43. After 44 days, rats were single-housed with access to 2 bottles in the home cage: one with EtOH in water, the other plain water. For Exp 1, rats (AIE n = 8, AIS n = 8) had EE in cages (PVC pipe), and were offered increasing concentrations of EtOH every 3 days ranging 3% to 9% (PND 87-111). For Exp 2, rats (AIE n = 8, AIS n = 8) did not have EE and were offered an identical 3% to 9% range of EtOH concentrations (PND 87-111), then examined up to 20% EtOH (PND 112-121). Rats in Exp 2 were subjected to abstinence for 2 wks and the alcohol deprivation effect examined: 2BC was returned with 20% EtOH (PND 135-138). We did not see the expected effect of escalated adult drinking following alcohol exposure in adolescence. There was a main effect of EtOH concentration (p = 0.04 for Exp 1, $p < 0.0001$ for Exp 2), reflecting increased consumption across 3-9% EtOH, but no main effect of group (AIS/AIE) for either experiment nor statistically significant interaction of adolescent treatment group and EtOH concentration (3-9% or 3-20%) for 3-day average of g/kg consumed. The 3-day average of g/kg consumed was not different between Exp 1 (1.0±0.2) and Exp 2 (1.0 ±0.1) for concentrations of 3-9% ethanol, indicating EE did not influence consumption. For Exp 2, both AIE and AIS rats displayed increased consumption during the first day of post-abstinence reinstatement testing compared to baseline ($t(7)$=3.610, p = 0.0086 for AIE, $t(7)$=4.236, p = 0.0039 for AIS), although consumption was similar between groups. BECs measured 1h after the last *i.p.* injection did not differ between experiments (Exp 1 = 154.6±13.9 mg/dL, Exp 2 = 190.9±14.2 mg/dL; p = 0.09). Thus, we were not able to model escalation of drinking following adolescent ethanol exposure using this AIE-2BC paradigm. Additional stressors or isolation in the adolescent period may be necessary to increase alcohol consumption in adulthood in some lab environments.

Title: Role of nociceptin receptor antagonist and nociceptin-containing neurons of the lateral septum in alcohol drinking behavior in mice.

Authors: *H. HAUN, T. KASH;
UNC- Chapel Hill, Chapel Hill, NC

Abstract: Excessive alcohol drinking in individuals diagnosed with an Alcohol Use Disorder (AUD) has seen a marked increase in recent years further reinforcing the need for novel therapeutic interventions aimed at curbing chronic, uncontrolled alcohol consumption. Antagonists targeting the nociceptin receptor (NOPR) have shown promise in attenuating excessive alcohol drinking, garnering much interest in this system as a druggable target for the treatment of AUD. However, little is known about the mechanisms by which NOPR antagonists influence drinking behavior nor the endogenous nociceptin-expressing populations that drive this effect. We have identified the lateral septum (LS) as rich in nociceptin-expressing neurons (LS^{Pnoc}) and this structure has been implicated in alcohol drinking and withdrawal. Thus, the present studies were designed to screen the effect of a NOPR antagonist (SB-612111; 10 mg/kg) on alcohol drinking and other behaviors, and determine the contribution of LS^{Pnoc} to alcohol drinking. Male C57BL/6J were given access to alcohol (20% v/v) in a 2-hr drinking session, 3-hrs into the dark cycle (N=24). SB-612111 treatment 30-min prior to drinking reduced alcohol intake compared to vehicle (2.8 vs 1.9 g/kg; $p< 0.001$). Next, the effect of SB-612111 was tested on the expression of alcohol-induced conditioned place preference (CPP) to determine if NOPR contribute to the rewarding properties of alcohol (N= 20). SB-612111 treatment 30-min prior to testing was without effect on CPP expression (72 vs 62.6%; $p> 0.05$). Subsequently, NOPR contribution to the aversive properties of alcohol was tested in an alcohol-induced conditioned taste aversion (CTA) test. Mice were given access to 1% sucrose for a 30-min drinking session and alcohol (2 g/kg) was administered immediately after (N=20). SB-612111 administration concurrent with alcohol treatment attenuated the expression of CTA the following day (-72.2 vs -50.1%; $p< 0.05$) suggesting that NOPR contribute to the aversive properties of alcohol. In a final experiment, we selectively targeted LS^{Pnoc} by infusing AAV8-hSyn-DIO-hM4Di (0.3uL/side) into the LS of male Pnoc-IRES-Cre mice (N=14). Challenge with clozapine-*N*-oxide (CNO; 3 mg/kg) or vehicle 30-min prior to drinking resulted in a reduction of alcohol drinking (2.6 vs 2.1 g/kg, $p< 0.05$). Together, these data support previous findings that NOPR antagonists are effective in reducing alcohol intake and suggest that this effect is mediated by influencing the aversive properties of alcohol. We then found that silencing of LS^{Pnoc} reduced alcohol drinking

pointing to this structure as an endogenous source of nociceptin that contributes to drinking behavior.

Title: Laminar profile of feature selectivity in V4 and its rhythmic enhancement with exogenous attention

Authors: *J. A. WESTERBERG[1], E. A. SIGWORTH[2], J. D. SCHALL[3], A. MAIER[1]; [1]Dept. of Psychology, [2]Dept. of Biostatistics, Vanderbilt Univ., Nashville, TN; [3]Departments of Biol. and Psychology, York Univ., Toronto, ON, Canada

Abstract: Visual search is a ubiquitous attention task necessitating rapid processing of sensory information. Attentional selection has been linked to altered cortical sensory responses and feature preferences (i.e., tuning). However, attentional modulation of feature selectivity during visual search is largely unexplored. Here we map the spatiotemporal profile of feature selectivity during a pop-out visual search task. Monkeys performed search where a single ("pop-out") feature determined the target of attention. We recorded laminar neural responses across 30 recording sessions from mid-level visual area V4 in two macaque monkeys performing a color-based pop-out visual search task. We first identified "feature columns" on a session-by-session basis which showed preference for individual colors. These columns had a consistent receptive field along cortical depth. Correctly performed trials where the pop-out stimulus appeared in the columnar receptive field were considered exogenously attended and trials when the pop-out was outside the receptive field were considered unattended. In the unattended condition, superficial layers of V4 feature columns showed significantly greater feature selectivity than middle and deep layers. Attending a stimulus increased feature selectivity along all layers, but not equally. Feature selectivity increased most in middle and deep layers, leading to a normalization of

feature selectivity across the cortical column. This attention-induced enhancement was rhythmically gated in phase with the beta-band local field potential. Beta power dominated both extragranular laminar compartments, but current source density analysis pointed to an origin in superficial layers, specifically. While this activity was present regardless of attentional state, feature selectivity was only beta-gated with attention. Neither the beta oscillation nor its gating of feature selectivity were predicated on microsaccades. Importantly, beta modulation of neural activity predicted response times, suggesting a direct link between attentional gating and behavioral output. Together, these findings suggest beta-range synaptic activation in V4's superficial layers rhythmically gates attentional enhancement of feature tuning in a way that affects the speed of attentional selection.

Title: Distinct attention modulation on noise correlation of V4 neurons during the absence and presence of visual stimuli.

Authors: *S. LIU[1], A. C. SNYDER[2];
[1]Brain and Cognitve Sci., [2]Univ. of Rochester, Rochester, NY

Abstract: The ability to selectively attend to more behaviorally relevant locations of the surrounding environment, known as spatial selective attention, is crucial to survival. The neural mechanism of this cognitive function has been vastly studied from the perspective of neural processing of visual stimuli. Typically, correlated variability, so-called noise correlation, between pairs of neurons in the visual cortex, has been observed to generally decrease with attention during stimulus response, which can improve stimulus encoding by reducing dependence of noise within a population. However, spatial attention can also be engaged during anticipation of visual information, when stimuli are absent. How spatial attention modulates neural activity during such anticipation periods was relatively poorly understood. In this study, we aim to understand how co-variability of V4 neurons change with spatial attention during

anticipation and whether it is distinct from when visual stimuli are present.
V4 neural activity was recorded when two rhesus macaque monkeys were performing an orientation change-detection task where location of one of the two gratings were cued to change with higher probability, encouraging selective attention. We computed noise correlation between pairs of V4 neurons using their response to repeated visual stimuli or their spontaneous activity during inter-stimulus-interval. When stimuli were absent, noise correlations were also modulated by covert spatial attention, in a way distinct from when stimuli are present. Overall, noise correlations decreased when attention was directed towards the receptive field of V4 neurons and when stimuli were present, but increased when stimuli were absent (i.e., the opposite effect). This suggests absence/presence of stimulus should be considered when we develop theory for attention neural mechanisms.
Studies have shown all directions of co-variability affect task performance. To explore whether such attention modulation on co-variability was task-relevant, we identified directions along which change of pair-wise activity of V4 neurons is meaningful to solve the task, which we call task vectors. Theoretically, high variability along them is harmful for task performance. By computing the variability of neural activity along the task vector direction and other directions, we found that variability is alway highest along the task vector. And the above noise correlation results are mainly contributed by change of variability along the task vector. This suggests that the considering context of stimulus and task is important for understanding why noise correlations change under attention.

Title: A neural mechanism for enhanced visual processing in peri-hand space

Authors: *H. RAMEZANPOUR[1,2,3], D. H. KEHOE[1,2,4], C. J. PERRY[1,2,3], M. FALLAH[1,4,2,3,5]; [1]Ctr. for Vision Res., [2]VISTA: Vision Sci. to Application, [3]Sch. of Kinesiology and Hlth. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Previous studies have provided indirect evidence that visual processing is enhanced in space near the hand, so called “peri-hand space”. It is hypothesized that these alterations are result of deploying attention to peri-hand space, like how the oculomotor system enhances visual processing at the endpoint of a saccade. This similarity notwithstanding, the underlying neural mechanisms that would drive altered visual processing near the hand are, as yet, not well understood. More specifically, it is not clear whether peri-hand attention might be solely due to vision of one own’s hand, proprioceptive feedback to visual cortex, or a combination of both signals. It has been already established that parietal neurons integrate sources of visual and proprioceptive information for visually guided reach movements. Hence, we hypothesize that enhanced visual processing in peri-hand space is a result of feedback from parietal to early visual areas. To unravel the neural underpinnings of enhanced visual processing in peri-hand space and specifically the nature of these feedback signals, we recorded from individual neurons in area V2 of rhesus monkeys, engaged in a passive fixation task in which an oriented bar was presented in the receptive field of V2 neurons in the presence or absence of a nearby hand. When the hand was placed near, yet outside the receptive field, responses to the preferred orientation were significantly enhanced no matter if the hand was visible to the animal or occluded. This result which resembled attentional gain modulation in the oculomotor system, diminished when the animal’s hand was far from the visual stimulus. These findings, together with the fact that the hand was not the target of future saccades (animals had to keep fixation to get rewarded) support the notion that there exist parallel effector-based mechanisms for deploying spatial attention which might ease decoupling of eye and hand movements, and the feedback signals responsible for deploying these attentional signals are proprioceptive in nature.

Title: Effects of feature attention on local field potential oscillations vary systematically across the visual processing stream

Authors: *A. UMOREN[1], D. MENDOZA-HALLIDAY[1], R. DESIMONE[2];
[1]MIT, Cambridge, MA; [2]MIT, McGovern Inst. Brain Res., Cambridge, MA

Abstract: Visual feature attention selectively modulates the spike rates of feature-selective neurons in multiple areas of the primate visual stream, with increasing strength as one progresses downstream. While some studies have shown that feature attention also modulates the power of local field potential (LFP) oscillations, no study has systematically examined and compared, under the same experimental conditions, the effects of feature attention on LFP power across multiple visual processing stages. To examine this, we trained two macaque monkeys to perform a spatially-global feature attention task in which they attended to one of two full-screen overlapping random dot surfaces (tests) moving in opposite directions, cued by a prior surface (sample). We recorded neuronal activity simultaneously from 5 laminar probes in several areas across multiple processing stages of the visual stream – MT, MST, LIP, MIP and LPFC. Feature attentional modulation was quantified as the effect size from the statistical comparison between the LFP power when monkeys attended to one or the other test surface. Feature attention modulated broadband LFP power in all areas, with modulation strength being lowest upstream (MT) and increasing in a downstream progression. Furthermore, attention most strongly modulated the lower frequencies in upstream areas, and progressively higher frequencies in downstream areas. Among all areas, attentional modulation strength showed two peaks along the frequency spectrum, one in the low (below 20 Hz) and one in the high (between 40 and 80 Hz) frequencies. In LIP and MIP, LFP sites were functionally segregated into two types showing attentional modulation exclusively in the low or high frequencies. Remarkably, we further found that a fraction of LFP sites showed an inverted feature attentional effect: an increase in LFP power when attending to the antipreferred direction compared to the preferred. The incidence of such effects was highest upstream and systematically decreased downstream. Our results show that attention modulates the oscillatory activity of neuronal populations across multiple visual processing stages, and that such effects have distinct characteristics that vary systematically across stages in a downstream progression.

Title: Large-scale bilateral optogenetic inactivation of the lateral prefrontal cortex decreases feature attentional effects in MT and MST neurons and impairs attentional performance

Authors: *D. MENDOZA-HALLIDAY, H. XU, F. AZEVEDO, R. DESIMONE;
McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: Previous studies have suggested that feature attention is mediated in part by feedback from LPFC, which is thought to enhance processing of attended features at multiple visual processing stages. To test the causal role of LPFC, we developed an optogenetic method for large-scale bilateral inactivation of LPFC with temporal specificity limited to the task period of attentional allocation. We replaced the native dura with a transparent artificial dura over LPFC bilaterally and expressed the inhibitory opsin *Jaws* across a ~100 mm^2 area via 168 viral injections. We designed a spatially-global feature attention task in which monkeys were cued to attend to one of two full-screen overlapping random dot surfaces moving in opposite directions (tests) in order to detect a small randomly-located speed change. We recorded the activity of motion direction-selective neurons simultaneously in bilateral LPFC and visual areas MT, MST and LIP. To measure the effects of feature attention, we statistically compared neurons' firing rates between trials in which monkeys attended to one test surface vs. the other. In half of the trials, both LPFCs were optogenetically inactivated during the test presentation using 635 nm lasers located above the cortical surface. We found that feature attentional modulation was weakest in area MT and increased downstream. Remarkably, half of the modulated neurons in MT showed an inverse effect: a significant firing rate increase with attention to the anti-preferred direction compared to the preferred. The fraction of neurons with inverse effects progressively decreased in downstream areas. These results suggest the need to update current attention models that predict attentional enhancements exclusively aligned to neurons' feature preference. Moreover, bilateral LPFC optogenetic inactivation impaired task performance and caused a reduction in the neuronal effects of feature attention not only locally but also in MT and MST. Our results serve as evidence that LPFC plays a causal role in the modulation of visual cortical responses during feature attention, and that this role is necessary for attentional performance.

Abstract: Dynamic coding of task rules by neuronal ensembles in the primate lateral prefrontal cortex Alireza Rouzitalab[1,2], Chadwick B Boulay[2,3], Julio Martinez Trujillo[4], and Adam J Sachs[2,31]Electrical and Computer Engineering Department, The University of Ottawa, Ontario, Canada[2]The Ottawa Hospital Research institute, Ontario, Canada[3]The University of Ottawa Brain and Mind Research Institute, Ontario, Canada[4]Department of Physiology, McGill University, Quebec, Canada

Introduction: One of the cortical areas heavily involved in multiple stages of the perception-to-action cycle is the lateral prefrontal cortex (LPFC). Neurons in LPFC encode sensory and motor signals, movement planning and execution, working memory, attention, reward expectation and task rules. Moreover, the LPFC is one of the regions of the cortex in which changes in the selectivity of neurons during learning of new task rules have been documented.***Task:*** Two macaque monkeys are presented with cue information while fixating on a central point on a screen. After a delay period, based on the received information, they should make a saccade towards one of eight possible targets uniformly arranged around the perimeter of the screen on a circle (Figure 1). During a random number of trials, only two of the three possible colors will appear while keeping the same possible two targets (Figure 2).***Methods and Results:*** We passed the single unit activities obtained from learned and not-learned trials to a neuronal generalized additive model tool (neuroGAM), to confirm the coding of task rules in learned trials and the presence of saccade information in not-learned trials (figure 3).A deep neural network decodes the rule information from the neuronal activities. Figure 4 shows the distinction of rules in a PCA/t-SNE space using the firing rates vs. the deep model.Furthermore, we decoded the saccade intention of monkeys from the pre-saccadic activities in different sessions using a deep model which compared to conventional methods [1], has improved significantly (Figure 5).***Discussion:*** We explored the existence of task rule information in population activities of LPFC neurons. While the monkey learns a rule presented in the task, the neuronal activities encode this information quickly. We also improved the decoding accuracy of saccade intentions using the pre-saccadic activities in LPFC neurons.***References:***[1] C. B. Boulay, F. Pieper, M. Leavitt, J. Martinez-Trujillo, and A. Title: Fixational saccades occur along a theta rhythm under covert visual spatial attention

Authors: *K. DOUGHERTY, B. WU, B. MOREA, R. CHEN, R. BOSHRA, S. KASTNER; Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: The rhythmic theory of attention (Fiebelkorn and Kastner, 2019) proposes that attention fluctuates over time along a theta rhythm, with periods of enhanced perceptual sensitivity followed by periods of diminished perceptual sensitivity in which shifts of attention and/or gaze may occur. This theory is based both on behavioral data showing that detection of a visual target fluctuates at theta frequency, as well as neural data indicating cortical visuo-motor neurons show theta-nested activity that is predictive of behavior during a visual attention task. One prediction from this theory is that small fixational saccades (< 2 dva), known to occur in covert attention tasks and thought to index attention shifts, are more likely to occur during periods when sensory processing is diminished. In other words, the theory predicts that the probability of fixational saccades fluctuates at a theta rhythm under covert visual spatial attention. To test this prediction, we recorded gaze position with an infrared-based eye tracking system while two macaques performed a visual spatial attention paradigm, known as the Egly-Driver task. Following initial fixation, two vertically-oriented or horizontally-oriented parallel bars appeared in the periphery on either side of the central fixation point. An informative (80% valid) cue appeared at one of the corners of the bar locations, indicating the likely position of an upcoming visual target. Following a variable delay (500-1700 ms), a target appeared at one of four possible locations, and the animal released a lever following onset of the target to receive juice reward. With gaze position data, we detected the onset of fixational saccades and their durations. We observed that the probability of a fixational saccade was not uniformly distributed during the cue-target interval, but instead waxed and waned with a theta-range rhythm. This fluctuation in oculomotor behavior, together with fluctuations in visual detection performance, suggest a dynamic interplay between sensory and motor processing during attention.

Title: Neural mechanisms of attentive object processing in primates structured by microsaccades

Authors: *K. SRINIVASAN[1,2], E. LOWET[3,2], B. GOMES[4,2], R. DESIMONE[2,1];
[2]McGovern Inst. for Brain Res., [1]MIT, Cambridge, MA; [3]Dept. of Biomed. Engin., Boston Univ., Boston, MA; [4]Inst. de Ciências Biológicas, Univ. Federal do Pará, Belém-Pa, Brazil

Abstract: Covert spatial attention is usually attributed to be directed without any eye movements. However, we had previously shown that even during visual fixation periods in a sustained attention task, the neural firing rates and stimulus representations in primate visual cortical areas V4 and the inferotemporal cortex (IT) are enhanced only following microsaccades (MS) towards the attended target locations (Lowet et.al., Neuron, 2018). Here we present evidence that the first MS towards the intended (cued) target location kickstarts the attentional modulation of neural firing rates typically observed in area V4. That is, at the neural level, the timing of the first MS structures the process of attention which continues for the remainder of the trial. Subsequent MS during the trial modulate the underlying attentional enhancement. Furthermore, the neural modulations triggered after the MS onsets have significant effects in shaping the object representation, tuning, and selectivity at the target locations. Decoding analyses of V4 firing rates for objects present in the target location confirms that the performance of the decoder is significantly increased for the MS towards intervals towards the attended stimulus compared to intervals following MS directed away from the attended stimulus. The type of MS, towards or away from the target, gives rise to distinct temporal regimes of representation, selectivity, and decoding performance. Such mechanisms are usually obscured when analyzing the neural activity during the full trial periods without taking MS into account. These results thus reveal a major link between spatial attention and its coordination with eye movements. We thus suggest that selective visual attention is not merely a covert cognitive process, but has visuomotor components that shape our ability to dynamically attend, recognize, and act on the objects in the world.

Title: Microsaccades are not necessary for attention-related modulation

Authors: *G. YU, J. P. HERMAN, L. N. KATZ, R. J. KRAUZLIS;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: The allocation of visual spatial attention is associated with both the enhancement of neuronal activity at the attended location and the tendency to make microsaccades towards the covertly attended stimulus while fixating. A recent study found that cortical neurons displayed attention-related modulation only after microsaccades directed towards the attended stimulus, raising important questions about how to interpret neuronal data obtained during fixation tasks commonly used in the study of visual attention. Here, we tested the relationship between microsaccades and attention-related modulation in the superior colliculus (SC), a brain structure crucial for allocating attention. We collected neuronal activity (64 units) and eye movement data in two monkeys (Macaca mulatta) during a covert spatial attention task. Our analyses focused on the 'delay period' when SC neurons displayed classic sustained attention-related modulation. First, we found that attention-related modulation in SC emerged over a similar time course during the attention task, regardless of microsaccades generation; Second, subsets of neuronal data with no microsaccades in 400-ms windows selected to match the microsaccades timing distribution still displayed substantial attention-related modulation when microsaccades were completely absent; Third, when microsaccades did occur, there was a relationship between attention-related modulation and microsaccade direction, however, we determined that the relationship was already present before the onset of microsaccades and persisted unchanged after the occurrence of the microsaccade. Together, our results suggest that microsaccades are not necessary for neuronal modulation during sustained attention. Instead, microsaccades provide an additional marker for the state of attention.

Title: Ensemble-level neural correlates of visual working memory from the local field potentials recorded from the lateral prefrontal cortex of non-human primates

Authors: *D. Y. JUNG, M. A. CONLEY, A. C. SNYDER;
Univ. of Rochester, Rochester, NY

Abstract: Visual working memory (VWM) allows transient maintenance of relevant visual information (hereafter, "items") for near-term goals. In non-human primates, individual neurons in the lateral prefrontal cortex (LPFC) significantly participate in item maintenance through ensemble-level interactions. But the ensemble-level interactions are mostly inferred from pseudo-populations of neurons pooled from separate recording sessions, an approach that potentially neglects *real-time* ensemble dynamics. Local field potentials (LFPs), related to summed electrical activity of an ensemble near a recording electrode(s), provide a means to indirectly study large ensemble dynamics at high temporal resolution. Through measuring high-density LFPs from the LPFC of monkeys, we studied ensemble-level neural dynamics especially during the *delay period* of a VWM task, when the item maintenance occurs. Spontaneous LFPs during the delay period, however, lack item-dependent features, which makes inferring items in VWM difficult. Therefore, we introduced a "perturbing" visual stimulus impulse that is task-irrelevant but can drive LFP responses in the LPFC, which we hypothesized to be dependent on the underlying LPFC ensemble dynamics. To be precise, we hypothesized that the LPFC ensemble maintains items in VWM and therefore LPFC LFP responses to the impulse stimulus would be dependent on the ensemble, which will allow us to infer (decode) items from the LFPs and reveal large neural ensemble interactions during item maintenance. We recorded high-density LFPs from LPFC of monkeys performing a memory-guided saccade (MGS) task. Critically, the impulse stimuli (i.e., task-irrelevant checkerboard stimuli) during the delay periods on half of the trials enabled us to decode the item. Importantly, checkerboard presentation did not improve decoding performance when the identical paradigm was presented to an untrained monkey, indicating that the item decodability from the LPFC LFPs is not due to passive visual processing. Interestingly, we failed to decode the item from LFPs collected extrastriate cortex (V4), a possible area participating in (visual) item maintenance. Our results, therefore, show the specificity of PFC's role in transient item maintenance and provide an approach to probe states of large neural dynamics of cognitive processes from the LFP responses to the impulse stimuli.

Title: Memory guided saccades in marmosets: behavior and electrophysiology in posterior parietal cortex

Authors: *H. CARNEY, E. HART, J.-O. MUTHMANN, A. C. HUK;
Univ. of Texas at Austin, Austin, TX

Abstract: Introduction: Persistent neural activity is a long-studied phenomenon thought to underlie working memory, but the detailed circuitry that supports it has been largely inaccessible in the primate. Marmosets represent an exciting opportunity to deploy powerful techniques, but it is unclear whether this species can be trained to perform memory-guided saccades (MGS), nor whether they have cortical areas functionally analogous to those studied in this context in macaques.
Methods: We developed marmoset-specific training techniques for the MGS task, and mapped neural activity in posterior parietal cortex during performance of this task using chronically implanted 3D "N-form" multielectrode arrays. We then compared the behavior and the neurophysiology to comparable data from macaques. All marmosets (N=3) learned the task and performed at levels acceptable for physiological study, with delay periods exceeding 1000ms.
Results: Marmoset memory-guided saccades were somewhat less accurate and consistent than macaque MGS, but marmosets were willing to perform significant numbers of trials per session (averaging 473 trials per session). In the first monkey's dataset, 490 individual units were identified across 78 sessions spanning a ten month period, and an average of 34 units were identified per session. Neural activity in marmoset PPC reflected an often-multiplexed combination of sensory, motor, and delay-period activity, both time-locked to relevant task events and with spatial selectivity. Of 490 identified units, 12% (n=61) of the recorded units had obvious spatial selectivity for visual and/or motor aspects of the task. The majority of non-spatially selective units were still modulated by visual or saccadic task components. 91% (n=56) of units with spatial selectivity were spatially selective during both visual and motor epochs. A similar amount (93% n=57) of spatially selective units exhibited distinct persistent activity during the delay period. This activity was similar to activity classically reported in macaque PPC during memory-guided saccades. The one clear difference to macaque PPC was that marmoset firing rates were considerably lower.
Discussion: Marmosets can be trained to perform the MGS task using shaping approaches not typically used with macaques, and activity in their PPC suggests functionally analogous signals to those observed in macaque LIP, including single neurons exhibiting persistent activity.

Title: Persistent activity in the prefrontal cortex of the common marmoset during a delayed-response task

Authors: *R. K. WONG, J. SELVANAYAGAM, K. D. JOHNSTON, S. EVERLING; Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: The common marmoset (*Callithrix jacchus*) has attracted attention in neuroscience research because of its small size, high reproductive efficiency and compatibility with gene editing techniques. This species' relatively lissencephalic cortex offers practical advantages for laminar recording, two-photon and calcium imaging. Marmosets have been established as a model for visual neuroscience, but its suitability for investigating higher order cognitive functions, such as working memory and its underlying neural circuitry, remain to be determined. The neurophysiological basis of working memory has been investigated in detail in the prefrontal cortex (PFC) of the macaque monkey. PFC neurons have been shown to exhibit sustained activity during the delay period of a delayed-response task in the absence of a stimulus. This persistent firing during the delay period is regarded as the neuronal correlate of a mnemonic event. It is unknown whether PFC neurons exhibit delay-period activity in the marmoset, as working memory in marmosets has been examined primarily at the behavioural level. Here, we addressed this gap by carrying out single neuron recordings in a common marmoset monkey performing a delayed-match-to-location (DMTL) task with varying delay lengths (2-8s) on a touchscreen attached to the home cage. Untethered extracellular electrophysiological recordings were obtained from a 96-channel Utah array (4x 4 mm, 1mm electrode length, 400μm pitch) implanted in areas 46d, 46v, and 8Ad. We recorded 706 units, of which 564 units were modulated during the task. Of these 564 units, 269 units (38.1%) displayed delay period activity, 167 units (23.7%) displayed cue-related activity and 513 (72.7%) units displayed touch-related activity. Of the 269 delay units, 90 units (33.5%) were excited and 179 units (65.5%) were suppressed, when compared to baseline firing rate. These data show that prefrontal cortex neurons in marmosets exhibit persistent activity during the delay period of a delayed-response task, and that marmosets are a suitable model for investigating the neurophysiological circuitry underlying working memory.

Title: Neuronal ensembles of primate lateral prefrontal cortex encode spatial working memory in different frames of reference

Authors: *R. LUNA[1,2], M. ROUSSY[1,2,3], B. W. CORRIGAN[1,2], R. A. GULLI[4], G. DOUCET[5], A. J. SACHS[5], S. TREUE[6], J. C. MARTINEZ-TRUJILLO[3,1,2,7];

Abstract: Neurons in the lateral prefrontal cortex (LPFC) of macaques encode spatial information during working memory (WM) tasks. Yet it is poorly understood whether ensembles of neurons could represent memorized locations on different frames of reference (FOR) - such as space centered frame. To tackle this question, we trained two rhesus monkeys on an oculomotor delayed response task with variable fixation and target positions. In a single trial, animals fixated a dot displayed at one of sixteen different positions on the screen and a target transiently appeared for 1 second at another one of the remaining positions. Animals maintained fixation for another second and upon extinction of the fixation dot they made a saccade to the remembered target location. Reward was delivered for correct trials. This task design allowed data analysis for remembered locations relative to the fixation dot (retinotopic FOR), and relative to the target location (spatiotopic FOR). We recorded and spike sorted the extra-cellular activity by implanting multi-electrode arrays in LPFC dorsal and ventral banks (areas 8a and 9/46) of each animal (3039 multi- and single units in the dorsal array and 2410 in the ventral array). Trials were pooled by visual quadrants of each FOR. We computed the average firing rate during the first 1-second interval of the WM delay for each unit and determined their spatial selectivity (Mutual information; 1000 permutations; $p < 0.05$). We found 820 (27%) spatial WM-encoding selective units in the retinotopic FOR, 334 (11%) in the spatiotopic FOR, and 169 (5.5%) for both FORs, in the dorsal array, as well as 681 (28.3%) in the retinotopic FOR, 325 (13.5%) in the spatiotopic FOR, and 175 (7.3%) for both FORs, in the ventral array. We then constructed neuronal ensembles of different sizes (n=1, ⋯, 50) and trained linear classifiers to decode the memorized quadrant out of each ensemble (five-fold cross validations; 20 decoding iterations; balanced conditions). On average, ensembles of units from dorsal and ventral arrays yielded decoding accuracies of 69%

and 79% in the retinotopic FOR, respectively, and 55% and 52% in the spatiotopic FOR (chance performance ~25%). Notably, decoding accuracies reached asymptotic values at ensembles of 4 to 18 units. Furthermore, neurons selective for either or both reference frames were sparsely distributed in the dorsal or ventral array, although distances between units were generally smaller than predicted by chance. Neuronal ensembles in the primate LFPC could encode locations during spatial WM in the retinotopic and spatiotopic reference frames, also showing some degree of grouping of informative units in the surface covered by the arrays.

Title: Different neural codes serve long and short-term memory functions in primate Hippocampus and Lateral Prefrontal Cortex during virtual navigation

Authors: *B. W. CORRIGAN[1], R. A. GULLI[2], G. DOUCET[3], M. ROUSSY[1], R. LUNA[1], A. J. SACHS[3], J. C. MARTINEZ-TRUJILLO[4];

Abstract: Neurons in the primate Hippocampus (HPC) and the lateral prefrontal cortex (LPFC) integrate high level information about objects, features and space during behavior. Previous lesions studies have suggested that while the HPC plays a role in the formation of long-term declarative memories, the LPFC plays a role in maintaining short term memories. These two functions have different underlying mechanisms. Here we hypothesize that neural codes in the HPC have evolved to support short-term synaptic plasticity while in the LPFC codes have evolved to support persistent firing in large neuronal ensembles without necessarily triggering

plasticity. We use a virtual reality task in which animals navigated through a maze using a joystick and selected one of two targets in the arms of the maze according to a learned context-color rule. We found that neurons and neuronal populations in both regions were similarly selective for the different task periods. However, HPC and PFC neurons differed substantially in the temporal structure of their spike trains. Using statistical analyses and linear classifiers, we demonstrated that while HPC neurons and populations 'packed' information into bursts of action potentials, their PFC homologues fire more sparsely. We propose that the HPC, a structure with limited connectivity, enhanced plasticity and known to encode episodic memories, uses a code that facilitates temporal summation of synaptic events. The PFC, a more widely connected structure and known to encode short-term memories uses predominantly a code with spikes temporally distributed across many neurons which allows encoding and broadcasting information to other brain regions without inducing short term plasticity in individual synapses. The latter may also allow encoding of short term memories.

Abstract: INTRODUCTION: Fast spiking (FS) parvalbumin (PV) expressing cells are one of the three major subpopulations of GABAergic interneurons. They show a consistent set of electrophysiological features across brain areas that are thought to be crucial for fast inhibition and generation of network oscillations associated with various cognitive phenomena. However, previous studies have shown a wide range of diversity in morphological and intrinsic electrophysiological properties between neocortical neurons across different species. In this study, we compare the somatodendritic configuration and subthreshold intrinsic properties of putative FS neurons from macaque primary visual area (V1) and dorsolateral prefrontal cortex (DLPFC, areas 9/46), and cells from multiple areas of mice and humans (Allen Institute Cell Type Database). METHODOLOGY:The electrophysiological properties of 195 cells from NHP were obtained from whole cell patch clamp recordings from the DLPFC and V1 of 5 male Macaca mulatta and 9 Macaca fascicularis (4 male, 5 female). Cells were filled with biocytin for morphological characterization. Putative FS neurons from NHP and human were identified using waveforms via a machine learning procedure trained using data from genetically labeled neurons obtained from the Allen Institute Cell Type Database. RESULTS AND CONCLUSION: We found that NHP/human neurons were more alike, having higher excitability and sag amplitude than those of mice. Compared to humans NHP cells showed higher excitability and sag than human cells. No significant difference was observed between subthreshold properties of DLPFC and V1 putative FS cells in NHP. Our results suggest that an increase of cortical surface in macaques and humans relative to mouse is accompanied by changes in the input resistance and somatodendritic configuration of PV+ interneurons. Such changes in FS cells may accommodate the demands of the local network, providing fast inhibitory inputs to pyramidal cells and facilitating a rich temporal dynamics that may be required for complex cognitive function.

Title: Non-linear mixed selectivity in prefrontal and posterior parietal cortex during working memory

Authors: *W. DANG[1], S. LI[4], S. PU[1], X.-L. QI[4], C. CONSTANTINIDIS[1,4,2,3];
[1]Dept. of Biomed. Engin., [2]Neurosci. Program, [3]Dept. of Ophthalmology and Visual Sci., Vanderbilt Univ., Nashville, TN; [4]Dept. of Neurobio. & Anat., Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: Neurons in the prefrontal cortex (PFC) and posterior parietal cortex (PPC) respond differently to the same stimuli depending on task context. Conjunctive representations of multiple stimulus and task features can be found on single-neuron activity, a phenomenon known as nonlinear mixed selectivity (NMS). Here we measured nonlinear mixed selectivity in PFC and PPC in a working memory task that required monkeys to observe two consecutive stimuli with an intervening delay period and make a judgment on whether they are the same or not. Neurophysiological recordings were performed in areas 8a and 46 of the dorsolateral prefrontal cortex, and areas 7a and lateral intraparietal cortex (LIP) of the posterior parietal cortex. We analyzed 404 PFC neurons and 671 PPC neurons with sufficient data from two male rhesus monkeys (*Macaca mulatta*). We identified neurons that exhibited NMS with respect to spatial tuning for the same stimulus when it appeared as first (cue) or second (match) in the trial. The percentage of NMS neurons in PFC was higher than in PPC (8.7% of neurons in PFC vs. 4.4% of neurons in PPC). In our task, the subjects' behavioral performance improved within a behavioral session as they learned the session-specific statistics of the task. Our analysis revealed that in PFC the proportion of neurons that exhibited NMS also increased as a function of time within a single session, while this was not the case in PPC. However, we did not find appreciable differences in the percentage of neurons that exhibited NMS between correct and error trials. Analysis of the combined population of neuronal activities showed that the distance between first and second stimulus in state-space was greater for the PFC than PPC, however for both areas the two stimuli could be projected in the same subspace, with little rotation. Our results provide evidence of greater plasticity and flexibility of neuronal representations in PFC than PPC in a task requiring maintenance of precise working memory information, suggesting a cortical specialization for processes representing.

Title: Geometry of neural computations unifies working memory and planning

Authors: *D. B. EHRLICH[1], J. D. MURRAY[2];
[1]Interdepartmental Neurosci. Program, [2]Dept. of Psychiatry, Yale Univ., New Haven, CT

Abstract: The ability to maintain information in working memory forms one of the key building blocks of cognition. Traditionally, computational models of working memory have been conceived as a form of extended sensory perception that preserves prior information to inform current computation. In this study, we recast working memory representations as an active part of ongoing goal-oriented computations. Using both Recurrent Neural Networks (RNNs) and human subjects performing a set of logical tasks, encompassing several known working memory paradigms, we demonstrate how such working memory representations may help to minimize computational complexity of cognitive operations.
The contextual delayed logic (CDL) task, is a novel delayed decision task in which subjects use a rule context to flexibly modulate their response to a pair of binary stimulus inputs separated by a mnemonic delay. On each trial the subject sees one of ten Boolean logical operations (e.g. 'AND'), must hold trial variables in memory across a delay, and then upon presentation of the second stimulus, must apply the stated logical operation. The different retrospective and prospective demands between rules allow us to disentangle memory, planning, computational or rule specific influences on representations and behavior.
We trained RNNs to perform the CDL task, analyzing resulting optimized networks and state trajectories. We found that delay epoch representations were organized computationally and prospectively with overlapping sub-problems sharing network resources (e.g. fixed points, transitions). Further, delay states were geometrically arranged within a stable mnemonic subspace to linearize the overall stimulus-output classification problem.
Intriguingly the resulting representations recapitulate known properties of prefrontal delay task firing patterns recorded in primate delay tasks. First we find that units represent task variables in a mixed rather than pure encoding structure, and can explain this mixing as a function of the underlying prospective tuning utilized by our models. Second, our network demonstrates behavior reflective of dynamic tuning, where the transition from retrospective encoding to prospective encoding from the stimulus to delay epoch leads to an apparent shift in the stimulus coding direction when each task is analyzed independently.
Lastly we designed a human version of our CDL task paradigm identifying behavior that is consistent with our models, demonstrating evidence of pre-computation during mnemonic delays and prospective representational organization.

Abstract: Electrophysiological single cell recordings during in vivo and in vitro experiments have been the backbone of system neurophysiology allowing for exploration of the functional properties of neurons in different brain areas. However, so far, the in vivo techniques have provided limited insight on the identity of the cell types recorded from. Linking response patterns to neuronal identities is fundamental for revealing the role of different cell types in the neural computations underlying information processing and behavior in the brain. Here, we use data from three species, mouse, macaque monkey and human to identify features of electrophysiological recordings that are common to in vivo and in vitro experiments and map them into genetically and histologically identified cell types in neocortex using computational techniques. We elaborate on a probabilistic classification of four main cell types, namely: Pyramidal, Parvalbumin, Vasointestinal Peptide, and Somatotastin positive from electrophysiological recordings in both in vivo and in vitro experiments. Our results provide electrophysiologists with a tool to probabilistically identify individual circuits components during functional exploration of the neocortex.

Title: Understanding Cognition through Connectivity Analyses: Examples from Working Memory Research

Authors: *D. PINOTSIS[1], E. K. MILLER[2];
[1]Univ. of London & MIT, London, United Kingdom; [2]Picower Inst. Learning Memory, Massachusetts Inst. Technol., Cambridge, MA

Abstract: Cognition arises from coordinated activity of different neuronal populations that form brain networks. The activity in each of these populations is the result of input from all other populations connected to it. Therefore connectivity is a central notion in describing the function of brain networks and understanding cognition. In this presentation, we will show how the analysis of connectivity patterns provides novel insights for understanding the mechanisms underlying an important cognitive function, working memory. We will present two studies of working memory. The first focused on a change detection task while the second focused on a spatial delayed saccade task. Both studies exploit modern machine learning algorithms, biophysical modeling and high resolution electrophysiology data.
First, in the change detection task, the number of items that the subject had to remember (memory load) was varied (1-3 items in the same visual hemifield). We will show that changing memory load resulted in changes in feedforward and feedback coupling in the network of brain areas supporting memory function (memory network). We will also show that feedback connectivity broke down when the cognitive capacity limit was exceeded (when more than 2 items were presented in the same hemifield, the animal's behavioral performance decreased dramatically).
Second, in the spatial delayed response task, the location of the item that had to be remembered was varied (six possible locations in the visual field). We will show that coding different locations resulted in different spatial organization of neural activity within each brain area in the memory network. Different neural ensembles (groups of neurons that coded locations) were formed. We will also provide a mechanistic explanation of a well-known behavioral effect, called the oblique effect (performance is better for stimuli on than off the horizontal axis) and link it to the structure of the underlying neural ensembles.

To sum up, in this presentation we will show that a combination of modern machine learning algorithms, biophysical modeling and high resolution electrophysiology data sheds new light to the mechanisms underlying working memory and explains important behavioral effects.

Title: Specialized prefrontal circuits explain population dynamics during working memory encoding and maintenance

Authors: *N. POLLÁN HAUER[1], B. PESARAN[2], A. COMPTE[3], K. WIMMER[4];
[1]Ctr. de Recerca Matemàtica, Barcelona, Spain; [2]Ctr. for Neural Sci. (NYU), New York, NY; [3]VAT# ESQ5856414G, IDIBAPS, Barcelona, Spain; [4]Ctr. De Recerca Matematica, Bellaterra (Barcelona), Spain

Abstract: Neuronal population activity recorded from primate prefrontal cortex carries information about the presented stimulus during working memory tasks. During cue presentation and in the beginning of the delay period the population code is dynamic, before it stabilizes and remains stable throughout the rest of the delay period. It is an open question how individual neurons support the dynamic and stable population codes and what are the underlying circuit mechanisms. Here, we show that a spiking network model composed of three specialized attractor circuits can explain the experimentally observed transition from cue to delay dynamics. Each conceptual ring circuit represents a specialized PFC sub-population (encoding, storage and

readout neurons). Based on experimental findings we structured the model such that the external input excites the encoding population while it suppresses the storage population. When a stimulus is presented, an activity bump forms in the encoding population. Recurrent connections are not strong enough to sustain persistent activity in the encoding ring, so that, after stimulus offset, the bump fades in the encoding units. At the same time, the strongly recurrent storage ring is released from inhibition and a stable bump emerges in the storage units. The readout circuit receives input from the other two populations and is thus active during cue and delay periods even without strong recurrency. We found that when we randomly select a subpopulation of the entire network, cross-temporal decoding analysis fails to generalize across cue and delay periods because different neuronal subsets are most informative during the respective epochs. We confirmed similar cross-temporal decoding patterns in prefrontal population recordings from a visual and memory task. Finally, from a functional point of view, the network model shows increased robustness to distractors once the activity bump has formed in the storage population, a prediction that can be tested experimentally. In sum, our findings suggest that the presence of a highly dynamic cue to delay transition originates mainly from different neuronal subpopulations. After this initial transient, a stable state is reached, and memory maintenance is achieved through attractor dynamics.

Title: Distinct neural codes for content and ordinal structure in human auditory sequence memory

Authors: *Y. FAN, Q. HAN, S. GUO, H. LUO;
Dept. of Psychology, Peking Univ., Beijing, China

Abstract: Two forms of information - frequency (content) and ordinal position (structure) - have to be stored when retaining a sequence of auditory tones in working memory (WM). However, the neural representations and coding characteristics of content and structure, particularly during WM maintenance, remain elusive. Here, in two electroencephalography (EEG) studies in human participants performing a delayed-match-to-sample task with a retrocue, by transiently

perturbing the ‘activity-silent’ WM retention state and decoding the reactivated WM information, we demonstrate that content and structure are stored in a dissociative manner with distinct characteristics throughout WM process. First, each tone in the sequence is associated with two codes in parallel, characterizing its frequency and ordinal position, respectively. Second, during retention, a structural retrocue successfully reactivates structure but not content, whereas a following neutral white noise triggers content but not structure. Meanwhile, a content retrocue is able to reactivate both content and structure information, while a subsequent neutral visual impulse successfully makes maintained structure information detectable. Third, structure representation remains stable whereas content code undergoes a dynamic transformation through memory progress. Finally, the neutral-impulse-triggered content and structure reactivations during retention correlate with WM behaviors on frequency and ordinal position, respectively. Overall, our results support distinct content and structure representations in auditory WM and provide efficient approaches to access the silently stored WM information (both content and structure) in the human brain.

Title: Neuronex exploration: how does the brain generate the mental representations that underlie working memory and abstract thought?

Authors: *J. MARTINEZ-TRUJILLO;
Schulich Sch. of Med. and Dentistry, Robarts Institute, Western Univ., London, ON, Canada

Abstract: How does the brain generate the mental representations that are the foundation of abstract thought? Mental representations that can be dissociated from incoming sensory inputs and ongoing motor actions are a step up in brain evolution. They exist ‘virtually’, so that the brain can load and keep online information acquired in the past to solve complex problems, e.g., “simulate” situations and “predict” outcomes without the need to immediately act. When and

how did mental representations arise during brain evolution? Current evidence indicates that they may have arose in anthropoid primates, with the development and expansion of the granular, dorsolateral prefrontal cortex (dlPFC).Studies in macaques performing spatial working memory tasks have found neurons in dlPFC with strong persistent firing resilient to distracter signals and representing a remembered location. This capability may arise from layer 3 microcircuits, containing neurons with abundant recurrent excitatory connections, extensive dendritic branching, and unique molecular regulation. However, the foundation of this hypothesis rests on data from disparate labs/approaches with poor integration across levels. In our NEURONEX we address the following questions. What are the features of neurons and circuits that allow mental representations to arise in the dlPFC?Are these features particularly salient in old world primates relative to new world primates?Are there unique molecular characteristics, e.g. in dopamine, NMDAR and calcium signaling, that are necessary to support mental representations?Answering these questions will reveal how evolution shaped primate cognition and vulnerabilities to mental disease. Our emerging data demonstrate that dlPFC neurons in macaque encode working memory representations in naturalistic environments, in both macaques and marmosets. In vitro electrophysiology shows neurons in dlPFC have distinct intrinsic properties than those in sensory cortices and the parietal lobe. The latter is supported by transcriptomic data. ImmunoEM and in vivo recordings show that dlPFC pyramidal cells have magnified calcium signaling near NMDAR synapses, and a focal location for dopamine D1R. Computational modeling shows gradients of neuronal and receptor types and distinct circuit motifs across the cortical hierarchy, consistent with the emergence of persistent firing capabilities resilient to distracting sensory and motor events. Our data suggest complex mental representations resulted as an emergent property of complex brains evolution due to changes in the make-up features of the primate neocortical mantle.

Title: Spontaneous blink-related BOLD-fMRI delay activity correlates with working memory performance

Authors: *T. ELLMORE[1], C. REICHERT PLASKA[3], B. A. GOMES[4], J. ORTEGA[2]; [1]Psychology, [2]The City Col. of New York, New York, NY; [3]City Univ. of New York, New York, NY; [4]Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Spontaneous blinks are typically considered a nuisance in cognitive neuroscience studies with instructions to inhibit blinks to minimize signal artifact. Recent findings, however, demonstrate the functional significance of spontaneous blink-related oscillations[1] and document a relationship between spontaneous blink rate during the working memory delay period and subsequent task accuracy[2]. Together these results motivate an investigation of the neural substrates of spontaneous blinking and its role in working memory. We studied 7 adults (mean age 27.8, 3 males) during performance of a Sternberg scene working memory task. Whole-brain 3 tesla BOLD-fMRI (2 mm^3, 2 sec TR) and continuous in-bore camera-based eye tracking data were collected. Single subject imaging data were preprocessed using *fmriprep* followed by exploratory voxelwise group analyses in *AFNI* using *3dMVM* with blink event-related responses during the working memory delay period and non-delay periods as separate conditions and working memory task accuracy as a covariate of interest. We found a cluster of voxels located within the inferior portion of right hemisphere central sulcus encompassing portions of the pre- and post-central gyrus (MNI: x=+54, y=-5, z=+23 mm] but also extending posteriorly to parietal cortex whose BOLD fMRI activity evoked by spontaneous blinks during the delay period correlated with working memory task accuracy (r=+0.88, p=0.008). We examined activity in this region during spontaneous blinks occurring at other times during the imaging runs and found these non-delay period evoked responses to be unrelated to task performance (r=-0.19, p=0.68). The spontaneous blink rate has been linked to dopamine function with higher and lower rates in Schizophrenia and Parkinson's disease, respectively. These disorders also present with deficits in working memory, with perseveration and compromised updating. The finding of the present study, that activity evoked by spontaneous blinks during the working memory delay period correlates with task accuracy, supports the idea that spontaneous blinking may serve a functional role in working memory. The localization of spontaneous blink related evoked activity to a region that is consistent with the location of eyelid/eyeball on the sensorimotor homunculus and including parietal cortex supports the idea that temporary memory may emerge from the coordinated interplay of circuits that include sensory-motor regions.

Title: Measuring the spatiotemporal scale of prefrontal population codes for visuospatial working memory

Authors: *J. XIANG[1,2,3,6,7], M. ROUSSY[2,4,6,7], B. CORRIGAN[2,6,7], M. H. MOFRAD[3,6], R. LUNA[2,6,7], L. MULLER[3,6,7], J. MARTINEZ-TRUJILLO[2,6,7], M. MUR[1,5,6];

Institute, Western Univ., London, ON, Canada

Abstract: The lateral prefrontal cortex (LPFC) plays a key role in working memory (WM). Electrophysiological studies in monkeys show that LPFC neurons robustly encode visuospatial WM content. However, fMRI studies in humans report weak WM signals in LPFC. We hypothesize that the contradiction arises because the spatial topography of prefrontal neural population codes for WM is too fine to be effectively resolved by standard fMRI (2x2x2 mm^3, 1-2 s resolution).
To test this hypothesis, we analyzed spike data from two microelectrode arrays (Utah array, 4x4 mm^2, 10x10 electrodes spaced 0.4 mm apart) implanted on the left LPFC areas 9/46 of two adult male rhesus monkeys performing a visuospatial WM task in a virtual reality environment. During the task, the animals had to remember one of nine target locations. To assess the spatiotemporal scale of neural population codes, we applied 13 degrees of spatial (2D Gaussian kernels, 0.2-4.4 mm full-width-at-half-maximum [FWHM]) and 12 degrees of temporal smoothing (1D Gaussian kernels, 2-2048 ms sigma) to the data and assessed how this affected decoding of WM content. We estimated decoding accuracy using linear support vector machines with five-fold cross validation across trials within each measurement session. We performed statistical inference using t-tests and ANOVA with measurement session as random effect (11 sessions in animal B, 8 sessions in animal T; $p < 0.05$ after correction for multiple comparisons). Decoding accuracy for the ventral array was above chance (chance performance = 0.11) for all levels of spatial and temporal smoothing with mean accuracy up to approximately 0.5 (mean ± sd from 0.13 ± 0.003 to 0.49 ± 0.05 for animal B, and from 0.14 ± 0.009 to 0.34 ± 0.06 for animal T). Both spatial and temporal smoothing affected decoding accuracy, with larger effect sizes for temporal smoothing. Effects of spatial smoothing were more pronounced at higher levels of temporal smoothing. Best decoding accuracies were observed for low levels of spatial smoothing (0.4 mm FWHM) and high levels of temporal smoothing (> 512 ms sigma). Similar effects were observed for the dorsal array. The results indicate that coding of remembered stimuli is stable across time for at least a few hundred milliseconds, but not stable across space - channels with similar selectivity do not seem to cluster together.
Our findings suggest that fMRI signals integrating LPFC information across voxels of several millimeters will reach suboptimal performance. We suggest fMRI will be most sensitive to WM

signals encoded in LPFC population activity measured with voxel sizes in the submillimeter range. Future studies could experimentally confirm this using high-field fMRI.

Title: Sequence structure reorganizes memory items in orthogonal planes of working memory network and leads to recency effect

Authors: *T. TANG[1], Y. MI[2], H. LUO[3];
[1]Sch. of Physics, Peking Univ., Beijing, China; [2]Ctr. for Neurointelligence, Sch. of Med., Chongqing Univ., Chongqing, China; [3]Dept. of Psychology, Peking Univ., Beijing, China

Abstract: Abstract: When retaining a sequence of items in working memory, human subjects typically demonstrate recency effect in behavior, i.e., better memory performance for recently presented item compared to early items. Our recent studies further demonstrate that items located at different ordinal positions in the sequence tend to be stored in different latent states of the memory network and are represented in different neural formats. Furthermore, when subjects do not need to retain the sequence order of items, the recency effect is largely disrupted. Here we built and trained a recurrent network model to perform sequence working memory tasks, aiming to examine i) how memory items in the sequence are represented in different task contexts and ii) how recency effect would emerge from the neural representations. **Methods:** A 256-unit LSTM recurrent network was built and trained to perform working memory tasks. Specifically, a list of items were first serially loaded in the network, and in the sequence task, the network was trained to memorize items as well as their ordinal positions, whereas in the non-sequence task, the network only needs to memorize items without sequence requirements. Moreover, we examined the multivariate neural representations of items in the principal component space (the first three PCs) of the network, in sequence and non-sequence tasks, respectively. **Results:** (1) The recurrent network model shows recency effect in sequence task and disrupted recency effect in non-sequence task, consistent with human behavior. (2) In sequence task, memory items that are located at different ordinal positions of the sequence are stored in different PC planes that are orthogonal to each other, and recent item is in planes with higher variation. (3) In non-sequence task, although memory items are represented in different PC planes during the encoding epoch, they start to transform to the same PC planes during the maintaining epoch. **Conclusion:** When sequence structure needs to be retained in working memory (sequence task), each item in the

sequence is stored in distinct and orthogonal PC planes of the neural network, from which the recency effect emerges. When sequence structure is not needed to be retained (non-sequence task), items in the sequence are maintained in the same PC planes, leading to the disruption of recency effect.

Title: Dissociating the causal contributions of frontal and parietal cortex to working memory capacity

Authors: *J. M. SCIMECA, A. KIYONAGA, M. D'ESPOSITO;
UC Berkeley, Berkeley, CA

Abstract: Goal-directed cognition and behavior require the ability to keep information temporarily activated in mind. Decades of neuroimaging and neurophysiology research indicate that fronto-parietal (FP) cortex supports this working memory (WM) function. However, this research has been inconsistent as to the precise roles that these regions play in WM, and patients with FP damage often present clinically with relatively spared WM performance. To address these inconsistencies, we carried out a large-scale, multi-modal Registered Report using fMRI, TMS, and quantitative modeling of behavior. On Day 1, we used fMRI to localize subject-specific regions within frontal and parietal cortex (Fig 1a; N=120) that are involved in the performance of two canonical visual WM tasks (Fig 1b). On Days 2-5, we used transcranial magnetic stimulation (TMS) to perturb these regions and assessed the impact on several measures of WM function (Fig 1c; N=52). On each day, we applied continuous theta-burst TMS to either a baseline control site or one of three target sites: dorsolateral prefrontal cortex (PFC), superior intraparietal sulcus (IPS), or inferior IPS. Following TMS, subjects completed interleaved blocks of the two WM tasks. In interim analyses, we found that TMS to PFC and IPS largely spared WM function when task demands were low. However, with greater task demands and increased memory load, TMS produced greater overall impairment and a dissociable pattern across sites: IPS stimulation was more detrimental in a low-resolution (change detection) WM task while PFC stimulation was more detrimental in a high-resolution (continuous report) WM task. This causal manipulation therefore reveals distinct contributions of FP regions that only

emerge under heightened task demands. This study employs the rigorous research standards of the Registered Report format to help resolve ongoing debates about fronto-parietal cortex and WM function. Furthermore, this project provides a large, publicly available dataset of fMRI and TMS measures that can be leveraged to query the neurocognitive mechanisms of WM function.

Title: Long-term learning transforms prefrontal cortex and medial temporal lobe activity patterns during working memory

Authors: *J. MILLER[1], A. TAMBINI[2], A. KIYONAGA[3], M. D'ESPOSITO[1];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Univ. of California Irvine, Irvine, CA; [3]Univ. of California San Diego, San Diego, CA

Abstract: The lateral prefrontal cortex (lPFC) is reliably active during working memory (WM) maintenance across human and animal models, but there is ongoing debate regarding the role of the lPFC in successful WM. For instance, non-human primate electrophysiology research finds that lPFC circuitry maintains WM representations (Leavitt et al., 2017), while human neuroimaging suggests that WM content is instead stored in sensory cortices (Serences, 2016). These seemingly incompatible accounts for WM are often confounded by differences in the amount of task training and stimulus exposure across studies, suggesting that long-term learning may influence the role of lPFC function in WM maintenance. Moreover, prior theories posit that WM function directly interfaces with representations and associations from long-term memory (LTM) (Fukuda & Woodman, 2017; Oberauer, 2009), predicting that such long-term training may bolster interactions between lPFC and medial temporal lobe (MTL) structures to facilitate WM. To test whether long-term learning influences (1) WM representations in lPFC and (2) the involvement of MTL in WM, we implemented a longitudinal functional MRI (fMRI) protocol in each of three human participants. Across three months, each participant was trained on (1) a serial reaction time (SRT) task, wherein complex fractal stimuli were embedded within probabilistic sequences, and (2) a delayed recognition task probing WM for trained or novel stimuli. This allowed us to track WM activity patterns over time and ask whether or how representations in WM are shaped by long-term associative learning. Participants showed learning benefits in the WM task for trained, but not novel, fractals. Pattern similarity analyses of WM delay activity demonstrate that across learning, item-level representations emerged within lPFC but not in sensory cortices or MTL. Single-item WM delay activity patterns in lPFC also reflected sequence information present in the SRT task even while not behaviorally relevant for WM. However, MTL involvement during the WM task did change across learning, as hippocampal activity increased over time in the WM probe period. Altogether, the results suggest that cortico-hippocampal interactions may emerge across learning to facilitate the comparison of information from WM and LTM. This work also shows that human lPFC develops stimulus-selective WM responses with learning and establishes novel evidence for long-term memory influences on WM maintenance. This influence of LTM over WM representations of stimuli in sequences likely reflects an integration process in lPFC that may emerge as a function of memory consolidation.

Title: Dynamic stability underlies cortical computations during working memory

Authors: L. KOZACHKOV[1], M. LUNDQVIST[1,4], J.-J. SLOTINE[2,3], *E. K. MILLER[1];
[1]Picower Inst. Learning Memory, [2]Dept. of Mechanical Engin., [3]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [4]Dept. of Psychology, Stockholm Univ., Stockholm, Sweden

Abstract: How does cortex keep its computations precise yet flexible? Recent theory has suggested that a variety of biologically plausible synaptic mechanisms—including anti-Hebbian plasticity and sparsity—endow neural networks with Dynamic Stability. Dynamic Stability is the ability of network activity to "stay in its lanes": be dynamic yet consistent, performing the same computations regardless of initial state and in the face of being perturbed by other activity, noise, distractions. In short, to be precise yet flexible. Here we test this theory by recording prefrontal cortical activity from rhesus macaque monkeys performing a distracted delayed-match-to-sample task (DDMTS). In an ordinary DMTS task, the animal must remember a sample item across a delay period. In DDMTS, 50% of trials have a mid-delay distractor item which the animal must ignore. The distractor acts as a perturbation to the cortex, from which it must recover in order to perform the task correctly. Theory predicts that the recovery from this perturbation will be *exponential*. Our findings indicate that this is indeed the case. Moreover, we find that the time constant of this recovery is consistent with previous time constants measured from prefrontal cortex in the literature—between 200 and 300 milliseconds. Finally, we train artificial neural networks (ANNs) to perform DDMTS while measuring their stability, as well as their similarity to the neural data recorded from the brain. Preliminary analyses show a tradeoff between network stability, task performance, and similarity to the brain. Too stable or too unstable and the ANNs cannot perform the task and they are dissimilar to actual neural activity. We found that there is an inverted U-shaped curve of Dynamic Stability. In the optimal range (not too much or too little Dynamic Stability) ANNs perform the task optimally and are most similar to the brain.

Title: Blink-related oscillations during the working memory delay period show a larger early evoked component compared to rest

Authors: *J. ORTEGA[1], C. REICHERT PLASKA[2], B. A. GOMES[3], T. M. ELLMORE[1]; [1]Psychology, The City Col. of New York, New York, NY; [2]City Univ. of New York, New York, NY; [3]Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Blink-related oscillations (BROs) are a neurophysiological response associated with spontaneous eye blinking and are believed to be reflective of environmental monitoring processes. BROs are characterized by an early negative peak around 100 ms followed by a positive peak occurring around 300 ms. Research on the modulation of these oscillations during visual and auditory sensory stimulation suggests that blink-related processing adapts to accommodate differences in sensory environments. These findings led us to investigate BROs during other cognitive processes such as working memory (WM). We investigated 17 adults (mean age 22.8 years, 7 males) while they completed a Sternberg scene WM task. High-density EEG data was collected using a Brain Products active electrode recording system. Independent component analysis (ICA) was performed, and artifact components were removed. Eye blinks were recorded using an electrooculogram. Blink epochs were evaluated post-ICA to confirm successful artifact removal. Denoised data was band-passed filtered to the 0-4 Hz frequency range, segmented into 3 s epochs, and separated into three conditions: a delay condition of blinks occurring during the delay period, a task condition of all blinks during the task excluding delay periods, and a rest condition of blinks occurring during rest. We found BRO waveforms during the delay period exhibited a greater negative peak (-3.173 μV ± 1.6 amplitude, p = .014) amplitude compared to the rest condition (-1.727 μV ± 1.6 amplitude) at approximately 75-120 ms latency (N1) in the POz electrode. This difference was not present during the task condition. We also found a smaller positive peak amplitude during the task condition (2.458 μV ± 1.3 amplitude, p = .004) compared to the rest condition (4.1 μV ± 2.4 amplitude) at approximately 225-300 ms latency (P3) in the POz electrode. We investigated BROs modulation during a working memory task and found a smaller positive P3 for the task condition compared to the rest. This expected reduction of the P3 amplitude is believed to reflect reduced resources for processing blink-related information. We also observed a novel finding: N1 amplitude during the delay condition exhibited a greater negative peak compared to the rest condition. BROs have been found to activate the parahippocampal gyri[1], a critical region involved in WM functions. Thus, our findings suggest that this early evoked component of BROs may play a role in WM.1.Liu, C. C. et al. Hum. Brain Mapp. 2019 Feb 1; 10.1002/hbm.24378

Title: Functional heterogeneity of prefrontal oscillations in a self-ordered working memory task

Authors: *F.-K. CHIANG, E. L. RICH;
Nash Dept. of Neuroscience, Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Working memory (WM) is the ability to manipulate information temporarily held in mind, and is critical to cognitive processes such as planning and reasoning. The prefrontal cortex (PFC) is important to the processes of WM, but it remains unclear whether there is functional heterogeneity among different subregions of PFC. To assess this, we trained monkeys to perform a sequential self-ordered target selection task and recorded from arrays chronically implanted in the dorsolateral prefrontal cortex (DLPFC, 128 channels) and frontal eye field (FEF, 128 channels). On each trial, monkeys were presented with a target configuration consisting of eight identical filled circles. The task required monkeys to saccade to each target, one at a time in any order, returning their eyes to the center after each selection. The same target configuration was presented repeatedly for every selection in a block of 40 trials, and different target configurations were used in six blocks per recording session. Within a trial, reward was delivered only once for each target and target revisits were not rewarded. Therefore, monkeys had to use WM to track which targets had been visited and prepare for the next target selection. Local field potentials (LFPs) were aligned to fixation and reward epochs across correct saccades, and preliminary data revealed specific modulations as a function of saccade order. Increased alpha/beta (10-25 Hz) activity was commonly observed in both DLPFC and FEF during the fixation epoch prior to the first target selection of a trial, when WM was not yet required, suggesting alpha/beta activity is involved in attending to a configuration at the beginning of the new trial. Theta (4-8 Hz), but not alpha/beta, in DLPFC, but not FEF, increased during the reward epochs and following fixation epochs after correct target selections, suggesting that DLPFC theta is important for updating or retrieving target-reward contingencies held in mind. Lastly, alpha/beta activity in FEF was observed across saccades during fixation epoch, suggesting this signal represents attention or saccadic preparation. These results indicate that LFPs in DLPFC and FEF are distinct and dynamically modulated during information updating and response selection in a self-ordered WM task.

Title: Prefrontal Neural changes in Early Adolescence related to working memory

Authors: *J. ZHU[1], C. M. GARIN[1], X. QI[2], A. W. LODISH[2], L. SILENZI[2], E. A. KATTNER[2], G. D. MYATT[2], T. R. STANFORD[2], E. SALINAS[2], C. T. WHITLOW[3], B. LUNA[4], C. CONSTANTINIDIS[1];
[1]Dept. of Biomed. Engin., Vanderbilt Univ., Nashville, TN; [2]Dept. of Neurobio. & Anat., [3]Dept. of Radiology, Wake Forest Sch. of Med., Winston-Salem, NC; [4]Dept Psychiatry, Lab. Of Neurocognitive Develop., Pittsburgh, PA

Abstract: Humans and nonhuman primates experience a protracted period of cognitive development that extends through adolescence and parallels the maturation of the prefrontal cortex (PFC). Little is known about changes in prefrontal neurons activities over this time period. To address this question, we tracked developmental measures, behavioral performance, neurophysiological activity in the PFC, and neuroanatomical changes evaluated with structural MRI as monkeys transitioned from puberty into adulthood. Eight macaques (2F, 6M *Macaca mulatta*) were trained to perform variations of the Oculomotor Delayed Response (ODR) task, and we recorded neural activity at the ages of 3.4±0.2, 4.0±0.3, 4.4±0.2 and 4.9±0.3 yrs. Eight animals performed the ODR task with a 1.5 s delay, while four animals also performed a version of the task with a longer delay period, and the ODR + distractor task. The monkeys performed the ODR task robustly in adolescence, with an average performance in the ODR task for 8 animals at 83%. Between the time points, modest improvement in performance in both tasks was observed, with greatest improvement for the most difficult tasks and conditions. Single neuron activities were collected from dorsolateral PFC. Anatomical localization of the recording sites was based on MRI of each animal. An increase in the percentage of neurons that responded to the task (35%, 45%, 58%, 57% respectively) was observed in the 4 time points. Robust cue and delay period activities were present across time points, with relatively stronger activities in later stages. In parallel we performed MRI that measured structural volumetric changes (T1) and microstructural changes (Neurite Orientation Dispersion and Density Imaging (NODDI)). Substantial increase of gray matter volumes and more specifically in frontal, parietal and occipital lobe was detected until the age of ~3.4 yrs. before plateauing, and white matter

measures display a linear increase without plateau detected up to ~5.3 yrs., showing an extended volumetric and microstructural development. Our results provide insights on prefrontal neuronal activity during working memory at the earliest time points achieved. Tracking of the cohort is ongoing allowing us to characterize how behavior, prefrontal activity and cortical structure change in these animals as they enter adulthood so as to account for enhanced executive functions.

Title: Functional and microstructural connectivity patterns predict working memory performance in older adults

Authors: *E. GOZDAS, B. AVELAR-PEREIRA, H. HOSSEINI;
Stanford Univ., Palo Alto, CA

Abstract: Introduction: Working memory enables the temporary storing of crucial information necessary for a wide range of cognitive tasks and is also a core component of age-related cognitive decline. Neuroimaging research over the past decades has improved our understanding of the neural substrates of working memory. However, the field lacks clarity on whether a specific neural architecture predicts item selection in working memory performance. Here, we integrated network neuroscience and predictive modeling with neurite imaging and functional MRI (fMRI) to identify microstructural and functional connectivity patterns that best predict working memory performance in older adults engaged in a classic working memory task.**Methods:** Seventy participants (age range 65-85 years, 37 female) were recruited for the study.The Sternberg working memory task fMRI (8 min.) and multi-shell diffusion MRI (dMRI) data were acquired for all participants. We preprocessed fMRI and dMRI data using standard procedures. Neurite orientation dispersion and density imaging (NODDI) were then computed using the preprocessed dMRI data to estimate neurite density (ICVF) and neurite complexity (ODI). The functional and neurite microstructural connectivity were computed for all pairs of nodes defined in the HCP brain atlas. Further, we adapted the connectome-based predictive modeling (CPM) method to identify functional and neurite microstructural connectivity patterns that predict working memory in older adults using leave-one-out cross-validation.**Results:** Significant correlations emerged between the predicted and observed working memory

performance (r=0.34, p=0.01) using functional connectivity. The functional connectivity pairs that contributed most to the prediction model were the lateral temporal cortex- posterior cingulate cortex, anterior cingulate and medial prefrontal cortex- posterior cingulate cortex, orbital and polar frontal cortex- posterior cingulate cortex. For the model trained on microstructural networks, stronger correlations were found between predicted and observed performance using ICVF (r=0.44, p=0.001) and ODI (r=0.59, p<0.001). The microstructural connectivity pairs with highest contribution to the model were the anterior cingulate and medial prefrontal cortex, and orbital and polar frontal cortex.**Conclusions:** We have demonstrated that specific functional and microstructural connectivity patterns predict decision in a working memory task in older adults. These results provide early evidence regarding the neural architecture predicting working memory performance in older adults above and beyond functional connectivity.

Abstract: Chimpanzees (*Pan troglodytes*), along with bonobos, are the closest living relatives of humans. As such, chimpanzee brains offer critical insight into the evolution of the neural substrates that underlie human cognition. In recent years, it has been demonstrated that the lateral cerebellar hemispheres play an integral role in mediating cognitive function by virtue of their expansive connectivity network with the neocortex, the cortico-cerebellar system (CCS). Furthermore, the CCS contains topographically-organized connections between specific lobules of the posterior lobe of the cerebellum and heteromodal neocortical regions, including the prefrontal and posterior parietal cortex. However, while quantitative comparisons of the CCS between humans and chimpanzees would glean insight into the evolution of the neural correlates of human cognitive function, these bidirectional connections between cerebellar lobules and their

neocortical counterparts have yet to be quantified in chimpanzees. Here, we report quantitative connectivity of the chimpanzee cortico-cerebellar system by performing a virtual dissection of CCS tracts using diffusion tensor imaging (DTI). A DTI sequence was applied at 3 Tesla using diffusion-sensitizing gradients in 64 directions with 5 averages in each of 2 phase encoding directions for 67 chimpanzee individuals. White matter tracts were reconstructed by applying a multiple ROI (region of interest) tractography technique. Masks for lobules VI though IX of the posterior cerebellar lobe were generated in template space. Next, masks were registered to native DTI space using ANTS for each of the individual subjects. Tractography was performed in native space using bedpostX. Thresholded results were then binarized, registered to template space, summed, and then averaged to produce composite images where the intensity value at each voxel corresponds to the percent of subjects with above-threshold connectivity at a given voxel location. Similarities and differences with human cortico-cerebellar connectivity patterns are described. These results may help inform our understanding of brain-behavior evolution in the hominid lineage.

Title: Characterization and manipulation of Corticothalamic neurons in associative cortices using Syt6 Cre transgenic mice

Authors: *L. VAASJO[1], X. HAN[1], A. TIEMROTH[2], A. N. THURMON[2], A. FIGUEROA[2], R. REYES[2], P. FELICIANO-RAMOS[4], M. GALAZO[3];

Abstract: Cortico-thalamic interactions between associative cortices and higher-order thalamic nuclei are involved in high-cognitive functions, such as decision-making and working memory. Corticothalamic neurons (CTn) in the prefrontal cortex and other associative areas have been much less studied than their counterparts in the primary sensory areas. The availability of characterized transgenic tools to study CTn in associative areas will facilitate their study, and contribute to overcome the scarcity of data about their properties, network dynamics, and contribution to cognitive functions. Here, we characterized the Syt6-Cre (KI148Gsat/Mmud) transgenic mouse line. In this line, Cre is strongly expressed in the prefrontal, motor, cingulate, and retrosplenial cortices, as well as in other brain areas including the Cerebellum and the

Olfactory tuberculum. Cortical expression starts embryonically and reaches the adult expression pattern by postnatal day 15. In the cortex, Cre is expressed by layer 6 CTn, and by layer 5 CTn to a lesser extent. We quantified Syt6-Cre + CTn axon varicosities to estimate the distribution and density of putative corticothalamic driver and modulator inputs to thalamic nuclei in the medial, midline, intralaminar, anterior, and motor groups. Also, we characterized the effect of optogenetic stimulation of Syt6-cre-CTn in the activity of the prefrontal cortex. CTn stimulation in the prefrontal cortex induces an oscillatory activity in the local field potential that resembles the cortical down-states typically observed during slow-wave sleep or quiet wake.

Abstract: Dynamic Functional Connectivity Between the Cerebellum and Dorsolateral Prefrontal Cortex Explains Variability in Memory Ability in Multiple Sclerosis
Authors: Mark D. Zuppichini, Dinesh K. Sivakolundu, Kathryn L. West, Darin T. Okuda, and Bart Rypma
Background: Network connectivity is disrupted in multiple sclerosis (MS) and is related to cognitive function. Memory impairment is common in MS yet the underlying neuropathology is still unknown. Research suggests both dorsolateral prefrontal cortex (dlPFC) and cerebellar (Cb) involvement in mnemonic function, and the cerebellum is known to be adversely affected by MS. Dynamic resting-state functional connectivity, or the time-varying connectivity, is strongly related to cognition in network neuroscience. Thus, investigating the role that Cb dysfunction

plays in MS-related abnormal dynamic connectivity and memory impairment may aid in understanding MS-related memory impairment. **Objective:** To investigate the relationship between dlPFC-Cb dynamic connectivity and memory impairment in MS.**Methods:** 32 MS and 20 healthy controls (HC) participants completed the Digit Span Test – Forward as a measure of memory and underwent magnetic resonance imaging. Dynamic resting-state functional connectivity analysis was used to assess functional and structural connectivity. **Results:** The MS group (M=7.12, SD=1.29) performed comparably to the HC group (M=7.65, SD=1.23) on the DST-F (t=1.47, p=.147). Analysis of dlPFC-Cb connectivity revealed differences in the relationship between dynamic connectivity and digit-span ability across groups. In the MS group, connectivity between the left dlPFC and Cb explained 15% of the variance in digit-span variability after controlling for age and education (F(1,28)=6.63, p=.016, ΔR^2=.15), and connectivity between the right dlPFC and Cb explained 13% of the variance in digit-span variability after controlling for age and education (F(1,28)=5.17, p=.031, ΔR^2=.13). In the HC, connectivity between the left (F(1,14)=2.43, p=.142, ΔR^2=.12) and right (F(1,14)=0.00, p=.949, ΔR^2=.00) dlPFC and Cb did not significantly explain any variance in the digit-span.**Conclusion:** Dynamic resting-state connectivity between the cerebellum and dlPFC is critical for the maintenance of memory function observed in MS. **Keywords:** Network connectivity; cerebellum; memory; resting-state connectivity; prefrontal cortex.

Title: The role of mPFC projecting populations in recent and remote expression of memories

Authors: *A. GOLBABAEI[1,2], S. A. JOSSELYN[1,2], P. W. FRANKLAND[1,2];
[1]Neurosci. & Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: As memories age, they undergo reorganization at the systems level. In particular, memories are known to initially depend on the hippocampus for expression, but become more dependent on the medial prefrontal cortex (mPFC) at remote time-points. Although retrieval-induced activity of mPFC neurons increases with time, it is unclear whether distinct mPFC projecting populations contribute to retrieval at different time points. Here, we aimed to delineate

how these distinct projection-specific populations of mPFC neurons contribute to memory expression at recent vs. remote time-points. To examine this, we virally labeled projection-specific populations in the mPFC and examined the extent to which these distinct mPFC populations are activated during contextual fear learning (i.e. encoding), and subsequently reactivated during recent vs. remote recall. Then, we used an activity-dependent tagging method to express excitatory or inhibitory opsins in these projection-specific mPFC populations during learning, and asked whether reactivating them is sufficient for memory expression at recent and remote time-points in a novel context. Conversely, we asked if inhibition of these populations can impair recall at recent or remote time-points. Our results provide evidence that different mPFC projection-specific populations differentially contribute to recent vs remote recall. In particular, basolateral amygdala (BLA) projecting neurons are reactivated at both recent and remote time-points, while Nucleus Reuniens (NRe) projecting population exhibited increased reactivation at the remote compared to recent time-point. Consistently, the manipulation of BLA projecting sub-population affected memory expression at both time-points while manipulation of NRe projecting sub-population affected only remote recall. Furthermore, the excitation of only the mPFC-NRe circuit decreased hippocampal activity in CA1 region at the remote time point, whereas inactivation of this circuit increased of CA1 activity at the recent time point. Together, our results suggest a model for temporal changes in brain circuits that express the memory. During expression at recent time-point, a limited engagement of mPFC is observed (e.g. mPFC to BLA projecting population) while at remote time-point the mPFC's engagement is enhanced by involvement of other projecting populations (e.g mPFC to NRe projecting population). This enhanced engagement is associated with decreased activity in CA1 region at remote time-point which suggests a top-down regulatory mechanism by mPFC on hippocampus during remote recall of memories.

Title: Medial prefrontal cortex flexibly links stimuli and conditioned responses through behavior-dependent sensory encoding

Authors: *B. EHRET[1], R. BOEHRINGER[1], E. A. AMADEI[1], C. HENNING[1], H. C. JOHANNSSEN[1], T. ROGERSON[2], M. J. SCHNITZER[2], B. F. GREWE[1];

Abstract: To survive in challenging environments, animals need to learn to perform adaptive behaviors in the presence of sensory information that predicts threats or rewards. The medial prefrontal cortex (mPFC) has been suggested to link sensory and motor aspects of such associations during learning and behavior execution. During learning, sensory-driven prefrontal responses emerge as stimuli gain behavioral relevance, and it has been shown that manipulation of mPFC activity can drive and inhibit the execution of learned behaviors. Yet, how prefrontal circuits map relevant sensory signals onto specific behaviors is still unclear. Here we investigate the involvement of mPFC in mediating such mappings using aversive auditory conditioning paradigms with dynamic stimulus-response associations. In addition to using a classic fear conditioning paradigm, we developed novel active avoidance experiments in which we vary the predictive stimuli and the instrumental behaviors induced by those stimuli by manipulating task contingencies. During these paradigms, we used miniaturized microscopes for calcium imaging in freely behaving mice to track the activity of mPFC neurons throughout learning. To isolate the relation between individual task variables and the recorded neural activity, we employed a model-based analysis approach, which allowed us to quantify coding changes over the course of an experiment. We find that neural correlates of sensory and behavioral signals are encoded by independent subpopulations. While tone-evoked responses are tightly linked to behavioral relevance, they do not directly correlate with behavior execution. Yet, how the identified tone signals are encoded depends on the associated tone-induced behavior. Specifically, changing the behavior that is induced by a given tone modulates the tone's representation through coordinated changes of the tone responses of individual cells. Conversely, the representations of different tones show increased similarity when the tones are associated with the same behavior. These results suggest that mPFC implements abstract stimulus-response mappings through behavior-dependent sensory representations, providing a flexible link between sensory information and conditioned responses. Our findings are thus consistent with a model in which mPFC provides contextualized information to downstream areas, rather than directly driving specific behaviors.

Title: The geometry of category and choice representations in human ventromedial prefrontal cortex.

Authors: H. COURELLIS[1], J. MINXHA[2], A. N. MAMELAK[3], R. ADOLPHS[2], U. RUTISHAUSER[4];
[1]Bioengineering, [2]Caltech, Pasadena, CA; [3]Neurosurg., [4]Dept. of Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: The ventromedial Prefrontal cortex (vmPFC) has been studied extensively as one of the neurophysiological substrates that supports social and affective processing, and reward-based decision making. This prevailing sentiment naturally gives rise to the question: what, if anything, is then encoded and processed if the decisions being made are not socially relevant or value-based? To answer this question, we conducted single-unit recordings in human patients implanted for clinical purposes who were instructed to alternate between two tasks, one involving a sensory-perceptual decision (Category Task) and the other involving a memory-dependent decision (Memory Task). Transitioning between the Category and Memory tasks involved a screen-wide cue and question related to the presented stimulus: either membership to target category or novelty of the stimulus, to which the patient gave a yes/no response using either a button-press or a directed saccade. We recorded 320 well-isolated single neurons from the vmPFC of 13 patients performing this switching task. We found that both abstract categorical representations and choice representations exist in single vmPFC units, allowing for this information to be decoded with varying degrees of representational invariance across tasks during stimulus presentation. Furthermore, our task allowed for comparison of task-relevant signals during baseline periods lacking visual stimulation. We identified representations of contextual variables such as target category and response modality encoded in baseline vmPFC neuron firing rates that did not generalize across tasks, suggesting an orthogonalized representation like concurrently recorded neurons in medial temporal and frontal cortices (MTL/MFC respectively). In contrast to MFC, we found that switching between tasks led to an increase in contextual information at baseline. Neurons in the vmPFC also exhibited task-modulated correlations with MTL and MFC, supporting the emergence of task-relevant neuronal ensembles whose synchronization supports proper task execution. In summary, the vmPFC is highly active, encoding a mixture of task-relevant information which, in conjunction with other regions of cortex and subcortex, supports flexible behavior when switching between tasks.

Title: The role of prefrontal neurons in memory and learning in the barnes maze apparatus

Authors: *E. NICOLAU[1], H. TENZA FERRER[1], E. MARTIANOVA[2], G. DA SILVA CABRAL[1], S. REZENDE MARTINS[1], E. MENDONÇA FARIAS[1], J. DUARTE CARDOSO[1], L. VIANA MAGNO[1], M. ROMANO SILVA[1];
[1]Univ. Federal de Minas Gerais, Belo Horizonte, Brazil; [2]Cervo Brain Res. Ctr., Quebec, QC, Canada

Abstract: For over decades the means for how learning and memory is processed and consolidated within the brain has been discussed and studied. However, only in the past decades has science advanced to technologies that allow precise spatial and temporal observation of neuronal activation patterns to specific types and circuits, while also observing behavioural traces. Here we investigate the dynamics of excitatory and inhibitory neurons in the mPFC of mice while undergoing a learning and memory task (Barnes Maze (BM). Groups: a total of 11 mice (c57bl/6) were used. 6 mice expressed cre-protein in vGlut1 positive neurons, while 5 other mice presented cre-protein expression in Gad2 positive neurons. Surgery: all mice received a viral injection of a jGCamP6 construct and fiber stub implantation at the mPFC (M.L.: +0.35, A.P.: +2.4, D.V.: -1.8) and were then allowed to rest for 20 days. BM: All animals were submitted to the BM protocol: animals were placed in a round platform, with 1 true and 19 false escape holes, and were then allowed to explore the apparatus for 2-3 minutes, over 6 days, 3 trials/day. Daily activities were as followed: 1 day of habituation, 4 days of learning and 1 day of memory. BM protocol objective is a search and locate true escape hole task, in which training results in fewer mistakes (wrong hole investigation), traveling smaller distances, faster execution and strategy adapting. Fiber Photometry (FP): while performing the task, calcium surges were detected through FP at a 500-540 nm window for both 405 (10µW) and 465 (30µW) excitatory inputs. Data was acquired at 12kbps and then processed and analyzed with the z-score $\Delta f/f$ method. Behavioral events were set as a TTL input for calcium surges overlap. All animals presented improved performance, with smaller errors, distance traveled and latency to task compared to initial days. In addition, both groups showed a shift in search strategy, from random (low efficiency), to serial (medium efficiency) and direct (high efficiency). All behavioral events

above were analyzed and paired to calcium surges. Initial data found no specific surges correlated to specific events, although at some days we found significant differences for excitatory neurons in total number of calcium surges during daily tasks, and number of surges within correct hole investigations, compared to previous days, which may suggest a change in calcium dynamic based on learning. There are yet many experiments and analysis to be performed, in addition to tweaks to be done for both FP rig setup and BM.

Title: Neuronal activity in the lateral prefrontal cortex during cued object selection

Authors: *M. KADOHISA[1], M. KUSUNOKI[2,1], M. J. BUCKLEY[3], J. DUNCAN[1,2];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Oxford Univ., Oxford, United Kingdom

Abstract: To investigate object learning, retrieval and selection in the lateral prefrontal cortex (LPFC), two monkeys were trained in a cued selection task. A semi-chronic system allowed recording of neuronal activity across large areas of the dorsal and ventral LPFC. The task involved a total of eight objects, divided into two four-object sets associated with different color cues. Each session consisted of a series of problems, each consisting of four cycles of trials. In each problem, two objects were defined as targets, one from each set. On each trial, the animal was required to gaze at the red central fixation point (fp) followed by a cue in the centre with six black squares in a circular array (cue phase). Then the six black squares were replaced randomly with six objects consisting of three objects from each set (visual search phase). The red fp turned cyan, and the animal was required to select one object by making a saccade to it (selection phase). If the object selected on the current trial was a target, this was followed by its associated color cue and reward; if it was a nontarget, the response led to a negative feedback signal and no reward (feedback phase). In cycle 1 of each problem, the cue was dark grey and the animal had to work through a series of trials, sampling objects at random until the two targets were discovered. In subsequent cycles, the trial began with a color cue and the animal had to select its associated target. Trials continued in each cycle until each target had been selected once, after

which the next cycle began. After all four cycles, new target objects were defined for the next problem. In both animals, behavioral performance improved cycle by cycle to more than 90 % correct in cycle 4. In ventral LPFC, across cycles 2-4, population activity encoded the presented cue color, followed by gradual emergence of encoding for the associated target object (retrieval). In the search phase, location coding emerged with a similar time course in the two regions. Following feedback (learning), cue and object information reappeared in ventral LPFC, though with no cross-generalisation to the codes earlier in the trial. The results suggest the ventral LPFC integrates relevant information to control object learning and retrieval, coordinating with dorsal LPFC to guide search and selection.

Title: Global functional connectivity of the cognitive control network predicts task-switching performance in older adults

Authors: *B. MADERO, C. HAMILTON, C. OEHLER, E. E. HAZELTINE, M. W. VOSS; Univ. of Iowa, Iowa City, IA

Abstract: Aging populations show declining performance in tasks that require recall and switching between multiple rule sets, commonly referred to as task-switching. Evidence suggests that age-related neurodegeneration disrupts white matter connectivity contributing to poor connections in large-scale networks such as the Cognitive Control network (CCN), which is believed to be critical for executive functions involved in task-switching. However, no research has directly examined the relationship between task-switching performance and CCN connectivity. Aging research using variants of switching tasks has shown an increased cost (i.e., Mixing Cost) when adding rule sets, but it is unknown how the underlying neural mechanisms are taxed (Verhaeghen 2011; Wasylyshyn et. al., 2011; Nashiro et. al., 2018). Studies using Global Functional Connectivity (GFC) from resting-state functional magnetic resonance imaging (rs-fMRI) have shown a positive relationship between GFC and fluid intelligence. These data suggest GFC in regions and networks supporting cognitive control is sensitive to individual differences in fluid cognitive ability in adults (Cole et al., 2012; Franzmeier et al., 2017). The present study bridges these two fields by examining whether GFC in the CCN predicts individual

differences in Mixing Costs in older adults. The sample included behavioral and rs-fMRI data from 47 neurotypical older adults who performed a modified task-switching paradigm consisting of switching conditions that reflect low (separate) and high (overlap) response rule overlap to magnify individual differences in Mixing Cost. We predicted that overlap in response rules would increase the difficulty to recall and manage multiple task rules, resulting in larger Mixing Costs (Mayr 2001). As in previous work with older adults (Franzmeier et al., 2017), the CCN was operationalized as the frontoparietal control network in the Yeo7 network parcellation. Consistent with predictions, older adults have greater Mixing Cost in the overlap compared to the separate condition. We also show that greater GFC in the CCN predicts lower Mixing Cost, an effect amplified by the overlap condition. Therefore, the more functionally integrated the CCN is with the rest of the brain, the better older individuals were able to maintain and switch between multiple, overlapping rule sets. This unique relationship to Mixing Costs and the CCN suggest a specialized mechanistic role for CCN integration in the aspects of task-switching that are affected most with cognitive aging.

Title: Neurocognitive differences between older professional and amateur orchestral musicians

Authors: J. KUO, *J. KING;
Neurosci., Pomona Col., Claremont, CA

Abstract: Musical training can contribute to plastic changes in the brain. While there is evidence of increased cognitive functioning in musicians compared to non-musicians, differences in cognition between professional and amateur musicians have not been explored. The cognitive and neurological benefits of music may be more evident in amateur musicians compared to professional musicians due to certain risk factors. The current study examined cognitive functioning of older professional orchestral musicians compared to older amateur orchestral musicians. Musicians (at least 65 years old) were recruited from various professional and community-based orchestras. Participants' (20 professional and 21 amateur musicians) demographics, health status, and musical background were collected using Qualtrics. The CNS Vital Signs (CNSVS) Remote Test was used to assess cognitive functions. Using the CNSVS

Remote Test, domain scores from several neuropsychological tests were compared between professional and amateur musicians. For processing speed, professional musicians showed significantly lower scores than amateur musicians ($p < 0.05$). When comparing musicians age 65-69, professional musicians had significantly lower processing speed, verbal memory, and lower composite memory compared to amateur musicians ($p < 0.05$). When looking at highest level of education, professional musicians with professional degrees had a significantly greater psychomotor speed compared to professional musicians with 4 year degrees ($p < 0.05$). Additional results show that female professional musicians had significantly lower processing speed compared to female amateur musicians. Male professional musicians had significantly higher motor speed compared to male amateur musicians ($p < 0.05$). Our results show that the CNSVS test reveals differences in the cognitive abilities between older professional and amateur orchestral musicians. Age, sex, and education level differences also attribute to differences in test performance within and between the musician groups, while ethnicity does not. This information can be utilized to understand how musical training can affect the development of neurodegenerative diseases such as Alzheimer's disease.

Abstract: Understanding speech in noisy environments is a key component of everyday life and requires effortful listening. Older adults' listening effort may be especially affected by noise, arising in part from a reduced ability to effectively track a target speaker among background speakers across prolonged time periods. The present study used 60-second audiobook segments to evaluate how different listening situations influence older adults' sustained effort when listening to meaningful speech. This experiment investigated the effect of 1) different signal-to-noise ratios (SNRs: quiet, 0dB, or -6dB) and 2) number of passage exposures (three times each in

the two noisy conditions) on listening effort, for 13 older adults with clinically normal hearing. We hypothesized that poorer SNRs would result in increased listening effort and that repeated exposures would result in decreased listening effort. While pupillary measures were recorded, participants listened to the audiobook segments, with larger pupil dilations indicating greater listening effort. Generalized additive mixed model (GAMM) results revealed that listeners showed evidence of increased listening effort in both noisy conditions relative to quiet. In the noisy conditions, participants exhibited decreased listening effort in the second, compared to the first, presentation of a passage. Furthermore, listening effort varied nonlinearly with listeners' subjective intelligibility ratings across SNR blocks. In comparison to the quiet condition, listening effort in the 0dB condition was associated with higher self-reported intelligibility ratings, suggesting that engaging in effortful listening only benefited perceived intelligibility when the speech was at least moderately challenging. The more difficult -6dB condition revealed dynamic changes in listening effort over time; higher intelligibility ratings were associated with increased listening effort at the beginning of the passage that decreased over time. The opposite effect was found at lower intelligibility ratings; initially participants showed low listening effort that increased over time. Taken together, our findings illustrate how SNR and repeated exposure influence listening effort when listening to sustained, continuous speech, and how effort can deviate from intelligibility in some listening conditions. Title: Cognitive Enhancement Training in Older Adults Improves Attention and Processing Speed

Authors: L. CHUKOSKIE[1], R. SPENCE[2], T. SIMMONS[1], A.-M. ENGLER[3], S. HACKER[3], L. HILL[4], Y. TAKARAE[6], *J. SNIDER[1], J. TOWNSEND[5];
[1]UCSD, La Jolla, CA; [2]UCSD, Dept. of Neurosciences, CA; [3]Dept. of Neurosciences, [4]Dept. of Family and Preventive Med., [5]Dept Of Neurosci, UCSD, La Jolla, CA; [6]Dept. of Neurosci., Univ. of California San Diego, La Jolla, CA

Abstract: In a 10-year follow-up NIH ACTIVE studies have shown that older adults trained to improve speed of processing and attention had a 29% decreased rate of dementia compared to a no-contact control group. We have completed a game-based training to enhance these cognitive functions in healthy older adults that resulted in improved cognitive function with some transfer to practical function. Methods: Previous ACTIVE studies required training in lab. Our games are gaze-driven which forces full engagement despite being played independently at home. Gaze is an observable indicator of attention focus and a powerful tool for training attention since eye movement and spatial attention recruit highly overlapping neural circuitry. We supplied participants with the intervention laptop and eye tracker. Training games were designed with embedded principles to improve processing speed and attentional control, including resistance to distraction and inhibitory control. Participants played 20-30 minutes a day five times per week for 12 weeks. We monitored compliance over a secure remote connection. Primary outcome measures were processing speed and selective attention. Additional measures were of general cognitive and practical function. Results: Attention distractibility improved significantly with training as did processing speed. Additional evidence for reduced attention distractibility was improved inhibition of eye movement in an anti-saccade task. A wait-list control showed no change in any of the assessed outcome measures following a wait period of 12 weeks but showed improved attention and processing speed following the subsequent 12-weeks of cognitive training. A 12-18-month follow-up assessment of 14 early participants found that gains in selective attention were stable after a year, but improvements in processing speed were reduced. After 2-weeks of booster training, however, improvements in processing speed were increased to previous post-training levels. We saw no change in general cognitive function, but performance on a driving simulator task that required processing of peripheral visual cues improved. Conclusions: We have developed an approach that successfully trains foundational attention and processing skills in older adults with some transfer to practical function. If successful in larger trials with appropriate controls, this approach would provide an inexpensive and broadly available tool that would improve cognitive function and that may have the potential to decrease risk of dementia.

Title: Plasticity in the adult human white matter: the effects and modifiers of response to aerobic exercise interventions

Authors: *A. MENDEZ COLMENARES[1], M. VOSS[3], J. FANNING[4], E. SALERNO[5], N. GOTHE[6], M. L. THOMAS[1], E. MCAULEY[6], A. F. KRAMER[7], A. Abstract: White matter provides a scaffold for brain function and cognition. Animal studies suggest that white matter plays an active role in brain plasticity and learning. However, evidence for experience-induced plasticity in the adult human white matter remains scarce and inconsistent, especially in old age. Here, we report the effects of 6-month aerobic exercise interventions (walking and dance, NCT01472744) on white matter integrity in healthy older adults (n = 180, 60-79 years) measured by changes (Δ) in the ratio of calibrated T1- to T2-weighted signal (T1w/T2w). We observed significant time-by-group interactions, with positive changes in the T1w/T2w signal in late-myelinating regions in the aerobic exercise groups and declines in the active control. The increases in T1w/T2w signal in the walking group correlated positively with Δ in memory performance, as reported in our recent publication (Mendez Colmenares et al., 2021). We further explored the possible modifiers of intervention-induced change in the T1w/T2w signal. Among participants randomized to the walking intervention, those who increased their participation in total daily light physical activity showed greater increases in T1w/T2w in the total white matter, cingulum, splenium of the corpus callosum, and superior longitudinal fasciculus. These effects persisted after controlling for Δ in moderate-to-vigorous physical activity, systolic blood pressure, age, and sex. Our findings suggest that increasing engagement in moderate-to-vigorous physical activity (i.e., walking and dance) results in group-level increases in white matter T1w/T2w signal, and these increases were the largest among those who additionally increased their daily light physical activity engagement. Our results show evidence that white matter regions that are vulnerable to aging retain some degree of plasticity that can be induced by aerobic exercise training and moderated by light daily activity.

Title: Spatial navigation declines with age in clinically normal participants

Authors: *L. COLMANT[1], Y. BELLAALI[1], A. BIERBRAUER[2], N. AXMACHER[3], P. LEFEVRE[4], B. HANSEEUW[1];
[1]UCLouvain, BRUXELLES, Belgium; [2]Ruhr Univ. Bochum, Bochum, Germany; [3]Inst. of Cognitive Neuroscience, Ruhr Univ. Bochum, Bochum, Germany; [4]ICTEAM and Inst. of Neuroscience, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: Spatial navigation performance declines with age. We studied a virtual navigation task, the "Apple Game" (Bierbrauer et al. 2020) focusing on path integration. Here, we expanded these results by investigating how navigation performance and the employment of different navigational strategies differ across the lifespan (median age 58.2, 21-81).Participants navigate in a virtual field and have to remember their initial location to return to it (path integration). Difficulty varies between trials according to two parameters: (1) the number of interim locations participants have to visit (0, 1, or 2) before they return to their initial location; and (2) the presence or absence of a landmark. This paradigm is a simplified version of the original task, suitable for older participants. We recruited 155 clinically normal participants (Mini Mental State Exam > 24/30). We used linear mixed models to predict the drop error, i.e., the Euclidean distance between the initial and final locations. We also analyzed the employment of landmark-based navigational strategies. As previously shown, the drop error increased with the number of interim locations and decreased with the presence of the landmark. Importantly, the drop error strongly increased with age. This age effect was present in all subtasks except one, which included two distractors and no landmark, suggesting this subtask was too difficult for all participants, including the younger. In contrast, in the easiest subtask, with a landmark and no distractor, the drop error increased with age, indicating it is appropriate for investigating age effects.
Interestingly, the distance between the landmark and the final position decreased with age, suggesting that older participants were attracted by the landmark instead of using the landmark to navigate correctly. Indeed, the positive effect of the landmark on spatial navigation decreased with age. The decrease in the positive effect of the landmark with age was only present with one or two distractors highlighting the importance of having at least one distractor to evaluate how the landmark affects spatial navigation in older participants.
This simplified version of the Apple Game is appropriate to test how path integration changes with age. Without distractors, older participants benefit from the presence of the landmark as

much as younger participants do. With distractors, the landmark's positive effect decreases in older participants, suggesting that older participants have difficulties to integrate their position with the landmark position. As a future direction, we aim to investigate the interplay between age effects and preclinical neurodegenerative disease.

Title: Choice-relevant bias influences decision-making measure differently as a function of age

Authors: *J. WALKER[1], M. E. WHEELER[2];
[2]Psychology, [1]Georgia Inst. of Technol., Atlanta, GA

Abstract: During time-dependent binary perceptual decision-making, evidence accumulation is defined as the timeframe when individuals are gradually integrating choice-relevant information.[1] There are many factors that influence this process, including the presence of prior knowledge that pushes individuals towards/away from given options and, thereby, may manipulate the amount of evidence required to reach decisions.[2] This effect is likewise reflected in blood oxygen level-dependent (BOLD) activity in the inferior temporal cortex (ITC). For example, a 2018 functional magnetic resonance imaging (fMRI) study by Dunovan & Wheeler used a task where participants were presented with visually noisy images and asked to classify them as either faces or places. Prior to each trial, they viewed probabilistic cues (80% chance face, 80% chance house, or unbiased 50/50 control). They found that bias toward the correct answer (valid trials) was associated with higher accuracy, shorter reaction times (RTs), and decreased ITC BOLD activity. Bias away (invalid trials) was associated with poorer accuracy, slower RTs, and increased ITC activity. The unbiased 50/50 control condition (neutral trials) was in the middle. Such findings are crucial for understanding brain-behavior relationships during decision-making. However, this 2018 work only included younger adults and age is another important factor to consider going forward. This is because some literature suggests that older adults may approach decision-making from a relatively more inflexible perspective, disregarding prior knowledge in favor of taking their time to consider all choices more equally.[3] It is unclear if

or how that is reflected in ITC activity. Therefore, the current fMRI study replicates the design in the aforementioned 2018 work and extends it to include a cross-sectional age comparison of younger (21-35 years old, n=16) and older adults (60-75 years old, n=18). Results indicate that only behavioral outcomes were consistent across age groups. Both younger and older adults were faster and more accurate for valid trials, followed by neutral, followed by invalid. However, while younger adults replicated the finding that lower BOLD signals are associated with valid trials and higher BOLD signals are associated with invalid trials in a selection of ITC regions, older adults' BOLD activity was consistent across conditions. These findings suggest, that as people age, the patterns of activity underlying their bias-relevant decision-making processes may change to maintain performance.

Title: Integrating knowledge about structure and reward contingencies for generalization and inference

Authors: *F. F. DEILMANN[1], M. M. GARVERT[1], C. F. DOELLER[1,2];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: The hippocampal-entorhinal system is remarkably efficient in organizing relations between sensory stimuli such as state transition probabilities in a cognitive map. Such a representation of knowledge is assumed to enable fast learning of novel relations and the generalization of reward, which likely facilitates goal-directed behavior. However, in addition to experienced transition probabilities, objects may simultaneously share other types of relational information, such as reward contingencies. Here we investigate how the representation of relational knowledge is influenced by a subsequently learned latent reward structure. Are structural relationships between objects still represented veridically, or do reward contingencies influence the representation of relational knowledge? In our task, participants initially acquire knowledge about the relationships between objects based on object transitions that follow a hidden graph structure. Behavioral data suggest that participants successfully acquire this

knowledge and can utilize it to find shortcuts when navigating around the graph. During a subsequent decision-making task, each object gets associated with fluctuating reward values. Critically, two parts of the graph structure share the same reward contingencies. Model-based analysis reveals that participants can extract this underlying latent reward structure and use it to their advantage by generalizing over states which share the same reward contingencies. Furthermore, participants can apply their acquired structural knowledge to correctly infer the current reward values of objects whose values they never directly experienced. This suggests that participants represent both the experienced transitions and the shared reward contingencies between objects; moreover, they can combine both types of information for generalization and inference. Using functional magnetic resonance imaging, we now investigate how object relationships and shared reward contingencies are represented in the hippocampal-entorhinal system and interact with other brain regions to guide choice behavior.

Title: Effects of prototype abstraction on pattern completion and inference in concept space

Authors: *T. A. J. SCHÄFER[1], E. SCHULZ[2], S. THEVES[1], C. F. DOELLER[1,3];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]MPI for Biol. Cybernetics, Tübingen, Germany; [3]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Processing of complex environments is greatly facilitated by the formation and use of concepts. Concepts represent combinations of features shared by similar entities and allow generalisation from limited experience to novel situations. Recent research suggests that concept formation is supported by cognitive maps within the hippocampal-entorhinal system that encode multiple relationships between experiences in a common representational format for flexible access. In a behavioral and functional magnetic resonance imaging experiment, we investigate if this map-like representation of concepts supports the retrieval of abstracted information to guide inference. In a novel behavioral paradigm, participants are first trained to categorize a set of exemplars based on the ratio of their two features. Subsequently, they encounter exemplars that exhibit only one of the features and are instructed to complete the missing feature according to their category label. Here we find that feature inferences are attracted more towards the category center (i.e. prototype) than to the nearest experienced exemplars, suggesting the retrieval of an

abstract representation. In an ongoing functional magnetic resonance imaging study, we examine to what degree the hippocampal system, in concert with visual areas, represents prototypes for feature inference. By decoding the inferred features and feature-combinations from brain patterns, we will test if each category's unseen prototype is formed during categorization and allows feature inference. This project can help us to understand the relationship between abstract representations and cognitive maps and the role of pattern completion in concept formation.

Title: Deepmreye: mr-based camera-less eye tracking using deep neural networks

Authors: *M. NAU[1], M. FREY[2], C. F. DOELLER[1];
[1]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Viewing behavior provides a window into many central aspects of human cognition and health, and it is an important variable of interest or confound in many fMRI studies. To make eye tracking freely and widely available for MRI research, we developed DeepMReye: a convolutional neural network that decodes gaze position from the MR-signal of the eyeballs. It performs camera-less eye tracking at sub-imaging temporal resolution in held-out participants with little training data and across a broad range of scanning protocols. Critically, it works even in existing datasets and when the eyes are closed. Decoded eye movements explain network-wide brain activity also in regions not associated with oculomotor function. This work emphasizes the importance of eye tracking for the interpretation of fMRI results and provides an open-source software solution that is widely applicable in research and clinical settings.

Title: Structural connectivity-based segmentation of the human entorhinal cortex

Authors: *I. F. SYVERSEN[1], M. P. WITTER[1], A. KOBRO-FLATMOEN[1], P. E. GOA[2], T. NAVARRO SCHRÖDER[1], C. F. DOELLER[1,3];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]Dept. of Physics, NTNU, Trondheim, Norway; [3]MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: The medial (MEC) and lateral entorhinal cortex (LEC), widely studied in rodents, are well defined and characterized. In humans, however, the exact locations of their homologues remain uncertain. Previous functional magnetic resonance imaging (fMRI) studies have subdivided the human EC into posterior-medial (pmEC) and anterior-lateral (alEC) parts, but uncertainty remains about the choice of imaging modality and seed regions, in particular in light of a substantial revision of the classical model of the EC based on novel insights from rodent anatomy. Here, we used structural, not functional imaging, namely diffusion tensor imaging (DTI) and probabilistic tractography to segment the human EC based on differential connectivity to other brain regions known to project selectively to MEC or LEC. We defined MEC as more strongly connected to presubiculum and retrosplenial cortex (RSC), and LEC as more strongly connected to distal CA1 and proximal subiculum (dCA1pSub) and orbitofrontal cortex (OFC). Although our DTI segmentation had a larger medial-lateral component than in previous fMRI studies, our results show that the human MEC and LEC homologues have a border oriented both towards the posterior-anterior and medial-lateral axes, supporting the differentiation between pmEC and alEC. In the future, we plan on testing the reproducibility of these results in another DTI dataset, as well as comparing results from DTI with fMRI.

Title: Investigating geometric determinants of semantic memory

Authors: *S. THEVES[1], T. A. J. SCHÄFER[1], W. J. DE COTHI[2], C. BARRY[3], C. F. DOELLER[1];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]CoMPLEX, Univ. Col. London, London, United Kingdom; [3]UCL, London, United Kingdom

Abstract: Recent work suggests that hippocampal codes, originally considered to underlie spatial memory, support the formation of conceptual knowledge by organizing information in cognitive maps that represent multiple relations in a common space. Yet evidence for the involvement of spatially tuned cells in the formation of such concept spaces in humans is elusive. As a window into the respective mechanisms, we leverage insights about the sensitivity of place cell firing to deformations of the environmental geometry. It has been shown that shifting the boundaries of a rodent's enclosure along one dimension causes firing fields of hippocampal place cells to stretch in the direction of environmental expansion. This 'stretchy box' effect has also been observed at the level of human spatial memory where recall of object locations mimicked place field distortions in rodents, indicative of a place cell code for spatial memory. Under the hypothesis that place cells might encode positions in concept space, we here ask whether relocation of categorical boundaries likewise distorts semantic memory. To this end, we first train participants to acquire a concept of two categories, defined as a square enclosure (category A) and its surrounding (category B) in a two-dimensional feature space. Further, participants learn to associate certain category A members with objects, thus assigning the objects a position in concept space. Subsequently, we relocate the boundaries of category A along one feature dimension, resulting in a rectangular shape of category A. Participants encounter this change and update their concept via a recategorization task. To probe whether deformation of the concept's geometry affects memory, we test participants on the associations between objects and category A members immediately before and after the recategorization. We find a significantly higher increase in memory errors along the stretched as compared to the non-stretched dimension, thus demonstrating a 'stretchy box' effect in concept space. We will further evaluate whether such distortions can be explained by a boundary vector cell model of place cell population activity. This project can provide insight in spatial coding mechanisms underlying the representation of conceptual knowledge.

Paris-Saclay, Gif Sur Yvette, France; [4]Max Planck Inst. for Brain, Cognition & Behavior, Leipzig, Germany

Abstract: The brain encodes the statistical regularities of the environment in a task-specific yet flexible and generalizable format. How it does so remains poorly understood. Here, we seek to understand this by converging two parallel lines of research, one centered on striatal-dependent sensorimotor timing, and the other on hippocampal-dependent cognitive mapping. We combined functional magnetic resonance imaging (fMRI) with a visual-tracking and time-to-contact (TTC) estimation task, revealing the widespread brain network supporting sensorimotor learning in real-time. Hippocampal and caudate activity signaled the behavioral feedback within trials and the improvements in performance across trials, suggesting that both structures encode behavior-dependent information rapidly. Critically, hippocampal learning signals generalized across tested intervals, while striatal ones did not, and together they explained both the trial-wise performance and the regression-to-the-mean biases in TTC estimation. Our results suggest that a fundamental function of hippocampal-striatal interactions may be to solve a trade-off between specificity vs. generalization, enabling the flexible and domain-general expression of human timing behavior broadly.

Title: Representing values for prospective decision making

Authors: *A. NITSCH[1], M. M. GARVERT[1], N. W. SCHUCK[2], C. F. DOELLER[1,3];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Max Planck Inst. For Human Develop., Berlin, Germany; [3]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Everyday decisions require us to plan ahead and predict how valuable different choice options will be in the future. Efficient prediction of such future values is facilitated by an internal model representing state transitions and associated reward contingencies in a task. Recently, it has been suggested that the hippocampal system represents relationships between states in a map-like format akin to its representation of relationships between landmarks and places in physical space. Such a map-like representation allows for efficient prediction of future states because it facilitates the computation of distances and directions. It is unclear, however, whether and how these spatial coding principles and geometric computations might contribute to mapping abstract dimensions such as values. Here, we aim to test the idea that the hippocampal system supports prospective decision making by representing values of choice options in a relational map. To this end, we used a novel decision task requiring participants to monitor and predict changing values of two options over a sequence of time points. Crucially and unknown to participants, such a sequence represents a trajectory in an abstract two-dimensional value space characterized by the reward magnitudes associated with the two options. Recognizing the nature of the particular trajectory allows for prediction of future values of the two options. Behavioral results show that participants are able to integrate changes along the two value dimensions to guide decision making, suggesting they form a map of the relationships between options. Preliminary fMRI results indicate prefrontal regions tracking the values of the options characterized by the trajectories in the two-dimensional value space. Ultimately, this study can help us elucidate whether the hippocampal system adopts spatial coding principles to support efficient prospective value-based decision making.

Title: Adaptive cognitive maps for curved surfaces in the 3D world

Authors: *M. KIM, C. F. DOELLER;
MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Terrains in a 3D world can be undulating but most of previous research exclusively investigated spatial representations on a flat surface, leaving a 2D cognitive map as a dominant model in the field. Here we investigated whether humans represent a curved surface by building a dimension-reduced flattened 2D map or a full 3D map. In the online experiments, participants learned the location of objects lying on a flat square and curved surface (similar to a half-pipe in a skate park) in the virtual environment by driving on the surface (Experiment 1, n=87), driving and looking vertically (Experiment 2, n=88), or flying (Experiment 3, n=41). Later they were asked to retrieve either the path distance on the surface or the 3D Euclidean distance between the objects. Path distance estimation performance was overall good, but we found a significant underestimation bias for the path distance on the curve, suggesting the influence of potential 3D shortcuts even though participants were only driving on the surface (Experiment 1). Euclidean distance estimation performance was better when participants were more exposed to the global 3D structure of the environment by looking and flying (Experiment 2,3). These results suggest that the representation of the 2D manifold embedded in a 3D world is neither purely 2D nor 3D, rather it is flexible and dependent on the behavioral experience and demand.

Title: Structuring time: The hippocampus constructs sequence memories that generalize temporal relations across experiences

Authors: *J. L. S. BELLMUND[1], L. DEUKER[2], N. D. MONTIJN[3], C. F. DOELLER[1];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [3]Utrecht Univ., Utrecht, Netherlands

Abstract: The hippocampal-entorhinal region supports memory for episodic details, such as temporal relations of sequential events, and mnemonic constructions combining experiences for inferential reasoning. However, it is unclear whether hippocampal event memories reflect temporal relations derived from mnemonic constructions, event order, or elapsing time, and whether these sequence representations generalize temporal relations across similar sequences. Here, participants mnemonically constructed times of events from multiple sequences using infrequent cues and their experience of passing time. After learning, event representations in the anterior hippocampus reflected temporal relations based on constructed times. Temporal relations were generalized across sequences, revealing distinct representational formats for events from the same or different sequences. Structural knowledge about time patterns, abstracted from different sequences, biased the construction of specific event times. These findings demonstrate that mnemonic construction and the generalization of relational knowledge combine in the hippocampus, consistent with the simulation of scenarios from episodic details and structural knowledge.

Title: Probing neural representations of scene perception in a hippocampally dependent task using artificial neural networks

Authors: *M. FREY[1], C. F. DOELLER[2], C. BARRY[3];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [3]UCL, London, United Kingdom

Abstract: Deep artificial neural networks (DNNs) trained through backpropagation provide effective models of the mammalian visual system, accurately capturing the hierarchy of neural responses through primary visual cortex to inferior temporal cortex (IT) (Yamins et al. 2016, Zhuang et al. 2021). However, the ability of these networks to explain representations in higher cortical areas is relatively lacking and considerably less well researched. For example, DNNs have been less successful as a model of the egocentric to allocentric transformation embodied by circuits in retrosplenial and posterior parietal cortex. These brain regions play a central role in spatial memory and perception being part of the 'pipeline' that transforms perceptual information to the spatial representations found in entorhinal cortex and hippocampus (Byrne et al. 2007, Bicanski et al. 2019). In humans, the Four Mountains task (Hartley et al. 2007) provides a test of egocentric to allocentric topographical processing. Subjects are required to match spatial scenes presented from different perspectives with performance being considerably impaired by damage or degradation to the ego-allocentric pipeline (Bird et al. 2010, Chan et al. 2016). We describe a novel virtual environment, inspired by the Four Mountains task, designed to probe the ability of DNNs to transform scenes viewed from different egocentric perspectives. The 'participant' is required to match scenes that correspond to the same configuration of distinct objects viewed from a different perspective - lures consist of the same or similar objects arranged in other configurations. Using a network architecture inspired by the connectivity between temporal lobe structures and the hippocampus, we demonstrate that DNNs trained using a triplet loss can learn this task. Analysis of the representations learnt in these artificial networks revealed late layers accurately encode the allocentric Euclidean distance between objects in the scene - the clearest representation of this quantity being in layers analogous to hippocampus region CA1.

Title: Activityscope: second-generation scanned line angular projection(slap2) two photon laser scanning microscopy for high speed live imaging at subcellular resolution

Authors: G. E. JAINDL[1], B. E. KIMMEL[1], J. KING[1], K. PODGORSKI[2], D. A. FLICKINGER[3], J. ARNOLD[2], N. ROUSSEL[1], P. ANGSTMAN[1], **S. TAPPAN**[1], *J. GLASER[1];

Abstract: Optical imaging of in vivo neuronal populations using fluorescent voltage and neurotransmitter indicators is an emerging frontier that requires microscopes capable of kilohertz-rate volumetric imaging in scattering brain tissue. The ActivityScope is a collaboration between Vidrio Technologies, MBF Bioscience the Podgorski lab, inventors of Scanned Line Angular Projection (SLAP) 2-photon laser scanning microscopy. ActivityScope uses a novel and unique scan technology. A vertical laser line is horizontally swept nearly 10,000 times per second across the surface of a Digital Micromirror Device (DMD) from where the excitation light is projected to the specimen. This approach enables scanning of multiple cell-sized ROIs at kilohertz rates. The DMD can switch “on" and “off" individual pixels within the field of view (FOV) of the ActivityScope, allowing highly flexible random-access imaging without the access time costs associated with previous random-access technologies.
We have developed software that improves the reliability and performance of the system and achieves user-friendly control of the specialized hardware for rapid imaging of multiple ROIs. Key features include automated calibration tools for tuning timing parameters, and real-time display of acquired data, which can be saved to disk. We are developing tools to allow experimentalists and technicians to easily configure complex imaging experiments comprised of both structural and functional activity imaging of multiple neurons, without requiring computer programming expertise.
ActivityScope is capable of imaging at subcellular spatial resolution and temporal resolution in the millisecond range (i.e., at 1000 Hz and higher) in the brain of mice in vivo and in brain slices in vitro. We believe that the ActivityScope microscope will be an asset to many experimental paradigms focused on live imaging of neuronal circuits.

Abstract: Studying the 3D architecture of the human brain at subcellular resolution is one of the current outstanding challenges. Having a robust method to map the anatomy, without introducing any visual artifacts or sampling bias, is becoming essential to obtain reliable quantitative information. Here, we report an innovative pipeline that allows 3D mapping of neurons in cm^3 of the human brain at high resolution using Light-Sheet Fluorescence Microscopy (LSFM). At first, we optimized SHORT, a new tissue clearing method to clear and stain mesoscopic volumes of human brain tissue. Then, to perform fast 3D imaging with subcellular resolution over cm-sized samples, we built a custom-made inverted light-sheet fluorescence microscope able to acquire up to four channels. Finally, we implemented a data management system able to deal with the large data volume produced during the acquisition and a machine learning technique to automatically count the neurons in 3D with high precision and sensitivity. We demonstrated the reliability of our approach by analyzing various human brain areas, and in particular, reconstructing a whole human Broca's Area of 4 x 4 x 2 cm^3. In conclusion, the proposed combination of a specialized tissue preparation protocol, an advanced LSFM and big data analysis allows mapping human brain architecture at the cellular level, paving the way to perform routinary analysis of 3D reconstructions of different tissue blocks up to the entire organ.

Abstract: The distribution of cell types in anatomical regions is fundamental to understand brain functions, yet classical stereological methods have been too laborious for comprehensive analyses across animals. New imaging techniques, such as serial two-photon tomography (STPT) and light-sheet fluorescence microscopy (LSFM), allow us to generate whole-brain datasets at a cellular resolution. To acquire and understand this enormous amount of information, however, it is also essential to automate acquisition and analysis of such data. In order to analyze and understand the organization of the brain, we developed an automated pipeline for the acquisition and analysis of cellular resolution histological brain data in rodents. First, we used NeuroTrace fluorescent Nissl-staining as a standard method to define anatomical brain structures to perform 3D brain imaging with STPT and LSFM. We use genetic labels such as Cre-based reporter mouse lines (eg ChAT-IRES-Cre) and whole mount immunolabeling of specific cell-types that will help to provide deeper understanding of neuroanatomical organization. We finally apply the developed pipeline to understand specie-specific neuroanatomical organization and cell-types patterns distribution.

Title: Clearscope: theta light sheet imaging for large intact tissues

Authors: P. J. LANG[1], D. S. DENU[1], S. J. TAPPAN[1], B. W. HAYDOCK[1], C. THOMAS[1], *N. J. O'CONNOR[1], B. S. EASTWOOD[1], I. C. MACFARLANE[1], R. TOMER[2], P. J. ANGSTMAN[1], J. R. GLASER[1];

Abstract: Advances in tissue clearing methods and improved Light Sheet Microscopy (LSM) techniques have opened new avenues of research into brain-wide exploration of connectivity patterns and molecular indicators of behavior and pathology. Working with the Tomer laboratory at Columbia University we have developed ClearScope, a revolutionary light-sheet microscope capable of imaging large, intact specimens at high resolutions. ClearScope uses advanced technology known as Light Sheet Theta Microscopy (LSTM), which utilizes a unique arrangement of two light sheets oblique to the specimen and detector axes. This arrangement allows the LSTM to image specimens of unprecedented size. ClearScope is a robust commercial technology that can be deployed in most neuroscience laboratories for use with virtually all tissue clearing techniques. It can be configured with up to seven laser excitation wavelengths for multi-channel imaging of most fluorescent reporters. ClearScope also provides a wide-field fluorescence imaging mode for quickly evaluating a specimen to select regions of interest for very high-resolution scans in light-sheet mode. ClearScope provides efficient imaging of cleared tissues at cellular resolution without a limitation on lateral tissue size. We present our most recent ClearScope developments including Streamlined workflows for high-speed image acquisition and hardware control; automated light-sheet optimization which maximizes axial resolution and overall image quality while minimizing training time required for system operation; and image volume stitching automatically performed as images are acquired and resulting in complete 3D images of tissue volumes viewable immediately after acquisition. A variety of file formats can be saved from ClearScope for easy analysis and collaboration.

Title: Improve widefield imaging contrast of neurons using actively controlled illumination

Authors: *Y. WANG, J. FAN, S. CHUNG;
Bioengineering, Northeastern Univerisity, Boston, MA

Abstract: In widefield neuron imaging, out-of-focus and scattered light often obscures dim fluorescent fibers. The scattering of light coming from bright cell bodies can also degrade the signal-to-background ratio (SBR) of nearby fibers. This phenomenon makes it difficult for widefield neuron imaging to visualize axons and dendrites near to their cell bodies. Scanning techniques, such as confocal and two-photon microscopy, can solve this problem but are limited by reduced imaging speed and increased cost, making them less accessible than widefield microscopes in many biological labs. We solve this obstacle by illuminating different structures with different light intensities in a common widefield microscope. With a simple spatial light modulator add-on to the microscope and real-time image processing, we illuminate bright structures, such as neuron cell bodies, with low light intensity. We illuminate dim, fiber-like structures, such as axons and dendrites, with high light intensity. Illuminating bright structures with dim light reduces the scattering surrounding them, exposing dim nearby fibers. In the actively controlled illumination setup, we illuminate only the in-focus portion of the targeted neuron. Moreover, we illuminate those parts with different light intensity levels to highlight fibers. Thus, we minimize background and enhance the visibility of fibers in the final image. Active illumination significantly improves fiber contrast quality while maintaining a fast imaging speed and low cost. Using a widefield microscope with our active illumination setup, we demonstrate improved neuron image quality in complex neurons of *C.elegans.*

Abstract: The advent of genetically-encoded calcium indicators, along with surgical preparations such as thinned skulls (Drew et al Nature Methods 2010) or refractive index matched skulls (Silasi et al Nature Methods 2016), have enabled mesoscale cortical activity imaging in headfixed mice. Such imaging studies have revealed complex patterns of coordinated activity across the cortical surface during spontaneous behaviors (Mohajerani et al Nature Neurosience 2013), goal-directed behavior (Allen et al Neuron 2017), locomotion (Musall et al Biorxiv 2018), motor learning (Makino et al Neuron 2017) and perceptual decision making (Orsolic et al BiorXiv 2019). However, studies have shown that neural activity during free, unrestrained behavior significantly differs from that recorded in headfixed animals. Furthermore, freely moving animals exhibit a repertoire of behaviors that is vastly increased from headfixed animals. The ability to perform mesoscale imaging of the cortex in freely behaving mice will potentially open up new avenues of scientific enquiry.Here we present the 'mini-mScope', a miniature, head-mountable imaging device compatible with transparent polymer skulls recently developed by our group ('See-Shells', Ghanbari et al Nature Communications 2019). With a 8x10 mm field of view, the mini-mScope can image most of the mouse dorsal cortex with resolution ranging from 39.37 to 55.68 micrometers. The current prototype weighs 3.8 g and incorporates a magnetic interlocking mechanism that allows quick fixation (<1s of temporary restraint) to a See-Shell implanted on an awake mouse. Open Field behavior tests indicate neither See-Shell implantation nor addition of mini-mScope significantly inhibits locomotion, even during trial durations > 30 min. The mini-mScope employs an array of blue LEDs to illuminate the cortical surface uniformly, with up to 8mW of light power. An additional green LED provides illumination for reflectance imaging of intrinsic optical signals arising from changes in cortical blood volume and oxygenation. We have used the mini-mScope to successfully record mesoscale cortical activity of the whole cortex in freely behaving mice, revealing intriguing coordinated activity patterns across cortical regions during a wide variety of behaviors which would be difficult to study in headfixed animals. Additionally, the mini-mScope is capable of simultaneously imaging mesoscale calcium dynamics and LFP electrode measurements during unrestrained behaviors.

Abstract: We present a novel microscopy platform that enables video-rate gigapixel-scale imaging of small model organisms. The optical system consists of a collection of 54 densely packed “micro-cameras” that each view a unique area of an 8 x 12 cm arena. Image data from all 54 sensors is computationally combined into large composite frames, containing many hundreds of megapixels, to reveal model organism behavior at high resolution (5 um/pixel) over an area large enough to enable natural movement and interaction. The demonstrated imaging system’s 54 micro cameras, each taking a volume of 7 cm^3, are tiled together in a compact rectangular configuration (1.35 cm between micro- cameras) to jointly stream data at high rates (~4 GB/sec) to a single computer, thus also enabling video capture. We demonstrate the performance of our new micro-camera array microscope (MCAM) in a variety of unique imaging and video experiments using model organisms including zebrafish, Drosophila and C. Elegans. For example, we simultaneously monitor the behavior of one hundred zebrafish larvae during free swim, and also record the fluorescent neural activity of freely swimming larvae at 5 um per pixel resolution over a 8x12 cm swim arena. We additionally highlight the ability of our new platform with recording 3D video by measuring the 3D movement of dozens of naturally interacting Drosophila. We additionally discuss future improvements for our new imaging method, which include higher video frame rates, automated organism detection and tracking, and the ability to acquire multi-channel fluorescence images.

Abstract: *In vivo* physiology and circuit structure complement each other in understanding brain function as they respectively reveal the computations a neural circuit performs and their biological implementation. We aim to apply this function-structure approach to mechanistically understand how odour representations are transformed in the mouse olfactory bulb (OB).
To this end, we aim to image a genetically targeted portion of mouse OB of $(\sim 0.5mm)^3$ containing tens of input structures (glomeruli) and hundreds of output projection neurons (PNs) with *in vivo* two-photon (2P) calcium imaging (using GCaMP6f). In order to link PN activity to corresponding inputs, we will then trace apical dendrites of identified PNs to their parent glomeruli in subsequently acquired synchrotron X-ray tomography (SXRT) and/or volume electron microscopy (vEM) datasets.
A key limiting factor of this multimodal workflow is the success rate of heavy metal staining necessary for generating X-ray or electron contrast (41% without 2P, n = 143; 33% with 2P, n = 24). To improve this, we tested several *en bloc* staining protocols on 0.6mm-thick dorsal mouse OB slabs[1,2], and examined staining homogeneity by X-ray microtomography and ultrastructure preservation by vEM. Without prior 2P, a perfusion based, two-step reduced osmium protocol stained all 8 samples homogeneously but with varying ultrastructural quality. Replacing perfusion with immersion dropped the yield to 50% (n = 4) but obtained consistently good ultrastructure. Improving tissue handling during surgery, imaging and dissection raised it to 70% (n = 10).
Another challenge of this workflow is to accurately locate structures of interest in each dataset. After functional 2P imaging, we imaged, in the same volume, fluorescently labelled blood vessels alongside GCaMP signal, which provides ample features for registering the 2P and SXRT/vEM fields of view. To assess warping accuracy, blood vessels in each dataset were independently traced, paired and aligned to a common space. We found that 2P to SXRT warping is as accurate as 2P to vEM warping. With an average error of ~10 µm, both glomeruli and PNs imaged *in vivo* by 2P can be located in the structural SXRT/vEM datasets.
With improved staining and reliable warping, future developments may focus on incorporating more complex physiology and targeted synaptic resolution post-SXRT vEM acquisitions to the workflow, which will give a richer, fully correlated function-structure dataset, driving a more complete understanding of mammalian olfactory processing across length scales and time.

Title: Preservation of Ultrastructure and Antigenicity after Rehydration of Cryofixed Brain Tissue

Authors: *J. PEREZ-GARZA, E. PARRISH-MULLIKEN, Z. DEANE, L. OSTROFF; Univ. of Connecticut Physiol. & Neurobio., Storrs, CT

Abstract: Immunohistochemistry at the EM level (immuno-EM) can reveal subcellular localization of molecules with full subcellular structural details, but compromises between sensitivity and morphological preservation are often required. Cryofixation followed by freeze-substitution can achieve an especially high level of structural preservation because tissue is dehydrated at low temperature. Freeze-substituted tissue is normally either embedded in resin at low temperature or fixed with osmium tetroxide before warming so that membranes are not extracted by the dehydration solvent, and both of these options preclude pre-embedding immunolabeling, which must be performed on hydrated samples near room temperature. Pre-embedding labeling is typically more sensitive than post-embedding and allows the use of higher-contrast stains for easier serial reconstruction, while cryofixation has the additional advantage of allowing long-term storage of tissue samples, making collection of large and complex sets of samples feasible. Here, we have developed a cryosubstitution approach that allows rehydration and sensitive immunolabeling of cryofixed tissue without loss of ultrastructure. Once rehydrated according to our method, tissue can be labeled with gold probes or chromogenic immunohistochemistry followed by standard EM staining and embedding. To assess the effect of our protocol on labeling and ultrastructure, we compared tissue freshly labeled and embedded without cryofixation to rehydrated cryofixed from the same animals. We choose to target the localization of three native antigens in the rat lateral amygdala (LA); gamma-aminobutyric acid (GABA), and two calcium-binding proteins, calbindin (CalB), and parvalbumin (PV). We found that rehydrated cryofixed tissue has better preservation of some subcellular structure contents while membrane ultrastructure was not affected by rehydration, showing smooth membrane continuity. For immunolabeling, differences in labeling patterns

between the two samples were not visible. This rehydration approach offers a new alternative to flexibly integrate sample storage, molecular labeling, and high-quality EM ultrastructure.

Title: Immersion fixation and staining of large volumes of human brain tissue for large scale connectomics

Authors: *N. KARLUPIA[1], R. SCHALEK[1], Y. WU[1], Y. MEIROVITCH[1], A. W. CHARNEY[2], B. KOPELL[3], J. W. LICHTMAN[1];
[1]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [2]Icahn Sch. of Med. Mount Sinai, New York, NY; [3]Dept. of Neurosurg., Mount Sinai Hlth. Syst., New York, NY

Abstract: Despite its obvious importance, the cellular and subcellular structure of healthy and diseased human brain is understudied. Recent advances in the field of connectomics has allowed mapping of cells and their circuits at the nanometer scale in volumes of about 1 mm^3. However, given that the human cerebral cortex can be 3 mm in thickness, substantially larger volumes are required. Larger volume electron microscopy (EM) studies in humans have been limited by three major challenges: a) availability of fresh brain biopsy samples instead of poorly preserved postmortem tissue; b) the requirement for excellently preserved large volume tissue blocks using immersion fixation instead of trans-cardiac perfusion fixation routinely used in animal studies; and c) the need for preservation of extracellular space (ECS) and heavy metal (osmium) stain penetration throughout the tissue block. Human cerebral cortical samples from neurosurgical patients are now accessible owing to interventions for epilepsy or lead placement for deep brain stimulation that involve removal of overlying tissue. We devised an immersion fixation and heavy metal staining method that provides excellent ultrastructure of both rodent and human surgical brain samples up to volumes of 8-27 cubic millimeters. Punched or otherwise excised biopsies were obtained from freshly harvested adult mice brains and also collected from the dorsolateral prefrontal cortex of anonymized patients undergoing lead placement for deep brain stimulation. For immersion fixation we optimized the composition and temperature of the fixative solution and minimized the time so as to allow excellent preservation of ultrastructure. We also tested whether anion channel regulators, anti-edematous drugs and higher

concentrations of buffer would benefit maintenance of ECS. To achieve homogenous heavy metal staining (Osmium-Reduced osmium-Thiocarbohydrazide-Osmium or ORTO) all the way to the core of 8 mm^3 tissue blocks without cracking we did variations at each step including the concentration of reagents, duration and incubation temperature of staining, washing, dehydration, infiltration and also tested thiocarbohydrazide alternative. We conclude that rapid immersion fixation in cold fixative containing mannitol and an optimized ORTO method that includes mannitol containing normal saline gives well preserved, homogenously stained, crack-less and non-brittle large volume blocks for EM.

Title: Use scalp electroencephalography to evaluate the severity of depression

Authors: *C. CHEN[1], A.-C. YANG[1,2,3];
[1]Inst. of Brain Sci., Natl. Yang Ming Chiao Tung Univ., Taipei City, Taiwan; [2]Digital Med. Ctr., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [3]Dept. of Med. Res., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Use scalp electroencephalography to evaluate the severity of depression
Authors*Ching Hao Chen , Albert C. Yang
Abstract
Background: The World Health Organization predicts that depression will be the most costly disease on average in the world by 2030(N Bains et al., 2020), with more than 300 million people suffering from depression and the number of patients continuing to rise. However, the current clinical diagnosis of depression relies on consultations, scales, and tests to assess the severity of depression, which is a time-consuming and costly process, and still relies on the judgment of the medical team in the assessment process, which can easily lead to subjective differences in the definition of depression severity. Early detection of depression requires a

patient-friendly inexpensive method based on easily measurable objective indicators. (M Bachmann et al., 2018) To solve the problem of subjectively assessing the severity of patients, we hypothesized that the severity of symptoms in patients with depression is associated with the features of electroencephalography (EEG), so that the features can be used as an indicator to assess the severity of depression by using scalp EEG analysis as a basis for diagnostic markers using artificial intelligence approach. **Objectives** (1) To create a highly accurate prediction model to assess the severity of depression in patients. (2) To identify indicators of depression severity in scalp EEG. **Methods:** The data were collected from 103 depression patients at Kaohsiung Kai-Shuan Hospital, and their 2-minute EEG were collected at resting state. 80 females and 23 males, with a mean age of 45 years, standard deviation of ±11, and a mean age at diagnosis of 39 years, standard deviation of ±12. The educational stages were divided into 7 stages and categorized as 1-7, with a mean educational stage of 3.8 and standard deviation of ±1.3. To avoid the error caused by the machine, we only took the middle 100 seconds and cut it into 10 segments. And used the previous study (Zimmerman et al., 2013) as the segments for the HAMD-17 severity classification. More than 4,000 pieces of data were compiled. Then, we created a prediction model to achieve the most accurate severity prediction, and used statistical analysis to identify the most significant features. **Results**: We created up to 90% - 80% of the depression severity evaluation models and found features in the spectrum transformation method that had a significant effect on depression severity. **Conclusions:** By using this depression severity prediction model, we can assist clinical care in assessing the severity of depression and improving the treatment process for depressed patients.

Title: Head motion in functional MRI scans does not drive results of brain-wide association study: an ABCD study multivariate analysis

Authors: *G. GRIMSRUD[1], N. BYINGTON[1], M. MOONEY[2], M. CORDOVA[2], O. DOYLE[2], R. HERMOSILLO[1], E. EARL[2], A. PERRONE[2], L. MOORE[2], A. GRAHAM[2], J. NIGG[2], W. THOMPSON[3], E. FECZKO[1], O. MIRANDA DOMINGUEZ[1], D. A. FAIR[1];

Abstract: Motion artifacts reduce both structural and functional image quality and are a major confound in studies of brain development and individual differences. Studies have highlighted

that results obtained with an original sample before quality control (QC) compared with a quality-controlled subset of the data results in significantly different findings, including differences in effect sizes and functional neuroanatomy. Moreover, neurodevelopmental studies often involve participants predisposed to high motion (e.g. ADHD, Autism), and may have increased motion relative to typically developing samples - exacerbating these misleading artifacts. Determining the optimal QC parameters of motion for such neuroimaging data could allow for more comparable and efficient analysis practices. The Adolescent Brain Cognitive Development study (ABCD; N=11,877, ages 9-10) has implemented several conservative methods to minimize motion artifacts, including new 'scrubbing' techniques. Utilizing the ABCD BIDS Community Collection (ABCC, Collection-3165) and the ABCD Reproducible Matched Samples, we built and validated a multivariate ABCD motion method for an additive model, the PolyNeuro Risk Score (PNRS) model of executive function. We conducted our analysis with varying QC thresholds to 1) determine the optimal parameters to conserve the largest participant pool and 2) confirm any result was not driven by head motion. Connectivity matrices were generated for varying combinations of framewise displacement (FD) thresholds (0.08, 0.1, 0.2, 0.4 mm) and amounts of data (5, 8, 10 min). All analyses included an additional 'outlier detection step' to scrub any additional frames with poor QC. Each QC threshold combination produced a different sample size for analysis ranging from N=1,775 to N=8,519. 3,076 participants, who survived at an FD $\leq$ 0.1 mm and 8 minutes of data, became our test sample. The analysis was run several times for this test group using varying amounts of their lower quality data. Overall, our model's predictive power increased when a larger sample size was used, and such power did not vary greatly using iterations of FD thresholds in the test group. These findings indicate: 1) that our procedures, that include outlier detection, are particularly adept at controlling for motion in PNRS studies, and 2) the increase in predictive power for PNRS studies is a function of sample size and not of head motion (for the thresholds tested). Overall, findings serve to better inform future analyses using the PNRS model in large-scale datasets and could help preserve more high-motion participants to better understand both typical and atypical brain-behavior relationships.

Title: Scale-invariant connectome dynamics across slow and fast timescales

Authors: *T. ALDERSON[1], J. WIRSICH[2], S. KOYEJO[1], S. SADAGHIANI[1];
[1]Univ. of Illinois, Champaign, IL; [2]Univ. of Geneva, Geneva, Switzerland

Abstract: Connectome dynamics arise from the moment-to-moment co-activation patterns among brain regions. To date, these interactions have principally been constrained to a single timescale of observation, namely, fluctuations in the hemo-dynamic properties of brain. A promising future direction lies in extending this approach to fast dynamics of electro-physiological interactions and characterizing the spatio-temporal rules governing dynamics across both slow and fast timescales. Accordingly, we analyzed concurrently recorded fMRI and source localized EEG from 26 young adults during resting state. Signals were averaged for each of 68 parcels of the Desikan atlas. To permit a frame-by-frame comparison, simultaneously recorded fMRI time series (<0.1 Hz) and bandpassed EEG amplitude envelopes (delta, theta, alpha, beta, gamma) were resampled to the same number of data points. Recurrent co-activation patterns-or states-corresponding to all possible interactions among canonical intrinsic connectivity network were detected and characterized in terms of their dynamic properties, including probability of occurrence, mean lifetime, switching frequency, and transition probability. Connectomes were expressed at all frequency scales (infraslow to gamma) and displayed dynamics defined by several highly correlated properties, including probability of occurrence, mean lifetime, switching frequency, and transition probability. Of special note was the correspondence in the transition probabilities of connectomes across modalities, which were scaled to express transitions at different rates (infraslow to gamma). Given that the observed self-similarity of connectome state sequences at all timescales was consistent with a scale-free phenomenon, we deployed wavelet-based fractal analysis and determined scale-free behavior in the connectomes of all frequency bands (infraslow to gamma). Finally, self-similarity of connectomes across modalities was confirmed by compressing slow fMRI sequences into fast EEG sequences. This simple transformation brought scaling exponents associated with long-range temporal correlations into register across “simulated” and observed EEG In conclusion, we find strong evidence that connectome sequences in concurrent fMRI-EEG recordings are scale-free over several orders of magnitude including infraslow (<0.1 Hz) fluctuations of the hemo-dynamic signal and considerably faster neural oscillations (~1-60 Hz). Our findings suggest that

fMRI- and EEG-derived connectomes are composed of the same spatial ingredients traversing the same state space, but independently, at different rates.

Abstract: Resting state functional connectivity (rsFC) in fMRI has been an important tool for studying functional brain organization in humans. In order to make reliable individual estimates of rsFC, it is necessary to collect large amounts of data per subject. Recently, researchers identified single time points ("events") during which many areas of the brain fluctuate together. Remarkably, rsFC network organization calculated from concatenating just a few of these time points resembles the rsFC network organization estimated from the entire data set. This observation offers at least two interpretations — (1) events are discrete points at which network-defining rsFC is inordinately strong or (2) rsFC is present over time, but is embedded in a background of varying noise. Here, we examined the discreteness of events in real and simulated resting state fMRI data. We find that events are not discrete - they show continuous properties with timepoints of intermediate fluctuation in real data. Second, we show that events are present in simulated data with a static rsFC structure, and that their presence is associated with the modularity of the static correlation structure. These results suggest that variable co-fluctuations in rsFC are a byproduct of a static network organization in a noisy measure, and moments of high cofluctuation may identify timepoints that are less affected by noise.

Title: Transcriptomic correlates of individual variation in brain activity

Authors: *N. HOANG[1], J. PARK[1], Y. CHEN[1], N. SARDARIPOUR[1], M. BENTON[2], J. CAPRA[3], M. RUBINOV[1];
[1]Vanderbilt Univ., Nashville, TN; [2]Baylor Univ., Waco, TX; [3]Univ. of California, San Francisco, San Francisco, CA

Abstract: A lack of simultaneous genotype, gene expression, and imaging data for large human populations constrains the search for genetic correlates of regional brain activity. Existing studies use data from a small number of individuals, imaged by consortia such as the Allen Institute Human Brain Atlas (AHBA). These data provide a useful snapshot of interregional transcriptomic relationships but cannot reveal relationships between gene expression and activity across individuals. Here, we integrated multiple neuroimaging and genomic datasets to impute gene expression profiles of ten brain regions in over 800 people. We used this method to probe the relationship between regional brain activity and gene expression levels across individuals. We modeled the relationship between individual-level genotypes and gene expression levels in the brain using PrediXcan, a machine learning method that finds combinations of regulatory alleles reflecting heritable gene expression and estimates the genetically regulated component of this expression (Gamazon, et al. 2015). We applied PrediXcan models for ten brain regions to 888 people from the Human Connectome Project (28.7 ± 3.7 mean age, 484 females), including twins and non-twin siblings. This produced imputed expression across individuals for an average of 4,000 genes per brain region. We found that our method accurately captures existing knowledge of genetic structures in families and populations, as well as gene co-expression on data from the AHBA. We then validated the utility of this method by linking the expression of several gene groups to commonly studied neural phenotypes. We found a substantial overlap between selected genes in relation to mean and variance of interregional coactivity. We thus report strong correlations between individual variation in gene expression and in brain activity and coactivity patterns. Our analyses open the way towards future large-population studies of relationships between heritable gene expression and large-scale brain organization.

Title: Influence of mechanical stress on peripheral nerve shear wave velocity in a tension-controlled setting

Authors: *C. L. RUGEL[1], S. S. LEE[1], C. K. FRANZ[2];
[1]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL; [2]Biologics, Shirley Ryan Abilitylab, Chicago, IL

Abstract: Clinical studies using shear wave ultrasound elastography to evaluate changes in the mechanical properties of pathologic nerve, consistently report greater nerve shear wave velocity in both diabetic and entrapment neuropathies. This finding is often interpreted as pathologic nerve having greater stiffness than unimpaired nerves, as the relationship between stiffness and shear wave velocity has been validated in various soft tissues. However, this relationship has yet to be evaluated in peripheral nerve. Furthermore, findings from in vivo studies that examine nerve shear wave velocity across limb positions suggest that shear wave velocity could be more indicative of nerve tension than stiffness, as nerve tension varies at different joint angles. Thus, it is the purpose of this study to determine the relationships between peripheral nerve shear wave velocity, tension, and stiffness. To do this, we performed traditional mechanical testing on feline sciatic nerves ex vivo (N=2), elongating the nerve by 0.25mm after one-minute relaxation periods while simultaneously recording the resulting nerve tensile force. Shear wave velocity of the nerve was measured both instantaneously after elongation and at the end of each relaxation period. To avoid potential bias of nerve morphometry, we performed data analysis in terms of nerve stress (tension normalized to nerve cross sectional area) and percent strain (nerve elongation normalized to initial nerve length). From stress and strain values, we were able to calculate elastic modulus, stiffness normalized to nerve size. Our results indicate that nerve shear wave velocity is highly influenced by nerve stress (R^2=0.75, p<0.001), but the relationship is not as strong as that of nerve stress and elastic modulus (R^2=0.97, p<0.001). These findings are not surprising considering stress is used to calculate elastic modulus, but the disparity between the coefficients of determination suggest that there are intrinsic properties of nerve that contribute to its shear wave velocity. This work highlights the importance of controlling nerve tension in clinical evaluations of shear wave velocity, such as by maintaining standard limb positioning. However, additional studies are needed to elucidate other potential factors, such as nerve structure, composition, and fiber directionality, that also affect nerve shear wave velocity.

Title: The importance of racial identity in neuroimaging research: Differences in brain morphometry between White and African Americans

Authors: D. ATILANO-BARBOSA, *F. A. BARRIOS;
Inst. de Neurobiología, Univ. Nacional Autónoma de México, Querétaro, Mexico

Abstract: There is a marked underrepresentation of ethnic and racial minorities in biomedical research, causing disparities in the understanding of genetic and acquired diseases, as well as in clinical treatments efficacy. These disparities are also present in neuroscience, emphasizing the negative consequences of extrapolating findings from small and non-representative samples of the population in the neurobiological and neuro-functional characterization of the human brain. Racial identity, understood as the sense of collective identity based on a perceived common heritage with a racial group, has generally been used as a demographic variable and nor as a variable of interest in neuroimaging research. Few brain morphometric studies between Whites and African Americans have reported differences in orbitofrontal volumetry and insula cortical thickness. Nevertheless, these studies are mainly implemented in small samples and in population with cognitive impairment. In this sense, we hypothesized that, in a representative sample of neurotypical young adults, there may be differences in brain morphometry between *Whites* and *African Americans*. To test this hypothesis, we analyzed the Human Connectome Project (HCP) brain morphometric data of a group of *Whites* (n = 266, $M_{age(y)}$ = 28.92, SD = ±3.59, $M_{education(y)}$ = 15.35, SD = ±1.60) and *African Americans* (n = 47, $M_{age(y)}$ = 29.11, SD = ±3.65, $M_{education(y)}$ = 14.55, SD = ±1.98). Permutations analysis between groups adjusting for *age*, *education* and *economic income* were implemented. Results indicated significant differences between Whites and African Americans in cortical thickness and surface area involving distinct brain regions in frontal, parietal, temporal and occipital lobes. In this regard, racial identity and inclusion of sub-representative minorities in neuroimaging research, such as African Americans, are fundamental for the comprehension of human brain morphometric variability.
Data were provided by the Human Connectome Project, WU-Minn Consortium (Principal Investigators: David Van Essen and Kamil Ugurbil; 1U54MH091657) funded by the 16 NIH Institutes and Centers that support the NIH Blueprint for Neuroscience Research; and by the McDonnell Center for Systems Neuroscience at Washington University.

Title: Establish a machine learning approach to predict sleep stages based on ECG

Authors: *P.-C. CHIU[1], A.-C. YANG[1,2,3];
[1]Inst. of Brain Sci., [2]Digital Med. Ctr., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan;
[3]Dept. of Med. Res., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Sleep study with polysomnography (PSG) contains multiple physiological signals.These signals have shown different conditions in sleep status of human body especially sleep stage of electroencephalography (EEG). However, PSG used for sleep staging may interrupt the subject's sleep quality and cannot easily be used for following the trend of sleep. In order to estimate sleep stage in long-term record and less sleep state interference using electrocardiography (ECG) through measuring autonomic system can quantify sleep stages by less than PSG signal outside the sleep lab environment. We used a dataset of a community cohort study from the American National Heart Lung & Blood Institute, which focused on cardiovascular disease and sleep breathing disorders. The dataset included 8,444 PSG records which were used for developing a machine learning model for sleep stages prediction. We identified heart rate rhythms between R peak waveform (R-R interval) and respiratory patterns based on ECG signal. Extracting the features of time domain, frequency domain and nonlinear method of heart rate variability (HRV) are to establish a machine learning model to predict EEG sleep stages based on physiological measures. For using a segment of every 120 seconds of most recorded epoch of sleep stage like continuing sleep stage 2 of ECG data to extract the features from heart rate including time domain, frequency domain, nonlinear methods have the performance of 83.8 percent accuracy. The significant features of machine learning are entropy of nonlinear method, total power of frequency domain, standard deviation of R-R intervals(SDNN) of time domain. Using machine learning approach, our results suggested that specific HRV features of continuing sleep stage pattern are associated with EEG sleep stages. We can use these approach to record sleep stage on a subject in any condition of household and hospital environment outside sleep lab than PSG.

Abstract: Introduction: Prenatal ethanol exposure (EtOH) can result in a complex developmental abnormality called fetal alcohol syndrome (FAS). Diagnostic criteria include ocular, periocular and other craniofacial abnormalities, deficient somatic and brain growth with abnormal morphogenesis, and neurobehavioral impairment. Although the ocular abnormalities are considered diagnostic of FAS, their pathogenesis is poorly understood. **Methods**: Fetal brain and eye tissues were collected at 11 to 21 wks gestation. The EtOH-exposed and control groups were matched for gestational age (GA), fetal gender, race, and maternal BMI, and were analyzed using ELISA, flow cytometry, immunohistochemistry, western-blot assay and the Caspase-3/7 assay. RNA expression for biomarkers was assessed using Real-Time PCR (qPCR) and Droplet Digital PCR (ddPCR), using a Pearson correlation for p-values. Eye morphometric assays were performed using a sliding digital caliper. *In vivo* rat FAS model was established for studies of toxic effects of EtOH on rat fetal brain and eye development. **Results**: Ten human EtOH-exposed cases (1st or 2nd trimester) were compared with GA-matched controls. EtOH exposure was associated with a consistent pattern of reduced eye and iris diameter. Markers of synaptogenesis were reduced, and caspase-3 activity was increased in human fetal brains. The reduction in eye diameter correlated with levels of EtOH intake ($p=0.001$). EtOH-associated caspase-3 activation correlated with decreased eye size ($p=0.0003$). Studies in the rat FAS model showed similarly increased levels of activated caspase-3 in the FAS pup brains compared to control. Body and brain weight were significantly lower in the EtOH groups at P8 and P15. The levels of Myelin Basic Protein (MBP) and Peripheral Myelin Protein (PMP22), which play important roles in oligodendrocyte development and myelin formation were decreased in EtOH-exposed human fetal brains and eyes. The levels of β-catenin were increased, and BDNF decreased in the EtOH groups of both human and animal brains. Expressions of these molecules play essential roles in neural development. There was a negative correlation between prenatal EtOH intake and brain and eye development. **Conclusion**: Prenatal EtOH exposure alters the

development of the eye in a dose-dependent manner, resulting in microphthalmia, which can be detected in human fetuses as early as 11 wks GA. Thus, recognition of reduced eye size, in combination with specific molecular markers of EtOH toxicity in the fetus may be predictive of FAS postnatally and be useful in the future as biomarkers to identify patients for *in-utero* treatments with targeted neuroprotective therapies.

Abstract: The purpose of this study is to examine the effect of different concentrations of lead on both cell survival and BDNF/TrkB expression. This research arises from the absence of studies that directly address the effect of lead contamination at the relevant concentrations measured in different regions in Puerto Rico. Physiologically relevant concentrations have been determined and used to treat human postnatal fibroblast (BJ) and embryonic kidney (HEK293) cell lines characterizing the effects of lead on both survival and BDNF/TrkB expression using immunocytochemistry. Results indicate significant changes in cell morphology associated with significant changes in both BDNF and TrkB expression. Interestingly, expression of BDNF and TrkB in BJ cells, showed an opposite trend to that observed in HEK293 cells. These results potentially highlight the importance of developmental stage as a key factor in determining the effects of which these cell models are found, one embryonic and the other postnatal. We further

examined the effects of lead in isolated hippocampal neuronal preparations indicating significant effects in both survival and protein expression. Our data thus far, once again highlights the importance of implementing and enforcing regulations on lead contamination in the Island.

Abstract: The developing nervous system is highly complex, generating an enormous diversity of cellular states over a lengthy gestational window. Although single-cell RNA sequencing is increasingly used to study the molecular architecture underlying this process, most studies to date have focused on particular regions, cell types, or developmental stages. To gain a comprehensive picture of brain development, we performed single-cell RNA sequencing on nearly 300,000 cells isolated from the embryonic mouse forebrain, midbrain, and hindbrain each day between neurulation and birth (E7 to E18.5). An analysis based on our Cytograph pipeline resulted in 798 clusters, which we manually annotated. In addition to a highly diverse set of radial glia, neuroblasts, and neurons, we characterized developing non-neuronal cells, particularly glial progenitors, immune cells, and meningeal fibroblasts. The dataset revealed the striking regional heterogeneity of neural progenitors in the brain, including the brain's

specialized secondary organizers that pattern the developing neural tube. To further investigate the spatial organizations of these cellular states in our dataset, we performed *in situ* mRNA sequencing of 119 genes across 24 sagittal sections in the embryonic day 10.5 mouse brain. Together the single-cell and spatial datasets provide a rich resource for exploring the genes and cellular lineages that contribute to mammalian nervous-system development and disease.

Title: Regulation of neural lineages by Hox genes to specify post-mitotic neuronal characteristics during circuit development

Authors: *D. VASUDEVAN[1], H. CARR[1], Y.-W. WANG[2], J. ZUNIGA[1], S. CORCORAN[1], E. HECKSCHER[2];
[2]Mol. Genet. and Cell Biol., [1]Univ. of Chicago, Chicago, IL

Abstract: During development, neural stem cells (NSCs) differentiate into neurons that wire together, forming circuits that drive behaviors. NSCs have enormous therapeutic potential in treating neurodevelopmental disorders and injury. But, this potential is untapped because how NSCs give rise to neural circuits is not fully understood. In the vertebrate spinal cord and invertebrate nerve cord, one set of NSCs are repeatedly found at all segmental levels along the anterior-posterior (A-P) axis. In different A-P locations there are different circuits that control specialized A-P functions. Thus, there must be naturally occurring variations in how stem cells give rise to circuits along the A-P axis. In general, Hox genes underlie A-P variation in multiple tissue types, but it is unknown how Hox genes generate A-P circuit diversity in the CNS. Here, I am developing the Drosophila larval nerve cord as a genetically tractable and numerically simple model to address this question. I am testing which post-mitotic characteristics of neurons is modulated by the posterior Hox gene, Abdominal-B (AbdB). The objectives of this study are first, to test whether the levels of Hox gene expression in NSC sets the levels of Hox gene expression in post-mitotic neuronal progeny. The second objective is to determine how changing

levels of Hox in post-mitotic neurons modulates their morphology, as well as the formation of anatomical and functional input synapses. Specifically, I will focus on NB3-3 neuronal stem cells and the lineage of even-skipped lateral (EL) interneurons that it produces, and investigate the role of the Hox gene, AbdB. This will provide insight into the Hox-based genetic mechanisms that regulate how stem cells give rise to neural circuits.

Title: Trpm8 activity is necessary for preventing spinal cord motor neuron apoptosis in Xenopus laevis larvae reared at cold temperature

Authors: *A. NAVARRETE VARGAS, O. VISINA, K. SPENCER, L. BORODINSKY; Univ. of California, Davis, Sacramento, CA

Abstract: During nervous system development neurons are produced in excess and as much as 50% of them are pruned by undergoing programmed cell death, in what is known as developmental apoptosis. The mechanisms underlying this process are unclear. Previous studies in the lab demonstrated that *Xenopus laevis* embryos and larvae grown at cold temperature exhibit a higher number of motor neurons than siblings grown at warm temperature and that this cold temperature-dependent increase in motor neuron number correlates with a decrease in motor neuron apoptosis and enhanced motor performance when cold temperature-grown larvae are tested at cold temperature. The mechanisms that contribute to the survival of motor neurons at cold temperatures remain unknown. Here we assessed whether the cold-sensitive transient receptor potential cation channel subfamily M member 8 (TRPM8) is necessary and sufficient in preventing apoptosis of spinal cord neurons, specifically motor neurons, in animals reared at cold temperature. To assess necessity, embryos were injected bilaterally at the two-cell stage with either control or TRPM8-morpholino and reared at cold (16°C) temperature until reaching larval

stage 40, when they were processed for immunostaining for the motor neuron transcription factor, HB9, and for Terminal deoxynucleotidyl transferase dUTP Nick End Labeling (TUNEL) assay to detect apoptotic cells. We observed that TRPM8 knockdown in animals reared at cold temperature leads to a 65-fold increase in number of apoptotic spinal cord cells compared to control and 48% of spinal cord motor neurons are apoptotic in TRPM8-deficient animals compared to only 1% in control counterparts. In contrast, TRPM8 knockdown in animals reared at warm (22.5°C) temperature did not change the number of apoptotic spinal cord cells or the proportion of apoptotic motor neurons. Current efforts are focused on assessing the sufficiency of TRPM8 activation in preventing motor neuron apoptosis in embryos grown at warm temperature and to rescue the deficient motor performance these larvae exhibit when tested at cold temperature. The results so far suggest that TRPM8 is necessary for preventing motor neuron apoptosis in cold temperature-reared animals and highlight the role of the environment in nervous system development. This study may contribute to the understanding of the mechanisms underlying the pathological loss of motor neurons in disease, in which a developmental origin has been considered.

Title: Brief exposure to delta^9 (-) THC affects embryonic and adult locomotion; the effect persisted in the offspring

Authors: *M. AMIN[1], K. AHMED[1], J. SZASZKIEWICZ[2], T. HAMILTON[3], D. ALI[1]; [1]Univ. of Alberta, Edmonton, AB, Canada; [3]ASSOCIATE PROFESSOR, PSYCHOLOGY, [2]MACEWAN UNIVERSITY, Edmonton, AB, Canada

Abstract: The stereoselectivity of a compound plays an essential role in it's pharmacological activity. δ^9 (-) THC is a stereoisomer of THC and is the predominant form present in the cannabis plant, *Cannabis sativa*. The goal of this study was to determine if brief exposure of zebrafish embryos to δ^9 (-) THC during the gastrulation stage impacted development. Our results show that embryos treated with concentrations of THC of 1 mg/L and higher did not survive past 15 dpf. Treatment with δ^9 (-) THC resulted in morphological defects, defective synaptic activity and altered motor neuron development in young zebrafish. Additionally, δ^9 (-) THC treatment

altered development of the swimbladder. To investigate the mechanism of action of THC, we stimulated hedgehog and Wnt signaling pathways prior to THC treatment since these pathways are involved in swimbladder development. Our findings showed that overactivation of the Shh pathway using purmorphamine prevented the THC-mediated abnormal swimbladder development, whereas activation of Wnt signaling (using BIO) did not. RNAseq analysis showed that more than 2750 genes were differentially expressed in embryos following treatment with 3 mg/L and 0.5 mg/L of δ^9 (-) THC. δ^9 (-) THC treatment resulted in the downregulation of sonic hedgehog-related genes such as ptch2, smo, gli1, and gli2b. Together, these findings suggest that THC treatment induces changes in the activity of the sonic hedgehog pathway, as suggested by previous work. To determine the long-term effects of exposure to δ^9 (-) THC, we reared THC treated animals to adults and investigated their behavior. Our results showed that there were changes in locomotor activity and swimming behaviors in adults and even into the next generation of animals (F1 embryos). Briefly, adult zebrafish (treated with 0.5 mg/L THC during gastrulation) spent more time near the walls of the tank and less time in the center zone compared with age matched controls. In addition, the F1 embryos from the THC treated parents exhibited decreased spontaneous activity and travelled smaller distances following mechanical, touch stimuli. These
findings suggest that a brief exposure to δ^9 (-) THC, of only 5 hr during gastrulation, may have persistent and long term effects on zebrafish mand even into the next generastion of animals.

Title: Nell2/nel promotes neuronal survival in the developing and aging brain

Authors: C. NAKAMOTO, E. BAKER, A. JARABEK, M. DUNSON, E. FRANGOPOULOS, ***M. NAKAMOTO**;
Dept. of Biol., Valparaiso Univ., Valparaiso, IN

Abstract: Correct functioning of the nervous system is critically dependent on the generation and maintenance of the proper numbers of neurons. During development, a significant portion of the newly generated neurons die through programmed cell death, and neuronal survival is

maintained only if they encounter appropriate environmental cues. Once neurons are selected for survival during the developmental cell death period, the proper numbers of neurons are normally maintained for the lifetime of the organism. Whereas previous studies have revealed factors that regulate developmental neuronal survival, the molecular mechanisms that control the generation of proper numbers of neurons during development and support the long-term neuronal survival in the adult brain are not fully understood. Nell2 (also known as Nel) is a multimodular extracellular glycoprotein that is predominantly expressed in the nervous system. Nell2 exerts diverse functions in neural development, including neuronal proliferation and differentiation, and axon guidance. Our previous study has shown that Nell2 acts as an inhibitory guidance cue for retinal axons in the eye-specific retinogeniculate projection. Nell2 has been shown to promote survival of cerebral and hippocampal neurons *in vitro* and protects retinal ganglion cells (RGCs) from cell death after optic nerve injury. We previously showed that overexpression of Nell2 in the developing chick retina increases the number of RGCs, whereas knockdown of Nell2 expression results in decrease in RGC numbers. Our study revealed that Nell2 positively regulates the RGC numbers by promoting their differentiation and survival during development. In the current study, we investigated the survival-promoting functions of Nell2 in neural development and aging by using Nell2 knockout mice. Nell2 is strongly expressed in RGCs and hippocampal neurons in developing and adult mice. We have found that the numbers of RGCs and hippocampal neurons are significantly decreased in developing (embryonic day (E) 19.5 - postnatal day (P) 4) Nell2 knockout mice. Deletion of the Nell2 gene does not significantly affect neuronal proliferation. However, Nell2 knockout mice showed increased apoptosis both in developing RGCs and hippocampal neurons, suggesting that Nell2 promotes neuronal survival in those areas during development. Furthermore, compared to wild-type, apoptosis of RGCs and hippocampal neurons is significantly increased in the adult and aging (~ P480) Nell2 knockout mice. Taken together, those results suggest that Nells acts as a survival promoting factor that is essential for production and maintenance of proper numbers of neurons.

Title: Characterizing phagocytic neural crest cells in early zebrafish neural development.

Authors: *K. E. LIU[1], S. C. KUCENAS[2];
[1]Neurosci. Grad. Program, [2]Dept. of Biol., Univ. of Virginia, Charlottesville, VA

Abstract: During neural development, sculpting of the central and peripheral nervous systems (CNS and PNS, respectively) is necessary to generate a functional and adaptable organism. This sculpting involves the over-proliferation of neurons and subsequent "pruning back" of neuronal projections and synapses to homeostatic levels. During the assembly of activity-dependent circuits, this pruning is necessary for circuit function and plasticity throughout life. Several cell types prune by consuming extracellular debris, apoptotic neurons, and their synapses through a process called phagocytosis. Notably, aberrant phagocytosis is implicated in several devastating neurodevelopmental (e.g. Nasu-Hakola disease, Rett syndrome) and neurodegenerative (e.g. Parkinson's disease, multiple sclerosis) disorders. During development we know that debris is cleared during early neurogenesis, yet there are no professional phagocytes (microglia or macrophages) present in the CNS or PNS. In studies using zebrafish, our lab identified neural crest cells (NCCs) as novel phagocytes that actively consume dying cells during an early developmental period (~24 to 40 hours post-fertilization [hpf]). While we now know that NCCs aid in debris clearance during this window, the mechanisms, interactions, and effects of NCC phagocytosis on neural development are not known. Zebrafish provide an unparalleled advantage to examine NCCs in early neurodevelopment because of their accessibility at early developmental stages, genetic tractability, capacity for *in vivo* time-lapse imaging, and targetable early-formed circuits. The early zebrafish touch-response circuit consists of primary sensory neurons in the dorsal spinal cord (Rohon-Beard [RB] neurons) which synapse with local interneurons and primary motor neurons. By 24 hpf, these connections form a touch-response circuit that facilitates early recoil responses in developing embryos. This circuit changes drastically over development: RB neurons quickly degenerate and are replaced by dorsal root ganglion neurons in this circuit, producing cellular debris in need of phagocytic clearance. Using zebrafish transgenic lines that fluorescently mark phagocytic components in NCCs (Lamp1, PI(3)P), we are characterizing the effects of NCC phagocytosis on the touch-response circuit *in vivo*. Understanding the molecular basis behind phagocytes in neural development contributes vital knowledge to their aberrant function in neurodevelopmental and neurodegenerative disorders and could lead the way to novel therapeutic strategies for these conditions.

Title: Preterm birth alters the maturation of the GABAergic system in the human prefrontal cortex

Authors: *H. LACAILLE, C.-M. VACHER, J. SALZBANK, J. O'REILLY, A. A. PENN; Pediatrics, Columbia Univ. Med. Ctr., New York, NY

Abstract: Alterations in neurotransmitter systems, particularly changes in GABAergic and glutamatergic systems, during frontal lobe development have been hypothesized to play a key role in neurodevelopmental disorders seen in children born very preterm (<32 weeks gestation) and at very low birth weight. Prematurity frequently results in neurodevelopmental disorders such as autism, attention deficit disorders or epilepsy in the absence of radiologically visible lesions, suggesting that long-term physiological alterations might underlie these pathologies. Recent magnetic resonance spectroscopy imaging studies have suggested that GABA concentrations may be lower in preterm than term infants, but cannot assess the components of the GABAergic system that may have altered development. Here we studied the molecular development of the GABAergic system specifically in the dorsolateral prefrontal cortex (Brodmann area 10-46), a region that plays a role in attention and working memory and that has been implicated in neurodevelopmental and psychiatric disorders. The maturation state of the GABAergic system in this region was assessed in human post-mortem brain samples of 17 male and 9 female term infants, ranging in age from 0 to 8 months obtained from the NIH NeuroBiobank. Gene expression levels were measured for 47 genes related to GABAergic development and this gene expression data was used to calculate a maturation index. The index correlated with the age of the donor and was more dynamic in male than in female infants, suggesting a link to the increased male infant susceptibility to impaired neurodevelopment . To evaluate the impact of premature birth on the GABAergic system development, 9 male and 4 female one-month-old term and 8 male and 6 female one-month corrected-age very preterm infants, were compared using the same gene list and methodology. The maturation index for the GABAergic system was significantly lower (-50% $p<0.05$) in male preterm infants, with major alterations in genes linked to GABAergic function in astrocytes. These preliminary findings support further investigations of astrocytic GABAergic development as a key contributor to abnormal neurodevelopment in preterm infants.

Title: Activity of Transplanted MGE-derived Interneurons over Their Period of Programmed Cell Death

Authors: *B. RAKELA[1], W. R. MANCIA LEON[2], M. HOSEINI[4], A. R. HASENSTAUB[5], A. ALVAREZ-BUYLLA[3], M. P. STRYKER[6];
[1]Physiol., [3]Eli and Edythe Broad Ctr. for Regeneration Med. and Stem Cell Res., [2]Univ. of California San Francisco, San Francisco, CA; [4]Physiol., Univ. of California, San Francisco, CA; [5]Otolaryngology / Ctr. for Integrative Neurosci., UCSF, San Francisco, CA; [6]Ctr. for Integrative Neurosci, Dept Physiol, Univ. California Med. Sch., San Francisco, CA

Abstract: Two major classes of inhibitory cortical interneurons (cINs) derived in embryonic development from the medial ganglionic eminence (MGE), one expressing parvalbumin (PV) and the other somatostatin (SST), are required for the induction of critical period plasticity within primary visual cortex (V1) in mouse. After their migration from MGE into the developing cortex, they undergo a period of selection via programmed cell death around postnatal day 7, ~60% survive to integrate into the local circuit. Why do some cINs survive and others die? cIN precursors transplanted into postnatal hosts develop according to the intrinsic cIN timeline making it possible to study genetic mutations that would render the donor animal non-viable and offering access *in vivo* to early developmental time points where the same cells can be tracked across maturation. Earlier studies have shown that programmed cell death takes place at the same time after neurogenesis in both endogenous and transplanted cINs (Southwell et al., 2012), and suggest that activity of cINs at the onset of programmed cell death predicts their survival (Wong et al., 2018). Here, we have studied mutant cINs lacking the cell surface homophilic-binding proteins in the protocadherin (Pcdh)-γ gene cluster, in which programmed cell death of PV and SST cINs is significantly increased (Mancia et al, 2020), to probe the role of correlated activity in the selection of cINs for survival. We transplanted wildtype and mutant cINs expressing GCaMP7f in order to monitor their activity *in vivo* in relation to that of host neurons during the period of programmed cIN death. These data show that transplanted cINs are active before the time of programmed cell death, activity was more highly correlated among host neurons than among transplanted cINs, and activity among mutant cINs was even less correlated. These findings on correlated activity are consistent with the notion that the increased cell death of Pcdh-γ mutant cINs may be due to impairment of their connectivity with surrounding cells or to signaling events that depend on particular patterns of activity.

Title: The critical role of selenium in perineuronal net and GABAergic inhibitory circuit development

Authors: *A. SASUCLARK, M. PITTS;
Cell and Mol. Biol., Univ. of Hawaii, Honolulu, HI

Abstract: Parvalbumin interneurons (PVIs) are an important class of highly metabolic GABAergic interneurons known for their role in modulating neuronal synchrony and activity. During development, PVIs are selectively surrounded by perineuronal nets (PNNs), extracellular matrix structures that assist in stabilizing synaptic input to PVIs and serve to protect against oxidative damage. Conversely, redox dysregulation disrupts maturation of both PVIs and PNNs, and is hypothesized to be a key contributing factor to PVI/PNN abnormalities in neuropsychiatric disorders, most prominently schizophrenia. Oxidative stress is countered by a host of antioxidant enzymes, including multiple selenoproteins, a unique clade of proteins characterized by the co-translational incorporation of selenium as the amino acid selenocysteine. Moreover, selenoproteins are required for PVI development. Yet, despite the known indispensable role of selenoproteins in PVIs, their influence on the temporal dynamics of PNN maturation has yet to be investigated. Thus, primary neuron/glia mixed cultures were grown in serum-free media containing deficient (10 nM), optimal (100 nM), or excessive (1 uM) levels of selenium, and assessed at various time points for PNN maturation, antioxidant activity, and electrical activity using micro-electrode array (MEA) plates. At 28 days in vitro (DIV), the density of both PNNs and PNN-labeled PVIs were significantly increased in the 100 nM selenium condition relative to the other groups. In parallel, cellular GPx activity was significantly elevated in both the 100 nM and 1 uM groups relative to the 10 nM group at 28 DIV. Finally, we also observed significant differences in our MEA data at 28 DIV, with our 100 nM selenium condition exhibiting significantly lower mean firing rates and burst frequencies than the 10 nM condition. In conclusion, our results show that selenium is an important modulator of PNN maturation and suggest that selenium-deficiency impedes proper development of GABAergic inhibitory circuits.

Title: Neural regeneration in adult Drosophila

Authors: *I. FERNANDEZ-HERNANDEZ, E. MARSH, E. HU, M. A. BONAGUIDI;
Stem Cells Biol. and Regenerative Med., USC, Los Angeles, CA

Abstract: Adult neurogenesis occurs at different extents in specific locations of the vertebrate nervous system throughout life, and its deregulation has been linked to diverse pathologies. Therefore, interventions aimed at restoring functional neurogenesis upon injury and ageing represent a promising strategy to rejuvenate the adult nervous system. With an unparalleled genetic and functional toolbox, *Drosophila* represents a compelling model to accelerate the investigation of mechanisms promoting neural regeneration. Yet, generation of new neurons in the adult fly has been elusive thus far. We generated a modified lineage tracing system which allows for the sustained identification of adult-born neurons in the fly and their genetic manipulation in a cell type-specific manner. Here I present evidence for the continuous generation of new neurons in the optic lobes, the auditory/vestibular, as well as the olfactory system of adult flies in physiologic conditions. Furthermore, acute injury and oral administration of small molecules enhance neuronal regeneration. These results unveil the hidden proliferative capacity of the adult *Drosophila* nervous system, and underscore its potential to expedite the identification of conserved mechanisms and compounds promoting nervous system regeneration at the single-cell, circuitry, and functional levels.

Title: Caesarean delivery stimulates neural stem cell markers in the postnatal mouse brain.

Authors: *J. K. LESSING[1], X. ZHOU[2], H. SUN[1], J. WANG[1], M. G. DOMINGUEZ-BELLO[1], E. DICICCO-BLOOM[2];
[1]Dept. of Biochem. and Microbiology, Rutgers Univ., New Brunswick, NJ; [2]Dept. of Neurosci. and Cell Biol., Rutgers Univ., Piscataway, NJ

Abstract: Neurodevelopmental diseases - including autism spectrum disorder, attention deficit hyperactivity disorder (ADHD), and learning disability - are thought to be caused by a combination of genetic susceptibility and environmental triggers. Caesarean-section delivery (CS) may be an environmental trigger of developmental disorders. Human cohort studies correlate CS to a ~20% increased risk of developing autism, a ~17% increased risk of ADHD, and increases in metabolic diseases like obesity and type-1-diabetes. Though CS is a medical necessity, the World Health Organization estimates CS rates above 10% do not improve maternal or neonatal health, in healthy mothers. While the global CS rate in 2015 reached 21.1%, it was 31.7% in US in 2019. Disorders associated with CS may be caused by many factors, including perinatal distress, maternal anesthesia, altered perinatal hormonal environment, and disrupted vertical transmission of microbiome from mother to neonate. To study effects of CS on neurodevelopment we designed a model system in outbred mice. Previous data from this model indicates CS alters gut microbiome composition by weaning at postnatal day 21 (P21). Further, CS induces changes in ileal transcriptome at P7. We now extend the paradigm to consider how CS affects neurodevelopment. Timed-pregnant dams were allowed to give birth vaginally (control) or underwent terminal CS at gestational day 19. Pups from both groups were cross-fostered by dams giving birth in the previous 24-hours. Following sacrifice on P8, we isolated cerebellum, hippocampus, and medial prefrontal cortex based on associations with neurodevelopmental diseases and periods of neurogenesis. Cerebellar external germinal layer proliferation peaks from P5-P10 and continues to P18; hippocampal dentate gyrus precursors proliferate throughout life; medial prefrontal cortex serves as negative control because neuronal

precursor proliferation is largely complete by E17.5, though gliogenesis is ongoing. Brain region protein extracts were assessed by immunoblotting for neurodevelopmental markers. Preliminary data in hippocampus shows that male mice that underwent CS had higher levels of proliferation marker cyclin E ($p = 0.001$; $n = 7$/group) and potentially increased doublecortin ($p = 0.08$). No significant differences were detected in females. In sum, CS was found to increase levels of neural stem cell markers in the hippocampus, and other regions are being analyzed. Interestingly, this CS effect was observed only in males. Future studies will analyze additional brain regions and time points, and investigate transcriptional and microbiome-based mechanisms underlying these effects.

Title: Tamoxifen administered via intraperitoneal injections leads to long-term suppression of adult hippocampal neural progenitor cell proliferation

Authors: *N. DEVASTHALI, B. M. SMITH, D. L. EINSTEIN, P. SARCHET, E. D. KIRBY; Dept. of Psychology, The Ohio State Univ., Columbus, OH

Abstract: Research on neurogenesis in the adult rodent hippocampus frequently uses the Cre-Lox system as a method for manipulating gene expression in the adult neurogenic cell lineage. Cre recombinase catalyzes recombination of LoxP-flanked genetic sequences, which can be used to knock down gene expression by excising LoxP-flanked target genes, or to express a novel transgene, via removal of a LoxP-flanked stop sequence. To specifically target such recombination to adult neural stem and progenitor cells, cell specific promoters, such as Nestin or GLAST, are often used to drive a TAM-inducible version of Cre: $CreER^{T2}$. In this system, TAM is required to drive Cre nuclear localization and thus LoxP recombination, but there are conflicting studies about the effects of TAM itself on neurogenesis. Thus, we investigated the effects of TAM on adult hippocampal neurogenesis. Male and female adult C57/Bl6J mice were treated with 5 daily IP injections of either TAM (n=11) or oil (n=12). On the last 3 days of TAM treatment, all mice also received daily IP injections of the mitotic marker 5-bromo-2'-deoxyuridine (BrdU). 21 days later, all mice received an IP injection of 5-ethynyl-2´-

deoxyuridine (EdU) 2h before perfusion and brain harvest. We found no significant differences in body weight between groups during TAM injections, but 21 days after injections, female TAM-treated mice weighed significantly more than oil-treated female mice. TAM had no effect on body weight in males. Neither sex showed any differences between groups in the number of surviving BrdU+ cells or in BrdU co-labeling with neuronal phenotype markers 3 weeks after TAM. In contrast, cell proliferation was significantly suppressed 3 weeks after TAM in both sexes: TAM treated mice had fewer total EdU+ proliferating cells, fewer EdU+/Sox2+ proliferating intermediate progenitors, and fewer Sox2+ total intermediate progenitors than oil treated mice. Our findings suggest that TAM suppresses the proliferation of progenitor cells 3 weeks after TAM is administered, while neurogenesis that begins during the period of TAM administration is not affected 3 weeks later. Similarly, body weight is unaffected by TAM during administration, but in female mice, previous TAM exposure leads to greater weight gain in the weeks following TAM. These results indicate that when studying genetic models that rely on TAM-dependent Cre recombination, oil injection is not an appropriate control for TAM injections even if evaluation time points are weeks after TAM. Rather, all mice should receive TAM and genotype comparisons should be used to avoid the confound of TAM effects of neurogenesis processes.

Title: Activity of Ciliated Ependymal Cells Controls Directional Flow and Polarity of the Ciliated Cells

Authors: *K. MELLANSON[1], N. PEUNOVA[2];
[1]State Univ. of New York, Stony Brook, EAST SETAUKET, NY; [2]Stony Brook Univ., Stony Brook, NY

Abstract: ACTIVITY OF CILIATED EPENDYMAL CELLS CONTROLS DIRECTIONAL FLOW AND POLARITY OF THE CILIATED CELLS Kennelia Mellanson[1,2,3], Tatyana V. Michurina[2,3], Anatoli Mikhailik[2,3], Ken-ichi Takemaru[4], Grigori Enikolopov[2,3], and Natalia Peunova[2,3] [1]Molecular and Cellular Pharmacology, SBU, NY 11794[2]Center for Developmental Genetics, SBU, NY 11794[3]Dept. of Anesthesiology,

Renaissance School of Medicine, NY 11794 [4]Dept. of Pharmacological Sciences, SBU, NY 11794
Efficient directional flow of the cerebrospinal fluid along of the walls of the brain ventricles requires coordinated and robust activity of the ciliated cells in the ependymal layer of the ventricles. Reciprocally, flow is recognized as a signal by multiciliated ependymal cells and by primary cilia of neural stem cells. Compromised flow has a negative feedback effect on the activity of the multiciliated cells and on the division of neural stem and migration of progenitor cells in the subventricular zone (SVZ) of the lateral ventricles. We investigated the effect of impaired ciliated cell activity in mouse mutant lines on directional flow, cilia beat frequency (CBF), ciliated cell polarity, and proliferation and migration of progenitor cells We studied the explants of the brain ventricles using live imaging, assessing the function of the ciliated cells in the experimental setup that we have developed to measure in parallel the ciliary beat and directional flow and to quantify the responses to various types of treatment within the same group of individual cells before and after a particular treatment, (rather than applying conventional averaging of the responses across different regions of a tissue), thereby significantly increasing the accuracy of the ciliary function analysis. We applied super-resolution fluorescent microscopy to determine the effects of mutations on the ciliated cell structure. We found that conditional mutation of CEP164, a component of the distal appendage of the cilia, when targeted specifically to the ciliary cells, compromises directional flow and CBF. Specifically, it affects the overall arrangement of the ciliated cells, their shape, and their rotational, translational, and tissue-level polarity. Ependymal cells of the CEP164fl/fl mutant are smaller and are more densely packed; their basal bodies cover a greater fraction of the apical surface of the ciliated cell and show greater displacement. We also show that decreased number of cilia generated in CEP164 mutant due to the defects in the docking of the basal bodies to the apical membrane of the ciliated cells. We also studied how proliferation and migration of neural progenitors in the CEP164$^{-/-}$ SVZ is dependent on the fluid flow.

Title: Similar reactive proliferation and neurogenesis in male and female rat dentate gyrus following alcohol dependence.

Authors: *K. R. THOMPSON, S. P. GUERIN, N. N. NAWARAWONG, K. NIXON; Pharmacol. & Toxicology, The Univ. of Texas at Austin, Austin, TX

Abstract: Neurodegeneration occurs with excessive alcohol consumption, the hallmark of an alcohol use disorder (AUD). However, in abstinence, cognitive and structural recovery is observed. Adult hippocampal neurogenesis is a mechanism by which recovery may occur in the hippocampus following alcohol dependence. Reactive neural stem / progenitor proliferation and subsequent neurogenesis has been reported in male rats following dependence, but it is unknown if reactive neurogenesis occurs similarly in females. To study this, we quantified the effects of alcohol dependence on proliferating cells in the dentate gyrus using 5'-bromo-2'-deoxurdidine (BrdU) and immature newborn neurons using Neuronal Differentiation 1 (NeuroD1) in the dentate gyrus. Ethanol was given to adult Sprague-Dawley rats (PND 65-70) by intragastric gavage (25% w/v ethanol in vanilla Ensure Plus®) every 8 hours for 4 days. Control animals received an isocaloric caloric diet. Average intoxication behavior was 1.4 ± 0.1 for females (0-5 scale; $p<0.05$ vs. males) corresponding to hypoactive activity and 1.8 ± 0.1 for males corresponding to ataxic with an elevated abdomen, resulting in animals receiving 10.9 ± 0.2 g/kg/day (F) and 9.8 ± 0.2 (M) ethanol and blood ethanol concentrations of 317.2 ± 19.8 (F) and 358.4 ± 15.7 (M). Withdrawal severity was scored 10 - 28 hours after the last dose of ethanol. Female rats averaged 0.3 ± 0.1 and males 0.6 ± 0.1 (0-4 scale; hyperactivity) with peak withdrawal scores of 2.1 ± 0.3 (F; arched back) and 2.7 ± 0.2 (M; general tremor). Females had significantly lower intoxication behavior, but no other differences were found between groups. Rats were injected with BrdU (300 mg/kg, i.p.) and sacrificed 2 hours later at either 7 days (T7) or 14 days (T14) after the last dose of ethanol. At T7, BrdU+ cells were significantly higher in ethanol-exposed animals (main effect of diet, $p<0.05$), but no differences were found for sex. As previously shown, at T14 NeuroD+ cells were significantly higher in the inner 1/3 of the granule cell layer of ethanol-exposed animals and in males (main effects of diet and sex, $p<0.05$), but no significant diet by sex interaction. Potentially ectopic NeuroD+ cells were also quantified (hilus, molecular layer), but no significant differences were found between either diet or sex groups. These results suggest that alcohol-induced reactive proliferation and neurogenesis are similar in male and female rats, but that basal rates of neurogenesis differ. Further, the lack of ectopic newborn neurons could indicate that reactive neurogenesis is also beneficial in adult female rats following alcohol dependence and may contribute to recovery of the hippocampus.

Title: Microglia-neuroblast interactions in the developing rostral migratory stream

Authors: *S. MELLER[1], L. HERNANDEZ[2], E. MARTÍN LÓPEZ[4], T. LIBERIA VAYÁ[3], C. A. GREER[5];
[1]Neurosurg. & Neurosci., Yale Univ., NEW HAVEN, CT; [3]Neursurgery & Neurosci., [2]Yale Univ., New Haven, CT; [4]Neurosurg., Yale Univ. Sch. of Med., New Haven, CT; [5]Dept Neurosurg, Yale Univ. Sch. Med., New Haven, CT

Abstract: This work examines the interactions between microglia, neuroblasts and radial glia in the developing rostral migratory stream (RMS) and investigates if microglia ablation disrupts neuroblast migration. CX3CR1-GFP mice, which express EGFP under the Cx3cr1 locus in microglia, were electroporated with a tdTomato plasmid in the cerebral lateral ventricles at postnatal day 0 (P0) to label proliferating neuroblasts and sacrificed at P4, P7, and P14. Additional pups were sacrificed at P8 and P21 for electron microscopy analysis. To selectively deplete microglia in vivo, CX3CR1-GFP/DCX-DsRed mice, which express Ds-Red under the dcx promoter, were injected with liposomal clodronate in the lateral ventricles bilaterally at P0. Mice were injected with 25 mg/kg BrdU two hours later to label dividing cells and sacrificed at P3. To assess microglia and neuroblast density, cells were segmented and quantified using Fiji (ImageJ) software. Differences in cell density were evaluated with a two-way ANOVA and Bonferroni's multiple comparisons posthoc test. Microglia closely associate with migrating neuroblasts in the RMS core and with radial glia processes at the dorsal border during early postnatal development. There was a significant decrease in RMS microglia density three days after liposomal clodronate injection. However, this was not accompanied by a corresponding decrease in neuroblast density at either the start of the RMS or along its descent. Thus, we found that microglia interact with migrating neuroblasts and radial glia during early postnatal development of the RMS. However, microglia ablation did not impact the density of migrating neuroblasts in the RMS. In ongoing work we are using a conditional genetic model to examine the effects of microglia knockdown on neuroblast migration and RMS architecture at later developmental ages.

Title: Similar Morris Water Maze-induced neuronal activation in the dentate gyrus following alcohol dependence: relationship to adult neurogenesis

Authors: *N. N. NAWARAWONG[1], C. G. NICKELL[2], J. R. PAULY[2], K. NIXON[1,2]; [1]Pharmacol. & Toxicology, The Univ. of Texas at Austin, Austin, TX; [2]Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: Abstinence from alcohol leads to structural and functional recovery in a number of brain regions, especially the hippocampus. Striking increases in neural stem cell (NSC) proliferation and subsequent "reactive neurogenesis" coincides with the structural recovery of the hippocampal dentate gyrus (DG) in a model of an alcohol use disorder (AUD). However, whether these reactively born neurons are functionally integrated into hippocampal circuits is not known. Utilizing a triple label immunohistochemical approach, we previously showed newborn neuronal c-Fos activation in the DG of ethanol-treated rats following Morris Water Maze (MWM) training / testing. Despite the specificity this method provided, we were limited by minimal DG c-Fos expression, which is known to decline with repeated trainings. Unlike c-Fos, the immediate early gene (IEG) Arc remains more consistent with repeated training experiences. Thus, we utilized Arc to examine whether neurons born during alcohol-induced reactive neurogenesis are incorporated into a learned MWM-induced ensemble. Male Sprague-Dawley rats were gavaged with either a 25% (w/v) ethanol diet or an isocaloric control diet every 8 h for 4 days in a Majchrowicz model. Rats received a mean dose of 9.7 ± 0.2 g/kg/day resulting in peak blood ethanol concentrations of 401 ± 14 mg/dL. Typical withdrawal severity was observed with scores averaging 1.4 ± 0.2 out of four (tail tremors) and peaking at 3.6 ± 0.1 (chattering teeth). On day 7 of abstinence (peak reactive NSC proliferation), rats were injected with bromodeoxyuridine (BrdU) to label dividing cells and left undisturbed for 6 wks. In the 7th week, all rats underwent the MWM for 4 days, then were sacrificed and tissue was collected 90 min after the final MWM session. We previously reported significantly more newborn neurons (BrdU+/NeuN+) in the dentate gyrus of the ethanol-treated rats compared to controls ($p<0.05$). Despite this increase, there were no observed group differences in the number of c-Fos+ cells or MWM-activated newborn neurons (BrdU+/c-Fos+/NeuN+). Here, we found 3.4x more Arc+ cells in the DG following MWM training / testing compared to our previous report of c-Fos+ cells ($p<0.05$). Despite the greater quantity of Arc+ cells overall, there was no group difference in the number of Arc+ cells in the DG of ethanol rats compared to controls, similar to our prior report with c-Fos. Thus, MWM training induces the IEG Arc similarly between control and ethanol rats with reactive neurogenesis. These data contribute to our growing understanding that ethanol-induced reactive neurogenesis may contribute to recovery of functional hippocampal circuitry.

Title: Testing time and light as environmental factors regulating behavioral phenotype expression in FMR1-KO mice

Authors: *M. ARROYO ARAUJO, R. KAT, R. HAVEKES, P. MEERLO, M. J. H. KAS; Groningen Inst. for Evolutionary Life Sci., Univ. of Groningen, Groningen, Netherlands

Abstract: The value of animal models in biomedical research relies on their capacity to partly represent a human disorder and to predict an outcome given specific baseline conditions. However, the translation of animal models into clinical trials has proven to be challenging given the high rate of conflicting results found in preclinical literature. One of the most informative approaches to investigate the consistency of results in big pools of scientific literature is by performing a systematic search and meta-analysis of published studies. The inconsistency in phenotype expression of the Fragile-X syndrome mouse model (FMR1-KO) drove us to run a systematic search on the behavioral phenotype of this line; 3194 articles showed as hits for the search terms used. Out of this set of publications, 336 articles were fully screened to extract the behavioral outcome data reports. Additionally, study characteristics of the studies' methodology were collected to inform us whether environmental conditions could explain the inconsistency seen in the phenotype expression. Given the large variability of results between studies and the incomplete methodological reporting, we conducted an experiment to investigate whether environmental factors such as the time of testing relative to the light-dark cycle and the light conditions during the test could influence the phenotype differences between FMR1 KO mice and their wild-type (WT) littermates. To this end, four of the most used behavioral tests according to our meta-analysis results were performed; these tests measure some of the typical Fragile-X/autism-like symptoms. Elevated plus maze, Open field test (OF), Acoustic startle response, and Pre-pulse inhibition (PPI) were carried out at the beginning of the light or dark phase. Animals were tested under lighting conditions matching those of their housing room at the time of testing or the opposite. With this study, we aimed to separate the influence of the lighting conditions *per se* from the possible circadian influence. Results suggest that the tests we performed are differentially sensitive to light and time of day. For example, while in the OF there was a robust hyperactivity phenotype in all conditions, in the PPI test there was a larger variation

in terms of the direction of the genotype effect depending on the environmental conditions. Altogether, this suggests that reporting of pre-clinical studies should become more transparent, and that environmental factor's influence should be further explored given the suggested impact on the interpretation and use of animal models and their potential translation to clinical trials.

Title: Parental Reports on Early Autism Behaviors in Their Children with Fragile X Syndrome as a Function of Infant Feeding

Authors: *C. J. WESTMARK;
Univ. of Wisconsin, Madison, WI

Abstract: This study evaluates the prevalence of autistic behaviors in fragile X syndrome as a function of infant diet. Retrospective survey data from the *Fragile X Syndrome Nutrition Study*, which included data on infant feeding and caregiver-reported developmental milestones for 190 children with fragile X syndrome enrolled in the Fragile X Online Registry with Accessible Database (FORWARD), were analyzed. Exploratory, sex-specific associations were found linking the use of soy-based infant formula with worse autistic behaviors related to language in females and self-injurious behavior in males. These findings prompt prospective evaluation of the effects of soy-based infant formula on disease comorbidities in fragile X syndrome, a rare disorder for which newborn screening could be implemented if there was an intervention. Gastrointestinal problems were the most common reason cited for switching to soy-based infant formula. Thus, these findings also support the study of early gastrointestinal problems in fragile X syndrome, which may underly the development and severity of disease comorbidities. In conjunction with comorbidity data from the previous analyses of the *Fragile X Syndrome Nutrition Study*, the findings indicate that premutation fragile X mothers should be encouraged to breastfeed.

Title: Auditory Hypersensitivity and Perceptual Disruptions in a Rat Model of Fragile X Syndrome

Authors: *B. AUERBACH[1,2], X. LIU[1,2], K. RADZIWON[2], R. SALVI[2];
[1]Mol. & Integrative Physiol., Univ. of Illinois at Urbana-Champaign, URBANA, IL; [2]Ctr. for Hearing and Deafness, State Univ. of New York at Buffalo, Buffalo, NY

Abstract: Abnormal sensory processing is a hallmark of autism spectrum disorders (ASD) and related neurodevelopmental disorders like Fragile X syndrome (FX), most notably manifesting as extreme sensitivity to sound (i.e. hyperacusis). Auditory hypersensitivity is not only a pressing clinical problem in FX and ASD, but it also likely reflects fundamental circuit defects that extend to more complex but less accessible features of the disorders, such as impaired communication and language development. We have developed a model of auditory hypersensitivity in a *Fmr1* knockout (KO) rat model of FX using an operant conditioning task to assess auditory reaction time-intensity (RT-I) functions, a reliable psychoacoustic measure of loudness growth, using a variety of stimulus frequencies, bandwidths and durations. *Fmr1* KO and littermate wildtype (WT) rats learn the task at the same rate and reach the same level of peak performance but *Fmr1* KO animals exhibited faster auditory RTs over a broad range of intensities and steeper RT-I slopes compared to WT controls, consistent with perceptual evidence of excessive loudness growth. *Fmr1* KO animals also displayed altered perceptual integration of sound duration and bandwidth compared to WT controls, suggesting that faster RTs in these animals is evidence of aberrant auditory processing rather than generalized hyperactivity or altered motor responses. This novel phenotype has the potential to uncover fundamental deficits at the core of FX and ASD pathophysiology while also having direct clinical implications for one of the most disruptive features of these disorders.

Title: Altered Developmental Trajectory in Fragile X Knockout Rats Revealed By Ultrasonic Vocalizations

Authors: *J. H. BLADON[1], A. HOOKER[1], Z. PRANSKE[1], N. DIAZ-RODRIGUEZ[1], S. P. JADHAV[2];
[2]Psychology, [1]Brandeis Univ., Waltham, MA

Abstract: Fragile X is the single most prevalent monogenetic cause of intellectual disability. Those with Fragile X are more likely to exhibit behavioral disabilities consistent with Autism Spectrum Disorder (ASD), that include delayed developmental milestones, poor communication skills, and cognitive inflexibility. One common early indicator Autism and Fragile X is delayed development of social skills. To more closely examine the altered developmental trajectory as it relates to the pathology of Fragile X, we examined the vocal development of young Fragile X knockout rats (FMRP null) using a maternal separation model. To do this, we recorded ultrasonic vocalizations (USV's) for three minute every two days in P4 to P18 rats during social isolation in a soundproof chamber. We then used image processing software in Matlab (DeepSqueak & USVseg) to isolate and analyze vocalizations. We found significant sex, age, and genotype effects, as well as interactions between the three on the number, principal frequency, duration, and tonal variety of the pups' USVs. Across all sexes and genotypes, call rate and length began low, peaked around P8, and fell again as the animals grew older. Interestingly, while call rate was not impacted by genotype, call length peaked at an older age in Fragile X males than it did in controls. Overall, calls became significantly shorter, higher in frequency, and more complex in their structure as animals aged (ancova on age, all $p<.0001$). These changes occurred abruptly within an animal, such that consecutive recordings in the same animal could be completely different. After considering age, we found significant effects of genotype on call duration, call frequency, and the variance of frequency within calls. Fragile X pups began with a higher call frequency but that fell to below wildtype rats with age (ancova, genotype*age $f(1)=7.64$, $p<.01$). Fragile X rat pups also uniformly had lower variance in the shape of their calls (ancova, tonality*age $f(1)=5.21$, $p<0.05$ and duration variance*age $f(1)=4.1$, $p<0.05$). These results first provide a normative description of rat vocal development during the initial two weeks of development. Then, by describing alterations in this trajectory in Fragile X null pups, they provide validity to the rat knockout model of Fragile X for studying altered communication skills during development.

Abstract: Autism spectrum disorder (ASD) is one of the most complex and severe neurodevelopmental psychiatric disorders, characterized by impaired social interaction and communication with multiple etiologies. Fragile X syndrome (FXS), the most common monogenetic, inherited disorder, is a leading genetic cause of ASD. FXS results from silencing the Fragile X Mental Retardation gene (*Fmr1*) and the loss of its protein product FMRP, an inhibitor of protein synthesis. Since the initial description of *Fmr1* knockout rats, there have been few studies on the behavioral characterization of this model. However, it is essential to define its phenotypes before using them in translational studies. Here, using the elevated plus maze (EPM), an open field task (OFT), and observational cued fear conditioning, we investigated anxiety responses and social interaction behavior and learning and memory in male *Fmr1* knockout (KO) Sprague Dawley rats. Consistent with the literature but unlike FXS patients, *Fmr1* KO rats did not show elevated anxiety levels. During the OFT, the rats (8-9 weeks, n=8/group) could freely choose to interact with a novel object (NO) or a novel rat (NR) matched by their sex and age. We found that the *Fmr1* KO rats interacted with the NR less frequently than wild-type (WT) rats. Also, the ratio of the time spent with the NR to the time spent with the NO was less for *Fmr1* KO rats than that of the WTs, suggesting a social deficit similar to the social phobia FXS patients present. Next, we placed the *Fmr1* KO or WT rats (observer) in an auditory fear conditioning chamber with a mesh divider separating it from a NR on the other side (demonstrator). There was a black plexiglass panel covering the grid floor on the observer rats' side so they could neither see nor feel the shocks during the training. However, they could see, hear, and smell the demonstrator rat through the mesh divider during the conditioning session in which the demonstrator was presented with several pairings of an auditory cue and foot shock. During this session, the observer rats could also hear the auditory cue that was presented to the demonstrator rat. During testing to the auditory cue in a novel context, we found that while both *Fmr1* KO and

WT observer rats acquired fear to the auditory cue, which occurred without ever receiving any foot shock presentations, *Fmr1* KO rats freeze significantly more than the WT rats. Taken together, these data suggest that *Fmr1* KO rats are impaired in social behavior but have improvements in observationally learned cued fear memory, which is not likely due to differences in anxiety. These results have important implications for translational studies on the FXS rat model.

Title: Chronic treatment with the selective GSK-3 inhibitor SB216763 reverses behavioral impairments in the Fmr1 knock out mouse model of Fragile X Syndrome

Authors: *J. KEALY[1], A. M. THORNTON[2], A. FREEBURN[1], C. GREENE[1], B. GARRONE[3], C. MILANESE[3], F. P. DI GIORGIO[3], C. K. CALLAGHAN[1], M. BIANCHI[1];

Abstract: Fragile X Syndrome is a complex neurodevelopmental disorder resulting from an inactivation of the *FMR1* gene on the X chromosome, leading to a loss of FMRP protein expression. Individuals with Fragile X Syndrome can be mildly or severely affected, with symptoms including intellectual disability, developmental delay, autism-like symptoms, and anxiety, amongst others. In mice, knocking out the *Fmr1* gene disrupts a wide range of signaling pathways, including the glycogen synthase kinase-3 (GSK-3) pathway, and results in a behavioral phenotype analogous to the human condition including cognitive impairment, disruption of social behavior, and an increase in stereotypic behaviors. For this study, male *Fmr1* knock out (*Fmr1*$^{-/y}$) mice and c57BL6/J wild type (WT) controls underwent behavioral testing following chronic treatment with SB216763 (30 mg/kg, one intraperitoneal dose per day over 10 days), an inhibitor of both GSK-3α and GSK-3β. Marble burying was used as a measure of stereotypy/repetitive behavior, and sociability was measured using the 3-chamber sociability task. Locomotor activity was assessed across the three trials of the 3-chamber sociability task. SB216763 significantly reduced marble burying in *Fmr1*$^{-/y}$ mice. SB216763 also reversed the social discrimination deficit observed in *Fmr1*$^{-/y}$ mice. There was no social recognition deficit in vehicle-treated *Fmr1*$^{-/y}$ mice and GSK-3 inhibition had no effect in *Fmr1*$^{-/y}$ mice. In 3-chamber

sociability trials where hyperlocomotion was observed, SB216763 had no effect on attenuating this behavior. These data show that GSK-3 inhibition is a robust strategy for ameliorating some of the behavioral deficits seen in *Fmr1*$^{-/y}$ mice, highlighting a signaling mechanism for novel therapeutics for treating some symptoms of Fragile X Syndrome. All animal experiments were approved by the Trinity College Dublin Animal Research Ethics Committee and the Health Products Regulatory Authority under the European Union directive 2010/63/EU.

Title: Mitochondrial inefficiency: from abnormal metabolism to behavioral deficits in Fragile X

Authors: *P. LICZNERSKI[1], S. NAIR[2], E. A. JONAS[1];
[1]Yale Univ. Sch. of Med., New Haven, CT; [2]Yale Univ., New Haven, CT

Abstract: Loss of function of the gene (Fmr1) encoding Fragile X mental retardation protein (FMRP) results in unregulated, elevated mRNA translation and aberrant synaptic morphology. We have recently discovered a completely novel function of a “leak channel” termed ATP synthase c-subunit leak channel (ACLC), formed by the C-subunit octamer within the ATP-synthase in the mitochondrial inner membrane. We showed in Fragile X syndrome that pharmacological inhibition of ACLC by the ATP synthase modulator Dexpramipexole (Dex) normalizes the elevated protein translation rates, induces synaptic maturation, and attenuates autistic behaviors, which raises the spectrum of new possibilities for therapeutic intervention in FX. We have also found that Fragile X neurons have a mitochondrial leak-dependent metabolic phenotype that is normalized by pharmacological inhibition of ACLC. We here further

investigate the effects of ACLC activity on mRNA translation. We find preliminarily that Dex alters the proximity of specific ATP synthase mRNAs to mitochondria, which could contribute to changes in ATP synthase stoichiometry by inducing assembly of ATP synthase and eliminating free c-subunit in the inner mitochondrial membrane. This stoichiometric alteration provides for a long-term change in the efficiency of ATP synthesis that may be required for normalization of behavioral abnormalities in Fragile X mice.

Abstract: Neural and sensory hyperexcitability are prominent in many individuals with Fragile X Syndrome (FXS). Previous work from our group and others has established translational electrophysiological biomarkers for sensory processing abnormalities in FXS, primarily at the EEG scalp/sensor level. While EEG provides robust equivalency across FXS patients and Fmr1 KO mice, the neural sources of these abnormalities remain poorly characterized. Transformation of scalp electrical data into source space allows for the separation of temporal and frontal cortical sources of neural activity, and thus can better characterize the pathways in which functional alterations exist. Participants (36 adolescents and adults with FXS and 39 age- and sex-matched typically developing controls (TDC) listened passively to an auditory chirp stimulus during continuous recording of dense-array EEG. We constructed a depth-weighted minimum norm estimate. Current source density was computed across a resultant triangular mesh (15,002 vertices) which represented the cortical envelope. Vertices were parcellated into 68 cortical nodes including sources of interest in left and right temporal and frontal cortices and a control node in cuneus. Morlet wavelets were calculated on source waveforms to reconstruct phase and

amplitude characteristics of neural responses to auditory chirps. In the temporal source, individuals with FXS showed increased gamma power, t(73)=-2.56, p=.012, theta power t(73)=-3.11, p=.003, and theta/alpha inter-trial phase coherence (ITPC) to stimulus onset t(73)=-2.37, p=.02, and decreased gamma phase synchrony to the auditory stimulus at 40 Hz, t(73)=2.18,p=.032, compared to TDC. For frontal and cuneus sources the only difference was during stimulus onset. Increased gamma power in temporal cortex was significantly correlated with increased autism-like behaviors and negative cognitive/clinical scores, whereas increased gamma phase synchrony was associated with positive clinical/cognitive scores. Disentangling early sensory (temporal) sources of group differences from top-down (frontal) sources is an important due to the orientation of Heschl's gyrus, which confounds temporal and frontal signals at the scalp. Our findings confirm expectations of a primarily early sensory deficit in temporal cortex, while suggesting that multiple sources may contribute variance in scalp signal power. Early sensory processing in auditory sensory cortex is thus the likely primary driver of FXS-related auditory processing deficits in neocortex in the chirp task, rather than top-down modulation via frontal cortices.

Title: Contagious behavior deficits in the mouse model of fragile X syndrome

Authors: *R. GONZALES-ROJAS, A.-N. RANA, P. MASON, C. RENFRO, V. ANNALURU, H. LEE;
Cell. and Integrative Physiol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Imitative deficits in patients with autism spectrum disorders (ASDs) foundationally impact their abilities to learn and socially interact. However, the exploration of these deficits in preclinical autism mouse models is limited. Fragile X syndrome (FXS) is a common form of inherited intellectual disabilities with a high risk of co-morbid ASDs, and the mouse model of FXS—*Fmr1* KO mice—recapitulates many autistic behaviors. Wild-type (WT) mice exhibit a rudimentary form of imitation through socially contagious itch behavior. When presented with a

video of a scratching demonstrator mouse, WT mice will look towards the screen and copy the observed behavior, as opposed to WT mice watching an ambulating demonstrator mouse as a control stimulus. We recently demonstrated that adolescent (P45-P59) and adult (P60-P130) male *Fmr1* KO mice fail to imitate scratching behavior, relative to age-matched WT controls (Gonzales-Rojas & Rana *et al*. 2020, *Scientific Reports*). Furthermore, WT and *Fmr1* KO mice showed no differences in the total number of looks towards scratching or ambulating demonstrator stimuli. This look behavior phenotype is notable because patients with ASDs show well-documented eye contact deficits, and FXS patients also show impaired vision. However, our findings illustrate that contagious itch deficits in *Fmr1* KO mice are independent of visual impairments. We are currently exploring if our autism mouse model shows similar deficits in other forms of contagious behavior. Collectively, we hope our novel behavioral assessments will enable the preclinical exploration of targeted therapeutic treatments for learning impairments in ASDs.

Title: BDNF-induced BDNF release mediates presynaptic LTP in the hippocampus

Authors: *C. BERTHOUX[1], K. NASRALLAH[1], P. E. CASTILLO[1,2];
[1]Dominick P. Purpura Dept. of Neurosci., [2]Dept. of Psychiatry and Behavioral Sci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The nervous system has evolved to adjust behavior in response to new experiences, ultimately ensuring animal survival. This crucial process mainly relies on activity-induced modifications of synaptic contacts, such as long-term potentiation (LTP) and depression (LTD). The mechanisms underlying these forms of plasticity are remarkably diverse and not fully understood. One key mediator of synaptic plasticity is the brain-derived neurotrophic factor (BDNF) and its receptor, tyrosine kinase B (TrkB). Despite many years of research, how exactly

BDNF/TrkB signaling mediates plasticity remains unclear. In the dentate gyrus, the main input region of the hippocampus proper, we have recently identified a presynaptic form of LTP at the mossy cell (MC) to dentate granule cell (GC) synapse. While MC-GC LTP requires postsynaptic BDNF/TrkB signaling, the precise source of BDNF and the downstream signaling pathway supporting synaptic plasticity is unknown. Here, we report that selective deletion of *Bdnf* in either the presynaptic (MC) or the postsynaptic (GC) neuron impaired MC-GC LTP in acute mouse hippocampal slices, indicating that both pre- and postsynaptic BDNF are required for this form of plasticity. Using two-photon live imaging of a BDNF sensor (BDNF-pHluorin) in combination with selective pharmacology and conditional knockout, we found that BDNF released from the presynaptic compartment can elicit postsynaptic BDNF release in a TrkB- and calcium-dependent manner. In addition, activation of type-1 cannabinoid (CB_1) receptors, which are highly expressed in MC axon terminals, negatively regulated presynaptic BDNF release and LTP, likely through inhibition of voltage-gated calcium channels. Finally, we found that BDNF is required for the induction of MC-GC LTP following exposure to an enriched environment. Altogether, these results strongly suggest that BDNF-induced BDNF release mediates presynaptic LTP and may contribute to dentate gyrus-dependent learning, as well as neuropsychiatric disorders such as epilepsy and anxiety.

Title: Heterosynaptic endocannabinoid-mediated long-term potentiation of non-nociceptive synapses

Authors: *A. D. FRANZEN, R. T. PAULSEN, B. D. BURRELL;
Univ. of South Dakota, Vermillion, SD

Abstract: Chronic pain is pain lasting longer than three months and while prevalent, its mechanism is poorly understood. One element of this condition is enhanced non-nociceptive afferent input onto nociceptive circuitry. Our laboratory studies modulation of nociceptive vs. non-nociceptive synapses via dual intracellular recordings in the CNS of the medicinal leech (*Hirudo verbana*). Previous results from our lab show that high-frequency stimulation (HFS) of a nociceptive neuron results in heterosynaptic potentiation of a non-nociceptive synapse. In this

study we examine how endocannabinoids, which are normally associated with synaptic depression, mediate LTP. HFS of the nociceptor elicits a depression of tonic inhibition onto the non-nociceptive afferent and this depression is 2-AG and TRPV-dependent. This resulting disinhibition leads to potentiation of the non-nociceptive synapses that requires NMDA receptor activation. We have also observed that this potentiation is PKMζ-dependent. As PKMζ is a neuron-specific aPKC isoform believed to be a memory engram, further studies are underway to determine PKMζ's role in eCB-mediated plasticity. These findings are relevant to understanding how the endocannabinoid system modulates pain and the utility of cannabinoid-based treatments to treat persistent pain.

Title: Endocannabinoid-mediated enhancement of hippocampal long-term potentiation

Authors: *F. LEMTIRI-CHLIEH, E. S. LEVINE;
Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: It is widely accepted that exogenous cannabinoids can impair short-term memory and cognition in humans and other animals. This is likely related to the inhibition of long-term potentiation (LTP), a form of synaptic plasticity, by the global and sustained activation of CB1 cannabinoid receptors in the presence of exogenous agonists. Conversely, the temporally and spatially-restricted release of endogenous cannabinoid ligands may enhance synaptic plasticity in a synapse-specific manner. The functional roles of endocannabinoids (eCBs) are complex because they modulate synaptic transmission via suppression of GABA and glutamate release, with opposing effects on postsynaptic excitability. We examined the role of eCB signaling in LTP by recording field excitatory postsynaptic potentials (fEPSPs) in the CA1 stratum radiatum in hippocampal slices from juvenile mice. Significant LTP (~50% increase from baseline) was induced by either 1 or 3 trains of TBS. The magnitude of this potentiation was significantly reduced by preventing cannabinoid receptor activation with the selective CB1 receptor antagonist NESS-0327 (~25% increase from baseline). LTP was inhibited to a similar extent by preventing the synthesis of the endogenous ligand 2-AG using the DAG lipase inhibitor DO34. A comparable effect of CB1 blockade was also observed with pharmacologically-induced LTP. These results suggest that activation of CB1 receptors by endogenous 2-AG normally enhances

the magnitude of LTP, leading to the prediction that the predominant eCB effect under these conditions is to suppress inhibition. We therefore examined TBS-induced LTP while blocking inhibitory synapses with the GABA-A receptor blocker picrotoxin (PTX). The addition of PTX alone caused a slight, but not significant, increase in LTP. Consistent with our hypothesis, PTX completely prevented the effect of blocking CB1 receptors, indicating that intact GABAergic transmission is required for the eCB effect. The presence of PTX did not unmask any enhancing effect of CB1 receptor blockade, suggesting minimal eCB-mediated suppression of glutamate release under these conditions. These results indicate that 2-AG activation of CB1 receptors enhances TBS-induced and pharmacologically-induced LTP, and this effect is caused by the actions of 2-AG at inhibitory synapses.

Title: Cholinergic signals optimize information transmission and learning in the hippocampus

Authors: *R. SHARMA, S. NADKARNI;
IISER PUNE, Pune, India

Abstract: Neuromodulators regulate and fine-tune nonlinear membrane and synaptic properties. This provides neural circuits with flexibility in function and across behavioral states. We focus, in particular, on acetylcholine which is released during active waking in the cortex and hippocampus. In the hippocampus, acetylcholine modulates neuronal activity predominantly via its action on M1 and M4 metabotropic receptors. Their distinct localizations and biophysical properties produce rich dynamics across multiple timescales. We have developed a detailed biophysical model for the presynaptic activation of M4 and postsynaptic activation of M1 receptors in the hippocampus. Our model describes activation of M1 receptors leading to IP3 production from membrane PIP2 molecules. The binding of IP3 to IP3 receptors ultimately causes calcium release from the endoplasmic reticulum (ER). The additional calcium release from the ER enhances the action of potassium channels like the calcium-activated SK channels and modifies other downstream synaptic signaling. Interestingly, an opposing effect of M1 receptors is to suppress SK channels and the voltage-activated KCNQ2/3 channels directly. We quantify the effect of enhanced calcium signaling from the ER and antagonistic effects on SK

channels via M1 receptor activation on long-term plasticity at Schaffer-collateral synapses in the hippocampus. Our model also describes the presynaptic reduction of the voltage sensitivity of voltage-gated calcium channels (VGCCs) and the resulting suppression of the neurotransmitter release via M4 receptors. We characterize the influence of the apparent dichotomy of suppression of synaptic transmission by M4 and enhanced neuronal excitability by M1 on synaptic signaling and memory formation in a range of physiologically relevant activity regimes.

Title: Short-term high-fat diet consumption impairs long-term potentiation in the aged hippocampus

Authors: *B. M. GONZALEZ OLMO, F. ZHAO, C. ASKWITH, R. M. BARRIENTOS; The Ohio State Univ., Columbus, OH

Abstract: More Americans are consuming diets higher in saturated fats and refined sugars than ever before, and obesity rates among older adults alone have doubled since 1980. These trends could have serious consequences for the older population because in addition to the gradual memory declines observed with normal aging, high-fat diet (HFD) consumption, known to induce neuroinflammation, has been shown to aggravate and accelerate memory declines. Because obesity is a complex disease with many comorbidities, making the study of underlying mechanisms difficult and confounded, we employ a short-term diet manipulation protocol. We have previously demonstrated that short-term consumption (3 days) of a HFD among aged rats produced profound impairments to contextual and emotional/fear memories, which depend on an intact hippocampus and amygdala. These impairments were precipitated by increases in proinflammatory cytokines, primarily interleukin-1 beta (IL-1b), in both brain regions. Here, we explored the extent to which HFD consumption amongst aged rats disrupts hippocampal long-term potentiation (LTP), the form of synaptic plasticity thought to underlie long-term memory consolidation in mammals. Young adult (3 months old) and aged (24 months old) F344xBNF1 rats were assigned to either chow or HFD (containing 60% saturated fat) for three days. Using transverse hippocampal slices, we examined the individual and combined effects of age and diet on several forms of synaptic activity. Specifically, excitatory post-synaptic potentials were

induced in the stratum radiatum of CA1 and LTP expression was triggered with a theta-burst stimulation protocol. Our preliminary data demonstrate that late-phase LTP was particularly compromised by the combination of aging and HFD while LTP maintenance was robust in chow-fed young and aged rats. These findings suggest that the previously observed neuroinflammation-mediated hippocampal memory impairments in aged HFD-fed rats occurs, at least in part, through deterioration of synaptic plasticity, as measured by LTP, in the hippocampus. Future studies will examine LTP in the amygdala.

Title: Postnatal age influences how Intermittent Hypoxia impacts hippocampal synaptic plasticity and NMDA receptor subunit expression.

Authors: *A. ARIAS-CAVIERES, A. J. GARCIA, III;
Univ. of Chicago, Chicago, IL

Abstract: The ability to scale synaptic strength supports the robustness and flexibility of learning and memory throughout a lifetime. Intermittent Hypoxia (IH) is a hallmark of several clinical conditions such as sleep apnea and apneas of prematurity. These conditions are associated with neurocognitive deficits. In adult mice, IH-dependent oxidative stress downregulates hippocampal GluN1, the obligatory subunit of the NMDA receptor, and eliminates NMDA receptor-dependent synaptic plasticity. However, how IH impacts NMDA receptor subunit expression and synaptic plasticity during early postnatal life is not well-understood. This ongoing study characterizes how IH impacts NMDA receptor-dependent synaptic plasticity during early neonatal life. Electrophysiological studies and protein analyses were performed using hippocampal brain slices taken from mice (P14-P15) exposed to ten days of neonatal IH (nIH, starting at P4-P5). In contrast to the effects of IH on the adult hippocampus, nIH neither suppressed GluN1 expression nor eliminated NMDAr-dependent synaptic plasticity. Additionally, nIH caused a downregulation of GluN2A while upregulating GluN2B. These findings suggest that postnatal age is a significant factor influencing the consequences of IH in the hippocampus.

Title: Graphene oxide nanoflakes prevent potentiation at amygdala synapses: a novel tool to block dysfunctional plasticity in anxiety disorders

Authors: E. PATI[1], G. CELLOT[1], A. FRANCESCHI BIAGIONI[1], K. KOSTARELOS[2,3], L. BALLERINI[1];
[1]Intl. Sch. of Advanced Studies, Trieste, Italy; [2]Catalan Inst. of Nanoscience and Nanotechnology (ICN2), CSIC and BIST, Campus UAB, Bellaterra, 08193, Barcelona, Spain; [3]Nanomedicine Lab, Natl. Graphene Inst. and Fac. of Biology, Med. & Health, The Univ. of Manchester, AV Hill Building, Oxford Rd, Manchester, M13 9PL, United Kingdom

Abstract: In the last decade, graphene-based nanomaterials have been proposed as innovative therapeutic tools in the field of precision medicine for neuroscience applications. In detail, graphene oxide nanoflakes with small lateral dimension (sGO) were found to target specifically and transiently glutamatergic synapses of the hippocampus *in vivo*, by reducing the release of neurotransmitter from the presynaptic terminal[1].Recently, this ability was used to rescue the aberrant glutamatergic transmission characterizing post-traumatic stress disorders (PTSD). Since PTSD is related to a hyper-function of the amygdala resulting from the long term potentiation (LTP) of glutamatergic synapses, our group reported that, in a rat model of PTSD, a single intra-amygdala injection of sGO administered after the stressful event triggering the disease and the related altered plasticity of the amygdala, could revert the anxiety related behaviours[2]. In order to elucidate how sGO could interfere at synaptic level with the pathological LTP underlying PTSD, we developed an *in vitro* model of amygdala potentiated glutamatergic synapses. To this aim, in rat dissociated amygdala cultures we induced chemical LTP through the brief application of glutamate (50 µM for 30 seconds), that was monitored through patch clamping as a 30-minute-long lasting increase in the amplitude of postsynaptic currents (PSCs). The co-application of sGO (20 µgr/mL) with glutamate abolished the expression of the LTP. By combining the recording of miniature postsynaptic currents (mPSC), informative for modifications in synaptic structure, with confocal analysis of pre- (VGlut1) and postsynaptic (PSD95) markers, we detected that LTP relied on functional and structural changes of the synaptic terminals, that were both impaired by the treatment with sGO. We recorded simultaneously mono-synaptically

connected neuron pairs and we observed that sGO decreased the probability of glutamate release from the presynaptic site, measured as a pair pulse ratio (PPR) increase between two consecutive evoked unitary PSCs. Such changes were concurrent with a lack of LTP induction.In our work, we explored from a mechanistic perspective how sGO, by targeting precisely the release of glutamate from presynaptic site of excitatory synapses, could prevent a form of pathological plasticity associated with PTSD. These findings might find application for the treatment for a broad spectrum of neuro-pathologies.

Abstract: Impact of virus sialidase blockage on synaptic plasticity in rat brain
Sialidase controls the level of sialylation and can alter cell–cell or cell–virus recognition processes. Sialidase neuraminidase (NEU) play a pivotal role during last stages of virus development. The lack of NEU in viruses makes them inactive viral particles which unable to infect host cells. NEU is a key enzyme that cleaves negatively charged sialic acid residues from membrane proteins and lipids. Polysialic acids (PSA) are widely distributed in neuronal tissue. Due to their position on the outer cell membranes and anionic nature, PSA are involved in a multiple cell signaling events. Using the specific blocker of NEU – N-Acetyl-2,3-dehydro-2-deoxyneuraminic acid (NADNA) we show that downregulation of NEU activity causes a significant increase in the level of hippocampal tissue sialylation. In the present work we investigated effect of blockage of endogenous NEU on synaptic plasticity in different regions of hippocampus and on EPSP-pop-spike (E-S) potentiation.Temporal lobe slices were prepared from Wistar rats aged postnatal day 19-21. Evoked synaptic responses were elicited through a bipolar electrode placed in the Schaffer collateral-commissural pathway. Extracellular recordings

were obtained from pyramidal cell layer and stratum radiatum CA1 regions. We examined the effect of bath application of NADNA on synaptic plasticity in cellular and dendritic layers of hippocampus. Analyzing mean and peak values of fPSP in control and NADNA-treated slices, we observed significant increase of both values in stratum pyramidale and radiatum. Data obtained shows that blockade of NEU leads to increase of different types of short-term plasticity (STP) in pyramidal cell layer without changes in STP of radiatum layer. We observed decrease of level and LTP-probability in NADNA-treated slices in stratum radiatum. Our findings indicate that origination of LTP lead to E-S potentiation in control slices, while in NADNA-treated slices its occurrence induced E-S depression. Also we show the increase of short-term depression level due to polysialilation. Our findings demonstrate that neuraminidase blockade primes long-term depression and suppresses long-term potentiation of synaptic transmission in the rat hippocampus. We propose that in NADNA-treated slices originate enhancement of transmitter release probability following synaptic activation.

Title: Effects of prophylactic treatment on hippocampal and amygdalar synaptic plasticity and gene expression in a rodent model of PTSD

Authors: *A. C. EVERETT, R. MILLER, E. SAITO, E. WINZENRIED, C. SMITH, Z. BOYCE, J. G. EDWARDS;
Brigham Young Univ., Provo, UT

Abstract: Post-traumatic stress disorder (PTSD) is a complex anxiety and depression disorder induced by exposure to traumatic stress and is characterized by symptoms of re-experiencing (flashbacks, nightmares, etc.), avoidance, and hyper-arousal. While it is widely accepted that brain regions of the limbic system - the amygdala, ventral hippocampus, and prefrontal cortex - are dysregulated in PTSD, the pathophysiology of the disorder is not well defined and therefore, pharmacological interventions are severely limited. Because stress hormones norepinephrine and cortisol (corticosterone in rats) are heavily implicated in the disorder, we explored whether antagonizing beta-adrenergic and glucocorticoid receptors via systemic propranolol and mifepristone administration is sufficient to mitigate pathological changes in LTP, gene

expression, and behavior induced by a novel social defeat (SD) protocol. Young adult, male Sprague Dawley rats were exposed to continuous light and social isolation with acute SD to induce PTSD-like symptoms. Drug-treated rats were given propranolol and mifepristone injections beginning prior to and continuing throughout SD stress. Using competitive ELISAs on plasma, field electrophysiology at CA1 of the ventral hippocampus (VH) and the basolateral amygdala (BLA), quantitative RT-PCR, and behavioral assays, we demonstrate that SD stress increased plasma corticosterone and behavioral anxiety, elevated long-term potentiation in the VH (~25% greater than control) and BLA (~35% greater than control), and altered the expression of mineralocorticoid, glucocorticoid, beta-3 adrenergic receptors, AMPA, and NMDA receptors. These measures largely reverted to control levels with the administration of propranolol and mifepristone, with the exception of plasma corticosterone, which remained elevated with drug administration likely due to corticosterone negative feedback inhibition by mifepristone or stress-inducing injections. Together these data validate our novel SD stress protocol as means of inducing PTSD-like symptoms, and suggest therapeutic potential for propranolol and mifepristone as a prophylactic treatment for preventing PTSD before stress onset.

Title: Expression of the immediate early gene, Arc, identifies a neural network supporting classical conditioning to time-of-day.

Authors: *R. R. MCHUGH[1], R. J. SUTHERLAND[2];
[1]Neurosci., Canadian Ctr. For Behavioral Neurosci. (unive, Lethbridge, AB, Canada; [2]Univ. Lethbridge, Lethbridge Alberta, AB, Canada

Abstract: The activity of the hippocampus is necessary for memory acquisition, storage, and retrieval. Much of the research focus has been on its role in spatial navigation and contextual memory. However, the encoding of temporal cues is not well understood in long-term memory. Here, we explore the expression of the *Arc* immediate early gene (IEG) after condition to a time-of-day cue in a novel conditioning procedure in rats. For 14 days, we video-recorded locomotor

activity and delivered a clocktime-specific, multimodal alarm signal to 12 cage-paired rats. The quantification of IEG expression in neurons is a useful method for mapping temporally-specific neuronal activity in the brain. Specifically, the expression of *Arc* mRNA participates in synaptic changes associated with long-term plasticity. We predicted the neural activity associated with a temporally-conditioned response would include expression of *Arc* genes in the hippocampus. The role of components of the observed network is under experimental examination.

Title: Activity-dependent localization of Camk2a mRNAs in dendritic spines of hippocampal neurons

Authors: *D.-W. HWANG[1], S. DAS[1], R. H. SINGER[2];
[2]Anat. & Structural Biol., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: It has been demonstrated that calcium-mediated activation of Calcium/calmodulin-dependent protein kinase type II (CaMKII) is sufficient to induce spine-specific structural long-term plasticity (sLTP). The synaptic tagging and capture hypothesis postulates that the induction of CaMKII kinase activity serves as a molecular tag, which further potentiates downstream molecular events such as the recruitment of protein components that are needed for long-lasting synaptic changes. The timing with respect to the onset of stimulation and spine-specific subcellular localization of this activation of CaMKII is extensively studied, whereas the preceding molecular events have not been clearly delineated. In particular, it has yet to be known how inactive CaMKII becomes available for calcium-mediated activation in stimulated spines. To answer this question, we combined single-molecule fluorescent imaging approaches with a novel bacteriophage stem loop-based genetic tagging system (i.e. MS2/PP7 hybrid) to assess the kinetics and subcellular localization of endogenous *Camk2a* mRNAs in response to neuronal stimulation. Our preliminary data indicate that upon global and local stimulation, *Camk2a* mRNAs are recruited to the spines on a time scale of seconds and minutes. Importantly, the spine-localization of *Camk2a* mRNAs coincides with the activation of spines, suggesting that the localization is functionally connected to calcium-mediated activation of CaMKII in dendritic spines. We are currently investigating the spatiotemporal aspects of this

activity-dependent *Camk2a* localization in dendritic spines and subsequent molecular events following the localization as they relate to the establishment of long-lasting synaptic changes.

Title: Bdnf-dt: a novel divergent rna in the bdnf locus

Authors: *S. V. BACH[1], G. PUNZI[2], N. E. SMITH[1], J. SHIN[2], L. COLLADO-TORRES[3], K. R. MAYNARD[4], S. C. PAGE[3], A. STRAUB[3], D. R. WEINBERGER[3], K. MARTINOWICH[3], G. URSINI[2];

Abstract: Divergent transcription from bidirectional promoters is frequently seen among transcriptionally active protein-coding genes, where divergent RNAs (divRNAs) fine-tune the expression of mRNAs. Here we characterize a novel divergent transcript in the brain-derived neurotrophic factor (*BDNF-DT*) locus that is conserved across both mouse and human genomes. The *BDNF* gene structure is complex, containing nine short non-coding exons that are alternatively spliced to one common-coding exon to generate multiple unique transcripts, all of which encode the same mature BDNF protein. In addition to *BDNF* mRNA transcripts, a *BDNF* antisense (*BDNF-AS*) long non-coding RNA has been described. We used RNA isolated from human postmortem dorsolateral prefrontal cortex (DLPFC) to conduct RACE-PCR with primers specific to novel antisense exons and detect the 5' start and the 3' end of multiple novel *BDNF-DTs*. We found two alternative 3' ends and three alternative 5' starts for a total of five novel divergent transcripts (*BDNF-DT1, 2, 3* and *BDNFAS-DTa, b*), three of which are evolutionary conserved and two of which have protein-coding potential. Using mouse primary cortical cultures we characterized the kinetics of *Bdnf-DT* expression following 6 hours of depolarization (100 mM KCl). While expression of *Bdnf* exon *1, 2* and *4* transcripts peaked 3 hours after KCl wash off, the *Bdnf-DT* transcript showed a delayed peak expression at 6 hours upon KCl wash off. Using a human neural progenitor cell (NPC) line stably transduced with CRISPR activation constructs (VPR - ReNcell VM), we showed that selective upregulation of *BDNF* exon *1* and *4* transcripts drive the expression of *BDNF-DT* 3 and 4-fold, respectively. Further, we found that

the expression of *BDNF-DT* is significantly higher in postmortem human dorsal prefrontal cortical tissue from brain donors diagnosed with schizophrenia compared to neurotypical controls (N=378, t=3.805, p= 0.000167). Finally, we found that the schizophrenia-associated C allele (Val-BDNF) of the rs6265 SNP is highly-significantly (p<1e-10) associated with the lower expression of the *BDNFAS-DT* read-through fusion transcript, as compared to the T allele (Met-BDNF). In summary, we describe a novel divRNA in the *BDNF* locus, define the structure of its isoforms, characterize its activity-dependent expression in mouse primary cortical cultures, and drive its expression with CRISPR activation constructs in human NPCs. Our functional studies suggest that *BDNF-DT* expression may regulate *BDNF* mRNA, which could explain the observation of reduced *BDNF* levels in patients with schizophrenia. Our study sheds light and poses new questions on the complex biology of *BDNF*.

Title: Acute stress differentially regulates BDNF expression in prefrontal excitatory and inhibitory neurons of chronically stressed rats. Modulation by lurasidone treatment.

Authors: *F. MARCHISELLA[1], I. PISANO[1], F. DE ROSA[1], K. C. CREUTZBERG[1], V. BEGNI[1], M. PAPP[2], M. A. RIVA[1];
[1]Univ. of Milano, milan, Italy; [2]Polish Acad. of Sci., Krakow, Poland

Abstract: One key trait in psychiatric patients is represented by disturbances in emotional control. While, emotional dysregulation is a human feature, exposure to acute challenges in rodents can be used to investigate key pathways and systems that may be relevant in emotional control. Here, we used the chronic mild stress (CMS) paradigm to identify changes in the responsiveness to an acute stress and we investigated the potential impact of a chronic treatment with the antipsychotic drug lurasidone (Lur).80 Male Wistar rats were exposed to either 7-week CMS paradigm or left undisturbed in home-cages. Lur (3.0 mg/kg, per os) or vehicle (1% w/v) were administered for 5 consecutive weeks, starting 2 wks after CMS. 1% sucrose intake was measured at weekly intervals to assess anhedonia. 30 min-restraint stress was performed before killing on half the animals per group. Analyses include ELISA, qRT-PCR and in situ

hybridization. Two-way ANOVA followed by Tukey's multiple comparison test was performed with significance set at p<0.05. CMS significantly lowered sucrose intake, which was progressively ameliorated by lurasidone (p<0.001). Following exposure to the acute restraint stress (ARS), peripheral CORT levels were significantly increased in control rats (p<0.05), an effect that was blunted by Lur treatment (p<0.01). We next investigated the mRNA levels of 4 markers of neuronal activity (*C-fos; Zif268, Arc/Arg3.1, Npas4*) and the data were combined in an overall Z-score. Exposure to ARS significantly increases PFC activity both in control and CMS-exposed animals (p<0.0001), an effect that was not affected by Lur treatment. We next analyzed *Bdnf* expression, a key trophic factor linking neuronal activity with functional stress responsiveness. *Bdnf* mRNA levels in the PFC were increased upon ARS exposure in control group but not in CMS-exposed rats, while Lur treatment was able to restore its modulation in rats subjected to CMS in comparison to chronically stressed animals treated with vehicle (p < .05). We also used RNAscope to map *Bdnf* expression. We found that the effect of the ARS in control animals is driven by parvalbumin- positive neurons (p < 0.05), whereas lurasidone increased *Bdnf* mRNA levels selectively in CAMKII- positive neurons (p < 0.01). In summary, these data indicate that lur may promote adaptive mechanisms that are crucial for the ability to improve specific psychopathological domains, such as anhedonia, associated with CMS exposure. Lur is also able to potentiate specific mechanisms under acute stress exposure to promote resilience.

Title: Rna-seq analysis reveals plasticity changes that co-occur with therapeutic electrical brain stimulation

Authors: *K. SANDERS[1], T. H. SANDERS[2];
[1]Johns Hopkins, Baltimore, MD; [2]Univ. of Colorado, Boulder, CO

Abstract: Deep brain stimulation (DBS) and vagus nerve stimulation (VNS) are known to ameliorate pathological brain signaling in conditions such as Parkinson's disease and epilepsy. However, the mechanisms of action remain largely unknown. Previously, we investigated gene

expression profiles in the cortex, subthalamic nucleus, striatum and hippocampus in stimulated and control rodents to show that chronic (4 days or more) stimulation modulates the transcriptome both locally and remotely. We used behavioral correlation and principal component subset analysis (PCSA) to identify transcriptome signatures of effective stimulation [1,2]. In the current study, we compare how stimulation of DBS and VNS impacts the transcriptome and report previously unpublished evidence indicating antiviral effects of VNS. DBS animals received stimulation at both high (100 Hz, 130 Hz) and low (30 Hz) frequencies. VNS rats were implanted with stimulation cuffs over the left vagus nerve and received a train of fifteen 100 ms pulses delivered at 30Hz every 17.5 s for 30 minutes each day over 4 days. Stimulated rats were compared to sham stimulated controls. Brains were removed, dissected, and frozen after the last session of stimulation. RNA was extracted, then quantified using RNA-seq and RT-qPCR. Differential mRNA and miRNA expression were performed using MATLAB and R. **We found that** DBS modulated a set of genes involved in plasticity, proliferation, and calcium signaling. Genes differentially transcribed in stimulated animals compared to controls included striatal nestin (Nes), cortical doublecortin (Dcx), and hippocampal S100a4. PCSA analysis identified region-specific optimal sets of features associated with effective DBS. Widespread, but different, transcriptome changes were identified in the hippocampus and cortex of VNS stimulated rats [2]. These rats also had greatly increased cortical expression of miRNAs associated with antiviral activity compared to age-matched sham stimulated rats from the same population.

Title: Determining the interaction model between Kismet and Amyloid Precursor Protein-like using the Drosophila neuromuscular junction

Authors: *B. PRATES DE OLIVEIRA ALBANEZ, E. HENDRICKS, F. L. LIEBL; Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Determining the interaction model between Kismet and Amyloid Precursor Protein-like using the *Drosophila* neuromuscular junctionSynaptic structure and function rely on the temporally appropriate expression of genes. Kismet (Kis) is a *Drosophila* CHD protein that is most similar to CHD7 and CHD8, which are implicated in CHARGE Syndrome and autism spectrum disorders, respectively. Kis regulates synaptic structure, the localization and clustering of postsynaptic glutamate receptors (GluRs), synaptic transmission, and endocytosis. *Kis* loss-of-function mutants phenocopy animal models of Alzheimer's Disease (AD) by displaying impaired endocytosis. *Kis* loss-of-function mutants also exhibit impaired locomotion and increased amyloid precursor protein like (*appl)* mRNA transcripts. Similar to *kis* mutants, expressing human APP and β-site APP cleaving enzyme (BACE) in *Drosophila* larval neurons decreases endocytosis. Further, overexpressing APPL in neurons decreases GluRIIC and expressing a secretion defective APPL in neurons decreases FasII. Based on these findings, Kis could interact with APPL in three ways, by regulating *appl* expression, in cooperation with AICD (a fragment generated during APP cleavage), or by acting as a cofactor to promote AICD transcriptional activity. I will examine these possibilities first by knocking down APPL in *kis* mutant neurons. These experimental results will contribute to better understand how the chromatin remodeling protein Kismet influences APPL at the synapse.Authors: Bruna Prates, Emily Hendricks, and Faith Liebl, PhD.

Title: Novel ReNcell VM neural progenitor line for CRISPR activation

Authors: *N. E. SMITH[1], S. V. BACH[2], E. A. PATTIE[2], S. C. PAGE[3], K. MARTINOWICH[3]; [1]Johns Hopkins Univ., Baltimore, MD; [2]Lieber Inst. for Brain Develop., Baltimore, MD; [3]Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: The ReNcell VM neural progenitor line, generated by overexpression of the MYC family transcription factors in human cells derived from the ventral mesencephalon, has been used for developing stem cell therapies and validating therapeutic interventions. Here we

describe generation of a ReNcell VM line that constitutively expresses a CRISPR activation (CRISPRa) system to facilitate convenient upregulation of desired target genes. ReNcell VM cultures were transduced with high-titer lentivirus carrying deactivated Cas9 (dCas9) endonuclease fused to a strong transcriptional activator, VPR (VP64-p65-Rta). Successfully-transduced cells were sub-cultured and passaged to create a stably-transduced VPR - ReNcell VM line. As with the original ReNcell VM, VPR - ReNcell VM cultures can be differentiated into neurons by the removal of growth factors (EGF and FGF) from the culture media and maintenance for 15 days in vitro (DIV). The expression of neuronal markers after differentiation was confirmed by qRT-PCR (NES, S100B, SLC6A1, RELN, GRIA1, GRIA2, GRIN1) and immunocytochemistry (TUJ1, MAP2, NEUN) analyses. Differentiated VPR - ReNcell VM cultures are responsive to depolarization with 100 mM KCl as assessed by robust induction of immediate early genes, such as ARC and FOS. Transduction with a single guide RNA targeting the promoter regions of BDNF exon 1 or exon 4, selectively upregulated the expression of corresponding BDNF transcripts 23-fold and 830-fold, respectively. These data describe development of a convenient cell culture-based model to rapidly test human guide RNA specificity for CRISPRa applications. The ability to efficiently manipulate target genes of interest in this line may facilitate novel methods for in vitro human disease modeling.

Title: Potential role of deregulated Cdk5 in the altered synaptic transmission associated with Mesial temporal lobe epilepsy with hippocamapal sclerosis (MTLE-HS) and Focal cortical dysplasia (FCD).

Authors: *A. DIXIT[1], J. BANERJEE[2], A. SRIVASTAVA[3], D. SHARMA[3], S. DEY[3], M. TRIPATHI[4], M. SHARMA[5], P. S. CHANDRA[3];
[1]ACBR, Univ. of Delhi, Delhi, India; [2]Biophysics, [3]Neurosurg., [4]Neurol., [5]Pathology, AIIMS, New Delhi, New Delhi, India

Abstract: Rationale: Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE-HS) and Focal cortical dysplasia (FCD) are the most common forms of drug resistant epilepsy (DRE) pathologies. Identifying factors involved in the abnormal synaptic transmission associated with MTLE-HS and FCD remains a challenge. Cyclin-dependent kinase-5 (Cdk5) regulates synaptic transmission by modulating synaptic composition of various synaptic proteins. Altered Cdk5 activity has been implicated in animal model of epilepsy and in patients with MTLE-HS, FCD and other neurodegenerative diseases. However, its role in abnormal synaptic transmission in DRE is not clearly understood. The present study is designed to delineate the contribution of Cdk5 signalling to the altered synaptic transmission in MTLE-HS and FCD patients. **Methods**: Brain tissue samples resected during surgery from the hippocampal and the anterior temporal lobe (ATL) regions of patients with MTLE (n=8), frontal or temporal lobe regions of patients with FCD (n=23) and non-epileptic controls (n=15), were analysed for the protein expression levels of Cdk5, p-Cdk5, p35/p25, NR2A, pNR2A in MTLE-HS and Cdk5, p-Cdk5, gephyrin, p-gephyrin, γ2 containing $GABA_A$ receptor in FCD by western blotting. Cdk5 activity was analysed by kinase assay in the samples obtained from patients with MTLE-HS. NMDAR mediated glutamatergic activity was measured with and without treatment of Cdk5-specific inhibitor roscovitine, using patch clamp in ATL and hippocampal samples of patients with MTLE-HS. Co expression analysis of Gephyrin and γ2 containing $GABA_A$ receptor was carried out by immunofluorescence in patients with FCD. **Results:** We found significant upregulation of protein expression of Cdk5, p-Cdk5, p35/p25, NR2A, pNR2A in ATL region as compared to hippocampal region in samples resected from patients with MTLE-HS. Similarly, Cdk5 activity was significantly higher in ATL region as compared to hippocampal region. Magnitude of reduction in the frequency of EPSCs by roscovitine in the ATL samples was higher than that in the hippocampal samples. Upregulation of Cdk5 and p-Cdk5 and co-localization of gephyrin with γ2 containing GABAA receptor was observed to be significantly high in FCD patients. **Conclusion:** Our results suggest that Cdk5 might be contributing to the pathophysiology of MTLE-HS and FCD by different mechanisms. Cdk5 might differentially regulate excitatory synaptic activity in the hippocampal and ATL region of patients with MTLE-HS by phosphorylating NR2A subunits. Whereas it might have a potential role in increasing the stability of gephyrin-dependent γ2 subunit containing GABAA receptor clusters in FCD.

Title: Investigating cellular and circuit mechanism of epilepsy in acute slices from resected human brain tissue

Authors: *T. BUTOLA[1], V. ROBERT[1], L. PENG[1], C. GONG[2], W. DOYLE[1], M. DUSTER[1], S. DEVORE[1], S. LIVINGSTON[1], M. SPINO[1], R. TOMER[2], O. DEVINSKY[1], J. BASU[1];
[1]NYU Sch. of Med., New York, NY; [2]Columbia Univ., New York, NY

Abstract: Nearly one-third of epilepsy patients suffer ongoing seizures despite multiple medication trials. There is an urgent need for therapies and studies that recognize better neural targets for therapeutic intervention. In humans, the hippocampus and the entorhinal cortex are central to the pathophysiology of temporal lobe epilepsy, the most common type of drug-resistant epilepsy. However, most of what we know about cortico-hippocampal circuitry is from rodent studies. Little is known about the cellular organization and synaptic function of the cortico-hippocampal circuit in the human brain. In our study, we aim to fill this gap by characterizing cellular intrinsic properties, circuit connections and integration of inputs in human cortex and hippocampus. We have leveraged the resolution and high-throughput of intracellular patch clamp electrophysiology, and light sheet theta microscopy to parse the functional properties, and structural morphology of human entorhinal cortex and hippocampal neurons. Further, using electrical stimulation we have established the strength, excitation-inhibition coupling and short-term plasticity dynamics of the long-range and local synaptic inputs that these human neurons receive. By systematically comparing these properties between human and mouse neurons derived from equivalent brain areas, we shed light on fundamental cross-species differences and similarities in the cortico-hippocampal circuit. Importantly, capitalizing on our close collaboration with clinicians at the NYU Comprehensive Epilepsy Center, we corroborate our single neuron and circuit level physiology with patient specific pathology of seizures vis a vis developmental timeline, focal area, spread and severity. Elucidating the cellular and circuit pathophysiology governing aberrant neural dynamics in the epileptogenic human brain is crucial to identifying potential targets and strategies for therapeutic intervention at the neuronal level.

Title: Metabolomic signatures of status epilepticus: a human case-control study.

Authors: *A. HANIN[1,2], C. CHOLLET[4], S. DEMERET[3], F. CASTELLI[4], V. NAVARRO[1,2,5]; [1]Paris Brain Inst., Paris, France; [2]Epileptology Unit, [3]Neuro-Intensive Care Unit, Pitié-Salpêtrière Hosp., Paris, France; [4]Médicaments et Technologies pour la Santé (MTS), Univ. Paris Saclay, CEA, INRAE, Saclay, France; [5]DMU Neurosciences 6, Sorbonne Univ., Paris, France

Abstract: Objective: Status epilepticus is a life-threatening prolonged epileptic seizure. Seizure recurrence may lead to cellular alterations and homeostasis disturbances responsible for neuronal loss, secondary cerebral atrophy and irreversible neurologic sequels. Understanding the metabolomic processes associated with status epilepticus excitotoxicity is of major importance in order to propose neuroprotective therapies for status epilepticus patients. **Methods**: A comprehensive untargeted metabolomic analysis was conducted on samples from status epilepticus patients (blood n=78; CSF n=29) and control patients (blood n=107; CSF n=29). In order to identify metabolomic signatures from status epilepticus, we used ultra-performance liquid chromatography coupled with an Exactive mass spectrometer. The features were annotated accordingly to biochemical and metabolomic databases. The chromatographic peak areas were compared between status epilepticus and control patients. We manually selected metabolites for which differences could not be explained by the treatment used or by the alimentation provided in intensive care unit, and we performed a metabolic pathway analysis on these features. **Results**: Significant differences between status epilepticus and control patients were identified for 1214 metabolites in the plasma and 358 metabolites in the CSF. We identified 188 metabolites in the plasma and 57 in the CSF for which differences can only be explained by status epilepticus. The pathway analysis identified that metabolic deregulations in status epilepticus were significantly associated with amino acid metabolism (pyruvate, arginine, tryptophan, cysteine and methionine), pyrimidine metabolism, lipid homeostasis and carbohydrate metabolism. We especially found, in SE patients' samples, higher levels of pyruvate, lactate, methionine, serine and ketobutyric acid, and lower levels of arginine, tryptophan, uracil and uridine. **Significance**: Together, our data indicate that status epilepticus is associated with impaired amino acid metabolism. Thus, modulation of amino acid metabolism might be a possible therapeutic approach to prevent status epilepticus excitotoxicity.

Title: The source of fast traveling waves during human seizures: resolving a controversy

Authors: *E. SCHLAFLY[1], F. A. MARSHALL[1], E. M. MERRICKS[4], U. EDEN[2], S. S. CASH[5], C. A. SCHEVON[6], M. A. KRAMER[3];
[2]Mathematics and Statistics, [3]Dept. of Mathematics and Statistics, [1]Boston Univ., Boston, MA; [4]Dept. of Neurol., Columbia Univ. Med. Ctr., New York, NY; [5]Dept Neurol, Mass Genl Hosp, Boston, MA; [6]Columbia Univ., New York, NY

Abstract: Two seemingly contradictory theories describe the source of ictal traveling waves. The first posits that the source arises from a slowly advancing ictal wavefront characterized by collapsing inhibitory restraint (*Smith et al., Nature Communications, 2016*). The second is that the source of traveling waves arises from a fixed location (*Martinet et al., Nature Communications, 2017*). Because these theories were developed using independent microelectrode array recordings and methods from different institutions, the different theories may reflect patient variability or method sensitivity. In this work, we combine the methods and microelectrode array recordings (n=11 patients, n=31 seizures) from the previous studies to analyze the source of ictal traveling waves and understand the factors that led to the different observations. We validate both existing methods on an *in silico* dataset before applying each method to the full cohort of seizures. We show that both of the previously established methods to characterize ictal traveling waves perform similarly, and that seizures show evidence of both theoretical paradigms. When an ictal wavefront is present (17/31 seizures), application of a novel third method shows the pattern of ictal wavefront propagation is correlated with that of traveling waves immediately before ictal wavefront passage, and anticorrelated after ictal wavefront passage. However, both correlations appear only transiently (n=17 seizures, t in [-10, 20] s surrounding ictal wavefront passage). Moreover, we identify multiple shifts in traveling wave directions, suggesting that neither a fixed network nor an ictal wavefront acts alone to produce traveling waves. Using a computational model, we illustrate how an ictal wavefront interacts with a fixed source, and show that this model reproduces features of the traveling wave dynamics observed *in vivo*. We conclude that the existing controversy around the source of ictal traveling waves does not result from differences in methods or patient populations. Instead, we find that ictal traveling waves are generated by interactions between both types of sources - ictal wavefront and fixed location - proposed in previous theories.

Title: Peri-ictal thalamocortical synchronization in focal epilepsy

Authors: *W. J. LIPSKI[1], S. W. COLLINS[2], M. CAPOGROSSO[2], J. GONZALEZ-MARTINEZ[2];
[1]Neurolog. Surgery, [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Medically refractory epilepsy is highly debilitating and lethal. Surgical treatment is often the only option; however, the conventional surgical interventions are often ineffective, costly, and lead to compilations. One of the major impediments to improving the diagnosis and treatment of refractory epilepsy is a basic lack of knowledge about how seizures are organized, how they start, spread and terminate. Intracranial monitoring of brain activity via stereo-electroencephalography (SEEG) has been employed to study electrophysiological signatures of seizures, in order to identify the epileptogenic zone (EZ) for possible resection or neuromodulation. However, despite considerable evidence for subcortical involvement in epilepsy collected over the past century, such studies now focus mainly on examining seizures in cortical brain regions, leaving largely unexplored the vast thalamo-cortical networks that are known to underlie many aspects of cortical synchronization. To characterize the patterns of ictal functional connectivity between thalamic nuclei and related cortical structures that are characteristic of medically refractory focal epilepsy, we studied 11 patients with MRE who were implanted with SEEG depth electrodes that simultaneously explore thalamic nuclei and cortical regions. Specific patterns of synchronized activity in these networks were quantified in the pre-ictal, ictal and post-ictal periods. We hypothesized that peri-ictal synchronization occurs between the cortical EZ and the associated thalamic nuclei. In support of this hypothesis, preliminary analyses showed a selective slow peri-ictal potential shift in thalamic electrodes accompanied by high-frequency (75-300 Hz) phase synchrony between the pulvinar nucleus and EZ identified in occipital cortex; whereas the anterior nucleus showed a similar synchronization with EZ located in frontal cortical areas in another patient. Furthermore, in a patient with posterior quadrant epilepsy, high-frequency pulvinar stimulation (30 seconds train duration, 100 Hz) produced a suppression of epileptiform activity in the EZ during the stimulation epoch. The effect appeared

to be frequency and location dependent, with optimal responses at 100 Hz stimulation applied in the posterior lateral pulvinar nucleus. These results support the hypothesis that thalamo-cortical networks critically participate in seizure initiation and termination via their reciprocal connections. This knowledge will advance the development of treatment options by defining optimal neuromodulation targets and parameters of therapeutic electrical stimulation intended to modify these networks.

Title: Linking altered sleep homeostasis to ictal recruitment using human intracranial recordings

Authors: *B. SEVAK[1], D. SCOTT[1], C. DENIS[1], V. KREMEN, JR[4], A. STRUCK[1], E. M. MERRICKS[5], G. MCKHANN, Jr.[6], S. A. SHETH[7], L. M. BATEMAN[8], G. TONONI[2], C. A. SCHEVON[5], M. BOLY[3];
[1]Neurol., [3]Neurol. and Psychiatry, [2]Univ. of Wisconsin, Madison, Madison, WI; [4]Neurol., Mayo Clin., Rochester, MN; [5]Dept. of Neurol., [6]Dept. of Neurol. and Neurosurg., Columbia Univ. Med. Ctr., New York, NY; [7]Neurosurg., Baylor Col. of Med., Houston, TX; [8]Cedar Sinai Med. Ctr., Los Angeles, CA

Abstract: Rationale: In neurotypical brains, synaptic strengthening during wake leads to an increase in slow wave activity (SWA, i.e. 1-4 Hz) during sleep, while, sleep dependent downscaling leads to SWA power an exponential decline overnight. Here we analyzed ictal and interictal sleep recordings from patients implanted with intracranial electrodes for clinical purposes to investigate the correlation between sleep SWA and ictal recruitment at the level of local cortical networks. We investigated the link between ictal increases in phase-locked high gamma (PLHG) - a proxy for neuronal firing - and interictal increases in sleep SWA.**Methods:**6 human epileptic patients were included in the analysis: 3 patients with depth electrodes (16, 24, and 59 electrodes in cingulate or hippocampal areas) and 3 patients with a combination of grid and strip subdural electrodes (55, 94, and 80 electrodes; 1 with poorly localized seizures, and 1 without seizures). For each patient, a whole night of recordings without seizures was selected and visually sleep scored using slow waves and spindles. Bad channels, bad epochs and 1-second epochs around interictal spikes identified by an epileptologist were removed from the analysis.

We computed the power for SWA (delta (δ)) and beta (β) bands, and compared the average δ power and δ/β ratio between the first and last hour of sleep in each electrode. δ power and δ/β ratio values within the first and last hour and their difference overnight were then Spearman-correlated to ictal PLHG. **Results:** Visual inspection of individual patient data suggested that highest δ power co-localized with the clinically identified SOZ. The average correlation between δ power during sleep and ictal PLHG was positive in each of the 5 patients with seizures (significant at $p<0.05$ at the individual level in the 3 patients with the most frequent seizures). δ power and δ/β ratio showed an average decline across all channels in 4/5 patients. In the 4 patients where seizure focus could be localized, a paradoxical positive correlation was observed between ictal PLHG and an increase (rather than a decrease) in δ/β ratio overnight. Interestingly, in contrast, overnight change in δ/β ratio was negatively correlated with ictal PLHG in the patient with unidentified focus. **Conclusions:** These preliminary results from intracranial recordings in 6 patients with focal epilepsy suggest that power adaptively decreases across the whole cortex during a night of sleep, while sleep homeostasis is selectively altered in the epileptic focus. If findings are confirmed in larger studies, interictal sleep SWA patterns may provide useful localization information about epileptogenic regions in patients.

Abstract: Title: Impact of cannabidiol (CBD) on anxiety symptoms in pediatric epilepsy patients: A preliminary analysis**Authors:** Saurav Singh, Breanna Borg, Austin Morales, Julia Evanski, Jamie MacDougall, Amanda Weber, Aimee Luat, Hilary Marusak
Funding: The Children’s Foundation
Cannabidiol (CBD) is used as a medication for treating seizures in children. Recent research

suggests that CBD can also reduce anxiety in adults. Importantly, anxiety disorders are the most common childhood mental illness, affecting up to one in three before age 18. Further, anxiety affects up to 50% of children with epilepsy which may negatively affect their quality of life. However, little is known about the effects of CBD on anxiety in children. Our ongoing study examines CBD as a potential treatment for childhood anxiety, by leveraging a group of patients undergoing clinically indicated treatments. We conducted a preliminary analysis (n = 4; ages 2-20; 3 female) of our ongoing 4-6-week observational study of pediatric epilepsy patients at the Children's Hospital of Michigan. Participants were followed as they started on CBD (Epidiolex, Jazz Pharmaceuticals) for clinically indicated seizures. Parents/guardians completed surveys about their child before starting on CBD, and again after achieving the maintenance dose (4-6 weeks; ~25 mg/kg). Surveys were about seizure frequency, medication side effects, and anxiety symptoms. At the end of the study, three out of the four parents reported that they would recommend Epidolex to other families (one parent was undecided). Three out of the four parents also reported a reduction in their child's seizure frequency from baseline ($M \pm SD$ = 6.05 ± 7.85 seizures/month) to the end of the study (2 ± 4 seizures/month), and three out of four reported fewer average negative side effects (e.g., speech difficulties, unstable walking) after starting the medication (baseline: 49 ± 29.13, end: 35.25 ± 17.58). All four parents reported more frequent positive side effects (e.g., improved mood, better sleep) at the end of the study (15 ± 6.92) as compared to baseline (6.75 ± 3.2). Three out of four parents reported a reduction in their child's anxiety symptoms from baseline (12 ± 11.6) to the end of the study (2.25 ± 1.71); one patient showed no change in anxiety symptoms. Taken together, these data are consistent with prior studies demonstrating the effectiveness of CBD for reducing seizures in pediatric populations, and that CBD may have fewer side effects than other anti-seizure medications. Although preliminary, these data also indicate that CBD may be a promising approach for reducing anxiety symptoms in pediatric samples. This notion will be explored in future studies.

Abstract: Accumulating evidence supports a causative relationship between the allele ε4 of apolipoprotein E (APOE4), the strongest genetic risk factor for Alzheimer's disease (AD), and olfactory dysfunction (OD), which is the prodromal AD symptom. Consistently, animal studies have showed olfactory behavior deficits and network dysfunction in the olfactory bulb (OB) and piriform cortex in transgenic (APOE4) mice carrying the human APOE4 gene at the age of 6 and 12 months, respectively, indicating initiation of APOE4 pathogenesis in the OB. However, the cellular and circuit substrates of these age-dependent APOE4 actions in the olfactory system remain unclear. We focused on APOE4 actions in the OB and its adjacent downstream structure the anterior olfactory nucleus (AON) at the cellular and circuit levels in 6-month-old APOE4 mice and had the following main findings: (1) APOE4 elevates excitability of OB mitral cells (MCs) and AON neurons in awake head-fixed and anesthetized mice, respectively; (2) APOE4 significantly prolongs MC responses to the stimulation of olfactory nerve, spontaneous excitatory (sEPSCs) and inhibitory postsynaptic currents (sIPSCs) in MCs, indicating neurotransmitter uptake deficit in the OB of APOE4 mice; (3) consistently, APOE4 mice display atrophic alteration in OB astrocytes, which play key roles in neurotransmitter uptake; (4) APOE4 mice exhibit deficit in olfactory habituation and dishabituation, which is rescued by chemogenetic activation of OB astrocytes. Ongoing work will expand to target the OB-AON synaptic pathways. Taken together, our study suggests that APOE4 acts on OB output neurons to dysregulate AON functions leading to OD at the early age.

Title: An autocrine role for apolipoprotein E in brain endothelial cell function

Authors: *F. M. MAROTTOLI[1], L. M. TAI[2];
[2]Anat. and Cell Biol., [1]Univ. of Illinois at Chicago, Chicago, IL

Abstract: The association of the apolipoprotein E4 genotype (*APOE4*) and neurovascular dysfunction with age and neurodegeneration underscores the importance of identifying the underlying mechanisms. Specialized brain endothelial cells (BECs) are the core component of

the neurovasculature yet changes in their function are often viewed solely as a consequence of altered astrocyte and pericyte signaling. Given that BECs are directly responsible for neurovascular function, this perspective critically overlooks their dynamic and complex functions. To better understand the extent *APOE* genotype of BECs modulates their phenotype, we isolated primary BECs from 2-month-old male and female *APOE*-targeted replacement mice and performed experiments without subculture. Initial biochemical and RNA-sequencing characterization revealed that compared to *APOE3*, *APOE4* BECs produce less apolipoprotein E (apoE) and have altered metabolic and inflammatory gene expression profiles. Further, through specific functional assays, we found that *APOE4* BECs demonstrate a greater preference for oxidative phosphorylation over glycolysis and, accordingly, higher markers of mitochondrial activity. Complementarily, *APOE4* BECs had higher mitochondrial superoxide levels, lower levels of antioxidants related to heme and glutathione, and higher markers/outcomes of oxidative damage to proteins and lipids. Either in parallel or through sequential processes, markers of inflammation were also higher in *APOE4* BEC cultures under both basal conditions and following a low dose of lipopolysaccharide (LPS). Further, a high dose of LPS resulted in greater paracellular permeability in *APOE4* BECs when assessed by electric cell-substrate impedance sensing. Importantly, guided by our transcriptomic data, we found that the nuclear receptor Rev-Erb agonist SR9009 improved functional metabolic markers, lowered inflammation, and modulated paracellular permeability at baseline and following LPS treatment in *APOE4* BECs. Collectively, our data identify a role for autocrine apoE signaling in BECs and represents a novel cellular mechanism for how *APOE* regulates neurovascular function.

Title: The effects of apolipoprotein E isoforms on spread of phosphorylated tau

Authors: *A. AFFANEH, A. K. LINDEN, J. A. KESSLER;
Neurol., Northwestern Univ., Chicago, IL

Abstract: The development and progression of Alzheimer’s disease (AD) are strongly correlated with the human apolipoprotein E (*hAPOE)* genotype. Tau pathology consisting of hyperphosphorylated neurofibrillary tangles is a hallmark of AD. The spread of phosphorylated tau (p-tau) is known to spread in a stereotyped manner starting in the entorhinal cortex

progressing lastly to the hippocampus and neocortex. While both *APOE*4 genotype and prion-like hyperphosphorylated tau propagation are linked to advanced disease progression, it remains unclear how heterologous expression of *APOE* effects p-tau spread. Here we sought to address this question by differentiating *APOE* E4/E3 and CRISPR/Cas9 corrected isogenic *APOE* E3/E3 into excitatory forebrain neurons while using microfluidic devices. This, in conjunction with the development plasmonic sensors sensitive to multiple species of tau, facilitates the ability to track release of pathological tau in real time. Using this nanotechnology, we evaluated the levels of p-tau spread between *APOE* genotypes. Specifically, *APOE*4 neurons have higher levels of intracellular p-tau/tau, as well as secreted p-tau/tau. Under biological stressors, levels of apoE increases in parallel with increases of p-tau. Future studies will investigate specific mechanisms in which apoE interactions effect the spread of neurotoxic proteins.

Title: APOE-ε4 but not APOE-ε3 genotype synergizes with chronic sleep disruption to accelerate Aβ plaque deposition in APPPS1-21 mice

Authors: *C. WANG, C. LEE, S. PARHIZKAR, C. E. WALLACE, A. C. MOORE, J. R. CIRRITO, D. M. HOLTZMAN;
Dept. of Neurol., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Alzheimer’s Disease (AD) is the most common cause of dementia and a major public health problem. Currently, around 47 million people worldwide are living with dementia. Thus, identifying modifiable risk factors for AD is critical. The apolipoprotein E *(APOE)* gene is the strongest genetic risk factor for late-onset AD. *APOE*-ε4 genotype is strongly associated with increased AD risk and amyloid-β (Aβ) plaque accumulation in humans, as compared to the other common *APOE* genotypes such as ε3. In relation to sleep, recent human studies suggest that

APOE genotype modulates the effect of sleep disruption on AD risk, suggesting a possible link between apoE and sleep in AD pathogenesis which is relatively unexplored. To test our hypothesis that *APOE* genotype modifies Aβ deposition in response to chronic sleep deprivation (SD), we used APPPS1-21 mice with targeted replacement of the murine Apoe locus with human *APOE*-ε3, or -ε4. At four months of age, experimental mice were placed in automated SD chambers set at a 30 sec interval for 6 hours per day (8 am to 2 pm) for 8 weeks or in normal cages with normal sleep (NS) conditions. After treating mice with chronic SD or normal sleep, we quantified total or fibrillar Aβ plaques. Interestingly, chronic SD in *APPPS1-21* mice significantly increased Aβ deposition in the presence of apoE4 but not apoE3. To have a better understanding why *APPPS1-21:ε4/4* mice are more significantly affected by SD, we are currently using several approaches, including assessing whether SD influences interstitial fluid (ISF) Aβ clearance in an isoform-dependent fashion.

Title: Loss of apolipoprotein E exacerbates microglial and astrocyte reactivity to sustained systemic glucocerebrosidase inhibition.

Authors: *K. J. CONNOLLY, O. R. BREKK, S. N. ROSENTHAL, C. N. CLOUSE, *P. J. HALLETT, O. ISACSON;
Harvard Med. Sch. / McLean Hos., Belmont, MA

Abstract: Elevated lipid storage is frequently observed in late-onset neurodegenerative diseases such as Alzheimer's disease (AD) and Parkinson's disease (PD). Genetic risk factors for AD and PD also include factors involved in lipid distribution and metabolism, such as *APOE* and *GBA*. Mechanisms for lipid transport between neurons and glia in response to mitochondrial stress and NMDA-induced excitotoxicity have been shown to depend on glial apolipoprotein E (apoE) expression *in vitro*. The promotion of lipid transport between neurons and glia during stress suggests that apoE, as the major transcellular lipid carrier in the brain, is a key factor in the cellular adaptation to stress. This in turn suggests that insufficient apoE activity may underpin the elevated lipid storage associated with neurodegenerative diseases. To determine whether apoE function is required for cellular adaptation to increased lipid load, 3-month-old WT and apoE-KO mice received daily intraperitoneal injections of the glucocerebrosidase inhibitor, CBE, for 9 or 18 d. Animals were perfused 1 d after the final dose for histological and biochemical analysis. Microglial and astrocyte reactivity to CBE were assessed by Iba1 and GFAP immunohistochemistry. Microglial reactivity was greater in the dentate gyrus, substantia nigra and layer V of the motor cortex in apoE-KO mice after 9 and 18 d CBE, relative to WT. Loss of apoE also elevated astrocyte reactivity in the dentate gyrus, substantia nigra and layer V of the motor cortex after 18 d CBE. Ongoing analyses into the molecular and cellular consequences of prolonged CBE include changes in lipid transport, α-synuclein aggregation, tau phosphorylation, lysosome biogenesis, autophagy and proteostasis, to determine how loss of apoE function may impact cellular adaptation to intracellular lipid formation resulting from sustained glucocerebrosidase inhibition. The exacerbated glial activation in apoE-KO animals receiving CBE suggests that apoE expression and function may, in part, determine the capacity of neuron-glia networks to overcome damaging stimuli. When apoE function is insufficient, failed resolution of lipids may then lead to persistent damage and degeneration. Therefore, characterizing the consequences of limited lipid clearance on the adaptation to rising lipid load is highly relevant to understanding how failure to overcome increased lipid storage contributes to neurodegenerative processes in AD, PD and related disorders.

Abstract The epsilon4 (ε4) allele of the APOE gene, which encodes the apolipoprotein E4 (ApoE4), is a strong genetic risk factor for developing Alzheimer´s disease (AD), the most common form of dementia. Astrocytes play a role in AD pathology but the impact of the disease and APOE alleles on human astrocyte maturation and function remains to be fully elucidated. To address this question, we have obtained induced pluripotent stem cells (hiPSCs) from fibroblasts of AD patients carrying the ε4 and ε3 alleles (in homozygosis), from healthy controls and from isogenic iPSCs lines carrying the different APOE alleles. Astrocyte differentiation was achieved by sequential addition of small molecules and growth factors. The hiPSC-derived astrocytes expressed GFAP, GLT1, AQP4 and S100ß. These cells showed Aβ and glutamate uptake capacity, produced Ca^{2+} waves and responded to inflammatory stimuli in both AD- and APOE allele-dependent manners. Our findings support the use of hiPSC-derived astrocytes as a model to study mechanisms of cell dysfunction in AD and reveal a tight connexion between APOE, astrocyte homeostasis and AD pathology.

Title: Regulation of neuronal beta-amyloid production by astrocytic cholesterol and mechanical force

Authors: *H. WANG[1], J. A. KULAS[2], C. WANG[3], D. A. KOZLOWSKI[4], D. M. HOLTZMAN[5], H. A. FERRIS[2], S. B. HANSEN[1];

Abstract: Alzheimer's Disease (AD) is characterized by the presence of β-Amyloid (Aβ) plaques, tau tangles, and loss of cognitive function. ApoE4 isoform and traumatic brain injury (TBI) are both risk factors for AD, but it is unclear if there are common underlying mechanisms. In this study we show that Aβ generation in neurons is regulated by apoE delivery of cholesterol and the nanoscale clustering of the amyloid precursor protein (APP) processing proteins in neurons while mechanical force works opposite to cholesterol. Using super-resolution imaging in mouse brain, we show that astrocyte-derived cholesterol is carried by apoE to specifically traffic neuronal APP in and out ganglioside (GM1) lipid clusters where it interacts with β- and γ-secretases to generate Aβ-peptide. We find that targeted deletion of astrocyte cholesterol synthesis robustly reduces amyloid and tau burden in a mouse model of AD. Treatment with cholesterol-free apoE or knockdown of cholesterol synthesis in astrocytes decreases cholesterol levels in cultured neurons and causes APP to traffic out of GM1 clusters where it interacts with α-secretase, however γ-secretase does not respond to cholesterol regulation and remains in the GM1 clusters. APOE4 expressing mouse brains have more cholesterol and greater association of APP with GM1 domains than APOE3 brains. In cell culture, we show that both APP and γ-secretase are mechanosensitive and they sense different thresholds of mechanical shear (normal and noxious respectively). In a controlled cortical impact rat model of TBI, high intensity (noxious) mechanical force causes both APP and γ-secretase to move from thicker GM1 clusters to the thinner disordered regions. Translocation of APP's γ-cleavage from thick to thin membrane results in a shift from Aβ40 to Aβ42 production. As animals recovered from the

injury, APP moves back into the GM1 clusters regulated by increased membrane cholesterol while γ-secretase does not respond to cholesterol change. We conclude that astrocytes regulate Aβ production through the delivery of cholesterol to neurons by apoE. This suggests that the cholesterol is used as a signaling molecule, and the concentration is kept low in neurons to allow for astrocyte signaling. In contrast, mechanical force translocates γ-secretase to the thinner membrane, leading to an increased Ab42/40 ratio.

Title: Structure of Human Lipidated Apolipoprotein E

Authors: *M. STRICKLAND[1], Y. CHEN[2], M. RAU[3], B. SUMMERS[3], R. KOSSINA[3], H. JIANG[1], J. ULRICH[1], J. FITZPATRICK[3], D. M. HOLTZMAN[1];

Abstract: The Apolipoprotein E (*APOE*) gene is the most important genetic risk factor for late-onset Alzheimer's Disease (AD). ApoE is a lipid associated protein that plays a vital role in intercellular cholesterol and lipid transport, especially in the central nervous system (CNS) where it is the primary apolipoprotein. ApoE has three major isoforms (ApoE2, ApoE3, and ApoE4) of which ApoE3 is the most common. A single copy of the ApoE4 allele increases AD risk approximately 4-fold and two copies increase disease risk approximately 12-fold relative to the ApoE3 allele. The ApoE2 allele decreases risk for AD relative to the ApoE3 allele. Despite resulting in a dramatic increase in disease risk, ApoE4 only differs from ApoE3 by a single amino acid. To better understand the significance of this change, we aim to study the structure of lipidated ApoE; its physiological confirmation. Previous studies investigating the structure of

ApoE have been hampered by both the lipid environment of the physiological forms of ApoE and the tendency of non-lipidated to rapidly aggregate. We aim to address these issues by utilizing single particle cryo-electron microscopy (cryoEM) in order to determine the structure of lipidated ApoE. Advances in direct electron detectors and automated data acquisition strategies now routinely allow the determination of protein structures to near-atomic resolution. Using this method, we plan to determine the structure of lipidated ApoE2, ApoE3, and ApoE4 in order to understand conformational differences between the isoforms to reveal mechanistic insights into the role of ApoE for AD risk. In this study, we utilize both astrocyte-produced ApoE particles and artificially-lipidated recombinant ApoE. We have characterized these particles using size-exclusion chromatography and nondenaturing gradient gel electrophoresis. We have shown in our study that the artificial particles recapitulate the features of astrocyte produced ApoE particles and are a good initial model for understanding ApoE structure. In this study, we have also utilized monoclonal Fab fragments to further characterize the ApoE particles and assist in alignment of the ApoE particles during 2D classification. Using this method, we show two ApoE proteins are present per lipoparticle and that ApoE adopts at least two major conformations on lipid containing particles. Currently, we have obtained low resulotion 3D electron density maps of the ApoE lipoparticles in the two major conformations. Future research will pursue obtaining a high-resolution structure of the three isoforms to better understand any conformational differences that exist between the ApoE isoforms.

Title: Different gliovascular alterations characterize the frontal cortex of sporadic and familial Alzheimer's disease: APOEch protection

Authors: *J. HENAO, N. OROZCO, C. LÓPEZ, R. MORAGA, J. TOLEDO, S. HÄRTEL, A. VILLEGAS, J. GUTIERREZ, F. LOPERA, G. CARDONA, R. POSADA;
Univ. de Antioquia, Medellín, Colombia

Abstract: In response to brain insults astrocytes become reactive. This process modifies the structural and functional properties of these cells giving rise to highly context-specific effects that frequently become maladaptive. In fact, astroglial reactivity is characteristic of brain pathologies such as Alzheimer's disease (AD). Interestingly, Colombia has the largest human group known with familial Alzheimer's disease (FAD). This kindred carry the autosomal dominant mutation E280A in PSEN1, which causes early-onset dementia. Recently, our group has identified an E280A carrier who did not develop FAD. The individual was homozygous for the Christchurch mutation in APOE3 (APOEch). Remarkably, most of apoE (the APOE gene product) -which is the main genetic risk factor for developing sporadic Alzheimer's disease (SAD)- is produced by the astroglia. Since astrocytes are central in highly delicate brain processes -as neuroinflammation, the maintenance of glutamate homeostasis, and the preservation of the gliovascular unit (GVU)-, in this study we characterized some of the cellular aspects of the astrocytes that could influence the mechanisms of pathogenesis or protection of the three different biological backgrounds of SAD, FAD and APOEch. Interestingly, we show that the frontal cortex of APOEch displays the mildest histological alterations despite presenting the highest amyloid burden. Furthermore, while FAD is characterized by a hyperreactive-like microenvironment and SAD exhibits astrodegeneration, the astroglia of APOEch resembles that of control. Also, we show that glutamate-regulatory astrocytic proteins are altered in the three conditions, but to a lesser extent in APOEch. Lastly, we demonstrate that gliovascular deterioration is characteristic of SAD and FAD but not of APOEch. Our results suggest a preponderant role of astrocytes in the maintenance of the GVU under the context of AD and, therefore, in the mechanisms of brain health and disease.

Title: Lrrk2 kinase activity and dopamine neurotransmission is differentially affected by vps35 p.d620n or knockdown

Authors: *M. BU[1], J. FOLLETT[2], I. TATARNIKOV[3], S. WALL[2], D. GUENTHER[2], K. DEMARES[2], A. J. MILNERWOOD[4], H. KHOSHBOUEI[1], M. FARRER[2];

Abstract: VPS35 is an essential component of the retromer complex required for endosomal sorting for lipid and protein recycling. A mutation in VPS35 (p.D620N) leads to autosomal dominant Parkinson's disease, whereas a reduction in VPS35 expression is associated with Alzheimer's dementia. Mutations in LRRK2 that constitutively increase its kinase activity and downstream Rab phosphorylation are also a leading genetic cause of Parkinson's disease, and LRRK2 and VPS35 may directly interact. Modulating this endosomal-vesicular trafficking system is an important therapeutic opportunity to slow or halt neurodegeneration. To better understand the relationship between retromer and Lrrk2, and to assess gain- versus loss-of-function, we have examined striatal dopamine neurotransmission by ex-vivo slice voltammetry in Vps35 p.D620N knock-in (VKI) and haploinsufficient Vps35 mice (hVKO, in which retromer is ~50% reduced). Evoked striatal dopamine release is significantly enhanced in 3-month-old VKI mice but declines to a level comparable to wild type (WT) in 12-month-old animals. Lrrk2 kinase activity is also constitutively elevated in 3-month-old VKI mice. As a corollary, in vivo treatment of VKI animals with the Lrrk2 kinase inhibitor, Mli2, normalizes both dopamine transporter (Dat) expression and striatal dopamine release. Here we demonstrate hVKO mice also exhibit a significant increase in evoked dopamine release compared to age-matched WT mice that is maintained at 12 months. Together, our results suggest Vps35 p.D620N and Vps35 haploinsufficiency may result in a similar loss-of-function with respect to Dat recycling and striatal dopaminergic neurotransmission. However, in contrast to VKI animals, LRRK2 kinase activity in hVKO mice is reduced compared to WT littermates. Thus hyper- and hypoactivation of LRRK2 kinase is associated with retromer induced dysregulation of dopamine neurotransmission, and these observations should be reconciled before LRRK2 kinase inhibitors are recommended for therapeutic use. Defects in vesicular trafficking from retromer and/or LRRK2 dysfunction may unproportionally affect dopamine specific cargos and dopaminergic neurons due to their extensively arborized, poorly myelinated axons and requirement for nigrostriatal axonal trafficking. Cellular context is important and is to be more fully explored.

Title: Dopaminergic network properties: implications in behavior

Authors: *D. R. MILLER[1], D. T. GUENTHER[2], A. P. MAURER[3], C. A. HANSEN[1], A. ZALESKY[5], H. KHOSHBOUEI[4];

Abstract: Dopaminergic neurons of the substantia nigra (SNC) and ventral tegmental area (VTA) exhibit spontaneous firing activity. The dopaminergic neurons in these regions have been shown to exhibit differential sensitivity to neuronal loss and psychostimulants targeting dopamine transporter. However, it remains unclear whether these regional differences scale beyond individual neuronal activity to regional neuronal networks. Here we utilized live-cell calcium imaging to show that network connectivity greatly differs between SNC and VTA regions with higher incidence of hub-like neurons in the VTA. Specifically, the frequency of hub-like neurons was significantly lower in SNC than in the adjacent VTA, consistent with the interpretation of a lower network resilience to SNC neuronal loss. We tested this hypothesis when activity of an individual dopaminergic neuron is suppressed, through whole-cell patch clamp electrophysiology, in either SNC, or VTA networks. Neuronal loss in the SNC increased network clustering, whereas the larger number of hub-neurons in the VTA overcompensated by decreasing network clustering in the VTA. We further show that network properties are regulatable via a dopamine transporter dependent mechanism. Our ongoing work expands our findings to an in vivo model system where we stimulate dopaminergic networks with simultaneous real time calcium imaging. The behavioral responses and dopaminergic network are tracked across experimental time and session instances. Thereby changes in dopaminergic networks are matched to behavioral changes beyond single neurons. Our results demonstrate novel regulatory mechanisms of functional network topology in dopaminergic brain regions and how they relate to behavior.

Title: In drug naive Parkinson's disease patients, Dopamine transporter and Tyrosine hydroxylase expression are increased in peripheral immune cells

Authors: *A. GOPINATH[1], P. M. MACKIE[1], A. SMITH[1], T. RIAZ[1], C. HANSEN[1], A. H. GITTIS[4], R. BOUCHARD[5], J. SCHWENK[5], P. HASHEMI[6], A. BUCHANAN[6], P. J. GASKILL[7], R. NOLAN[7], S. MATT[7], A. DOTY[2], A. RAMIREZ-ZAMORA[1], M. OKUN[1], W. J. STREIT[3], H. KHOSHBOUEI[3];

Abstract: Introduction: While the scientific debate about the origin of sporadic Parkinson's Disease (PD) i.e. body-first vs. brain-first hypothesis, has not been settled, it is well-established that PD pathology affects both CNS and peripheral dopamine transmission. The vast majority of PD research has focused on neuronal and glial dysfunction, but there is strong evidence demonstrating the dysregulation of innate immunity in PD at the systemic level. In PD, there is a loss of dopamine neurons as measured by decreased markers of dopaminergic neurons, the dopamine transporter (DAT) and tyrosine hydroxylase (TH). Objective: Since peripheral immune cells express dopaminergic proteins, including DAT and TH, we tested the hypothesis that in drug naïve PD patients there is a similar reduction in DAT+/TH+ peripheral blood mononuclear cells (PBMCs). Methods/Results: We first established a highly sensitive and reproducible flow cytometry assay to assess DAT and TH expression in PBMCs of 12 drug naïve PD patients (newly diagnosed), 84 PD patients receiving treatments and 67 aged/sex matched healthy subjects. We found there is no change in total PBMCs ($p>0.91$, healthy vs. PD, vs. drug naïve, One-way ANOVA), but contrary to our hypothesis we found that percentages of DAT+/TH+, but not NET+, PBMCs are significantly higher in drug naïve PD patients (n=12) compared to healthy controls (n=67) ($P<0.001$, One-way ANOVA). Importantly, in PD patients receiving treatments (n=84), irrespective of the treatment modality, the percentages of

DAT+/TH+ monocytes declined significantly compared to drug naïve patients, but remain significantly higher than healthy controls (P<0.001, one-way ANOVA), suggesting that treatment for PD can modulate peripheral immune cells expressing DAT/TH. Similar to human PD, the percentages of DAT+/TH+ myocytes are increased in two animal models of PD and reduced following L-dopa+Carbidopa, but not L-dopa alone. To test whether changes in DAT+/TH+ PBMCs are increased in other neurodegenerative diseases, we recruited a patient cohort with Alzheimer's disease (n=6) and found increased DAT+/TH+ PBMCs to be specific for PD. Alzheimer's patients did not exhibit changes in the DAT+/TH+ PBMCs. We also discovered that PD patients exhibit increased DAT+/TH+ myeloid derived suppressor cells (MDSCs) suggesting a compensatory immune response in PD. Ongoing studies are focused on investigating the mechanism underlying increased DAT+/TH+ PBMCs in PD. Collectively, these data suggest a system-wide dysregulation of the dopamine signaling on peripheral immune cells in PD, providing a novel diagnostic and therapeutic perspective for PD.

Title: In Parkinson's disease patients Tyrosine Hydroxylase expression is increased in CD14+ monocytes and linked to TNF

Authors: *A. DAGRA[1], A. GOPINATH[1], M. G. TANSEY[3], G. SHAW, Dr[4], D. MILLER[1], C. HANSEN[1], P. M. MACKIE[1], A. RAMIREZ-ZAMORA[1], M. OKUN[1], W. J. STREIT[1], H. KHOSHBOUEI[2];
[2]Box 100244, [1]Univ. of Florida, Gainesville, FL; [3]Physiol., Emory Univ. Sch. of Med., Atlanta, GA; [4]McKnight Brain Inst., Gainesville, FL

Abstract: Introduction: Peripheral immune cells (human and mouse) express tyrosine hydroxylase (TH), the rate limiting enzyme in catecholamine synthesis. TH is classically studied in the context of brain catecholamine signaling, but little is known about TH production and function in peripheral immune cells. This knowledge gap is due, in part, to the lack of an adequately sensitive assay to measure TH in immune cells expressing lower TH levels compared to cells with high TH expression. **Objective/Methods**: We developed the TH-Bio-ELISA that can quantify TH picogram levels of TH protein. We then applied the TH-Bio-ELISA, to measure TH in the $CD14^{+}$ monocytes of 11 Parkinson's disease (PD) patients, and 11 aged matched healthy control subjects from both sexes. We hypothesized that the loss of TH+ neurons in the brains of PD patients is accompanied by lower levels of TH in the peripheral monocytes of PD patients. **Results**: We found that TH-Bio-Elisa is highly sensitive and reproducibly quantifies picogram levels of TH in multiple TH expressing cells such as primary human macrophages, murine dopamine neurons, PC12 cells and primary human monocytes. We applied this assay to monocytes isolated from venous blood of PD patients (n=11) and healthy age-matched control subjects (n=11). Contrary to our hypothesis, we found that monocytes from PD patients express significantly higher levels of TH protein than those form healthy controls ($P<0.01$, two-tailed t-test). Next, we focused on understanding the mechanism of increased monocytic TH in PD. It is known that tumor necrosis factor (TNF), a pro-inflammatory cytokine, is increased in the brains and peripheral circulation of PD patients and animal models of PD. Therefore, we investigated a possible connection between higher levels of TH protein and increased TNF in PD. Monocytes isolated from healthy donors were treated with TNFα or with TNF in the presence of an inhibitor (XPro1595). Tissue plasminogen activator (TPA) was used as a positive control. We observed that TNF stimulation increased both the number of TH+ monocytes and the quantity of TH per monocyte (N=3-6 independent biological replicates per group, $P<0.01$), without increasing the total number of monocytes. **Conclusions**: Our results show that TNF modifies monocytic TH production and serves a regulatory role in peripheral immune function. In addition, the TH-Bio-ELISA provides a novel and sensitive tool to investigate the immune regulatory pathways between brain and peripheral immune system in PD.

Title: Loss of function in Parkinson's patient-derived dopamine neurons precedes neuronal degeneration

Authors: *H. KHOSHBOUEI;
Univ. of Florida, Gainesville, FL

Abstract: The pathophysiological mechanisms for degenerative changes in dopamine neurons during early stages of Parkinson's disease (PD) remain unknown. The inaccessibility of living diseased tissue has been a limitation in studying progression of PD pathophysiology prior to degeneration of dopamine neurons. To address these issues, we differentiated induced pluripotent stem cells (iPSCs) from a PD patient carrying the α-synuclein triplication mutation and an unaffected first-degree relative into spontaneously firing dopaminergic neurons. Around 96% of iPSC-derived dopamine neurons expressed DAT, TH, D2, GIRK2 and indicators for neuronal maturation such as Nurr1, FOXA2, PRK8 and MAP2 (n=6 from three independent rounds of differentiation). In 157 iPSC-derived dopamine neurons from three independent rounds of differentiation, we found that human-like dopamine neurons overexpressing α-synuclein exhibited a unique up-state (depolarized plateau) and high frequency of spontaneous firing activity with a pause between subsequent broadbrimmed bursts. Investigating the underlying mechanism revealed that α-synuclein overexpression diminished D2 receptors and GIRK channels autoinhibition. Back-translating these findings into primary mouse neurons overexpressing α-synuclein revealed a similar phenotype and mechanism, supporting the causal role for α-synuclein reduction of autoinhibition in dopamine neurons. Live-cell GCaMP6 calcium imaging revealed α-synuclein overexpression perturbed intracellular calcium homeostasis, increased TH and extracellular dopamine levels along with reducing arborization of dopaminergic neurons and neuronal survival. Importantly, a GIRK channel activator or application of D2 receptor agonist, quinpirole, prevented neuronal loss, restored the firing activity, TH levels and the morphology of PD patient-derived dopaminergic neurons to the quantity measured in dopaminergic neurons from healthy subjects. These results provide novel insights into the pre-degenerative pathophysiology induced by α-synuclein overexpression and introduce a potential mechanism for the long-established clinical efficacy of D2 receptor agonists in the treatment of PD.

Abstract: Nolan, Kaitlyn Runner, Stephanie Matt, Peter J. Gaskill, and Habibeh Khoshbouei Monocyte-derived macrophages are key players in tissue homeostasis and disease regulated by a variety of signaling molecules. Recent literature has highlighted the ability for the biogenic amines dopamine and norepinephrine to regulate macrophage functions, but the mechanisms governing dopamine and norepinephrine signaling on and around immune cells remains nebulous. In the central nervous system, biogenic amine transporters are regarded as the master regulators of neurotransmitter signaling. While we and others have shown macrophages express these transporters, relatively little is known of their function on these cells. To address these knowledge gaps, we interrogated the function of norepinephrine (NET) and dopamine (DAT) transporters on human monocyte-derived macrophages. Using multiple complementary approaches, we found that both NET and DAT are present and can uptake substrate from the extracellular space at baseline. Not only was DAT expressed in cultured macrophages, but it was also detected in a subset of human intestinal macrophages in situ. Surprisingly, we discovered a NET-independent, DAT-mediated immuno-modulatory mechanism in response to lipopolysaccharide (LPS). LPS induced reverse transport of dopamine through DAT, engaging autocrine/paracrine signaling loop that regulated macrophage cytokine release and phagocytic capacity. Pharmacologically inhibiting this signaling loop enhanced the pro-inflammatory response to LPS. Finally, we found that this DAT-immune axis was disrupted in Parkinson's disease macrophages with macrophages from a cohort of PD patients exhibiting dysregulated DAT activity and subsequent DAT de-regulation of the LPS-induced immune response. Collectively, our data introduce a novel role for DAT in the regulation of innate immunity during health and disease.

Abstract: Ventrolateral striatum injury modifies the activation pattern of the cerebellum, supporting the idea that both structures function as an integrated system (Vásquez, 2019). In contrast, Herrera Meza, 2014 described an expression pattern of IR-Fos, which shows an increase in the hemispheres, specifically in sim B, crus II and dentate nucleus (with emphasis on the last 2 structures) that was interpreted as an increase in multiunit activity (MUA). For this reason, the MUA was recorded in Crus II, Dentate Nucleus and Inferior Olive (IO) was added to complete the cerebellar circuit. The aim of this study was to analyze and characterize the effect on the MUA of cerebellar neurons after damage caused by the insertion of an electrode in the ventrolateral striatum (VLS). Male rats (N=21) of the Wistar strain weighing (250-350 g) were used. Animals were divided into control (n=10) (without VLS lesion) and experimental (n=11) groups (with VLS lesion). Each subject was implanted with 1 to 3 recording electrodes in Crus II, dentate nucleus, and inferior olive. Finally, 10 traces were randomly selected to characterize and compare basal activity and jaw tremor, in this way, jaw tremor traces were analyzed and compared between groups and structures for 4 weeks. Recordings showed an increase in the maximal amplitude in the experimental group compared with the control group. On the other hand, the IO increases its maximal amplitude during the tremor with respect to dentate nucleus and Crus II. During the 4 weeks of recording, the maximal amplitude shows a downward trend.

Title: Involvement of raphe nuclei in depressive-like behavior and short-term memory in an animal model of rotenone-induced Parkinson's disease

Authors: *D. C. RAMOS[1], J. C. F. VIEIRA[1], L. C. SOUZA[1], M. BORTOLANZA[2], R. ANDREATINI[1], M. A. B. F. VITAL[1];
[1]Univ. Federal Do Paraná, Curitiba, Brazil; [2]Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Parkinson's disease (PD) is a neurodegenerative disease characterized by motor symptoms and non-motor disturbances such as fatigue, cognitive impairment, constipation, anxiety and depression. The dopaminergic neurodegeneration is a hallmark of PD, however the noradrenergic and serotonergic systems also present deficiencies. Studies have shown that an impaired serotonergic neurotransmission plays a role in the development of cognition deficits and mood disorders. In the central nervous system, serotonin-containing neurons are located, mainly, in the raphe nuclei, and send projections to several encephalic regions, such as limbic structures, and basal ganglia. In this context, the tryptophan hydroxylase (TPH), the rate-limiting enzyme in serotonin biosynthesis, has the potential to affect several brain functions through the regulation of encephalic serotonin levels in those regions. Thus, we aimed to investigate the involvement of serotonergic neurons in the raphe nuclei in depressive-like behavior and short-term memory. In this study, male Wistar rats were intraperitoneally treated for 10 days with rotenone (2.5 mg/kg) or its vehicle (sunflower oil). Both groups underwent locomotor and behavioral assessments, and we performed immunohistochemical and neurochemical analysis. One day after the last rotenone injection, we observed hypolocomotion in the rotenone-lesioned animals tested in the open field. Conversely, animals recovered the motor function when tested 7, 14, and 21 days afterwards. Furthermore, the systemic administration of rotenone was able to impair the short-term memory assessed in the social recognition test performed 22 days after the last rotenone injection. In the modified swim test, conducted on day 29, we observed an increase in immobility time in the rotenone group, compared to the control. Subsequently the behavioral tests, we performed the immunohistochemical analysis for TPH positive neurons in the raphe nuclei. Our results did not reveal significant differences between the groups regarding the number of TPH-immunoreactive neurons, neither in the dorsal raphe nucleus (rostral, mid, and caudal parts), nor in the median raphe nucleus. In contrast, we observed a significant reduction in serotonin levels in striatum, hippocampus and prefrontal cortex of rotenone-lesioned rats. These data indicate that the nigrostriatal lesion induced by rotenone - revealed by reductions of tyrosine

hydroxylase-positive neurons in substantia nigra compacta and dopamine levels in striatum - did not affect the number of TPH-immunoreactive neurons in raphe nuclei but led to lower serotonin levels and behavioral disturbances.

Title: Drd1 induced Nr4a2, controls locomotor sensitization to L-DOPA

Authors: *I. MANTAS[1], X. ZHANG[1], E. FRIDJONSDOTTIR[2], M. SAARINEN[1], K. TIKLOVA[1], T. LI[1], P. ANDRÉN[2], T. PERLMANN[1], P. SVENNINGSSON[1];
[1]Karolinska Inst., Stockholm, Sweden; [2]Uppsala Univ., Uppsala, Sweden

Abstract: Nr4a2 is a transcription factor, which is associated with disorders of the dopaminergic system such as Parkinson's disease. However, Nr4a2's function as an immediate early gene is largely unknown. In the present study, we revealed that chronic L-dihydroxyphenylalanine (L-DOPA) administration causes a robust Nr4a2 upregulation in the Drd1 expressing neurons of the dopamine depleted striatum and deep cortical layers. Mice lacking Nr4a2 in Drd1 cells (Drd1-cKO) exhibit profound less locomotor sensitization and slightly worsened dyskinesia scores. The behavioural changes observed in Drd1-cKO mice were accompanied by alterations in dynorphin and enkephalin neuropeptides at both mRNA and protein level. Even though Nr4a2 is well known to control dopamine related genes, we showed that both wild type and Drd1-cKO mice display L-DOPA induced striatal tyrosine hydroxylase mRNA upregulation. Accordingly, we unveiled that striatal Nr4a2 cells compose a distinct group, which is not overlapping with the tyrosine hydroxylase population. Nevertheless, mass spectrometry imaging of metabolites revealed an L-DOPA associated increase of α-glycerophosphocholine in control striata, which was absent in Drd1-cKO mice. Since Nr4a2 has been proposed to control mitochondrial

integrity, these results indicate a possible role of L-DOPA induced Nr4a2 in regulating lipid oxidation. The current study unravels unexplored functions of Nr4a2 in Parkinson's disease

Title: Charge neutralization of lysines by carbamylation and acetylation creates multiple aggregation hot spots in tau sequence

Authors: *S. GUPTA[1], J. GADHAVI[1], S. SHAH[1], A. JAIN[2];
[1]Indian Inst. of Technol. Gandhinagar, Gandhinagar, India; [2]Birla Inst. of Technol., Ranchi, India

Abstract: The impact of various post-translational modifications (PTMs) on tau protein aggregation has been well documented. However, whether these PTMs such as phosphorylation or glycosylation are drivers of aggregation or mere functional modulators is still an open question. As many PTMs are very dynamic in nature and endless combinations exist, perhaps a site-specific context-dependent model makes the most sense. Recent cryo-EM structural analysis of tau fibrils extracted from patients suffering from various tauopathies, including Alzheimer's Disease (AD), Picks Disease, Progressive supranuclear palsy (PSP), and Corticobasal degeneration (CBD) has revealed the presence of unidentified charge densities near lysine residues. As there are 44 lysine residues in full-length tau protein and charge neutralization on any of them can alter the nature of lysine from anti-aggregation to pro-aggregation, lysine modifying charge neutralizing PTMs are back in focus. In this context, carbamylation is one such charge neutralizing non-enzymatic age-dependent PTM, which is very similar to acetylation, an enzymatic dynamic PTM. We looked beyond the core fibril and assessed the aggregation potential of "lysine-rich" regions. Thus formed amyloid fibrillar assemblies were characterized by various biophysical methods, including ThT fluorescence enhancement, CD spectroscopy, congo red staining, fluorescence microscopy, and SEM. We observed that lysine carbamylation could convert previously unsuspecting sites in the flanking region to aggregation hotspots. We also demonstrate that this stickiness is strong enough to overcome the resistance from neighboring amino acids such as Proline and arginine. We further compared the aggregation propensity of carbamylated sequences with acetylated ones and observed that carbamylation is a

much stronger driver for aggregation. Atomic-level MD simulation studies further supported this. We have also looked at the impact of carbamylation and acetylation on the stability of AD core-derived peptides and determined that the β8 fragment that aligns opposite to the notorious β1 (VQIVYK) fragment aggregates if acetylated or carbamylated. When we ran the MD simulation, core fibrils unfold unless lysines on β8 are carbamylated or acetylated. Other core fragments were also impacted by modification but didn't seem to affect the stability much. Overall our results suggest that while carbamylation and acetylation could be significant drivers of tau aggregation in general, carbamylation on the non-core fibril region could further accelerate the aggregation process by generating additional aggregation hotspots.

Abstract: Neurodegenerative diseases, ranging from Alzheimer's dementia to Parkinson's Disease pose a formidable challenge to medical science, as well as a burden on those who are afflicted and their families. The societal costs are enormous. Protein aggregation is a hallmark of these diseases. Various environmental factors such as temperature, and pH affect amyloid formation. However very little is known regarding the impact of gravity on these aggregates. Here, we demonstrate the effect of microgravity on amyloid formation in the presence and absence of some potential anti-amyloidogenic drugs. The microgravity disruptive environment allows for additional biophysical screening. The opportunity to study drugs and cells at microgravity permits exploration of chemical and biological properties that might not be present at usual conditions. Such explorations under extreme conditions is an elegant tool for drug discovery.

Title: Somatic mutations in PRNP identified in patients with prion diseases using Nanopore sequencing

Authors: *A. DIMITRIADIS, F. KROLL, T. CAMPBELL, L. DARWENT, J. COLLINGE, S. MEAD, E. VIRE;
MRC Prion Unit at UCL, London, United Kingdom

Abstract: Accurate and rapid sequencing of the prion gene PRNP is paramount to human prion disease diagnosis and for animal surveillance programmes. Prion diseases are fatal neurodegenerative conditions that affect humans and animals. Current methods for PRNP sequencing are based on Sanger or next-generation sequencing of relatively small fragments within the coding region of the gene. Yet, the contribution of variants in the non-coding regions of PRNP is poorly understood. Here we combined long-range PCR and nanopore sequencing to sequence the full-length PRNP in human blood (n=21) and brain (n=5). In genetic cases of prion diseases, we show that variants in PRNP are picked up as efficiently by nanopore as they are by Sanger. In sporadic cases of prion disease, nanopore also identified novel variants but none of them with highly pathogenic potential. Finally, we used our method to explore somatic mosaicism of the PRNP octapeptide repeat region in inherited cases of prion diseases. Here we uncover, for the first time, somatic events in the prion gene detected a rate ranging from 0 to 0.28% of the reads per individual. These somatic mutations are more frequent in inherited prion diseases, suggesting that genomic instability of PRNP provide fertile grounds for more genetic mutations. Our study highlights the power of long-read sequencing for prion disease diagnosis and monitoring.

Title: "Investigating the mechanisms responsible for turnover of the ER stress sensing protein PERK"

Authors: *H. GUDLAVALLETI[1], B. J. STOVEKEN[2], R. VISWANTHAN[1], S. POLUSANI[3], J. D. LECHLEITER[1];
[1]Cell Systems and Anat., Univ. of Texas Hlth. Sci. center San Antonio, San Antonio, TX; [2]Cell Systems and Anat., Univ. of Texas Hlth. Sci. center San Antonio, University of Texas health Science center San Anto, TX; [3]Univ. of Texas Hlth. Sci. center San Antonio, San Antonio, TX

Abstract: PKR like endoplasmic reticulum (ER) Kinase (PERK) is an early ER stress sensor. It is a transmembrane protein that activates the unfolded protein response (UPR), first by luminal-dependent dimerization, followed by autophosphorylation of the cytosol domains and subsequent phosphorylation eIF2α. This early stress response reduces elF2α-mediated translation in cells when there is an accumulation of unfolded proteins to help restore homeostasis. PERK variants associated with tauopathies have been identified that show increased turnover rates and decreased kinase activity. However, the underlying mechanisms of PERK turnover have not been clearly resolved, which could help explain how PERK variants increase the risk of developing neuropathology. Preliminary studies indicate that pharmacological inhibition of autophagy with the drug chloroquine increases detectable levels of PERK using western blot analysis. Early estimates suggest chloroquine treatments (50uM) of cultured mouse embryonic fibroblasts (MEFs) increase PERK levels by 8-fold over a 28-hour period. We are also testing the role of proteasomal inhibition on PERK turnover. Thus far, treatment of cultured MEFs with the proteasomal inhibitor MG-132 (25uM), does not appear to significantly affect total PERK levels at similar timepoints. Experiments are currently underway to use photoconvertible fluorescent proteins (PCFPs) fused to PERK. These studies will permit us to monitor protein turnover by imaging changes in converted fluorescent protein (green to red in response to near-UV irradiation). Following the total fluorescence of converted PCFPs is the experimental equivalent of measuring radioactivity in pulse chase methodology. The primary advantages of PCFP measurements are both total levels and the spatial location of PCFP-PERK can be monitored in live cells. Preliminary measurements indicated significant loss of PCFP-PERK, 24 hours after photoconversion. We plan to investigate the impact of various PERK mutations on turnover. Co-localization studies of PCFP-PERK with lysosomal markers are also planned to determine if PERK is degraded through a lysosomal or ER - Phagy pathway. Data generated from these studies will lead to a better understanding of PERK turnover, which in turn, may lead to new pharmacological targets for treating neurodegenerative disorders associated with PERK.

Title: Postherpetic neuralgia - a new amyloid disease?

Authors: *A. BUBAK[1], M. NAGEL[2];
[1]Univ. of Colorado, Denver - Dept. of Neurol., Aurora, CO; [2]Neurol., Univ. of Colorado Anschutz Med. Sch., Aurora, CO

Abstract: Postherpetic neuralgia (PHN) is defined as dermatomal-distribution pain that persists > 90 days after herpes zoster (HZ). The risk of PHN increases with age with up to 40% of HZ individuals over 65 years of age developing PHN. PHN is difficult to manage, significantly impacts activities of daily living and quality of life, and is the leading cause of suicide in older adults with chronic pain. The cause has been attributed to a chronic VZV ganglionitis and/or ganglionic damage leading to neuronal dysfunction but exact pathophysiological mechanisms are not well-characterized. Recent studies from our laboratory found that VZV infection of spinal astrocytes *in vitro* induced intracellular amylin and Ab42 expression, intracellular amyloid, and an amyloidogenic extracellular environment, likely in part through self-aggregating and catalytic VZV glycoprotein B peptides. Further support for VZV induction of an “amyloidogenic state” is provided by studies of: (1) plasma from acute herpes zoster individuals that contain increased amyloid and promotes aggregation of cellular amyloidogenic peptides; and (2) cerebrospinal fluid from VZV vasculopathy patients that similarly contain increased amyloid and an amyloidogenic environment. Because amyloid deposition on neurites tags them for complement-mediated microglial pruning, we hypothesized that VZV infection of sensory ganglionic neurons leads to amyloid deposition on neurites leading to neuronal degeneration. To test this hypothesis, we infected human sensory ganglionic neuronal cells (HD10.6s) with VZV, conducted targeted RNA sequencing, then confirmed findings by immunocytochemistry (IHC). Compared to mock-infected cells, VZV-infected cells had significant enrichment of gene sets associated with amyloidosis and had predicted upstream regulators associated with the amyloid-associated disease, Alzheimer's disease (APP, PSEN1, and Tau); upregulation of complement pathways and synaptic pruning were also seen. IHC revealed striking amylin aggregates (amyloid) along VZV-infected neurites that also co-localized with the post-synaptic density marker PSD93. Taken together, VZV-infection of sensory neurons produces amylin aggregates on neurites that can potentially induce microglial pruning and neurodegeneration. In combination with host and genetic factors, this may explain the development of PHN in a subset of HZ patients.

Title: Heparin and octadecyl sulphate induced tau fibrils follow clathrin-mediated endocytosis in SH-SY5Y-derived differentiated neurons

Authors: *P. HIVARE, G. SWARUP, A. BANSAL, D. BHATIA, S. GUPTA;
Indian Inst. of Technol. Gandhinagar, Gandhinagar, India

Abstract: Tau is a microtubule-associated protein that is intrinsically disordered in nature and associated with more than 20 tauopathies in progressive neuropathological disorders (NDs). The intracellular proteinaceous aggregates of misfolded tau protein form the paired helical filaments (PHFs) and neurofibrillary tangles (NFTs). The aggregated tau species spread across neurons via transcellular propagation, and the mechanism of spreading remains unclear. The heparin-induced tau filaments differ structurally and do not reproduce the key structural features as found in Alzheimer's disease (AD) filaments raising questions about the use of *in vitro* tau assembly. Here in this study, we have prepared tau fibrils using heparin and octadecyl sulphate and studied the cellular internalization pathway in SH-SY5Y neuroblastoma cells and differentiated neurons. We studied the tau fibrils internalization using multiple cell-based approaches such as cellular uptake and recycling kinetics, standard endocytic probes, and protein colocalization. Transferrin is used to mark Clathrin-mediated endocytosis (CME), while Galectin-3 mark Clathrin-independent endocytosis (CIE). We further blocked the specific endocytosis pathway with inhibitors and found that tau fibrils follow the CMEpathway. The internalization pathway of tau fibrils formed by heparin and octadecyl sulphate will help understand the spread of tauopathies and Alzheimer's disease.1

Title: Creutzfeldt-Jakob disease with distinct PrP plaque phenotypes and PrP type 1 variants

Authors: R. BAYAZID, R. ASLAM, *I. CALI;
Pathology, Case Western Reserve Univ., Cleveland, OH

Abstract: Sporadic Creutzfeldt-Jakob disease (sCJD) comprises five distinct subtypes, which are identified by two major molecular modifiers of disease phenotype: (i) gel mobility of the pathogenic prion protein (PrP^D), commonly identified as PrP^D type 1 (T1) and type 2 (T2), and (ii) the polymorphic genotype (methionine (M)/valine (V)) at codon 129 of the PrP gene (129MM, -MV or -VV). The five sCJD subtypes are: MM(MV)1, VV1, MM2, MV2 and VV2 (Parchi et al., Ann Neurol 1999). Sporadic CJDMM1, the most common human prion disease, is characterized by T1 protease-resistant PrP^D and disease phenotype with fine spongiform degeneration (SD). The sCJDMM2 subtype harbors T2 PrP^D and large vacuoles SD whereas -MM1-2 shows mixed -MM1 and -MM2 histopathological features that correlate typically with the proportion of co-existing T1 and T2 PrP^D (Cali et al, Brain 2009). Furthermore, all sCJD cases with 129MM genotype (sCJDMM) are free of PrP amyloid plaques. Recently, sCJDMM1 with PrP^D kuru-plaque pathology has been described (Rossi et al., Acta Neuropathol Communic 2017). Here, we retrospectively examined 523 sCJDMM cases – referred to the National Prion Disease Pathology Surveillance Center (NPDPSC) – comprising 366 sCJDMM1, 48 -MM2 and 109 -MM1-2 cases. PrP^D plaques (p) were detected in 14 cases (~3%) populating either the white matter (p^{WM}-sCJD, n=7) of virtually all brain regions examined or the grey matter (p^{GM}-sCJD, n=7) of the cerebellar cortex. The two phenotypes correlated with distinct T1 gel mobilities: T1 migrated to ~20 kDa ($T1^{20}$) in p^{GM}-sCJD or to ~21 kDa ($T1^{21}$) in p^{WM}-sCJD. Furthermore, $T1^{20}$ and $T1^{21}$ showed distinct molecular features and brain distribution, indicating that T1 variants may be different human prion strains. These findings highlight the presence of PrP^D amyloid plaques in subjects with sCJDMM and suggest that $T1^{20}$ and $T1^{21}$ PrP^D are modifiers of histopathological phenotype.

Title: The outer brain

Authors: *R. A. NORMAN;
Robert A. Norman, D.O., P.A., Tampa, FL

Abstract: Much of my interest and research over the last decade has been on the connection between the skin and the brain, including searching for skin biomarkers to detect Alzheimer's disease (AD) and the connection between Parkinson's disease (PD) and melanoma. Parkinson's disease is a neurodegenerative disorder that triggers death of dopaminergic neurons within the brain's substantia nigra. Melanocytes are the pigmented cells that give rise to skin, hair and eye color, and melanoma is a potentially deadly cancer arising from melanocytes. As noted in a recent article by Dexter N. Dean, PhD, and Jennifer C. Lee, PhD, "Although these two diseases fundamentally differ, with PD leading to cell degeneration and melanoma leading to cell proliferation, epidemiological evidence has revealed a reciprocal relationship where patients with PD are more susceptible to melanoma and patients with melanoma are more susceptible to PD." Where is the hypothesis here? Let's look into the key pathology of each disease. Intracellular inclusions primary composed of proteinaceous α-synuclein (α-syn) amyloid fibrils, is the hallmark of PD. The α-Syn also has been detected in cultured melanoma cells and tissues derived from patients with melanoma. As Dean and Lee point out, an inverse correlation exists between α-syn expression and pigmentation and this has led to the prevailing hypothesis that α-syn inhibits enzymes involved in melanin biosynthesis. The two researchers recently reported an alternative hypothesis in which α-syn interacts with and modulates the aggregation of Pmel17, a functional amyloid that serves as a scaffold for melanin biosynthesis. In addition, α-syn may disrupt melanogenesis in melanoma cells by a disruption of TH and TYR enzymes involved in melanin biosynthesis. The hypothesis here is that uncovering the behavior of α-syn in melanoma could both provide novel approaches for treating melanoma and insights into the role of α-syn in PD.Although Tau protein has previously been assumed to be exclusive to the central nervous system, it is also found in peripheral tissues. My colleagues and I reported our research to determine whether there is a differential Tau expression in oral mucosa cells according to cognitive impairment.RT-QuIC and PMCA assays for formalin-fixed and paraffin-embedded skin tissues have also been utilized.The poster will provide a clear overview of the data in the abstract.

Title: Accelerated accumulation of mature tau isoforms in Tau P301S-hiPSC-derived cerebral organoids instigates microtubule defects and early phases of axonal degeneration

Authors: *X. SUN[1], P. CHANG[1], C. M. KARCH[2], P. W. BAAS[1], L. QIANG[1];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Psychiatry, Washington Univ. In St Louis, Saint Louis, MO

Abstract: Tauopathies are hallmarked by accumulation of pathological tau species derived from either MAPT mutations or other disease pathways. Tau, which is encoded by MAPT, is one of the most abundant microtubule (MT) associated proteins in the axon, but surprisingly, little is known about how tau impacts the properties of axonal MTs or how axonal MTs are affected by pathological changes in tau. Because pathological tau binds less avidly to them, conventional wisdom has been that MTs respond by becoming less rich in tau, which in turn results in a reduction in their levels and stability. However, recent studies have called into question the dogma of tau as a MT stabilizer, suggesting that tau's true role in this regard is to maintain portions of labile MTs. In addition, tau pathology is complicated by the existence of both mature and immature isoforms. To elucidate changes in axonal MTs resulting from pathological tau (separate from the contribution of non-tau confounders in diseases such as Alzheimer's), we used forebrain organoids derived from human induced pluripotent stem cells (hiPSCs) bearing the tauP301S mutation found in patients with Frontotemporal Dementia. A significant increase in the levels of 4R-tau and 1N-tau was observed in 2.5-month tauP301S-organoids, but not 3R and 0N tau isoforms, compared to the isogenic controls. Such phenotypes, further characterized by greater phosphorylation at the isotopes recognized by AT8 and TNT2 but not TOC1, were not identified in 2-dimensional differentiated glutamatergic neurons cultured for the same period. An early axonal degeneration phenotype in the tauP301S-organoids was documented via multifaceted analyses using amino-cupric silver stain, immunohistochemistry via SMI32, axonal swelling revealed by bIII tubulin and neuronal activity recording via multielectrode array. Other studies revealed that the increase in tau levels is accompanied by a decrease in MT stability as well as a decrease in the levels of MAP6, which is a genuine stabilizer of MTs. These results are

consistent with the view that tau keeps MTs from being stabilized (rather than the inverse) such that a significant rise in tau levels early in the pathology overcomes the reduced binding affinity of the tau to the microtubules. As for a toxic gain-of-function effect of the pathological tau, an uptick in mal-oriented MTs in the axons of the tauP301S-organoids was corrected by a drug that increases MT mobility, and this in turn rescued the aberrant axonal swelling in these neurons. Overall, our findings suggest that accelerated accumulation of mature tau isoforms instigates MT defects that accompany (and may underlie) early phases of axonal degeneration.

Title: Pathological tau drives the cytoplasmic aggregation of nuclear speckle scaffold protein SRRM2 in Alzheimer's disease neurons and models

Authors: *R. ECK[1], P. J. MCMILLAN[2], T. J. STROVAS[4], M. BAUM[4], B. K. MITCHELL[4], N. HENDRICKS[4], J. M. WHEELER[4], C. S. LATIMER[3], C. D. KEENE[4], B. C. Educ. and Clin. Ctr., Veterans Affairs Puget Sound Hlth. Care Syst., Seattle, WA

Abstract: Tau aggregation and toxicity requires several nuclear and well-conserved RNA binding proteins (*sut-1*, *sut-2*, *parn-2*, *sut-12*) in *C. elegans*, mice, and human cells. The mammalian homology of SUT-2 (MSUT2) normally resides in nuclear speckles (NS), membranelles organelles composed of phase-separated RNAs and RNA binding proteins that regulate transcription, mRNA processing, and splicing. Given the role of NS in RNA metabolism and the association of MSUT2 and other suppressors of tauopathy with NS, we used human pathological tissue and transgenic mice to identify any Alzheimer's disease-specific changes to NS. We observed that NS constituent scaffold protein SRRM2 is mislocalized and accumulates in cytoplasmic lesions in AD brain tissue. These SRRM2+ lesions significantly colocalize with

pathological tau. Furthermore, progression of tauopathy in transgenic mice is accompanied by increasing mislocalization of SRRM2 from the neuronal nucleus to the cytoplasm. In AD brain tissue, SRRM2 mislocalization is also associated with increased severity of pathological tau deposition. In *C. elegans,* we further explored the molecular mechanisms driving ectopic localization of RSR-2, the *C. elegans* homolog of SRRM2, and the resulting cellular consequences for neurodegeneration. Our findings suggest potential mechanisms by which pathological tau impacts nuclear speckle function in diverse organisms ranging from *C. elegans* to mice to humans. Future translational studies aimed at restoring nuclear speckle homeostasis may provide novel candidate therapeutic targets for pharmacological intervention.

Title: Pharmacological inhibition of histone deacetylases (HDACs) presents an enriched neuronal platform in the brain for neurorehabilitation

Authors: *H. MAEJIMA[1], M. KITAHARA[2], Y. TAKAMATSU[1], H. MANI[1,3], T. INOUE[2,4]; [1]Dept. of Rehabil. Science, Fac. of Hlth. Sci., [2]Grad. Sch. of Hlth. Sci., Hokkaido Univ., Sapporo, Japan; [3]Oita Univ., Oita, Japan; [4]JSPS, Tokyo, Japan

Abstract: Therepeutic exercse is a primary intervention to rehabilitate the motor impairment of patients with central nervous system (CNS) disorders. Specifically, aerobic exercise increases the expression of neurotrophins including brain-derived neurotrophic factor (BDNF) in the brain and contributes beneficially to the improvement of motor impairment. Histone deacetylases (HDACs) inhibitors acetylate histones and enhance gene transcriptions. In the present study, we examined the interactive effects of pharmacological treatment with an HDAC inhibitor and aerobic exercise on the modifications of epigenetic markers including HDAC activity and histone acetylation levels and neurotrophic gene expressions including neurotrophins and immediate-early genes (IEGs) in the motor cortex. The objective of this study was to find a more enriched neuronal platform in the brain for neuronal rehabilitation. ICR mice, 13-week-old, were divided into four groups based on two factors: HDAC inhibition and exercise. Intraperitoneal administration of an HDAC inhibitor (1.2 g/kg sodium butyrate, NaB) and moderate exercise at

10 m/min for 60 min were conducted five days a week for four weeks. NaB administration inhibited total HDAC activity and increased acetylation level of histone H4. NaB administration also increased the transcription levels of IEGs including c-fos and Arc, and neurotrophins including BDNF and NT-4 in the motor cortex. Moderate treadmill exercise enhanced HDAC activity and acetylated histone H4 and H3, whereas exercise did not affect transcription levels of IEGs and neurotrophins. In addition, there were no significant synergic effects between HDAC inhibition and the exercise regime on the gene expressions. Altogether, this study showed that daily HDAC inhibition could present more enriched condition for neuroplasticity to the motor cortex, suggesting that pharmacological treatment with HDAC inhibitor could precondition neuronal platform for neurorehabilitation in patients with CNS disorders.

Title: The effects of exercise on GDNF and estrogen concentration in male and female rats

Authors: *J. M. VANGYSEGHEM, J. M. SPITSBERGEN;
Western Michigan Univ., Kalamazoo, MI

Abstract: Males and females differ hormonally and neurologically as they age yet are given the same treatment for many neurological diseases. As aging occurs there is a loss of motor neurons, which could be explained by the reduced neurotrophic factor concentration. A possible way to maintain neuroprotection would be the production and release of a target-derived neurotrophic factor, such as glial cell line-derived neurotrophic factor (GDNF). Previous studies have shown that GDNF concentration has increased in skeletal muscle after exercise. However, this study has only been done in male rats. While exercise has been shown to mitigate the rate of development of degenerative loss of skeletal muscle mass, quality and strength called sarcopenia it has additionally been shown to increase estrogen receptors on skeletal muscle and increase levels of GDNF in skeletal muscle. Furthermore, it has been shown that GDNF and estrogen signal through similar intracellular pathway, and through such pathways, estrogen can enhance intracellular GDNF signaling. Our hypothesis is that GDNF concentration will be lower in sedentary rats when compared to exercised. In order to gain a more complete picture of what is happening neurologically as we age, I will be looking at female rats and comparing them to male rats of the same age. Hindlimb skeletal muscle was taken from Sprague-Dawley rats, from both sedentary and voluntarily exercised males and females. Their ages ranged from 4 weeks to 18

months. Sedentary muscle was taken at 4 weeks, 6 weeks, 8 weeks, 12 weeks, 12 months and 18 months. Exercised muscle was harvested from 4 week old rats that had access to running wheels for 2 weeks, from, 8 week old rats exercised for 4 weeks, and from 12 month old rats who voluntarily exercised for 6 months. Western blot and ELISAs were used to measure GDNF concentration, while immunohistochemistry was used to visualize the motor neuron, end plates, and GDNF. There were differences in GDNF concentration between male and females as they aged and if they were sedentary vs. exercised. Motor end plates showed more complexity and larger surface area from skeletal muscle in exercised rats as compared to sedentary. Future studies will investigate if estrogen concentration changes in the same trend in these groups as GDNF concentrations. Understanding the role that neurotrophic factors play in neuroprotection as we age and exercise between different sexes, may help develop novel pharmacological treatments and could impact our healthcare system, as we can think about it in a more nuanced way.

Title: Primary Cilia Regulate Hippocampal Bone Morphogenic Protein Signaling

Authors: *S. R. DUNLOP, C.-Y. PENG, J. A. KESSLER;
Neurol., Northwestern, Chicago, IL

Abstract: In the adult hippocampus, exposure to exercise or environmental enrichment (E/EE) attenuates bone morphogenetic protein (BMP) signaling and increases expression of the BMP inhibitor noggin. Additionally, E/EE has been shown to increase neurogenesis and enhance cognitive performance. Reducing BMP signaling in adult mice by ventricular infusion, transgenic overexpression, or viral overexpression of noggin reproduces many of the effects of exercise on both neurogenesis and behavior. Immuno-cytochemical and in-situ hybridization analyses indicate that noggin is expressed by dentate granule neurons, but the subcellular localization of the protein and the mechanisms regulating its synthesis and release are unknown. To address these questions, we generated primary hippocampal cultures from microdissected dentate gyri of postnatal day 3 (P3) C57B6 mice. Noggin protein expression was assessed by immunoblot, mRNA transcript expression via RT-qPCR, and extracellular release via sandwich

ELISA. Our results demonstrate that under normal conditions noggin is localized to primary cilia, immunolabeling in-vivo confirms this localization. However, under depolarizing conditions (20 mM KCl) noggin is redistributed in the cytoplasm and released extracellularly into the culture medium. Further, disruption of primary cilia leads to bulk release of noggin and depletion of intracellular stores of the protein. While TGF-beta signaling has been previously described in primary cilia, this is the first evidence of noggin localization in primary cilia and evidence of noggin protein regulation. Our observations indicate that ciliary integrity is required for noggin homeostasis and that primary cilia appear to be involved in noggin extracellular release.

Title: Optogenetic re-activation of cortico-thalamic circuits for stroke recovery

Authors: *Z. CAO[1], T. C. CHIANG[2], A. KIM[1], M. Y. CHENG[2], G. K. STEINBERG[1]; [2]Neurosurg., [1]Stanford Univ., Stanford, CA

Abstract: Introduction: A stroke injury can severely disrupt neuronal activity in local and remotely connected regions, leading to network-wide deficits. In particular, cortical stroke disrupts neuronal activity in the cortico-thalamic circuit, resulting in the development of secondary degenerative injury in the remote thalamus. This secondary thalamic degeneration is associated with worsened functional outcomes. In this study, we use optogenetic strategy to selectively restore neuronal activity in the cortico-thalamic circuit and examine its effects on the thalamic injury and functional outcome after stroke. **Methods**: Optogenetic selective cortico-thalamic circuit re-activation was achieved by injecting AAV1-CaMKIIa-hChR2 virus in the ipsilesional somatosensory cortex (iS1) and implanting in the ipsilesional thalamus (iTH) (C57BL6 male mice, 6-8 weeks old). Cortical ischemic stroke was generated by permanent occlusion of the left middle cerebral artery. Stimulated stroke mice received daily stimulations between Post-stroke Day (PD) 4 to 14. Long-term functional outcome was evaluated by

ErasmusLadder tests at pre-stroke baseline, PD3, 7, 14 and 28. Mice were sacrificed at PD29 and immunostaining was used to detect primary cortical injury and secondary thalamic injury (NeuN), neuroinflammation (CD68), and oligodendrogenesis (Olig2 and CC1) in the thalamus. **Results**: Histological staining confirmed expression of ChR2 in the somatosensory cortico-thalamic tract. Stimulated group showed similar performance on the total H-H step and right side of the H-H step, but a trend of less total jump step compared to the non-stimulated group. We did not observe significant difference in the primary and secondary injuries, and neuroinflammation between the two groups. Interestingly, stimulated mice exhibited an increase in the number of mature oligodendrocyte ($Olig2^{+}CC1^{+}$) and oligodendrocyte progenitor cells ($Olig2^{+}$) in iTH. **Conclusion**: As the secondary thalamic injury allows an extended treatment window, targeting secondary injury is a promising approach to improve stroke recovery. Our preliminary results show that restoring neuronal activity in the cortical-thalamic circuits may promote functional recovery and oligodendrogenesis after stroke. Current studies are investigating the effects of cortico-thalamic circuit stimulation in oligodendrogenesis in the degenerative thalamus after stroke.

Title: Selective inhibitory circuit dysfunction after chronic frontal lobe contusion.

Authors: *A. NOLAN[1], V. S. SOHAL[2], S. ROSI[3];
[1]Univ. of Washington, Seattle, WA; [2]Dept. of Psychiatry, U. California, San Francisco, San Francisco, CA; [3]Brain and Spinal Injury Ctr., Univ. of California San Francisco, San Francisco, CA

Abstract: Traumatic brain injury (TBI) is a leading cause of neurologic disability and the most common associated cognitive deficits affect prefrontal cortex (PFC)-dependent functions such as: attention, working memory, social behavior, and mental flexibility. Despite this prevalence, little is known about the pathophysiology that develops in frontal cortical microcircuits after TBI. In a mouse model of frontal lobe contusion that recapitulates aberrant mental flexibility as measured by deficits in rule reversal learning, we investigated if alterations in subtype-specific inhibitory circuits are associated with cognitive inflexibility after TBI. Patch clamp recordings

and optogenetic stimulation were performed in layer V two months after injury in the orbitofrontal cortex (OFC). Selective vulnerability in the non-fast spiking, somatostatin-expressing subtype of inhibitory neurons was identified in chronic TBI. Specifically, these neurons exhibited a reduction in excitability and a decrease in their associated synaptic input onto pyramidal neurons. In contrast, fast spiking, parvalbumin-expressing neurons did not show changes in excitability or PV-specific synaptic input onto pyramidal neurons. SOM-mediated disinhibition with TBI was not simply action-potential dependent. Synapse specific properties including the amplitude and frequency of SOM-mediated quantal IPSCs were diminished with TBI as well. This selective vulnerability of SOM+ neuronal function identified in the OFC with chronic TBI was also associated with a hyperexcitable network in 0 mm Mg^{2+}/ 5mM K^{+}. These findings support targeting of subtype specific inhibition in therapeutic development for cognitive dysfunction in TBI.

Title: Hidden Markov Modelling of altered cortical networks during reach in people with Multiple Sclerosis and intention tremor

Authors: *J. C. WAGNER[1,2], G. BALLARDINI[2], G. BOMMARITO[3], M. INGLESE[4,3], M. CASADIO[2], A. CANESSA[2], R. A. SCHEIDT[1], S. A. BEARDSLEY[1];
[1]Dept. of Biomed. Engin., Marquette Univ., Milwaukee, WI; [3]Neurol., [2]Univ. of Genova, Genova, Italy; [4]Mount Sinai Sch. of Med., New York, NY

Abstract: Up to 58% of Persons with Multiple Sclerosis (PwMS) live with tremor that impacts daily activities like reaching for items. These brain networks can be identified with Electroencephalography (EEG). Recently, Hidden Markov Modeling (HMM) has been used with EEG to identify brain network state changes during tasks. We used HMM to identify how cortical networks engaged in visually guided reaching are altered in MS.Ten Healthy Controls (HC) (7 male, 24-60 years) and 7 PwMS (5 male, 33-58 years) performed a reach and hold task using a 1-D passive wrist robot while 64-channel EEG was recorded. Subjects were to track a user-controlled cursor over a target that pseudorandomly moved to a new position (104 movements total). Kinematic measures such as Reaction Time (RT) and Target Acquisition Time

(TAT) were quantified from wrist position traces. After typical EEG preprocessing and source reconstruction, regions of interests were defined for each subject within visual-parietal-sensorimotor regions of both hemispheres. EEG signals ([-1 2] seconds about target movement) were used in the HMM to identify sequential brain states involved in the task. Timing of peak state probability and state transitions were estimated.On average, RTs were longer in PwMS than HC (PwMS: 485 ± 134 ms; HC: 387 ± 40 ms) as were TATs (PwMS: 327 ± 141 ms; HC: 193 ± 38 ms). Four brain states were identified for HC. State 1 ([-1 0.36] s), localized in the occipital lobe, coincided with attention to the trial. State 2 ([0.25 0.59] s), occurred in contralateral somatosensory, motor, and premotor cortices. Peak probability coincided with RT suggesting a role in movement planning and execution. State 3 ([0.51 1.24] s), occurred in visuomotor cortices, and captured the final stages of reach and stabilization. Cortical networks returned to baseline in State 4 ([0.97 2] s). Although the timing of states was similar between HC and PwMS, the brain networks present in states 2 and 3 were different. PwMS with tremor showed greater network variability and a shift in state dynamics towards bilateral brain activation. In contrast to HCs, occipital and parietal activity increased in state 2 associated with target tracking and motor planning. Importantly, PwMS RT occurred later, in the transition between states 2 and 3. Differences in brain network states in PwMS with tremor suggest disruptions in target detection and motor planning which delayed downstream processing of visually guided movement. Additionally, the shift to bilateral brain activation implies engagement of compensatory brain networks. Understanding how MS alters brain network states will facilitate development of targeted therapies to mitigate tremor.

Title: Electrophysiological effects of taVNS on the basal cholinergic system, intracortical GABA-A-ergic system, and cerebellar inhibitory Purkinje-cell system: a TMS study

Authors: *V. M. VAN MIDDEN[1], Z. PIRTOSEK[1], M. ZIVIN[2], M. KOJOVIC[1]; [1]Neurol., Univ. Med. Centre, Ljubljana, Ljubljana, Slovenia; [2]Inst. of Pathophysiology, Ljubljana, Slovenia

Abstract: Introduction: Transcutaneous auricular vagus nerve stimulation (taVNS) is an emerging treatment option for various neurological and psychiatric diseases. Functional magnetic resonance imaging studies show increased activity of nucleus tractus solitarii, locus coeruleus, and raphe nuclei during taVNS, suggesting that taVNS may affect diffuse neuromodulatory networks. Yet, it remains unknown whether these changes translate to changes in downstream neuromodulator and neurotransmitter activity. We used different transcranial magnetic stimulation (TMS) paradigms to address the possible neurophysiological effects of taVNS: short latency inhibition (SAI) to assess the activation of the basal forebrain cholinergic system, short latency intracortical inhibition (SICI) to assess the activation of the intracortical inhibitory GABA-A system, and cerebello-cortical inhibition (CBI) to assess effect of inhibitory locus coeruleus projections on cerebellar Purkinje cells.**Methods:** 23 healthy participants (mean age 27 years, 57% females) completed 2 visits, separated by 5 days. In a randomized order they received 25min of taVNS at the left cymba conchae or sham stimulation (sVNS) at the left earlobe, using following stimulation parameters: square shaped 100Hz pseudobiphasic pulses, interphase interval 80 us, pulse duration 300ms, intensity 100uA above the sensory threshold level. For SAI we used 3 interstimulus intervals (ISI): 20, 22, and 24ms. For the SICI curve, we used 4 conditioning stimulus (CS) intensities: 70%, 80%, 90%, and 100% of the active motor threshold. For CBI ISI was 5ms and CS was at the maximum intensity tolerated by the participant. Each TMS paradigm was repeated before, during, and after taVNS/sVNS (b-d-a). For each TMS parameter we performed rmANOVA with within-subject factors: stimulation (real/sham), time (b-d-a), and additional factors ISI and CS intensity for SAI and SICI, respectively.**Results:** For SAI and SICI, rmANOVA revealed no significant 2-way or 3-way interactions, suggesting no difference in the effect of real and sham taVNS on these parameters. There was no significant difference between the effect of taVNS and sVNS on CBI. **Discussion and conclusions:** Our group analysis suggests that taVNS does not affect electrophysiological measures of intracortical cholinergic and GABAergic systems, nor does it affect cerebellar inhibition of the motor cortex. Our findings could be explained by a) a ceiling effect due to strong baseline inhibition in young healthy subjects that could not be further modified by intervention; b) high variability of TMS measures; c) suboptimal taVNS parameters; or d) a true absence of an effect of taVNS.

Title: Exploiting polypharmacology: targeting multiple kinases to promote axon regeneration and behavioral recovery after CNS injury

Authors: *K. MAH[1], H. AL-ALI[1], W. WU[2], N. O'NEILL[1], J. LOWELL[1], M. MUNOZ[1], X.-M. XU[2], V. P. LEMMON[1], J. L. BIXBY[1];
[1]Univ. of Miami, Miami, FL; [2]Indiana Univ., Bloomington, IN

Abstract: Central nervous system (CNS) axons generally lack the ability to regenerate and reconnect, which hampers recovery after spinal cord injury. This can be attributed to both growth repressive factors in the CNS environment and a lack of intrinsic regenerative potential in adult CNS neurons. Kinases regulate many cellular processes including axon growth and regeneration; kinase inhibitors may therefore regulate multiple signaling networks to overcome regeneration inhibition. We developed a platform that combines phenotypic and target-based screening to identify a) kinase targets and b) kinase inhibitors of interest in neurite outgrowth. Using this approach on a library of kinase inhibitors, we identified “target” kinases whose inhibition promotes axon outgrowth and “anti-target” kinases whose inhibition limits this process (Al-Ali; PMID: 26056718). Simultaneously inhibiting each of two target kinases, Rho kinase (ROCK) and ribosomal protein S6 kinase 1 (S6K1) had a synergistic effect on promoting neurite outgrowth. Notably, we identified a single compound (RO48) that inhibits both ROCK and S6K1, as well as other target kinases, while exhibiting better overall kinome selectivity than several FDA approved kinase inhibitor drugs. RO48 promoted substantial axon outgrowth in a variety of cultured neurons, as well as corticospinal tract (CST) sprouting and regeneration in two mouse models of spinal cord injury, accompanied by improved recovery of sensorimotor function in rotarod, gridwalk, and pellet retrieval tasks. We subsequently identified RO48 derivatives with improved pharmacokinetic parameters that also produced robust neurite outgrowth in vitro. One of these derivatives was shown to promote CST axon growth in the pyramidotomy model. These results support the relevance of identified target kinases to regeneration, and are the first steps in generating candidate lead compounds for clinical development.

Title: Rolipram delivered by PgP nanocarrier enhances motor function in a rat contusion SCI model

Authors: *Z. LIAO[1], J. GAO[2], M. KHANG[1], M. R. DETLOFF[3], J. LEE[2];
[2]Bioengineering, [1]Clemson Univ., Clemson, SC; [3]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) is a major source of morbidity and mortality throughout the world. One of important pathological events after SCI is significant decrease of intracellular cAMP level in injured spinal cord. Phosphodiesterase 4 (PDE4) activation after injury causes excessive degradation of cAMP and this impairs cAMP signaling which affects cell metabolism, survival, and behavior. Rolipram (Rm), a PDE4 inhibitor, is used to effectively improve neuronal survival and reduce neuroinflammation after SCI. Previously, we reported that Rm was loaded in to an amphiphilic nanocarrier, poly(lactide-co-glycolide)-graft-polyethenimine (PgP) developed in my lab (US patent: US 10,232,050) and Rm- loaded PgP (Rm-PgP) nanoparticles injected at the SCI lesion can restore cAMP levels to sham level and reduce inflammation and apoptosis in rat compression SCI model. In this study, we evaluate the therapeutic efficacy of Rm-PgP treatment on secondary injuries, functional recovery, and neuropathic pain in a rat moderate contusion SCI model. Moderate contusion injury model was created at T9-T10 spinal cord of SD rats (200-250 g) using the impactor (IH-0400, PSI) with a force of 200 kdyn. Rm-PgP (10 μg Rm) was administered immediately after injury by intraspinal injection using microinjector (MICRO2T, WPI) with injection speed 2 μL/min. Rm-PgP effect on cAMP level was measured using cAMP ELISA kit at 1 and 2 days post treatment. Motor functional recovery of the hindlimb was evaluated using BBB locomotor rating scale and neuropathic pain was evaluated using von Frey filament up to 4 weeks after SCI. At 4 weeks post-injury, rats were sacrificed via cardiac perfusion and the spinal cord (1 cm) was retrieved, fixed, embedded in OCT block, longitudinally sectioned, and stained for inflammatory response, apoptosis, neuronal survival, and astrogliosis. We observed that cAMP level in Rm-PgP treated animal group was significantly different with that in untreated SCI group at 1 DPI and significantly fewer $ED1^+$ cells, $TUNEL^+$ apoptotic cells and $GFAP^+$ cells in the spinal cords from animals treated with Rm-PgP relative to the untreated animal group. For the motor function recovery, BBB scores of the treated animals were significantly higher than those of untreated SCI animals from 2 week upto 4 weeks. For the neuropathic pain, withlold threshold of the the treated animals were higher, but the threshold was not significantly different with untreated SCI animals at all time points. In conlussion, local delivery of Rm by PgP nanocarrier reduced secondary injury and improved motor function after SCI in a rat contusion SCI model.Funding was provided by NIH/NINDS grant 5R01 NS111037-02.

Title: The role of plasma derived purified exosome product for improved locomotor recovery in spinal cord injured rats

Authors: *F. MOINUDDIN, C. ONYEDIMMA, M. BYDON;
Mayo Clin., Rochester, MN

Abstract: Study design: Animal Study **Introduction**: Preclinical studies indicate that mesenchymal stem cell-derived secretomes exert immunomodulatory and neuroprotective effects in various spinal cord injury models. Exosomes as one of the secretomes, have been shown to successfully aid wound healing for the skin and following myocardial infarction. However, the effects of human plasma-derived purified exosomal products (PEP) on spinal cord injury (SCI) have not been explored to this date. **Objective:** To determine the impact of PEP on locomotor recovery in the rat model of SCI followed by a comparison of the intrathecal and Intravenous (I.V) routes of administration for the delivery of PEP. **Methods**: Twenty-four female rats were randomly divided into five groups. These included 2 control groups for the I.V or I.T injected PEP groups and a sham group. Groups were subject to a T9 laminectomy, followed by a moderate contusion SCI. After 24 hours, lactated ringer solution or PEP was injected through I.V or IT routes. Rats were assessed weekly for a total period of 10 weeks by an open field Basso, Beattie, and Bresnahan (BBB) motor score and a postmortem quantification of external scaring, neuronal regeneration, cavity volume, and glial scarring was carried out at the end of the follow-up period. **Results**: Animals treated with I.V PEP or IT PEP had significant improvement within the first-week post-injury (1.05±1.2 vs. 2.16±3.15) and (1.08±3.5 vs. 4.5±0.083) respectively, with sustained improvement in BBB score at 10 weeks (11±1.16 vs. 13.8±1.90),(11.3±1.4 vs. 14±1.16). **Conclusion**: Our preliminary results suggest that I.V or IT PEP injection without immunosuppression might provide beneficial effects initially following traumatic SCI.

Title: Critical role of mitochondrial aldehyde dehydrogenase -2 (ALDH2) in acrolein-mediated neurotoxicity in mouse spinal cord injury

Authors: *S. SUN[1], Z. ZHANG[2], S. HERR[2], R. SHI[3];
[1]PULSE Integrative Neurosci. Purdue Univ., West Lafayette, IN; [3]Depat. Basic Med. Sci., [2]Purdue Univ., West Lafayette, IN

Abstract: Oxidative stress-associated lipid peroxidation-derived aldehydes such as acrolein have emerged as key mediators in sustaining secondary injury that contributing significantly to the functional loss after spinal cord injury (SCI). Mitochondrial aldehyde dehydrogenase-2 (ALDH2), a key oxidoreductase and powerful endogenous anti-aldehyde machinery, is thought to play a critical role in acrolein-mediated pathology. Therefore, the gene mutant that encodes an inactive form isoenzyme (ALDH2*2), a genetic condition that exists in more than 600 million people worldwide, could potentially impair the individual's ability to remove toxic acrolein that leads to exacerbated injury following spinal trauma. Recently, a novel transgenic (TG) ALDH2*2 mouse that recapitulates the human condition was developed that offers an ideal model to study the clinically relevant scenario of heightened neurofunction impairment for individuals with this mutation. Further equipped by the ALDH2-selective agonist, Alda-1, such study could not only further demonstrate the critical role of ALDH2 in suppressing acrolein in SCI, but also explore ALDH2 as a potential target for anti-acrolein pharmaceutical intervention.The ALDH2*2 TG mice that received thoracic contusion SCI showed a more exaggerated ascension of the acrolein level when compared to the wildtype (WT) injury mice at 2-days post-injury. In addition, such acrolein buildup remained at a significantly higher level at 7 days when the WT mice had started to recover towards the baseline in the spinal cord. Moreover, the application of Alda-1 significantly rescued the ALDH2 enzymatic activity, mitigated the post-SCI acrolein elevation, and enhanced the neurofunctional recovery. These findings support our hypothesis that the activity of ALDH2 is an essential neuroprotective factor in acrolein sequestration and functional amelioration in SCI. A better outcome could be achieved by boosting its activity after SCI and possible other neurotrauma diseases, especially in individuals with such genetic deficits.

Title: Oxygen therapeutic to limit secondary spinal cord injury (SCI) in a rodent model

Authors: J. HOU[1,3], D. PLANT[3], S. TSUDA[1,3], B. RENGERT[3], J. ZHU[1], T. PARSONS[1], M. FRANKLIN[1], F. THOMPSON[3], C. GARVAN[1], B. SPIESS[1], P. BOSE[1,3,2];

[3]North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL

Abstract: Acute SCI creates a spectrum of tissue damage. Damage results from both primary injury caused by immediate neural cell death and secondary injury resulting from ischemic and inflammatory cascades. Secondary injury contributes to lesion expansion and worsening neurological deficit. Injury and neuron death lead to swelling, reduced perfusion/O_2 delivery, and an expanding penumbra. This ischemic penumbra is an obvious target for therapeutic interventions because a rapid reduction of ischemia can show substantial benefits for neuron salvage and motor function. The objective of this study is to test the preclinical evaluation of the safety and efficacy of a novel patented IV emulsions of perfluorocarbon (PFC) nanoparticles, $NanO_2$ (NuVox Pharma LLC, Tucson, AZ), to limit the ischemic penumbra and improve motor disabilities following SCI. $NanO_2$ is a pentane-based, low molecular weight, nanodroplet (250-300 nm) PFC emulsion. Unlike other PFCs, $NanO_2$ has unique properties of higher levels of respiratory gas transfer and deeper O_2 penetration to areas not able to be perfused by red blood cells. NanO2 has a better tolerance and safety profile, and there have been no FDA hold safety concerns to date. Although $NanO_2$ is in Phase 1B and II clinical trials for stroke and cancer in the US, it has not been investigated for SCI. Randomized $NanO_2$ or normal saline (NS) were administered 20 minutes after SCI (0.6 ml/kg, 2 hrs apart, three doses total) via lateral tail vein. At post-injury week 5, the NS treated C-SCI animals showed significant increases in ankle torque and time-locked EMG burst amplitudes at 8 test velocities as compared to recordings in naïve animals, revealing an enduring velocity-dependent spasticity of the extensor muscles of the lower limb. In contrast, the $NanO_2$ treatment apparently blocked spasticity development. Moreover, $NanO_2$ treated animals exhibited rate-sensitive depression of the soleus H-reflex toward normal values especially in higher test frequency compared to significant loss of rate-depression exhibited in NS-treated SCI animals. Moreover, hindlimb step cycle knee-ankle coordination showed robust improvement following $NanO_2$ treatment compared to extensive loss of joint coordination in C-SCI animals. *Ex vivo* diffusion tensor imaging (DTI) MRI revealed robust preservation of the dorsal corticospinal and rubrospinal descending motor tracts following $NanO_2$ treatment compared to NS treated SCI animals. Our preliminary therapy-induced behavioral/physiological/MRI improvements data to date indicate that $NanO_2$ therapy in SCI may have prevented the ischemia-mediated neurological damage and improved motor disabilities.

Title: Lack of significant neuroprotection from either durotomy or methylprednisolone after cervical spinal cord injury in a rat model

Authors: *J. BERGQUIST, T. PRASSE, N. AL-KHAYAT, J. BUSHNELL, C. P. HOFSTETTER, Z. Z. KHAING;
Dept. of Neurolog. Surgery, Univ. of Washington, Seattle, WA

Abstract: Traumatic spinal cord injury (SCI) results in a wide range of outcomes from partial paralysis to complete tetraplegia. Importantly, there is a high density of motor neurons in the cervical region involved in important motor outputs such as breathing and hand function. Previous work in thoracic injury models has demonstrated surgical decompression (i.e., durotomy) is beneficial for tissue and neuron sparing, and for behavioral recovery; retrospective clinical studies suggest durotomy may improve outcomes in cervical injury as well, however prospective, randomized evidence is still needed to determine whether durotomy benefits this region. The present study aims to minimize the secondary damage after cervical SCI by addressing multiple interrelated contributors to neuron death via either surgical manipulation (durotomy), FDA-approved methylprednisolone sodium succinate (MPSS), or both surgical and pharmaceutical treatments. Clinically relevant 200 kD bilateral contusion-type injuries were introduced at the C5 spinal cord segment in a cohort of adult female Long Evans rats. Animals were randomly assigned to one of 5 groups: sham (n=1), SCI only (n=5), durotomy (n=5), MPSS (n=5), and durotomy + MPSS (n=5), and were allowed to survive for 14 days post injury (dpi). Treatment effectiveness was assessed by comparing neuron and tissue sparing, inflammatory response, and functional deficits between treatment groups. The durotomy + MPSS group showed statistically insignificant trends towards greater neuron sparing and tissue sparing 1mm caudal to injury epicenter compared to SCI-only controls (2162 +/- 250 vs. 1954 +/- 504 neurons), (83.6 +/-6 % vs. 73.5 +/- 10% spared). There were no differences in inflammatory (Iba1, GFAP) response between treatment and control groups, as measured by fluorescence intensity in immunohistochemistry ($p = 0.413$, 2-way ANOVA). Finally, all animals showed similar deficits in forelimb joints' range of motion and weight support at 4dpi and recovered most functions except forelimb-hindlimb coordination by 14dpi. The present study highlights a critical need for re-evaluation of the approved, yet still controversial use of MPSS. It is also likely that the 14 dpi survival time did not allow enough time for histological differences to manifest, therefore future studies will include longer survival times. Given the complex and

dynamic evolution of architecture and environment of the spinal cord after SCI, examining more chronic effects of durotomy and MPSS on different injury severities will be crucial.

Title: Conditional Rac1 Knockout in Astrocytes Reduces Hyperreflexia Associated with Spasticity after Spinal Cord Injury

Authors: *C. BENSON[1], K.-L. OLSON[2], S. PATWA[2], S. G. WAXMAN[3], A. M. TAN[4]; [1]Neurol., Yale Univ., West Haven, CT; [2]Yale Univ., New Haven, CT; [3]Neurol., Yale University, Neurosci. and Regeneration Res. Ctr., West Haven, CT; [4]Neurol., Yale University/VA Connecticut Healthcare Syst., West Haven, CT

Abstract: Spasticity is a hyperexcitability disorder resulting from damage to the spinal cord or brain (e.g., SCI, TBI, stroke). A clinical sign of spasticity is an amplified H-reflex response (aka knee-jerk spinal stretch reflex). Although conventional anti-spasticity drugs, such as baclofen, provide positive relief of spastic symptoms, they are not curative, only palliative, and may carry safety risks with long-term use. Our research has identified abnormal dendritic spines morphology on spinal alpha-motor neurons associated with spasticity after SCI. Specifically, we have shown that systemic pharmacological treatment with a Rac1-inhibitor restores close-to-normal dendritic spine morphology and reduces hyperreflexia after SCI. These studies, however, did not identify whether the beneficial effect of Rac1 inhibition was due a neuronal or non-neuronal mode of action. Here, our study aims to examine the relationship between Rac1 molecular signaling in astrocytes and spasticity after SCI. To address this aim, we investigated the effect of disrupting of Rac1 in GFAP+ astrocytes using a transgenic conditional knockout

(KO) mouse model, i.e., a cre-flox system, in a longitudinal study design. To induce spasticity, animals received a moderate contusion SCI at vertebral segment T10. Three weeks after SCI, injured wildtype (WT) animals showed a loss of H-reflex rate-dependent depression (RDD), a physiological sign of spasticity. In contrast, astrocytic Rac1 KO animals with SCI displayed a H-reflex response similar to measurements at baseline, before injury, and significantly lower than compared with WT controls. Importantly, the absence of significant hyperreflexia in astrocytic Rac1 KO animals was associated with near-normal dendritic spine profiles on alpha-motor neurons. As expected, control WT animals with SCI presented with abnormal dendritic spine morphology associated with hyperreflexia disorder. Finally, we observed that ventral spinal tissue in GFAP Rac1 KO expressed increased levels of the glial specific glutamate transporter, GLT-1, compared to WT controls. Collectively, structural plasticity along with changes in glutamatergic signaling appear to underlie the role of Rac1 activity in spasticity after SCI. Taken together, this study begins to deconstruct the contribution of Rac1 signaling in spinal motor neuron hyperexcitability after injury, and reveals a novel opportunity for developing targeted cell-specific therapies for alleviating SCI associated hyperexcitability disorders.

Abstract: Role of Cyclosporine A in apoptosis after spinal cord injury Preeja Chandran P.C[1*], Khaviyaa Chandramohan[1], Krithika Iyer[1],Felicia Mary Michael[1,2], Sankar Venkatachalam[1]. [**]1-Department of Anatomy, Dr. ALM PGIBMS, University of Madras, Taramani Campus, Chennai 600 113. 2-University of Kentucky, Lexington, USA* Presenting Author; ** Corresponding Author
The cyclosporine A (CsA), an immunosuppressant is long known for its potential neuroprotective nature. The speculation was rooted in the finding that CsA improves

mitochondrial integrity and reduces the Cytochrome C release. Through its manipulative action on mitochondrial pores, it is believed to have an anti-apoptotic effect on the injured cells. Despite these facts, its usefulness is still controversial, especially after spinal cord injury. The present study was carried out to re-analyze its role in SCI treatment using a highly standardized rodent model of contusive SCI.
Contusion SCI model in rats was created following the MASCIS model guidelines. In Wister-albino rats of 70 to 90 days of age (Bodyweight: 150 to 250 g), moderate contusion injury (12.5 mm) was created using MASCIS impactor at T10-T11 spinal segment level. SCI animals were randomly divided into three groups as a) Lesion group b) SCI + 5mg/kg CsA i.p. 3 days following injury day and c). SCI + 5mg/kg CsA i.p., 3 days following injury day and again on sixth to the ninth day. received first three days and sixth day to the ninth day. All animals were sacrificed after 8 weeks of postoperative survival. Histology for assessing tissue sparing was carried out. Motor recovery during the postoperative period was objectively assessed through a series of behavioral tests such as BBB, Narrow Beam walking test, and ladder walking task. Numerical data were analyzed for statistical significance of the differences observed by GraphPad Prism Version 7.0.Results indicate improvement in the behavior scoring-based assessments. There was a gradual improvement of motor function - both gross locomotor ability and fine motor movements. Histological preparations showed evidence of tissue sparring at the injury site substantiating the anti-apoptotic effects of CsA. Further studies may be required to fine-tune the strategy to enhance the beneficial effects observed so that a statistically significant functional recovery may be achieved.Acknowledgment: Funding from SERB, Govt of India to SV, and ICMR-SRF to PC.

Title: Bringing the clinic into the lab: An evaluation of how clinically common drugs and physical therapy muscle stretching influence the functional recovery of rodents after spinal cord injury

Authors: *M. SHARP[1], G. CESARZ[2], J. WILKERSON[3], A. SHUM-SIU[4], C. CASTILLO[4], J. C. PETRUSKA[5], D. S. MAGNUSON[4];

Bioengineering, [4]Dept. of Neurolog. Surgery, [5]Dept. of Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Stretch-based physical therapy remains a frontline intervention following spinal cord injury (SCI) utilized to combat secondary complications such as muscle atrophy, spasticity, and contractures. In addition to rehabilitation and physical therapy sessions, SCI patients receive a barrage of pharmacological treatments to ameliorate acute and/or chronic sequelae such as neuropathic pain and spasticity, among many others. However, the effects of many medications on motor/locomotor function after SCI remains unknown, and in some cases, has been shown to be detrimental to functional recovery. Furthermore, despite the clinical prevalence of stretching, numerous studies have shown that clinically modeled hindlimb stretching of rodents following SCI significantly impairs functional recovery and causes dramatic deficits in locomotor capacity. Thus, other interactions that may be occurring between physical therapy and pharmacological interventions after SCI remain unexplored in clinical and basic science research and may reveal novel cellular mechanisms mediating the detrimental effects of stretching. To address these fundamental questions, adult female Sprague-Dawley rats received a T10 spinal cord contusion (n=12). After 4 weeks of recovery, all animals received daily hindlimb muscle stretching for 2 weeks in combination with daily pharmacological intervention administered intraperitoneally at high functional doses, including acetaminophen, morphine, or control saline. After 2 weeks of stretching, animals recovered for 3 weeks without physical therapy or drug administration. Following recovery, animals underwent an additional 2 weeks of muscle stretching combined with daily administration of ibuprofen, baclofen, or control saline. Functional recovery was assessed weekly using the Basso, Beattie, and Bresnahan (BBB) Locomotor Scale and kinematic gait analysis. Von Frey, Hargreaves, and tail-flick sensory assays were performed weekly to assess mechanical and thermal cutaneous sensitivity. Locomotor analysis revealed that clinically common pharmacological interventions did not ameliorate the detrimental effects of stretching on functional recovery. Furthermore, BBB assessments suggested that hindlimb stretching combined with treatments such as opioids may exacerbate the deleterious effects of stretching on locomotion. These results emphasize the need to further model and evaluate commonly used drugs and therapies after clinical SCI and their combinatory effects on locomotor recovery in rodent models and the clinic.

Title: Enhancing forelimb recovery from cervical spinal cord injury in juvenile rats with the constitutive application of excitatory DREADDs

Authors: *R. D. SMIT, T. J. CAMPION, III, R. L. STINGEL, G. M. SMITH;
Shriners Hosp. Pediatric Res. Ctr., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: A hallmark found across mammalian species is that neonates recover more notably from spinal cord injury (SCI) compared to adults. Research in rodents indicates that the superior recovery, which ceases abruptly beyond postnatal day 10, is owed to the more robust regeneration of corticospinal neurons (CST) across the injury site whereas older animals are reliant on sprouting from uninjured subcortical populations. Few studies have simultaneously analyzed the discontinuation of axonal regrowth with aging and how each pathway's response translates to functional outcomes. Our aim is to define the specific regenerative and sprouting mechanisms of the CST and subcortical pathways after SCI in juvenile rats (14 days of age), and facilitate recovery through the constitutive activation of chemogenetic modifiers (DREADDs). This is the first study demonstrating successful co-infection of the CST in neonatal rats using a two-viral vector system where we simultaneously injected Cre-dependent-excitatory DREADD into the motor cortex and retroCre recombinase into CST axon terminals of the cervical spinal cord.

At postnatal day 5 rats received transcranial (motor cortex) injections of either non-Cre-dependent excitatory DREADD (hM3Dq), non-Cre-dependent inhibitory DREADD (hM4Di), control fluorescent (GFP), or the two-viral injection of Cre-dependent excitatory DREADD (AAV2-DIO-hM3Dq) + Cre (retroCre). At postnatal day 14, all animals received C5 hemisections. Subsequently, the constitutive activation of either excitatory or inhibitory DREADDs was achieved by treating diet gel with actuators (clozapine-N-oxide) for 30 days. Behavioral assays consist of isometric pull strength, IBB, single pellet reach, kinematics, and electrophysiological recordings. This study is exploring the age-dependent response to severe SCI and whether excitatory DREADDs could stimulate recovery during the infantile period. Thus far, the excitatory groups have demonstrated superior functional recovery of the forelimb compared to the control and inhibitory groups.

Co-infection of the motor cortex

Abstract: Local inflammation plays a pivotal role in the process of secondary damage after spinal cord injury (SCI). We previously showed in a rat model that acute intravenous application

of extracellular vesicles (EVs) secreted by human umbilical cord mesenchymal stromal cells dampens the induction of inflammatory processes following spinal cord injury. However, systemic administration of EVs is associated with delayed delivery to the site of injury and the necessity for high doses to reach therapeutic levels. In this project, we compared the impact on the functional regeneration and structural integrity of EVs injected directly into the lesion site following spinal cord injury, with the former treatment in which EVs were injected intravenously.
Female Fisher 344 rats of 10 weeks of age received a 200 kdyn contusion on the spinal cord (Th8) which resulted in a moderate to severe incomplete spinal cord injury. The rats received acutely after lesion either an intra-parenchymal administration of vehicle or EVs, or an intravenous injection of EVs. Gene expression of pro and anti-inflammatory cytokines in the spinal cord were determined at 24 hours post-injury. Histological analyses were performed 2 and 8 weeks after contusion. Locomotor recovery was assessed until 8 weeks after contusion. MRI, diffusion tensor imaging (DTI) and microCT analysis were performed ex vivo 8 weeks after injury.
Intralesional EVs application was found to be the most efficient to improve locomotor function recovery during the first 8 weeks post-injury based on the BBB score and BBB sub-score. The acute intralesional application of EVs resulted in a marked reduction of pro-inflammatory cytokines expression measured at 24h post-tSCI. Even at 14 days post-injury, the accumulation of inflammatory cells around the lesion was significantly lower in rats treated with EVs. Furthermore, the deposition of collagen and CSPGs, as well as astrogliosis, were more attenuated by the intralesional application of EVs. Finally, 8 weeks post-injury, we measured with DTI that an acute intralesional EVs treatment could preserve more neuronal fibre bundles in the proximity of the lesion site, as compared to the vehicle administration
Our observation demonstrates that EVs are particularly potent to address the processes of inflammation and scarring when applied very early and close to the site of injury, and promote a better long-term motor function recovery. Moreover, an improvement of the lesion microenvironment and the additional structural sparing obtained with local EV treatment constitute valuable assets for follow-up interventions aiming for endogenous axonal regeneration or involving cell therapies

Title: Isoflurane anesthesia, but not ketamine, blocks the induction of nociceptive induced hemorrhage after SCI in rats

Authors: *J. A. DAVIS, R. E. BAINE, M. M. TARBET, G. N. K. FAUSS, G. GIDDINGS, J. W. GRAU;
Texas A&M Univ., College Station, TX

Abstract: Spinal cord injuries are often accompanied by additional tissue damage (polytrauma), providing a source of pain (nociceptive) input. Research has shown that nociceptive stimulation soon after SCI impairs long-term recovery and increases tissue loss. This effect has been related to a pain-induced breakdown of the blood spinal cord barrier and hemorrhage at the site of injury. Using an animal model (rats), we have shown that inhibiting cellular activity at the site of injury (T10-11) with lidocaine blocks the adverse effect of noxious stimulation (Turtle et al., 2017, J Neurotrauma, 34, 1200). Other work suggests that this local effect depends, in part, on communication with rostral (brain) systems. Supporting this, nociceptive stimulation has no effect on tissue sparing in contused rats that received a rostral (T2) spinal transection (Reynolds et al., 2017, Frontiers Sys Neuro, 13.) or pharmacological transection with lidocaine at T2 (Davis et al, 2020, J Neurotrauma, 40, 9186). These observations led us to test whether treatment with a general anesthetic would have a protective effect. Pentobarbital delivered at a moderate to high (25-50 mg/kg, i.p.), but not low (12.5mg/kg), dosage blocked pain-induced hemorrhage in contused rats. Here we explore whether other anesthetics have a protective effect. Gas anesthesia was induced using isoflurane. A day after rats received a contusion injury at T10-11, they were placed in the induction chamber and delivered a 5% oxygen/isoflurane mixture or just oxygen. Anesthesia was reduced to 3% and half the animals in each condition received noxious electrical stimulation (shock) to the tail for 6 min. Three hours after shock, rats were sacrificed and one cm of tissue was collected surrounding the injury site. Pain input induced hemorrhage in non-anesthetized rats, but not in those treated with isoflurane. Ketamine was tested to examine the protective potential of dissociative, rather than anesthetic states. Interestingly, neither a high dose of i.p. ketamine (100mg/kg) alone, nor in combination with xylazine (12.5mg/kg), prevented pain-induced hemorrhage after SCI. Further work is being conducted to determine why these treatments yield divergent results.

Title: Treatment with norepinephrine after spinal cord injury increases tissue loss and impairs functional recovery

Authors: *D. T. JOHNSTON, E. T. LOUT, R. E. BAINE, J. W. GRAU;
Psychological & Brain Sci., Texas A&M Univ., College Station, TX

Abstract: Prior work has shown that engaging pain fibers after spinal cord injury (SCI) by applying noxious electrical stimulation or the irritant capsaicin increases tissue loss and impairs long-term recovery (Grau et al., 2017, *J Neurotrauma*, 34, 1873). These adverse effects have been related to a breakdown in the blood-spinal cord barrier and the infiltration of blood (hemorrhage). Noxious electrical stimulation also induces an acute increase in blood pressure. The current studies examined the effects pharmacologically inducing hypertension with norepinephrine (NE) after SCI has on the induction of hemorrhage and recovery of locomotor function. In all experiments, male Sprague-Dawley rats received a contusion injury at the T10-11 vertebrae and had their baseline locomotor function (BBB) and blood pressure (BP) measurements assessed prior to receiving a subcutaneous (SQ) injection of either 0 or 0.5 mg/kg NE. In experiment 1, subjects received NE or vehicle and were allowed to recover for 21 days in which BP and BBB was assessed throughout and tissue was collected for histological analysis. Acute effects of pharmacologically induced hypertension were assessed in the following experiments. In experiment 2, subjects received NE or vehicle 1.5 or 6 hrs post-SCI to assess the window of time in which the spinal cord is most vulnerable to hypertension. In experiment 3, subjects received NE or vehicle at the beginning of treatment and then again 1.5 hr later to examine the effects of maintained hypertension. In experiment 4, subjects received either six-minutes of electrical stimulation to the tail or no shock followed by NE or vehicle to determine if a detrimental synergistic effect occurred when pain input was given in addition to pharmacologically inducing hypertension. In experiments 2-4, blood pressure measurements and BBB scores were assessed immediately, one, two, and three hours after treatment and then a 1-cm region of tissue encompassing the injury site was collected and assessed for hemorrhage and inflammatory markers. Treatment with norepinephrine undermined long-term recovery and increased tissue loss. Hypertension occurring 24 hours, but not 1.5 or 6 hr post-SCI was detrimental to locomotor recovery, but was not sufficient to induce hemorrhage. Hypertension and tail shock increased hemodynamic measures and undermine locomotor recovery in a synergistic fashion, however only shock treatment alone led to increased levels of hemorrhage. Additional studies are being conducted to assess the mechanism by which NE treatment is leading to a decrease in locomotor recovery.

Title: Brain-dependent processes fuel pain-induced breakdown of the blood-spinal cord barrier after spinal cord injury

Authors: *S. R. PARTIPILO, G. N. K. FAUSS, D. T. JOHNSTON, R. E. BAINE, J. A. DAVIS, J. W. GRAU;
Texas A&M Univ., College Station, TX

Abstract: Spinal cord injury (SCI) is often accompanied by other injuries which provide additional sources of pain input. Our laboratory has found that pain input soon after SCI, in the form of electrical stimulation or capsaicin injection, leads to an increase in inflammation and hemorrhage at the lesion site (Grau et al., 2017, J Neurotrauma, 34, 1873). The breakdown in the blood-spinal cord barrier (BSCB) likely proceeds this infiltration of blood and immune cells. Recently, we have found that a rostral spinal transection blocks this increase in hemorrhage seen after a spinal contusion injury, suggesting the involvement of brain systems in the exacerbation of secondary injury. Given this, the current study explores whether blood-spinal cord barrier (BCSB) permeability increases after pain input and if this is blocked by rostral transection. In experiment 1, adult male Sprague-Dawley rats were given a T12 spinal contusion injury. Twenty-four hours later, the rats received 6 minutes of intermittent electrical stimulation delivered to the tail or an equal period of restraint (no shock). Evan's Blue dye (2%) was administered (i.p.) immediately after treatment. Three hours later, the spinal cords were collected and processed for spectrophotometry. In experiment 2, rats received a T12 contusion and a subsequent T2 complete transection or sham surgery. Twenty-four hours later, rats in both groups either received 6 minutes of electrical stimulation or no shock. Evan's Blue dye was administered and spinal cords were collected and processed as described in experiment 1. It was found that shock after a spinal contusion increased Evans Blue dye extravasation in the spinal cord and that transection blocked this effect. These results suggest that pain input increases BSCB permeability after injury and that this is dependent on brain systems. Future studies will explore how pain input damages the BSCB and the brain systems/processes that drive this effect.

Title: Estrous cycle modulates the harmful effects of pain after spinal cord injury (SCI)

Authors: R. E. BAINE[1], E. D. GILES[2], ***J. GRAU**[2];
[1]Texas A&M Univ., Bryan, TX; [2]Texas A&M Univ., College Station, TX

Abstract: In addition to deficits in sensory/motor function, spinal cord injuries (SCI) often induce chronic pain and other debilitating acute and chronic complications. The initial insult to the cord incites secondary injury processes by engaging maladaptive inflammation and fueling hemorrhage at the site of injury, expanding the lesion site over the following days to weeks. While sufficient alone to produce these effects, pain associated with accompanying injuries (polytrauma) exacerbate the damage inflicted by the original trauma and inhibit functional recovery. This painful (nociceptive) stimulation has been studied experimentally through the administration of intermittent electrical stimulation to the tail or intradermal capsaicin to the hindpaw. Given the greater incidence of SCI in males, our research has historically utilized male rats, while others have used female rats for their lower susceptibility to bladder infection. However, the rising incidence of SCI in females necessitates greater understanding of the role of sex in response to injury. In studies examining sex-dependent effects, multiple strategies are employed to incorporate sex as a biological variable and account for differences in gonadal hormones between males and females. These approaches are complicated by fluctuations in female sex hormones across the estrous cycle—a concern commonly mitigated by randomly assigning females to experimental treatments. Our results demonstrate how this approach may obscure the impact of changes in hormones across the estrous cycle on SCI outcomes. Prior to SCI, female rats were balanced according to their stage of estrous cycle at time of injury. Twenty-four hours after a moderate contusion injury at T10-11, female rats received nociceptive input (shock or capsaicin) or nothing. One set of animals (n=8) was sacrificed 3 hours following treatments, with locomotor function (BBB) and blood pressure assessed at each hour after stimulation. A one-cm section of tissue centered on the lesion site was collected and analyzed for hemoglobin content with immunoblotting. Another group of rats recovered over a period of 28-days and changes in locomotor function and estrous cycle were assessed. Tissue was collected and stained for lesion analysis. We found that pain, regardless of type, negatively impacted behavioral function and exacerbated hemorrhage in female rats. Importantly, the stage of estrous cycle at time of injury modulated both the response to injury and the adverse effects of

nociceptive input, suggesting that fluctuations in sex hormones play an important role in SCI outcomes.

Title: Global, low amplitude cortical state predicts response outcomes in a selective detection task in mice

Authors: *K. MARRERO[1], K. ARULJOTHI[2], B. ZAREIAN[2], C. GAO[3], Z. ZHANG[1], E. ZAGHA[2];

Abstract: Spontaneous neuronal activity strongly impacts stimulus encoding and behavioral responses. We sought to determine the effects of neocortical prestimulus activity on stimulus detection. We trained mice in a selective whisker detection task, in which they learned to respond (lick) to target stimuli in one whisker field and ignore distractor stimuli in the contralateral whisker field. During expert task performance, we used widefield calcium imaging to assess prestimulus and post-stimulus neuronal activity broadly across frontal and parietal cortices. We found that lower prestimulus activity correlated with enhanced stimulus detection: lower prestimulus activity predicted response versus no response outcomes and faster reaction times. The activity predictive of trial outcome was distributed through dorsal neocortex, rather than being restricted to whisker or licking regions. Using principal component analysis, we demonstrate that response trials are associated with a distinct and less variable prestimulus neuronal subspace. For single units, prestimulus choice probability was weak yet distributed broadly, with lower than chance choice probability correlating with stronger sensory and motor encoding. These findings support a low amplitude, low variability, optimal prestimulus cortical state for stimulus detection that presents globally and predicts response outcomes for both target and distractor stimuli.

Title: Classification of epidural field potentials from the hindpaw representation in S1 cortex of awake behaving rats.

Authors: *D. KILINÇ BÜLBÜL, B. GÜÇLÜ;
Inst. of Biomed. Engin., Boğaziçi Univ., Istanbul, Turkey

Abstract: Cortical neuroprostheses are crucial to provide movement capability and somatosensory feedback for patients with severe disorders, such as spinal cord injury and amyotrophic lateral sclerosis. Mini- and micro-ECoG grids are promising for that purpose with a trade-off between less invasiveness and selectivity compared to penetrating microelectrodes. Here, we recorded epidural field potentials (EFPs) with a wide bandwidth (4-312.5 Hz) by using 16-channel Pt-Ir surface arrays (site diameter: 25 μm) implanted on the hindpaw representation in S1 cortex of two awake Wistar albino rats. The rats performed a very simple task by pressing a lever to start a trial, in which vibrotactile stimuli with randomly selected amplitudes (12-111 μm) and frequencies (40 or 80 Hz) were presented for 0.6 s on the glabrous skin of the hindpaws. In some trials, no stimulus was presented. Time-frequency analysis (Morlet wavelet transform) showed evoked activity mostly at the onset (0-0.2 s) of the stimulus duration, consistent with our previous acute experiments. Wavelet coefficients for gamma (25-70 Hz) and high gamma (70-125 Hz) bands were used in machine learning algorithms to classify frequency (3 classes) or amplitude (4 classes) of the stimulus offline. Average squared coefficients in two bands and from 10 working channels were input as 20 features into four different algorithms: multinomial logistic regression (MLR), k-nearest neighbor, linear discriminant analysis (LDA), and support vector machine. The data were used as a training and a test set with 8:2 ratio and with 5-fold cross-validation. Classification accuracies from all the test algorithms were ~0.4-0.5 for each rat, but MLR and LDA yielded slightly better results. Specifically, class-averaged precision, recall, and F1 scores were somewhat better for predicting amplitude (LDA: 0.53, 0.50, 0.50) versus frequency (LDA: 0.41, 0.43, 0.41) in Rat #3. However, the opposite was true in Rat #4 (amplitude LDA: 0.39, 0.40, 0.38; frequency LDA: 0.47, 0.46, 0.46). Studies are underway to include other frequency bands and refine feature selection in the machine learning algorithms.

Classifying stimulus information in cortical surface potentials can help to evaluate the effects of somatosensory feedback and improve the closed-loop performance of a neuroprosthesis.

Title: Computational stereognosis: how should tactile and proprioceptive signals be integrated to support object recognition?

Authors: *P. MATHIALAGAN[1], A. SOBINOV[1], N. S. CHEREPANOVA[1], E. OKOROKOVA[1], S. J. BENSMAIA[2];
[1]Neurosci. Inst., [2]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: When we grasp and manipulate an object, we vividly sense its three dimensional shape via sensory signals from the hand and forearm, an ability termed stereognosis. At each point of contact with the object, tactile signals convey information about its local contours, for example surface curvature or an edge. The global shape of the object is computed from proprioceptive signals about the conformation of the hand. These two streams of information - cutaneous and proprioceptive - are then integrated to give rise to stereognosis, a process about which virtually nothing is known. To shed light on the underlying computations, we simulated grasping of more than 50 everyday objects and geometric shapes in a physics engine and trained a simple neural network to recognize them based on the tactile and proprioceptive signals. In brief, objects were presented to the hand in varying positions and orientations and were grasped with all or a subset of digits. We then trained single-layer networks to recognize the grasped objects based on the hand joint angles (proprioception) and contact locations (tactile). First, we trained a fully connected model and found that this network could accurately recognize objects across differences in grasp shape. Then, we trained several networks with restrictions on the nature of their connectivity, while maintaining the same number of fitted parameters to allow for performance comparisons across models. The constraints were: (i) nodes only received either tactile or proprioceptive information, but never both (no cross-modality integration); (ii) nodes only received information from a single finger (no cross-digit integration); (iii) nodes only received information from neighboring fingers (limited cross-digit integration). We found that the fully connected model performed substantially better than models where modalities or digits were segregated, but on par with the model that integrated information only from the

neighbouring fingers. We conclude that stereognosis requires the integration of proprioceptive and cutaneous signals across digits and relate these findings to the known properties of neurons in higher order somatosensory cortices.

Title: A Bayesian observer model for tactile spatial perception

Authors: *S. DEHNADI[1], D. GOLDREICH[2];
[2]Neurosci., [1]McMaster Univ., Hamilton, ON, Canada

Abstract: The human brain is remarkably adept at producing an accurate perception of the world from noisy and ambiguous sensory information. The very success of perception suggests underlying neural mechanisms, not yet understood, that achieve accurate inferences from imprecise sensory inputs. Bayesian inference provides an optimal method for drawing perceptual conclusions from sensorineural activity, but this approach has scarcely been applied in studies of tactile perception. We explored whether a Bayesian observer with access to spike counts of simulated cortical neurons with Gaussian receptive fields (RFs) and Poisson firing rate variability could replicate fundamental aspects of human passive tactile spatial perception. We ran the Bayesian observer on a battery of tactile tasks that test spatial perception using punctate stimuli delivered to the skin, and we compared the Bayesian observer's performance to previously collected human participant data. The Bayesian observer broadly replicated human performance on three tasks that assess tactile spatial acuity: classic two-point discrimination (C2PD), sequential two-point discrimination (S2PD), and two-point orientation discrimination (2POD). The Bayesian observer's performance confirmed that C2PD is the least reliable method of assessing tactile acuity due to the presence of non-spatial cues and that S2PD provides the most sensitive measure of spatial acuity. The performance of the Bayesian observer decreased on these tasks when, unbeknownst to the decoder, jitter was applied to the position, width, and amplitude of the RFs. Still, the Bayesian observer was in many cases robust against jitter, suggesting that the brain may not need to keep track of the exact characteristics of its RFs in order to achieve accurate inferences. The Bayesian observer was additionally able to replicate two illusions of tactile spatial perception: an adaptation-induced repulsion illusion and an

anisotropy illusion in which horizontal distances are judged to be greater than equal vertical distances. The Bayesian observer replicated these illusions only when the decoder was unaware of the adaptation state of the neurons and of the smaller horizontal than vertical separation between RFs. Taken together, these results suggest that the brain may produce perceptual inferences using a decoder that is unaware of the precise characteristics of its inputs.

Title: Studying the contribution of tactile afferent classes to information encoding using large scale simulations

Authors: *M. A. CASAL[1,2], G. CORNIANI[3], S. PANZERI[4,1], H. P. SAAL[3];
[1]Italian Inst. of Technol., Genova, Italy; [2]Dept. of Computer Science, Bioengineering, Robotics and Systems Engin., Univ. of Genova, Genova, Italy; [3]Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom; [4]Dept. of Neural Information Processing, Univ. Med. Ctr. Hamburg-Eppendorf (UKE), Hamburg, Germany

Abstract: The spiking activity of tactile afferents in the human skin has been widely investigated, from their responses to simple or complex tactile stimuli to the relationship between spiking activity, brain processing, and elicited touch sensations. The vast majority of the studies only explore the activity of individual or a handful of afferents due to technical limitations imposed by the commonly used acquisition tools. However, the glabrous skin of the human hand is innervated by approximately 17,000 afferents, and thus any natural mechanical interaction is expected to activate hundreds of receptors. The human glabrous skin is innervated by four classes of tactile afferents, which traditionally have been viewed as functionally segregated. This notion has lately been challenged with evidence that most stimuli excite all classes of afferents, and most tactile percepts are shaped by multiple submodalities. Still, our understanding of tactile information encoding on a population level remains primitive. Here, we exploit a published computational model, Touchsim [1], to simulate the activity of thousands of peripheral tactile afferents of three classes in response to precise and well-defined stimuli. To pinpoint the contribution of the entire neural population in the stimulus encoding, we first used Non-Negative Matrix Factorization (NMF) to linearly decompose single-trial population spike trains into non-

negative basis functions and coefficients. Then, we asked whether afferents of different classes and at different locations on the hand send redundant or complementary information to the brain. To this end, we fed a generalized linear model with the compact representation of the population activity found by NMF aiming at decoding stimulus features. We found that a significant portion of the stimulus information is redundant, i.e. it is shared among different afferent classes. Still, single classes provide unique information. Consequently, we observed that for every stimulus feature considered, the decoding performances improved when considering a combination of classes rather than single ones. Our results suggest that analyses based on single afferents might not unveil the complexity of the tactile coding strategies, which is driven by joined efforts of all the afferents classes even with relatively simple stimuli. These results will pave the ground for a deeper understanding of the convergence and integration of tactile submodalities in the brain. [1] H. P. Saal, B. P. Delhaye, B. C. Rayhaun, and S. J. Title: Establishing the ferret as a model for whisker-based somatosensory processing

Authors: *T. BURNETT, D. H. O'CONNOR, K. J. NIELSEN;
Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Rodent and primate models of somatosensation have enabled key insights into neural mechanisms of touch. However, translating findings across species poses major challenges due in part to differences in sensory organs and cortical organization. Rodent work has most commonly used the whisker system, allowing precise quantification of sensory input and access to well-defined circuits. Non-human primate models allow the direct study of hand-based sensing and have a more elaborated set of somatosensory cortical areas that more closely resembles that of the human. Putting findings from rodent and primate studies into a common framework would be aided by having an additional model system that relies on whiskers but has a cortical organization more similar to that of primates. Ferrets (*Mustela putorius furo*), an established animal model in vision and auditory research, could serve this role. Ferrets possess whiskers, similar to mice, and research suggests a cortical organization typical of carnivores, including multiple somatosensory areas beyond S1. While previous research has shown conservation of the leminscal touch pathway in ferrets, our current knowledge of ferret

somatosensory cortex (S1) is incomplete with respect to the somatotopy, response properties, and cortical borders. We address these knowledge gaps with the aim of establishing the ferret as a new model for investigating touch processing. In this project, we used tungsten electrodes and cytochrome oxidase staining to investigate the organization and borders of S1. Through cytochrome oxidase staining, we delineated the approximate borders of S1 and determined that ferrets lack a barrel cortex. The potential borders were then verified through electrophysiology. Receptive fields of individual neurons were recorded to determine somatotopy of S1. In our recordings, as expected we found receptive fields corresponding primarily to the contralateral body, but also observed bilateral receptive fields in the trunk representation. In agreement with previous studies, medial S1 possessed the representation of the body, and lateral S1 contained the representation of the face. Within S1, we found robust responses to whisker deflections and observed receptive fields that contained a clear principal whisker as well as multi-whisker surrounds. Together, our work serves as a foundation to establish the ferret as a new model of whisker somatosensation.

Title: The Role of Parvalbumin-expressing Inhibitory Interneurons on Spike Synchrony Between Feature Encoding Neurons of the Somatosensory Cortex

Authors: *M. DUHAIN[1], K. WANG[1], M. GOMEZ-RAMIREZ[2];
[1]Neurosci., [2]Brain & Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Object sensing and manipulation (i.e., haptics) requires discriminating myriad of tactile features through the sense of touch. Key to this process are mechanisms of feature-based attention, which provide preferential processing of attended sensory features, while filtering out sensory information representing non-attended features. A previous study showed that selection of behaviorally-relevant features is represented in the synchronized spiking between neurons tuned for the attended feature. However, the underlying circuit mechanism generating this feature-specific spike synchrony effect is yet to be elucidated. We propose that this feature-specific spike synchrony effect is generated by a parvalbumin (PV) and pyramidal microcircuit, whose cells are tuned for the same tactile feature. We hypothesize that feature tuned PV

interneurons generate local inhibition in similarly-tuned excitatory cells, followed by a short window of high spiking probability that promotes co-activation of the feature tuned pyramidal ensemble. To test this circuit and its dynamics, we trained mice to perform a 2-alternative forced choice task requiring discrimination of vibration frequencies delivered to the forepaws. Animals were visually cued to discriminate stimuli in one paw, while ignoring all stimuli in the uncued location. We will make acute neural recordings in somatosensory cortex while animals perform this task. PV cells will be identified based on waveform classification analyses. We will determine whether correlated spiking between putative-PV and regular spiking cells is increased for pairs tuned for vibration features. This project aims to identify a novel functional circuit within somatosensory cortex that implements feature-based attention to enable preferential processing of attended features within local and cross-cortical areas.

Title: Neuronal sensitivity and variability mediate 3 parallel strategies for encoding natural translations in the primate vestibular system

Authors: *M. PROSTEBBY[1], J. CARRIOT[2], I. MACKROUS[3], M. J. CHACRON[3];
[1]McGill Univ. Integrated Program in Neurosci., Montreal, QC, Canada; [2]Physiol., [3]McGill Univ., Montreal, QC, Canada

Abstract: As we navigate and explore our environment, our motions can be described as a combination of linear translational motion and rotational (angular) motions. Everyday movements (e.g. walking, playing soccer) are composed of these two independent forms of motion which occur with characteristic statistics. Our previous investigations show that vestibular sensory neurons at the first stages of central processing are adapted to match their tuning curves to these characteristic statistics in the rotational component of natural motion. These neurons within the vestibular nucleus of the brainstem (VN) produce responses which are less redundant, and which are independent of frequency (i.e. temporally whitened). However, the responses of VN neurons which are sensitive to the translational component of natural motion (otolith VOs) have not been explored. Moreover, their increased heterogeneity in tuning curve profiles to artificial stimuli as well as differences in the sensitivity of their incoming afferents together comprise key differences which may change their coding strategy. Our study explores

whether, and if so, how the responses of otolith VOs in the VN of awake, behaving rhesus macaques are adapted to process naturalistic translations. Our results demonstrate that otolith VOs do not always employ efficient coding strategies matching natural statistics, instead responding as one of three classes ranging from strong low pass to optimally whitened. Thus, this study is the first to explore otolith VO responses and reveals 3 parallel encoding strategies used in the processing of translational motion which may relate to slow-varying head motions relative to gravity and faithful stimulus reconstruction needed for navigation and self-righting reflexes.

Title: Natural statistics of head orientation relative to gravity in humans: implications for modeling spatial orientation

Authors: *C. SINNOTT[1], P. HAUSAMANN[2], P. R. MACNEILAGE[3];
[1]Univ. of Nevada Reno, Reno, NV; [2]Tech. Univ. of Munich, Muenchen, Germany; [3]Psychology, Cognitive and Brain Sciences, Neurosci., Univ. of Nevada, Reno, Reno, NV

Abstract: The orientation of the head relative to gravity modulates both visual and vestibular sensory stimulation. In particular, the otoliths of the vestibular system are stimulated by the sum of linear acceleration driven by both self-motion and Earth's gravity. The nervous system must decompose this summed signal into gravitational and inertial components to generate independent estimates of orientation and linear self-motion. Various approaches have been proposed to model this process including frequency segregation, Bayesian estimation, and observer models. All of these approaches incorporate parameters representing prior knowledge of head orientation and motion statistics. While statistics of summed linear acceleration recorded by inertial measurement units (IMUs) have been reported previously, the separate statistics of gravitational and inertial components are generally not reported. In the current study we present measurements obtained using the Intel Realsense T265, a tracking camera that uses both visual and inertial data to generate robust estimates of both gravitational and inertial acceleration, i.e. head orientation and linear head motion. Ten clinically normal participants wore the T265 on

their heads during five hours of unstructured, everyday activity. The T265 was connected to a laptop worn in a backpack. Across all participants, distributions of head orientation were generally centered close to upright, as might be expected. Distributions were more variable in pitch than roll, and pitch distributions were skewed towards downward angles. Data were then separated into low- and high-velocity subsets to generate separate distributions for stationary and locomotor epochs. Distributions were generally more variable during locomotor than stationary epochs. These distributions were then incorporated as empirical priors in a Bayesian model that predicts biases in orientation perception that depend on shape and variability of the prior. The model using empirical priors generally predicted biases that were reduced relative to those observed in previous studies, but it did predict previously observed asymmetries in biases for pitch perception, consistent with pitch distribution skewness. In addition, power spectra of gravitational, inertial, and sum total linear acceleration revealed a crossing point just below 1Hz, with power of gravitational acceleration matching total acceleration power below this frequency, and power of inertial acceleration matching total acceleration above this frequency, providing an empricial basis for the cutoff frequency to be applied in frequency segregation models of vestibular processing.

Title: Robust vestibular self-motion signals in macaque posterior cingulate region

Authors: *B. LIU[1,2], Q. TIAN[1,2], Y. GU[1,2];
[1]CAS Ctr. for Excellence in Brain Sci. and Intelligence Technology, Key Lab. of Primate Neurobiology, Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: Vector-based navigation (also known as path integration) is essential for organisms to survive and explore the world, especially in the absence of effective external landmarks. Self-motion signals, which have been found to be ubiquitously distributed across parietal-temporal lobes, are thought to provide the most important idiothetic information for path integration. However, how they propagate to the hippocampal system for vector-based navigation is still up

in the air. We proposed that the information is transmitted via hubs including posterior cingulate cortex (PCC) and retrosplenial cortex (RSC) to the navigation circuit. Although numerous studies have indicated that posterior cingulate areas are involved in spatial tasks, it is unclear how their neurons represent self-motion signals. Providing translation and rotation stimuli to macaques on a 6-degree-of-freedom motion platform with a sophisticated virtual-reality system, we discovered robust vestibular responses in PCC with significant temporal and spatial tuning. The preference of horizontal plane with a tendency of leftward and rightward in translation indicating the potential heading discrimination function of PCC, which is further confirmed by PCA analysis. In rotation, the distributed preferred axis tends to be around pitch and roll, but not yaw, which indicating a potential role of azimuth tuning of head direction cells in the three-dimensional (3D) environment according to a previous work. Moreover, we decomposed temporal and spatial components of neural response by a combined 3D spatiotemporal model. The model captured data well and revealed multiple temporal components including velocity, acceleration, jerk, and position with spatial modulation. Compared to PCC, RSC contained moderate vestibular temporal modulations and lacked significant spatial tuning. Visual self-motion signals were much weaker in both regions compared to the vestibular ones. We conclude that macaque posterior cingulate region carries vestibular-dominant self-motion signals with plentiful temporal components that could be useful for path integration.

Title: Population coding of naturalistic self-motion in vestibular nucleus and ventral posterolateral thalamus

Authors: *M. MOHAMMADI[1], I. MACKROUS[1], G. MCALLISTER[1], J. CARRIOT[1], K. E. CULLEN[2], M. J. CHACRON[1];

Abstract: The vestibular system detects head motion in space and provides information about self-motion perception as well as reflexes required for stabilization of posture and gaze. While

the physiology of the vestibular system has been well characterized via single-unit recordings, how the activity of neurons form perception and generate reflexes is not well understood as perception and behavior, in general, emerge from the collective activity of the population of neurons. Recent studies have investigated population coding in the vestibular pathway by recording simultaneously from multiple vestibular-only (VO) neurons in vestibular nuclei (VN). However, the stimuli used in these studies were either artificial or low in amplitude and thus strongly differed from natural self-motion stimuli that are characterized by higher amplitudes and a spectrum of frequencies. Accordingly, we investigated population coding in the vestibular system by recording simultaneously from multiple neurons in the vestibular pathway and characterizing their response during rest, artificial, and naturalistic head motion stimulation. In particular, we measured signal and noise correlations between VO neurons. VO neurons are thought to mediate vital reflexes and perception as they project to the spinal cord and thalamus, respectively. Furthermore, we will record from target neurons in the ventral posterolateral nucleus (VPL) during rest, artificial, and naturalistic head motion stimulation to determine how information is being decoded from neural populations in VN and whether/how it is influenced by correlation structure in VN. Our analysis so far shows that, under naturalistic stimulation, VO pairs displayed strong signal but negligible noise correlations thereby minimizing redundancy. These results are expected to provide critical insight for developing effective neuroprosthetics for patients with vestibular deficits.

Title: Coding strategies for representing natural self-motion through the vestibular pathway

Authors: J. CARRIOT[1], I. MACKROUS[3], K. E. CULLEN[4], M. J. CHACRON[2];
[1]Physiol., [2]Univ. McGill, Montreal, QC, Canada; [3]McGill Univ., Montreal, QC, Canada; [4]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Understanding the neural mechanisms by which sensory input gives rise to behavior requires knowledge of how the sensory representations of this input evolve between successive

brain areas. Here we investigated how natural self-motion stimuli are represented in ascending vestibular pathways ranging from more peripheral to central cortical areas contributing to both vital reflexes as well as spatial perception. Recordings were made from neurons within the vestibular nuclei (VN), vestibular thalamic neurons within the ventral posterior lateral (VPL) Thalamus and neurons within the parieto-insular vestibular cortex (PIVC) during both artificial and naturalistic self-motion. Our results show that neurons within ascending vestibular pathways gradually become more optimized to natural stimuli. Further, our results demonstrate radical changes in neural coding strategy of self-motion across successive brain areas. Specifically, while VN neurons transmit information through a combination of changes in firing rate and precise spike timing, VPL and PIVC neurons instead represent self-motion exclusively through changes in firing rate. Finally, we found that information in this thalamocortical pathway, in contrast to postural reflex pathways, optimally represents the instantaneous head velocity. Taken together, our results suggest that dynamic information carried by precise spike timing is used to mediate vital reflexes in order to maintain posture, while information carried by firing rate is further optimized across brain areas in order to faithfully and optimally code a neural representation of instantaneous head velocity. Our results thus provide the neural basis for previous behavioral studies showing that self-motion perception is centered on head velocity rather than another sensory representation.

Title: Behaviourally dependent gating of sensory response for early vestibular processing in mouse

Authors: *H. CHANG[1], A. LAWRENCE[2], K. E. CULLEN[3];
[1]McGill Univ., Montreal, ON, Canada; [2]Johns Hopkins Univ., Baltimore, MD; [3]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Vestibular afferents respond identically to externally-applied (vestibular exafference) and self-generated (vestibular reafference) movements. However, modulation at the next stage of vestibular processing occurring in the vestibular nuclei (VN) is markedly suppressed during self-generated movement via a cerebellar-based mechanism in both monkeys and mice (Roy & Cullen 2001; Medrea & Cullen, 2013; Brooks & Cullen, 2014). In particular, this suppression is specific to a class of neurons termed vestibular-only (VO) neurons that project to the spinal cord for mediating the vestibulo-spinal pathways and to the vestibular thalamus. Previous work done

in monkeys elegantly showed that when proprioceptive feedback resulting from self-generated motion is disrupted, VO neurons cannot distinguish between self-generated and externally-applied motions, thereby encoding both passive and active components of movement. To date, however, it remains unknown whether neurons in the VN of rodents show the behaviorally dependent gating of vestibular responses observed in a non-human primate model. We hypothesized that modulation in VO neurons in mouse, as in primate, will be suppressed when there is a match between the predicted and actual consequence of voluntary head-movement but not when there is a mismatch. Accordingly, we recorded the activity of VO neurons with the 960-channel high-density Neuropixel 1.0 probes when perturbations were applied to the mouse head while it made active head movements. Mice were trained to move their head to the left or to the right upon the presentation of an auditory cue. Head-restrained behavioral protocols (Beraneck & Cullen 2007; Medrea & Cullen, 2013) were used to characterize the passive vestibular sensitivity of VO neurons. Then to confirm neurons were insensitive to eye motion, we simultaneously recorded eye movement with an AMR magnetic field sensor. Finally, the responses of VO neurons were recorded during 3 conditions in which (1) the mouse was passively rotated, (2) the mouse actively rotated its head, and (3) the mouse head was subjected to an expected perturbation (adding load to the head) while making active head movements. Head velocity sensitivity of the VO neurons estimated from each condition was compared. Our preliminary results indicate for the first time that neurons in the VO neurons of mice robustly encode head velocity signal when a perturbation is introduced during head-free behaviour (a mismatch between expected and actual sensory feedback). Overall, this present study has specific implications for understanding how the brain ensures accurate posture, motor control, and spatial perception.

Title: Visual-vestibular conflict detection with central versus peripheral visual stimulation

Authors: *S. HALOW[1], A. HAMILTON[1], E. FOLMER[2], P. MACNEILAGE[1];
[1]Psychology, [2]Computer Sci. and Engin., Univ. of Nevada, Reno Integrative Neurosci. Grad. Program, Reno, NV

Abstract: Stable perception depends on mechanisms which compare visual and vestibular cues to self motion and evaluate them for congruence. Conflict between signals can result in motion or simulator sickness. Here we investigate how characteristics of an observer's field of view (FOV) impact their ability to detect visual-vestibular conflict. Experiments were conducted using a head-mounted display (HTC Vive Pro Eye) which displayed a virtual optokinetic drum and tracked head and eye movements. In a 2x2 design, subjects performed one type of fixation behavior (head or scene-fixed) with one type of field of view restriction (peripheral or central) in each condition. Subjects fixated a target during the trial which remained either stationary relative to the environment (scene-fixed) or centered relative to their FOV (head-fixed). The FOV was restricted either by a virtual scotoma that encompassed the central ~40 deg of visual angle (peripheral stimulation) or reduced the FOV to ~40 deg (central stimulation) centered on the fixation point. During each trial, subjects made yaw head movements of between 15 and 50 deg over ~1.5 sec and the gain of the visual scene motion was manipulated to move slower or faster than the subject's head movement, and subjects were asked to report whether the environment appeared to be moving with (gain < 1) or against (gain > 1) their head movement. Fitting a psychometric function to the resulting data yields the gain perceived as stationary (PSE) and the range of gains that are compatible with perception of a stationary visual environment (JND). Our results show lower visual gain (low PSEs) in the head-fixed fixation conditions suggesting that smooth pursuit eye movements resulted in greater perceived speed of scene motion. Sensitivity to conflict was also increased (lower JND) in the scene-fixed and central stimulation conditions, suggesting naturalistic eye movements and the central visual field are important for detecting sensory conflict. Results from SSQ and discomfort score data show lower subjective levels of sickness in conditions where the periphery was obscured, consistent with the known effect of FOV restriction on simulator sickness.

Title: Neural variability, information encoding, and noise correlations in the mouse vestibular nuclei

Authors: *A. LAWRENCE[1], H. V. CHANG[1], K. E. CULLEN[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: In primates, regular semicircular canal afferents encode more average information about the stimuli across the behaviourally relevant frequencies ranging from 0 to 20 Hz compared to their irregular counterparts (Sadghei et al. 2007). At the next stage of vestibular stimuli processing, the vestibular-only (VO) neurons in the vestibular nuclei (VN), which contribute to the posture control and self-motion perception, show even lower information transmission capabilities. This occurs due to the higher variability in their responses when compared to even irregular afferent neurons (Massot et al., 2011). It has been suggested that the high neuronal variability of VO neurons is beneficial for the encoding of highly transient movement information. Indeed, recent studies have shown that these neurons use precise spike timing on the order of milliseconds to encode highly dynamic stimuli (Jamali et al. 2016). The mouse has become an increasingly popular system in neuroscience research. Single-unit recordings in the vestibular nuclei have shown that mice VO neurons show similar responses as the primates for low-frequency sinusoidal rotations but have lower sensitivities. To date, however, neither their information coding nor responses dynamics have been studied over the frequency range of natural head movements. We hypothesized that the high neuronal variability and lower sensitivities of mouse VO neurons would decrease their overall information capacity relative to monkey VO neurons. To test this proposal, we used the neuropixel probes to record the activity of VO neurons in the medial VN by subjecting the mice to a 1) broadband noise perturbation of 0-20 Hz frequency range 2) sinusoidal stimuli at 0.5 Hz in the yaw plane. As in monkeys, the mice VO neurons (n=3) in this study had lower coding fractions and higher gain and phase than did their afferent inputs. Our preliminary analysis further showed that the mouse VO neurons had similar mutual information density and coding fractions across the physiologically relevant frequency range of 0 to 20Hz. Finally, our analysis of population coding during sinusoidal stimulation using neuropixel probes revealed significant excess synchrony between the firing of mouse VO neurons (n=15 pairs; 0.0510±0.03), which was significantly greater than previously seen in the monkey using lower density probes. Taken together, our findings have important implications in understanding the neural coding strategies and information transmission in the neural circuitry of the mouse vestibular pathways.

Title: Effect of varying levels of sensory prediction error on the suppression of reafferent signals in the deep cerebellar nuclei

Authors: *O. ZOBEIRI[1], R. L. MILDREN[2], K. E. CULLEN[3];
[1]Dept. of Biomed. Engin., McGill Univ., Baltimore, MD; [2]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: The ability to distinguish between self-generated (reafference) vs. externally-applied (exafference) sensory information is fundamental for ensuring accurate motor control as well as perceptual stability. This ability is particularly relevant in the context of the vestibulo-spinal reflexes, which are essential for providing postural responses to unexpected perturbations yet would impede voluntary movement. Accordingly, the brain suppresses vestibulo-spinal reflexes during active movements. To do this, it computes a prediction of the sensory consequences of the motor command, which is then compared with the actual sensory input. In the conditions where there is a match as would be the case during active movements, vestibulo-spinal reflexes pathways are suppressed (i.e. vestibular reafference is canceled). In contrast, in conditions when an unexpected head perturbation is experienced, there is a mismatch. As a result, the vestibular responses of neurons in the deep cerebellar nuclei and vestibular nuclei, which contribute to vestibulo-spinal reflexes, robustly encode head motion (i.e. vestibular exafference is not canceled; reviewed in Cullen and Zobeiri, 2021). To date, however, experiments have only considered conditions in which large perturbations were applied. This raises the question of whether systematically perturbing active head movements so they span movements both within and outside the range of natural variability will result in neurons encoding actively-generated vestibular inputs as reafference and exafference, respectively. To address this, we recorded neuronal responses of DCN neurons (rostral fastigial) during an experiment in which we randomly applied assistive or resistive perturbations to the head during a fraction of active head movement trials. The torques applied during these perturbation trials were calibrated, so the smallest perturbation changed head velocity within the band of natural variability, while the largest levels approximately doubled (assistive) or halved (resistive) head velocity. We found that on average DCN neurons showed reduced reafferent suppression in response to both the assistive and resistive perturbation. Notably, we observed increased sensitivity even for the small loads that changed head velocity within the range of natural variability. These findings suggest that even small externally-applied head movement perturbations result in a proportional shift in encoding from reafferent to exafferent. Taken together, these data reveal rules underlying cerebellar-based processing of sensory prediction error.

Title: Tilt-translation discrimination in goldfish vestibulo-ocular reflex

Authors: *S. TADOKORO[1,2], Y. SHINJI[1], M. NAKANO[1], Y. HIRATA[1,3,4];
[1]Robotic Sci. and Technol., Chubu Univ. Grad. Sch. of Engin., Kasugai, Japan; [2]Otolaryngology, Head and Neck Surgery, Natl. Def. Med. Col., Tokorozawa, Japan; [3]Ctr. for Mathematical Sci. and Artificial Intelligence, [4]Acad. of Emerging Sci., Chubu Univ., Kasugai, Japan

Abstract: As stated by Einstein's equivalence principle, the otolith responds indistinguishably to an inertial motion (e.g., lateral translation) and a change in head orientation relative to gravity (e.g., roll tilt) (Fernandez et al., 1972). This is called tilt-translation ambiguity. Nonetheless, we can perceive these two self-motions distinguishably in the light as well as in the dark while producing compensatory vestibuloocular reflexes (VORs) differentially, i.e., horizontal (H) VOR for lateral-translation, and torsional (T) VOR for roll tilt (Koizuka et al., 1999). Therefore, the ambiguity must be resolved in the brain using extra-otolith signals (Merfeld et al, 1999; Angeraki et al., 1999). In parallel with the perception and VOR behavior, translation-selective cells have been found in the vestibular and cerebellar nuclei among other areas, while in the caudal vermis both translation-selective and tilt-selective Purkinje cells have been identified (Yakusheva et al., 2007; Laurens et al., 2013). However, it is still enigmatic how these brain areas solve the tilt-translation ambiguity problem. Here we investigated the VOR elicited by tilt-translation combined stimuli in goldfish to reveal the neural mechanism for solving the problem. Goldfish is one of the animal species most thoroughly understood for visual and vestibular behavior, and their underlying neuronal structure/function. Specifically, their angular VOR has been found to be induced robustly around all 3D axes. Presently we show that goldfish produce vertical (V) VOR in response to both roll tilt and lateral translation in the dark, appearing that their VOR does not distinguish the two motions. However, in lateral-eyed animals VVOR is appropriate for both motions if they are to stabilize the visual scene from the bottom. We hypothesized that they would stabilize the vision from the front or the side by producing H or TVOR, respectively if trained adequately by using visual-vestibular combined stimuli. Because optokinetic response (OKR) to visual stimulation in goldfish has been characterized only for horizontal rotation, we evaluated V and TOKR in preparation to test the hypothesis. We employed a custom-made virtual reality system that enables full-field optokinetic visual stimuli (OKS) around all 3D axes. We found that gains for V and TOKR in naïve animals are very small in contrast to robust HOKR. Nevertheless, their gains increased after prolonged exposure to OKS around each axis. Based on these results, we envision that goldfish VOR would distinguish tilt from translation after visual-vestibular combined training that updates internal models and Bayesian priors used to estimate self-motion.

Title: Second-order attribute of head motion is encoded at single-neuron level in the vestibular nuclei.

Authors: *I. MACKROUS[1], J. CARRIOT[1], K. E. CULLEN[2], M. J. CHACRON[1];
[1]McGill Univ., Montreal, QC, Canada; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: The vestibular system encodes head motion during our daily activities giving rise to vital autonomous reflexes as well as self-motion perception. Previous studies have shown that natural head motion stimuli are characterized by complex spatio-temporal attributes that differ from artificial stimuli (i.e., sinewaves). Specifically, natural self-motion stimuli consist of a fast time-varying waveform (i.e., first order) whose amplitude (i.e., second order or envelope) varies more slowly. Previous studies have shown that vestibular afferents can respond to the envelope only for higher amplitudes, yet behavioral studies have shown that human subjects can perceive changes even at low amplitudes. In order to investigate this apparent discrepancy, we recorded from downstream vestibular-only (VO) neurons within the vestibular nuclei in response to stimuli consisting of a noisy waveform whose envelope varied sinusoidally at lower frequency. Importantly, stimulus amplitude was kept low such as not to elicit static nonlinearities and thus no envelope response from afferents (e.g., rectification, saturation). Overall, we found that VO neurons robustly encoded the envelope with a gain that was independent of frequency. Interestingly, VO neural responses increasingly lagged the envelope stimulus as frequency increased. Computational modeling revealed that envelope responses in VO neurons were not due to static nonlinearities, instead it could be due to either a dynamic nonlinearity or are caused by external input. Further, we computed neural amplitude discrimination thresholds. Overall, our results show that the activities of~80 neurons are necessary to account for perception, which is much greater than what was found previously in the thalamus (Carriot et al., 2021). Overall, our results show that self-motion stimuli amplitude is encoded at single-neuron level in the vestibular nuclei and that amplitude discrimination begins at that level. This has critical implications for our understanding of how early processing of vestibular signal can encode second-order attributes of head motion that will further be used to ensure stable perception of the world and accurate motor control.

Title: Perceptual vestibular integration is influenced by the encoding vestibular end-organs

Authors: *A. CHEN, C. KUO, J.-S. BLOUIN;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The vestibular end-organs encode head linear and angular acceleration in space, relaying signals critical to our perception of self-motion. Our internal representation of self-rotation is thought to depend on semi-circular canal encoding and a central integration process (velocity storage). Velocity storage enables the prolongation of our internal representation of rotation after signals encoded by semi-circular canal afferents have adapted. Computational models explaining the velocity storage process all assume its operations are independent of the rotational axis. Physiological data, however, demonstrate that the axis of head rotation influences the perception of head rotation. The purpose of our study was to determine if the contribution of distinct vestibular end-organs influence the duration of perceived self-rotation to constant velocity stimuli. We recorded perceived rotation while varying the vestibular end-organs (semi-circular canals and otoliths) encoding head rotation by changing head orientation relative to an Earth-vertical rotational stimulus. First, we tested if the number or type of semicircular canal pair(s) activated were responsible for changes in velocity storage duration (n=16). Perceptual responses suggested that the number or type of semicircular canal pair(s) activated did not fully explain the results. We performed an additional experiment (n=9) to determine whether differential otolithic signals contribute to the perception of self-rotation by comparing three head orientations that altered otolith contributions to head rotation while maintaining similar semi-circular canal contributions. The perception of self-rotation was shorter when otolithic contributions were minimized. We propose a non-linear vestibular model discretizing the relative contribution of vestibular end-organs to explain our inference of self-rotation.

Title: Modulation of the vestibular nerve response by GABA-B activation

Authors: Y. RAMAKRISHNA[1], ***S. G. SADEGHI**[2];
[1]State Univ. of California at Northridge, Northridge, CA; [2]Univ. of Buffalo, Buffalo, NY

Abstract: Vestibular end organs in the inner ear receive GABAergic inputs from efferent fibers and/or supporting cells. We have previously shown that activation of GABA-B receptors results in an excitatory effect on calyx nerve terminals. Here, we used *in vitro* patch clamp recordings from calyx afferent terminals to further explore the effect of baclofen, a GABA-B agonist, on the response properties of calyx terminals and nerve fibers. We injected a sweep of sines (0.01-100 Hz) or single sines (at different frequencies from 0.1 - 100 Hz) to the calyx before and after baclofen application. Following the activation of GABA-B receptors, there was an increase in the frequency range that calyces responded to (i.e., fired action potentials) and an overall increase in the gain of the response. The phase of this response decreased. Overall, the calyces responded faster and at higher rates, with stronger phase locking to the stimulus. Consistent with these findings, *in vivo* intracochlear injection of baclofen in anesthetized mice produced an increase in synchronized response of irregular afferents to a fast linear movement, as measured by vestibular sensory evoked potentials (VsEP). Intracochlear injection of a GABA-B antagonist (CGP 35348) had the opposite effect, suggesting the presence of spontaneous release of GABA in the vestibular periphery. Together, these results provide evidence for a modulatory role for GABAergic inputs in the vestibular periphery, which could modulate the phasic properties of irregular afferents.
These studies were funded by NIH DC015091 and DC019380 grants, and a research grant from the American Otological Society to SGS.

Title: Spatial dimension of resonance phenomena in mouse primary visual cortex

Authors: *R. GULBINAITE[1], M. NAZARI-AHANGARKOLAEE[2], E. BERMUDEZ-CONTRERAS[2], M. X. COHEN[3], M. H. MOHAJERANI[2];

Abstract: Sensory cortices stimulated by rhythmic sounds, lights, or touch will respond in a rhythmic manner, with frequencies identical or harmonically related to the stimulus. Although such responses are preserved across species, reported temporal frequency tuning curves in human and mouse primary visual cortex (V1) do differ. In human EEG recordings (macroscale), V1 shows temporal frequency tuning with characteristic resonance peaks at around 10, 20, and 40 Hz, whereas only a single peak below 8 Hz is present in temporal tuning curves derived from multiunit and spiking activity (microscale) in mouse V1. By imaging transgenic animals expressing high temporal resolution fluorescent glutamate reporter iGluSnFR, we sought to characterize temporal frequency tuning in awake mouse V1 and its spatial distribution at the mesoscale. For this, we used a wide range of sine-wave modulated temporal frequencies (2-72 Hz). We found that mouse V1 responded to flickering light as high as 52 Hz - a limit dictated by the kinetics of iGluSnFR fluorescent reporter. Most importantly, temporal tuning curves showed resonance peaks at 8 Hz, 15 Hz, and 33 Hz, indicating that resonance phenomena in mouse V1 highly resemble that of humans. We also observed a variation in temporal frequency preference across V1: (1) lower flicker frequencies activated larger portions of V1 as compared to higher flicker frequencies; (2) all temporal frequencies elicited a retinotopic response in V1, with additional spatial peaks present at certain temporal frequencies. The latter finding suggests some spatial organization of temporal frequency responses in mouse V1. In conclusion, temporal frequency tuning with prominent resonance peaks in humans and in mice exhibit a high degree of similarity.

Title: Theta synchrony between mouse primary and lateromedial visual cortices following visual experience

Authors: *Y. TANG[1,2,3], A. A. CHUBYKIN[1,2,3];
[1]Biol. Sci., Purdue Univ., West Lafayette, IN; [2]Purdue Inst. for Integrative Neurosci., West Lafayette, IN; [3]Purdue Autism Res. Ctr., West Lafayette, IN

Abstract: Visual cortical circuits undergo dynamic functional and structural changes following visual experience. In the mouse primary visual cortex (V1), 4-8 Hz oscillations emerge following passive visual experience and persist beyond the visual stimulus time window. Such low-frequency activity has been associated with working memory. Its expression depends on the familiar spatial frequency content, suggesting that this resonant activity may involve functionally similar neuronal ensembles. Higher-order visual areas (HVA) in mice are also selective to distinct spatial and temporal features of the visual stimuli. We hypothesized that the persistent 4-8 Hz oscillations might be the underlying working memory process within V1 and the feature-specific HVAs. By recording in V1 and lateromedial area (LM) simultaneously using silicon probes in awake mice, we found stronger 4-8 Hz phase synchrony between these two areas following visual experience. This synchrony was higher when the visual stimulus spatial and temporal features were preferred by LM. V1 units that fired during the first two 4-8 Hz cycles were better phase-locked to the 4-8 Hz LM activity, while LM units that fired after but not during the first cycle were better phase-locked to the 4-8 Hz V1 activity. Furthermore, we found that V1 and LM units within the superficial layers showed higher correlated firing following the experience. These results demonstrated that visual experience induced persistent and synchronized 4-8Hz oscillations between V1 and LM. This finding suggests that the 4-8 Hz persistent oscillations emerging after experience may synchronize visual cortical areas based on their functional specificity to maintain information during working memory.

Title: A physiological and anatomical survey of the visual cortex in the northern treeshrew

Authors: *J. WEKSELBLATT[1], F. LANFRANCHI[3], M. SHAPIRO[2], D. Y. TSAO[1];
[2]CCE, [1]Caltech, Pasadena, CA; [3]CALTECH, Pasadena, CA

Abstract: The macaque monkey has classically provided a key model for visual processing, due to its amenability to psychophysical tasks and well-delineated visual hierarchy. More recently, the rodent has emerged as a new model for visual processing, due to the availability of molecular and genetic tools. An ideal model system would satisfy both needs: amenability to complex psychophysical tasks and tractability for molecularly-based recording and perturbation techniques. Towards this goal, we have embarked on an effort to establish the northern treeshrew as a model organism for study of high-level object vision.A diurnal animal, the treeshrew has high visual acuity (>10x that of rodents), a cone-dominant retina, and a columnarly-organized visual cortex. Moreover, treeshrew cortex is lissencephalic, enabling increased optical access for imaging neural circuit dynamics compared to the macaque. Due to its small size (~150-200 grams) and relatively short reproductive and developmental cycles (6 weeks gestation, 4-6 months from birth to adulthood, 1-6 offspring per litter), the treeshrew offers experimental and genetic accessibility similar to rodents.We have begun high-throughput recordings using up to three simultaneously implanted neuropixel electrodes in different areas along the treeshrew visual hierarchy including primary visual cortex (V1), secondary visual cortex (V2), and inferotemporal cortex (IT). We report our initial results from over 1000 active recording sites per session in awake animals viewing various classical stimuli including simple oriented bars, Simonchelli textures, and a large number of objects. We find differential modulation across brain areas and stimulus sets, including replication of findings from primates suggesting a particular functional role for V2 in the representation of natural image structure. We also report our findings on connectivity patterns in visual cortex of treeshrew using a combination of retrograde tracing (cholera toxin subunit B), anterograde tracing (adeno-associated virus), and cytochrome oxidase staining. We have developed a cortical flatmount preparation which allows tangential slices through the entirety of each hemisphere, providing a full view of the projections to and from several cortical areas for which we have electrophysiological data.This work is supported by HHMI.

Title: Intrinsic neural dynamics predict category selectivity in ventral visual cortex

Authors: *M. J. BORING[1], R. M. RICHARDSON[3], A. S. GHUMAN[2];
[1]Ctr. for Neurosci., [2]Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA; [3]Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: The intrinsic dynamics of neural populations constrain the computational processes by which regions process information and the timescales over which they integrate information. Further, different domains of perceptual information require different information processing capacities. Therefore, we hypothesized that the intrinsic dynamics of ventral visual regions should predict the category of visual stimuli that those regions selectively process. We tested this hypothesis using 1,350 intracranial electroencephalography contacts implanted within ventral visual cortex of 41 patients with intractable epilepsy. Patients completed a 1-back task where they viewed pictures of bodies, words, faces, tools, houses, and phase-scrambled images. We then tried to predict which ventral visual contacts would demonstrate selective neural activity for each of the object categories using intrinsic dynamic features calculated from prestimulus activity. These dynamic features included measures of the distribution of prestimulus activity, its periodicity, autocorrelation, and power in canonical frequency bands. Across the patients, we could reliably predict whether contacts from a left-out patient would be selective for each of 6 object categories or not based on these intrinsic, prestimulus dynamics. Further, these intrinsic dynamics could differentiate between contacts selective for different object categories. This shows that, for example, word selective regions have different intrinsic dynamics compared to body selective regions in the ventral visual stream. Previous studies have demonstrated consistent differences in the dynamics of different brain regions across subjects. So, to ensure the dynamic features were not simply predicting the anatomical location of the contacts, which is also predictive of category selectivity, we compared category classifiers trained on the dynamic features to those trained on the anatomical location of the contacts. These analyses demonstrated that the predictive ability of the dynamic features was not purely driven by broad differences in dynamics across ventral visual regions. This suggests that subject-to-subject variability in the cortical localization of category selective regions may be related to variability in the dynamic properties of these regions across subjects. Several open questions remain, including the degree to which these intrinsic dynamics are conserved across spatially discrete regions selective for the same stimuli and how these intrinsic dynamics are influenced by connectivity with other brain circuits.

Title: Laminar and columnar response profiles of color, disparity, and naturalistic texture in human early visual cortex

Authors: *H. AI[1], W. LIN[3], N. CHEN[1,2], P. ZHANG[3];
[1]Dept. of Psychology, [2]THU-IDG/McGovern Inst. for Brain Res., Tsinghua Univ., Beijing, China; [3]Inst. of Biophysics, Chinese Acad. of Sci., Beijing, China

Abstract: The early visual cortex can process a variety of basic visual features, such as color, disparity, and naturalistic statistical information. However, how these features are processed hierarchically in the visual system remains unclear. Using 7T BOLD fMRI at 1mm isotropic resolution, we investigated laminar and columnar response profiles of these basic features in human V1 and V2 by presenting three independent stimulus contrasts: (1) color versus luminance, (2) binocular disparity (3D) versus 2D control, (3) naturalistic texture versus spectrally matched noise. Different laminar profiles were observed. Compared to spectrally matched noise, naturalistic texture evoked a larger response in the deep cortical depth than in the middle and superficial depth, both in V1 and V2. On the other hand, color- and disparity-selective responses were stronger in the superficial depth than in the middle and deep cortical depth of V1, and no difference across different depth of V2. These results suggest that in V1 and V2, cortico-cortical feedbacks play important roles in the processing of naturalistic texture, while color and disparity representations might initially arise from V1 superficial layers and are further processed in V2 and beyond through the feedforward pathway. Color-selective thin and disparity-selective thick stripe columns can be robustly detected in V2. The contrast between naturalistic texture and noise showed no obvious columnar organizations. We further defined pale stripe ROIs in-between the thin and thick stripes. No response preference for naturalistic texture was found across the three types of stripes in V2. Altogether, these mesoscale response profiles reveal stronger feedback activity in V1 and V2 for naturalistic statistical visual processing compared to other basic features, without preference in V2 stripes.

Abstract: The establishment of neural circuitry during early infancy is critical for developing visual, auditory, and motor functions. However, how cortical tissue develops postnatally is largely unknown. By combining T_1 relaxation time (T_1=1/R_1 relaxation rate) from quantitative MRI and mean diffusivity (MD) from diffusion MRI in 13 infants, we tracked cortical tissue development in infants across three timepoints (newborn, 3 months, and 6 months, *N*=10 at each timepoint). Lower T_1 and MD indicate higher microstructural tissue density and more developed cortex. Our data reveal three main findings: First, primary sensory/motor areas have lower T_1 and MD at birth than higher-level cortical areas. However, all primary areas show significant reductions in T_1 and MD from newborns to 6-months-olds, illustrating profound tissue growth after birth. Second, significant reductions in T_1 and MD from newborns to 6-month-olds also occur in all visual areas of the ventral and dorsal visual streams. Strikingly, this development was hierarchical across the visual streams: Earlier areas are more developed with progressively denser tissue at birth than higher-order areas, but higher-order areas had progressively faster rates of development. Finally, transcriptomic gene analyses comparing gene expression in postnatal (early infancy) vs. prenatal brain tissue samples showed significantly stronger postnatal vs. prenatal expression of genes associated with myelination, synaptic signaling, and dendritic processes. Our results indicate that these cellular processes may contribute to profound cortical tissue growth during early infancy observed with *in-vivo* MRI. These findings suggest a novel principle of postnatal maturation of sensory systems: development of cortical tissue proceeds in a hierarchical manner, enabling the lower-level areas to develop first to provide scaffolding for higher-order areas, which begin to develop more rapidly following birth to perform complex computations for vision and audition.

Title: Uniform cortical stimulation in the early visual cortex evokes modular patterned activity through intracortical network interactions

Authors: *H. N. MULHOLLAND[1], M. KASCHUBE[2], G. B. SMITH[1];
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Frankfurt Inst. For Advanced Studies, Frankfurt Am Main, Germany

Abstract: Modular (columnar) activity is a fundamental mode of neural activity in the cortex of primates and carnivores. Work in ferret visual cortex has shown that already prior to visual experience, early spontaneous activity in ferret visual cortex is modular, revealing large-scale correlated networks that are predictive of future functional networks and exist in the absence of long-range horizontal projections and patterned feedforward activity. Computational models predict a striking ability of developing cortical circuits to self-organize into modular coordinated patterns of activity, but this prediction has not yet been directly tested during early development in vivo. Here, we combine widefield epifluorescence calcium imaging with excitatory optogenetics to simultaneously image and stimulate pyramidal neurons in layer 2/3 of developing ferret visual cortex (postnatal day 24-29). We found that optogenetic stimulation of the cortex with a large (~3 mm) spatially uniform stimulus lead to the rapid emergence of highly non-uniform, modular neural activity. The probability of evoking a modular pattern increased with optogenetic light intensity, suggesting a network activity threshold to generate structured activity from this spatially uniform input. Moreover, these modular opto-evoked events resembled spontaneous activity in their spatial structure and scale and revealed highly similar large-scale correlated networks as spontaneous activity. Notably, opto-evoked activity resided in a moderately low-dimensional subspace that is indistinguishable from that of ongoing spontaneous activity. In contrast, activity patterns elicited with visual stimulation are highly stereotyped and strongly low dimensional. Importantly, we found that modular opto-evoked events required activity propagating through local intracortical synapses for their emergence, and that modularity persisted even in the absence of feedforward input from the LGN. Together, this provides strong evidence that modular patterned activity is an emergent property from intracortical interactions through a self-organizing network. Furthermore, our approach provides a path towards studying the input-output transform of early cortical networks at the scale of several millimeters.

Title: Behavioral measurements of motor readiness in mice.

Authors: *E. MANGIN[1], J. CHEN[2], J. LIN[2], Y. HAO[3], N. LI[2];
[1]Neurosci., [2]Baylor Col. of Med., Houston, TX; [3]Neurosci., Baylor Col. of Medicne, Houston, TX

Abstract: Many movements occur too quickly for online correction; the brain plans goal-directed movements before they are executed. Classic experiments suggest the existence of a "state of readiness" which, once entered, permits rapid and precise execution of the prepared movements. In humans and nonhuman primate studies using delayed response tasks, reaction time (RT) decreases if subjects are given time to prepare for a movement before a Go cue. However, behavioral measurements of motor preparation are currently lacking in mice, an increasingly popular model system ideal for circuit dissections of motor preparation.
Here we examine non-body-restrained mice in an autonomous behavior system in which animals voluntarily engaged in two different delayed response tasks: a licking task involving the tongue and a reaching task involving the forepaw. In these tasks, animals planned their upcoming movement during a delay epoch (1.3s) and had to correctly lick or reach an instructed target after an auditory Go cue to receive a water reward. These behaviors were captured with high-speed videography and quantified using markerless tracking. We replicated classic experimental findings in mice, which demonstrated a RT savings with more preparation. On occasional probe trials, on which the Go cue arrived before the end of the delay epoch, mice were unprepared and thus slower to initiate the movement. RT decreased with increased delay duration before reaching a plateau. The shape of the RT curve thus reflected the degree of readiness. To date, we analyzed high-speed videos of the tongue, nose, and jaw in the licking task. Tongue movement was more precise with increased degree of readiness. Moreover, we found that the degree of readiness was reflected in the position of the jaw and nose before movement onset. Mice positioned their jaws and noses toward the instructed target and the direction of the upcoming lick movement could be read out from the jaw and nose position. The jaw and nose position predicted the RT in both control and probe trials and this relationship was common across mice, though idiosyncratic differences among animals were also found. These results provide behavioral signatures of motor preparation in mice and suggest body features as a viable way to measure readiness online. The measured readiness suggests a learned timing in which mice

anticipated the timing of the Go cue. We are currently examining these behavioral features in a dynamic preparation task in which mice rapidly select between and initiate licking or reaching movements.

Title: Disparity between default plan and default movement representation in the motor cortex

Authors: *A. SULEIMAN[1], F. MAWASE[2];
[1]Biomed. Engin., Technion Israel Inst. of Technol., Haifa, Israel; [2]Physical Med. and Rehabil., Technion - Israel Inst. of Technol., Haifa, Israel

Abstract: Goal-directed behavior involves planning and execution of actions that incorporate information about the target, our bodies and the environment. Within this motor repertoire, we often perform some actions more than other, resulting in probability distributions over possible movements. Distribution of recent executed action affects movement representation in the primary motor cortex (M1) as revealed by biases in movements evoked by Transcranial Magnetic Stimulation (TMS). However, little is known whether M1 represents also the plans of these movements. In three behavioral-TMS experiments, we manipulated the distribution of executed movements and the distribution of upcoming target location and compared the default movement (DM)- the TMS-evoked thumb movement, and default plan (DP)- the distribution of movement begins prepared by default, in accordance with expectations about which movement would most likely be required. In Exp. 1 (n=20), we compare the baseline distribution of DM with DP using a time-response task in which participants heard a sequence of 4-tones (500ms apart) and were trained to initiate their thumb movement with the fourth tone. In a subset of trials, no target ever appeared but participants were still required to move, enabled us to assess participants' DP. We found two clusters of participants: one showed a large overlap between DP and DM whereas a second cluster showed remarkable disparity between the distributions. Next, we manipulated the distribution of recent movement by asking participants to intensively repeat a movement toward a specific direction (Exp. 2, n=15). We found that DMs were remarkably sensitive to prior distribution of movement whereas distribution of DP did not change. Lastly, we tested whether DP could be affected by distribution of the most expected movement (Exp. 3,

n=15). Here, we biased the distribution of upcoming targets by increasing the probability of target appearance in a specific direction, and found that distribution of DP, but not DM, was attributable to anticipation of upcoming movements. Overall, we demonstrated that DM in M1 reflects probability distributions of prior actions whereas DP reflects individual expectation for upcoming reaches.

Title: Hierarquical organization of corticomesencephalic projections

Authors: *V. LOPEZ-VIRGEN, M. MACIAS-RAMIREZ, P. RODRIGUEZ-MORENO, R. OLIVARES-MORENO, V. DE LAFUENTE, G. ROJAS-PILONI;
Inst. de Neurobiologia, UNAM, Santiago de Queretaro, Mexico

Abstract: One major goal in neuroscience is to understand how different aspects of movements are regulated in parallel by the cerebral cortex. Output commands of cortical sensorimotor areas are driven by pyramidal tract neurons (PTNs) which projects to several subcortical structures. An open question is if PTNs are hierarchically organized generating different and specific output commands for sensorimotor integration. Here, using single cell 3D reconstructions in *In vivo* identified motor cortex PTNs projecting to mesencephalic red nucleus, or pons, we found morphological and electrophysiological characteristics for corticopontine and corticorubral neurons. Moreover, using photometry in both class of PTNs during a motor execution task, revealed a different relationship of this neurons with movement. The results indicates that PTNs are organized into different subsystems controlling in a coordinated manner distinct subcortical circuits related with different aspects of sensorimotor integration and thus, proper movement execution.

Title: Collapse of complexity of brain and body activity due to excessive inhibition and MeCP2 disruption

Authors: *J. LI, P. A. KELLS, A. C. OSGOOD, S. H. GAUTAM, W. L. SHEW;
Univ. of Arkansas Fayetteville, Fayetteville, AR

Abstract: Complex body movements require complex dynamics and coordination among neurons in motor cortex. Conversely, a long-standing theoretical notion supposes that if many neurons in motor cortex become excessively synchronized, they may lack the necessary complexity for healthy motor coding. However, direct experimental support for this idea is rare and underlying mechanisms are unclear. We address this problem in motor cortex of awake, freely behaving rats, comparing normal rats and a transgenic rat model of Rett syndrome (RTT), as well as pharmacologically inducing enhanced synaptic inhibition. We record single-unit neuronal activity with multi-electrode arrays in the deep layer motor cortex (M1). Simultaneously, we record the three-dimensional body movement of the rats by capturing representative beads on the rats with an infra-red camera system. First, we examined cortex-body interactions using spike triggered average body speed functions and CCA analysis. We found that both RTT and enhanced inhibition cause stereotyped, low dimensional cortex-body interactions. Next, we looked at synchrony of the neural activity, along with PCA-based analysis and spike triggered average population activity functions. Similarly, we found that synchrony is the lowest for normal rats. Both RTT and enhanced inhibition result in a significant higher synchrony, lower dimensional and stereotyped intracortical interactions. Last, we applied PCA-based analysis and B-SOiD analysis on the body movement data, and found that body activity is also less complex for RTT and enhanced inhibition. In summary, we found a collapse of complexity in the motor system for both RTT and enhanced inhibition. Reduced complexity was apparent in lower dimensional, stereotyped brain-body interactions, neural synchrony, and simpler behavior. Our results indicate that excessive inhibition leads to stereotyped, low-complexity relationships among neurons in motor cortex and body movements, and this imbalanced inhibition may contribute to motor dysfunction in Rett syndrome.

Title: Reaching errors resulting from the misestimation of arm position

Authors: C. BUNEO, *P. PHATARAPHRUK, P. VANGILDER;
Arizona State Univ., Tempe, AZ

Abstract: The planning of visually-guided reaching movements requires the integration of visual and somatosensory inputs to estimate the arm's position. In some contexts (e.g., in dimly lit environments, during experimental manipulation of sensory feedback, or following neurological damage) the integration of visual and somatosensory inputs can lead to an arm position estimate that is biased and imprecise, leading to errors in movement planning and execution. To understand the neural correlates of this process we have developed a virtual reality based experimental paradigm for studying visual, proprioceptive, and tactile integration for arm position estimation in non-human primates. Animals reach from a defined start position to four targets in a semi-immersive VR environment that incorporates a fully-rendered monkey avatar arm. The avatar arm is viewed either in a position consistent with a real starting position ('veridical') or in a visually shifted position ('perturbed'). Veridical and perturbed arm positions are varied in separate blocks of trials. Behavioral analyses focus on changes in initial movement directions that are induced by perturbing the arm position. Here we report the results of computer simulations used to predict the behavioral consequences of perturbations in different directions and amplitudes. Two joint (shoulder and elbow) horizontal plane arm movements were simulated using an inverse model that first determined the joint torques corresponding to nominal endpoint trajectories. A forward model was then used to simulate movements in an open-loop fashion, i.e., feedback control was not included. Perturbations were simulated by introducing uncompensated bias and variance into the estimate of initial hand position. Simulations produced movement errors that were dependent upon movement direction, starting position, and perturbation direction and amplitude. For the primary start position used in our experiments, simulation results were consistent in several ways with behavioral data obtained from one animal performing reaching movements under visually perturbed conditions. These results provide important insights into the movement errors that result from misestimating arm position, which could prove useful for understanding corresponding errors that arise during investigations of the neural correlates of multisensory integration, as well as those arising from neurological damage.

Title: Posterior parietal area 5b neurons with somatosensory receptive fields on different segments of the forelimb act differently during locomotion

Authors: *W. U. NILAWEERA[1], I. N. BELOOZEROVA[2];
[1]Sci., Des Moines Area Community Col., Des Moines, IA; [2]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA

Abstract: Posterior parietal cortical area 5b is a part of the cortical pathway that processes visual information while conveying it from visual to motor cortex (M1), equipping M1 with information for guiding limbs. During locomotion, neurons in M1 with somatosensory receptive fields (RF) on different forelimb segments behave differently (Stout & Beloozerova 2012). The source of this difference is unclear. Here we assessed the activity of the main cortical provider of visual information to M1, area 5b, to examine whether it differentially processes information regarding different segments of the forelimb and how this can influence locomotion-related activity of M1.Experiments were conducted on two cats walking on a flat surface and horizontally placed ladder. Accurate stepping on the ladder requires vision, whereas walking on the flat surface does not. The activity of 38 neurons with RF on the shoulder (SH), 29 with RF involving the elbow (EL), and 42 with RF on wrist/paw (WP) was analyzed, including 20 neurons that responded antidromically to electrical stimulation of M1, thus confirming projecting to M1, cortico-cortical neurons (CCs): 7 SH, 5 EL, 8 WP cells. We found that on the flat surface the group activity of SH cells, both CCs and neurons whose axon projection was unknown (noIDs), peaked during stance-swing transition, similar to that of M1 SH group (Stout & Beloozerova 2012). The activity of EL noIDs was steady over the step cycle, while that of EL CCs peaked at the swing, both different from the activity of M1 EL group. The discharge rate of WP noIDs was maximum during stance-swing transition, similar to that of M1 WP group, whereas, the activity of WP CCs peaked during swing-stance transition, an opposite phase. Thus, during vision-independent locomotion, area 5b may contribute to the stride-related activity modulation of M1 SH and possibly WP groups, but not the EL group. During ladder locomotion the group activity of SH noIDs was steady, while that of SH CCs had two maxima: during stance-swing and swing-stance transitions, both profiles different from that of M1 SH group. The activity of EL noIDs peaked during stance, later in the cycle than M1 EL group, which peaked during swing-stance transition. The activity of EL CC group was minimal during this latter phase. The activity of WP noIDs peaked during stance-swing transition, earlier than M1 WP group, which peaked during swing. The activity of WP CCs, however, was maximal later, during early stance when M1 WP group activity was depressed. Thus, it is unlikely that area 5b SH

group determines the activity of M1 SH cells during vision-guided locomotion, while EL and WP CCs may influence respective M1 groups via M1 inhibitory interneurons.

Title: Trimodal integration of visual, tactile, and proprioceptive cues influences reach planning in a virtual environment

Authors: P. PHATARAPHRUK, P. VANGILDER, *C. BUNEO;
Arizona State Univ., Tempe, AZ

Abstract: The planning of reaching movements requires integration of visual and proprioceptive cues to estimate the position of the arm before and during movement. Although bimodal (visuo-proprioceptive) integration has been well-characterized in human subjects, less is known about trimodal integration processes, e.g., for reaching movements performed when tactile information is initially present. Moreover, few studies have examined multisensory integration in non-human primates (NHP), which are more amenable to examination of the neural correlates of multisensory integration. Here, we used a semi-immersive virtual reality (VR) environment to study how visual, proprioceptive, and tactile cues about arm position are integrated prior to movement execution. A NHP was trained to reach from a single start position to four targets in VR while viewing a fully-rendered monkey avatar arm that was animated via a reflective-marker based motion capture system. Trials began with no visual feedback of the arm but once the starting position was cued and acquired, the avatar arm was displayed for 1-1.5 seconds prior to movement. The virtual arm appeared either in a position consistent with the physical location of the starting position (veridical vision (VV)), or shifted 6 cm toward the animal's body (perturbed vision (PV)). VV and PV conditions were varied on a trial-by-trial basis. In addition, tactile feedback was varied in separate blocks of trials by adding or removing a circular plastic button from the starting position. Evidence for multisensory integration was assessed by comparing mean reach directions at peak tangential acceleration across visual and tactile conditions. We observed target-dependent differences in initial reach directions between PV and VV conditions, regardless of tactile conditions. For targets with clear differences, initial reach directions tended to be more accurate (i.e. less deviated from cued target directions) on VV trials than PV trials. Notably, both the target-dependence and the direction of deviation on PV trials were largely

consistent with forward dynamics simulations of visually perturbed reaches. Initial reach directions also tended to be more accurate for reaches made with tactile feedback than without, with larger effects being observed for targets influenced by arm visual feedback. The results indicate that visual and tactile cues influence the planning of reaches performed in a virtual environment. The consistent nature of the observed effects suggest visual and tactile cues are integrated along with proprioception to form a more accurate estimate of initial arm position used in movement planning.

Title: Effects of Tactile Cues on Arm Movement Planning and Execution in a Virtual Environment

Authors: *P. VANGILDER, P. PHATARAPHRUK, C. BUNEO;
Arizona State Univ., Tempe, AZ

Abstract: During the planning of arm movements, visual and somatosensory inputs are combined to compute an estimate of the current arm position through a process known as multisensory integration. This estimate is used to determine the desired movement vectors as well as joint-based motor commands for action. Although multisensory integration for reaching has been extensively studied in humans, investigations involving non-human primates (NHP), which serve as an important model for understanding the underlying neural mechanisms, are relatively sparse. Here, we used a semi-immersive virtual reality (VR) environment paired with a motion capture system to study the integration of visual, proprioceptive, and tactile cues during reaching movements. Two NHPs were trained to wear a motion capture sleeve on their right arm, which served to animate a virtual replica of their own limb in real-time within the VR environment. The VR arm and environment were projected from a 3D monitor onto a mirror blocking vision of the animals' actual arm. After acquiring a central starting position, the animals made reaches to one of four targets in the horizontal plane during which visual feedback of the virtual arm was provided or removed on a trial-by trial basis. Physical properties of the virtual start and target positions were rendered to resemble those of real tactile cues, which were circular plastic buttons that were added or removed from the workspace in separate blocks of trials. Analysis focused on quantifying the variability in hand movement direction and distance

(relative to the starting position) as a function of movement extent (i.e., from 10-100% of movement on a given trial, in increments of 10%). We found that for all task conditions, directional variability decreased with movement extent, while conversely there was an increase in variability in distance traveled. Variability in direction and distance was reduced in conditions where tactile cues were provided, though this effect was more apparent during the later stages of the reaching movements. Reduced variability in direction and distance was also observed in conditions employing visual feedback but only when tactile cues were absent. These results show that the presence of tactile cues reduces the variability of reaching movements performed in a virtual environment. Moreover, the results suggest that tactile cues interact in a complex manner with ongoing visual and proprioceptive feedback to determine motor output.

Title: Heritable differences in the expression level of the zinc transporter zip11 drive individual-to-individual variation in learned birdsong tempo

Authors: *D. METS[1], W. H. MEHAFFEY[1], B. COLQUITT[1], R. J. VELINE[1], M. S. BRAINARD[2];
[1]Physiol., [2]Physiol. and Psychiatry, UCSF Ctr. For Integrative Neurosci. and HHMI, San Francisco, CA

Abstract: Complex learned behaviors exhibit striking variation within populations, yet how heritable factors contribute to such inter-individual differences remains largely unknown. Here, we used genetic linkage analysis within a Bengalese finch population (*Lonchura striata domestica*) to investigate molecular and circuit mechanisms underlying heritable differences in the tempo of learned birdsong-a fundamental aspect of song performance suggested to be a target of sexual selection and known to be influence by experience, genetics, and their interaction. We identified a genomic locus encoding the zinc transporter ZIP11 and found that *zip11*(*SLC39A11*) transcript was expressed at higher levels in song control circuitry of faster singing birds. Reducing soluble zinc increased synaptic currents in motor circuitry and accelerated song, whereas reducing ZIP11 slowed song. Our results reveal a novel zinc-dependent mechanism that

modulates neural activity to drive differences in behavior and suggest that natural variation in learning may preferentially target modulatory processes rather than core neural machinery. Further, this work establishes genetic linkage and molecular manipulations in the songbird as a powerful system for studying the molecular and circuit level mechanisms that structure learned behavior and provides a framework for similar future studies. In particular, other aspects of song (syllable sequencing, amplitude, spectral flatness etc...) display heritability in this population of Bengalese finches and similar analyses of these phenotypes will provide insights into differing mechanisms influencing complex learned behavior.

Title: Assessing how the introduction of daf-7 (e1372) in unc-33 affects rescue of dauer formation and locomotion in previously uncoordinated C.elegans.

Authors: *A. CRISTANCHO, R. VALTIERRA, M. C. MIRANDA, S. BECK, J. CANTU, A. VACIO, A. HOLGADO;
Dept. of Biol. Sci., St. Edward's Univ., Austin, TX

Abstract: Recent studies show that the sixth-leading cause of death in the United States is Alzheimer’s disease with the number of deaths doubling between 2000 and 2018. Collapsin response mediator protein-2 (CRMP2) in humans, (UNC-33 in *C. elegans*) is a molecule that mediates axonal stability and degeneration. It is a potential drug target that could be used to treat Alzheimer’s and other neurodegenerative diseases, which can often be attributed in part to aging. In the aging process, CRMP2 becomes hyperphosphorylated, decreasing its functionality and leading to aging in neurons. *C. elegans* aging can be slowed by dauer formation, a developmental stage identified as a non aging stage. DAF-7 is the *C. elegans* homolog of transforming growth factor beta (TGFβ), which enables development in both humans and *C. elegans.* The mutation of *daf-7* leads to constitutive dauer formation, while the mutation of unc-33 leads to the inability to form dauers in response to environmental stress. Herein, we are introducing the *daf-7* mutation to an *unc-33* mutant to test for rescue of dauer formation.To this end, we created *unc-33; daf-7*

double mutants and assessed dauer formation. Double mutants were treated with 1% SDS to test for proper dauer formation after exposure to unfavorable conditions. Analysis of experimental data showed that *unc-33 (mn407); daf-7 (e1372)* double mutant had 94% survival to SDS treatment, compared to 0% in the *unc-33 (mn407)* mutant. The *unc-33 (e204); daf-7 (e1372)* double mutant had 89% survival, compared to 0% in the *unc-33 (e204)* mutant. In addition to dauer formation, we tested the rescue of locomotion and found that the distance traveled on plates was f 54.8 ± 5.3 nm in the Wild Type compared to 45.4 ± 8.6 nm in the *unc-33(e204); daf-7(e1372)* double mutant. When tested in liquid there were 189.3 ± 5.9 body bends/min in the Wild Type compared to 70.0 ± 3.1 body bends/min in the *unc-33(e204); daf-7(e1372)*double mutant. Based on these results, we conclude that the problem behind dauer formation in *unc-33* mutants lies within the DAF-7 pathway. Specifically, *unc-33* mutants have a problem suppressing DAF-7 signaling, leading to the continuation of reproductive programs even under unfavorable conditions. Results from the plate locomotion verify rescue in the *unc-33(e204); daf-7(e1372)* double mutant. In aging, where CRMP2/UNC-33 is hyperphosphorylated, the DAF-7 levels can be manipulated to increase lifespan. Animals that have an *unc-33* mutation concurrent with a *daf-7* mutation can live longer and potentially have slower neurodegeneration.

Title: Mesoscopic wide-field calcium imaging during a reaching behavioral task in mice.

Authors: *R. E. CARTER, E. FLAHERTY, C. HUFFMAN, A. SHEKHAR, T. J. EBNER; Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Reaching is a fundamental behavior exhibited by a number of organisms and involves complex limb movements coordinated and executed by many distinct brain areas. Wide-field, chronic calcium (Ca^{2+}) imaging through transparent polymer skulls is a relatively new technique that involves surgically replacing opaque cranial structures with transparent polymer windows. These windows allow for real-time visual imaging of brain activity across wide regions of the cortex in mice that are awake and behaving, allowing for innovative comparisons between brain

activity and behavior to be made. Thus, wide-field imaging of reach behaviors should be able to provide new insights into the brain regions involved with reach behaviors, as well as provide insights on how these brain areas work together in reach behaviors. We implanted our transparent polymer windows in Thy1-GCaMP6f mice that express GCaMP6f in pyramidal cells in layers II/III of the cerebral cortex. These mice were trained in a head-fixed, cued, reaching behavioral task. The task consists of a stimulus tone signifying the delayed presentation of a water droplet at the end of a spout in front of the mouse, requiring the mouse to reach out to obtain the water droplet. Mice were water-restricted to incentivize the reaching behavior. Following proficient reaching to the spout, simultaneous dual-wavelength wide-field Ca^{2+} imaging (20 Hz) and high-speed behavioral imaging (100 Hz) was performed during the behavioral task. Water rewards were delivered in either two paradigms over a 5-minute imaging session: 1) once every 30 seconds resulting in 8 deliveries per imaging session; or 2) in 1 of the 8 random deliveries, no water was delivered following the tone. Limb tracking during the reaching behavior was tracked using DeepLabCut, and the hemodynamic corrected Ca^{2+} signal was analyzed using Localized semi-Nonnegative Matrix Factorization (LocaNMF). In relation to the task, there were widespread changes in Ca^{2+} activity across much of the dorsal cerebral cortex that were coupled to both the tone and reach. Preliminary analysis shows that mice express a consistent functional connectivity map during the reaching task, between imaging sessions within the same day to across multiple days and mice. The functional connectivity evolves during the reach, with higher functional connectivity between the primary motor cortex, hind limb/forelimb region of the somatosensory cortex, and the retrosplenial cortex during the task compared to baseline behavior. These results demonstrate that the act of reaching widely engages the cerebral cortex, using a consistent, well-defined cortical network.

Title: Wide-field calcium imaging of dynamic cortical networks during locomotion

Authors: *S. WEST[1], J. ARONSON[1], L. POPA[1], R. CARTER[1], K. FELLER[2], S. KODANDARAMAIAH[1], T. EBNER[1];
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Union Col., Schenectady, NY

Abstract: The cerebral cortex is widely activated during movement, including during locomotion. Evidence suggests that the cortex enters a new functional state compared to rest that enables the motor and sensory computations needed to accurately navigate the environment. However, the cortex-wide activity patterns underling this locomotion functional state have not been fully characterized. Here, we used widefield calcium imaging to evaluate the activity and functional relationships among cortical regions during locomotion. Clear polymer windows were implanted on 8 individual Thy1-GCaMP6f mice expressing the Ca^{2+} indicator GCaMP6f in layers II/III and V pyramidal neurons, allowing for wide field-of-view imaging of most of the dorsal cerebral cortex. Mice were head fixed on a freely moving disk treadmill that allowed free limb and body movements, including spontaneous walking. For each mouse, calcium imaging was recorded for 6-8 sessions, for a total of over 60 hours of mesoscopic data. Treadmill position was tracked with a rotary encoder, while behavior was tracked with infrared cameras. Paw movement was extracted using DeepLabCut. Mice spontaneously locomoted for 21.3 ± 10.4% of the time on the treadmill. Spatial Independent Component Analysis was used to identify independent functional regions. The mean fluorescence time series was extracted from each region, and this activity was regressed to behavior parameters as well as correlated to other cortical regions to compute the functional connectivity. Regressions show that treadmill and paw velocity explain a significant faction of the fluorescence variability across the cortex during locomotion, with the strongest effects at the onset and offset. Prior to the onset of locomotion, there is a large increase in correlation between most cortical regions. However, once a continued, steady state of locomotion is reached, the correlations between primary motor, somatosensory, and parietal regions decrease to levels lower than at rest. In contrast, the correlations from secondary motor (M2) and retrosplenial regions with most other regions increase compared to rest. At the locomotion offset, correlations increase between most regions before the network returns to the rest state. The results suggest the cerebral cortex passes through a transition state at locomotion onset, enters a new state during continued locomotion, then again passes through a transition state before returning to rest. Granger causality analysis shows that the most anterior regions of M2 Granger-cause activity in many other regions during locomotion, indicating anterior M2 may play a role in controlling the locomotion cortical state.

Title: In vivo characterization of cortical noradrenergic activity during motor learning using an optical noradrenaline sensor in a mouse model of autism

Authors: *N. JONES[1], X. YIN[1], S. CHEN[2,1];
[2]Dept. of Cell. and Mol. Med., [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Clinical studies have reported that children with autism spectrum disorder (ASD) often exhibit difficulties with the acquisition of new motor movements; these motor symptoms can present earlier than social or cognitive indicators. However, the underlying mechanisms responsible for these motor learning disruptions remain unclear. Noradrenaline (NA) is garnering attention for its putative underlying role in ASD, in part, due to its powerful control over neuronal activity. Furthermore, recent perspectives highlight the abundance of ASD symptoms that can be viewed through the lens of inefficient neuromodulation by the locus coeruleus (LC) NA system. LC projects ubiquitously to cortex, and NA exerts neuromodulatory control on cortical activity. It has been well established that NA regulates motor learning and proper motor execution in the primary motor cortex (M1). Recent work in our lab revealed dysregulation in LC NA function as a culprit of motor learning delays, manifested in a behavioral phenotype by the 16p11.2 deletion mouse model (+/-) of ASD (Yin et al, 2021). Using adult male mice due to the predominance of ASD in males, we found that 16p11.2$^{+/-}$ mice exhibit delayed motor learning caused by a reduction of NA levels in M1, accompanied by elevated pyramidal neuron (PN) activity. Chemogenetic activation of LC rescued elevated M1 PN activity along with the delayed motor learning, underscoring the importance of M1 NA dynamics. Thus, to fully characterize changes in NA levels during motor learning in awake and behaving mice, I employed a newly developed optical NA sensor, combined with *in vivo* two photon imaging, to visualize spatiotemporal activation patterns of NA in M1. This allows us to characterize NA levels in the same M1 region throughout the entirety of the motor learning process. I found that M1 NA levels increase significantly during the initial learning phase in wild type (WT, n=7) and return to baseline levels as mice develop more consistent motor movements. This trajectory alludes to critical network modulation of M1 PNs by NA during the early phase of the motor learning process. In contrast, 16p11.2$^{+/-}$ mice (n=5) display an increase of NA levels in M1 in the later stages of learning, which corresponds with their delayed motor learning phenotype. These results align with our previous work to confirm a crucial role for LC NA in early motor learning, which, if disrupted, produces learning delays. This study provides a novel glimpse into the LC NA system in ASD, which can provide valuable insight for clinicians.

Title: Correcting physiological noise in whole-head functional near-Infrared spectroscopy

Authors: *F. ZHANG, D. CHEONG, A. F. KHAN, Y. CHEN, L. DING, H. YUAN;
Biomed. Engin., The Univ. of Oklahoma, Norman, OK

Abstract: Functional near-infrared spectroscopy (fNIRS) has been increasingly employed to measure cerebral hemodynamics under normal and diseased conditions. However, fNIRS suffers from its susceptibility to superficial activity and systemic physiological noise. We have developed a new method, namely PCA-GLM (Zhang et al., 2021, doi: 10.1016/j.jneumeth.2021.109262), for denoising fNIRS recordings in a whole-head montage. To demonstrate the denoising performance, a high-density montage consisting of 109 long-separation channels and 8 short-separation channels was used for recording. In addition, auxiliary sensors were used to measure pulsation, respiration and head movements simultaneously. Our PCA-GLM method incorporates principal component analysis and general linear model to identify and remove a globally uniform superficial component, which is implemented in an automatic pipeline. The method was evaluated in experimental data acquired from a group of healthy human subjects during a visually cued motor task and further compared with four commonly used preprocessing methods in the literature, including a minimal preprocessing method and three other denoising methods. The results showed that after applying the proposed denoising method, the whole-head topography of fNIRS revealed focal activations in both the primary motor and visual areas. Further, quantitative evaluation of contrast-to-noise ratio, within-subject standard deviation and adjusted coefficient of determination showed that our PCA-GLM method yielded superior and robust denoising. In this study, an automatic method was established for removing physiological noise in whole-head fNIRS recordings. Our method can facilitate the clinical application of fNIRS in monitoring large-scale, network-level brain activities (Chen et al., 2020, doi: 10.3389/fnins.2020.560878; Khan et al., 2021, doi: 10.1088/1741-2552/abfdf9).

Title: Neural correlation of simulated walking versus upper limb and lower limb movement: A fMRI study

Authors: *A. ALIVAR[1,2], S. SALEH[1,2], C. H. JIANG[3], G. YUE[1,2];
[1]Ctr. for Mobility and Rehabil. Engin. Res., Kessler Fndn., West Orange, NJ; [2]Rutgers New Jersey Med. Sch., Newark, NJ; [3]Capital Univ. of Physical Educ. and Sports, Beijing Key Lab. of Physical Fitness Evaluation and Tech. Analysi, Beijing, China

Abstract: The neural mechanism of movement differs for upper and lower limbs. Such isolated movements have simpler neural properties than compound motor tasks requiring multi-limb coordination. We expect that isolated movement have different neural correlates than complex tasks. Previous functional imaging studies have compared upper and lower limb movements in various brain regions and none of them have reported differences in activation maps across motor areas compared to the intra-limb movement task like simulated walking. It is important to compare isolated and coordinated multi-limb movements to understand control mechanisms for guiding development of targeted rehabilitation strategies. Thus, this study aimed at evaluating and comparing activation maps during three motor tasks involving arm and leg movements performed in equal frequency and amplitude while functional magnetic resonance imaging (fMRI) data were obtained from 17 young and healthy subjects. The three motor tasks were performed as follows: alternating left and right arm movements, alternating left and right leg movements, and alternating left arm-right leg and right arm-left leg movements (simulated walking). General linear models (GLM) were used to identify the activation maps in each condition and compare the extent of activation within the motor control network to isolate upper extremity sub-region and lower extremity sub-region within the left and right motor cortices. In Simulated Walking compared to ARM, the activation map was highlighted in medial part of motor cortex (M1) ([x=-0.09,y=-30, z=57), p=6e-05, Z=6.48, k=1190) and compared to LEG, in lateral part f M1 ([x=28,y=-25, z=54), p=0.005, Z=5.32, k=556). Task specific functionally activated regions within M1 were used as seed region of interest (ROI) to perform Psychophysiological interactions (PPI) analysis and study the connectivity maps of M1 in each condition. Overall results show task specific activation map where simulated walking task recruits large activation within the motor cortex than arm and leg movement tasks. The significance of this study is to identify potential differences in the neural mechanism of each isolated and non-isolated limb movements and guide precise clinical treatments and rehabilitations.

Abstract: Electroencephalographic (EEG) theta activity in the frontal cortex has been associated with infant attentional control and information-encoding. Peaks in theta power have been observed over frontal electrode sites in infants with typical development (TD) during active toy-exploration and handling of objects. Increased frontal alpha power has been observed during periods of infant sustained attention towards dynamic visual stimuli. Emergence of frontal alpha and theta power both have been linked to infant modulation of attention and may contribute to development of goal-directed motor behavior. As infants learn to reach, we anticipate functional and structural cortical changes related to attention and motor learning. We expect these changes to differ between TD infants and infants at-risk (AR) for developmental disabilities. Here, we assessed longitudinal changes of relative theta (3-6 Hz) and alpha (6-9 Hz) power over 7 frontal electrode sites in 25 TD and 11 AR infants. We collected and analyzed EEG data during resting state, when infants looked at a glowing toy out of arms distance before and after a reaching assessment. Each infant was assessed once per month across 3-5 months as they learned to reach. Data collections took place between 38 and 230 days of gestation-adjusted age. We expected a positive correlation between age and frontal alpha/theta power in TD infants, yet not AR infants. We also calculated variance of gradients to assess within-group heterogeneity. In contrast to our hypothesis, our TD calculations showed no statistically significant correlation between age and relative theta ($r= -0.15$; $p= 0.11$) as well as alpha ($r= -0.16$; $p= 0.11$) power. AR also showed no significant correlations (theta: $r= -0.10$; $p= 0.26$; alpha: $r= -0.05$; $p= 0.38$). Variance in gradients for theta were 2.26E-7 for AR and 2.30E-7 for TD. For alpha, they were 7.62E-8 for AR and 9.13E-8 for TD. Although attention has been linked to infant motor skill acquisition, developmental trajectories are likely variable across infants. Additionally, attentional processes

can be modulated during the motor task, but this may not be as prevalent during resting state. These results are a first step in assessing potentially-distinct EEG profiles in TD/AR infants related to motor skill acquisition and emergence of attentional control in infant motor development. Further group analysis can potentially aid in advancing methods of early intervention for infants at-risk for atypical development. Moving forward we will refine our investigation by statistically testing for group differences.

Title: Effects of High-Definition Transcranial Direct Current Stimulation on Upper Extremity Function and Hemodynamic Changes in Stroke Patients

Authors: *H. KIM[1,2], J. KIM[1,2], J. LEE[1], G. LEE[1], S. SHIN[1], W. CHANG[1], Y.-H. KIM[1,2,3]; [1]Dept. of Physical and Rehabil. Medicine, Ctr. for Prevention and Rehabil., Samsung Med. Ctr., Seoul, Korea, Republic of; [2]Dept. of Hlth. Sci. and Technology, SAIHST, [3]Dept. of Med. Device Mgmt. & Research, Dept. of Digital Health, SAIHST, Sungkyunkwan Univ., Seoul, Korea, Republic of

Abstract: This study aimed to investigate the effects of high-definition transcranial direct current stimulation (HD-tDCS) over the ipsilesional primary motor cortex (M1) on upper extremity function and cortical activation during the finger tapping task (FTT) in chronic stroke patients. Twelve-six chronic stroke patients (20 males; mean age: 59.4 ± 12.8 years) were enrolled. The inclusion criteria were (1) unihemiparetic stroke patients between the ages of 19 and 80 years, (2) patients with subcortical lesion stroke, and (3) patients capable of individual finger movements. Patients with contraindications to tDCS application were excluded. HD-tDCS (1 mA for 20 minutes, 41) was administered to the ipsilesional M1 using the Starstim 8 (Neuroelectrics®, Spain) for four days. Upper extremity function was assessed by the FTT, the Box and Block test, and the Fugl-Meyer assessment (FMA) before and after the interventions. The cortical activity was measured during the FTT with the affected hand using the NIRScout® functional near-infrared spectroscopy (fNIRS) system (NIRx Medical Technologies, Germany). fNIRS topomap using 67 channels covered partial areas of frontal, parietal, temporal, and

occipital cortices. Regions of interest (ROI) were determined as supplementary motor area (SMA), primary motor cortex (M1), and premotor cortex (PM) to investigate changes in cortical activation in the motor areas during the FTT. fNIRS data were analyzed using NIRS-statistical parametric mapping software package (NIRS-SPM) (KAIST, Korea). There were significant improvements in Box and Block test scores, the accuracy of the FTT, and the FMA scores after HD-tDCS intervention. The cortical activation was showed in M1 and SMA of bilateral hemispheres and PM in the affected hemisphere during the FTT with the affected hand before the interventions. After the interventions, only M1 and PM in the affected hemisphere were activated. The cortical activation during the FTT with the affected hand, which was observed in bilateral hemispheres before the interventions, was shifted to the affected hemisphere after the interventions. These results of the present study implies that HD-tDCS over the ipsilesional M1 in chronic stroke patients enhanced upper extremity function and effectively modulated cortical activation patterns. To confirm the better effect of HD-tDCS on rehabilitation, a comparative study using conventional tDCS is further needed.

Title: Brain changes associated with force control deficits during ankle dorsiflexion in individuals with Parkinson's disease

Authors: *J. CHUNG[1], A. BOWER[1], I. MALIK[2], J. P. MARTELLO[3], C. A. KNIGHT[1], J. J. JEKA[1], R. G. BURCIU[1];

Abstract: A consistent observation from numerous functional magnetic resonance imaging (fMRI) studies is that during voluntary movements, the functional activity of the basal ganglia nuclei and the primary motor cortex (M1) is reduced in individuals with Parkinson's disease (PD) relative to healthy controls, and in several instances the reduced activity of the basal ganglia relates to the severity of motor symptoms. Although PD progresses to affect lower extremities, most fMRI studies focused primarily on identifying the neural correlates of upper extremity dysfunction. Thus, there is still a limited understanding of the brain circuitry

underlying lower limb symptoms in PD in part due to excessive head motion during leg movements in a supine position affecting the fMRI signal. Here we present preliminary results from a study that employs a force control paradigm to study brain changes during ankle dorsiflexion in individuals with and without PD. Seven PD (mean age: 65.8 ± 10.0; 4 males and 3 females) and fourteen healthy older adults (mean age: 62.3 ± 10.1; 6 males and 8 females) performed a visually cued isometric ankle dorsiflexion force production task at 15% of the maximum voluntary contraction (MVC). PD patients was tested following a 12-h withdrawal from antiparkinsonian medication and on the more affected side. Motor symptoms were assessed with the motor section of the MDS-sponsored revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS-III). The tested side in controls was randomized. While both groups were able to produce 15% of MVC during the task (p=0.222), PD had a slower rate of force increase (p=0.044) and force decrease (p=0.022) than controls. The fMRI analysis revealed that compared to controls, PD had reduced brain activity during ankle dorsiflexion in the striatum, bilaterally, left globus pallidus, left M1 and left supplementary motor area. PD also had decreased force-related signal in the cerebellum, in vermis I-IV and the ipsilateral dorsal dentate nucleus. Our preliminary findings suggest that force control deficits during ankle dorsiflexion are associated in PD with extensive functional abnormalities that span both the basal ganglia- and cerebellar-cortical loops.

Title: Modeling proprioceptive feedback evoked by intracortical microstimulation using topographical variational autoencoders

United Kingdom; [8]Data Sci. Inst., London, United Kingdom; [9]Shirley Ryan AbilityLab, Chicago, IL

Abstract: Tetraplegic patients can make visually guided reaches using efferent brain-machine interfaces (BMIs). However, the reaches are slow and imprecise, a bit like the deficits of people who can generate movement but have lost somatosensation. Restoring somatosensation will likely improve the use of BMIs. While intracortical microstimulation (ICMS) can provide touch feedback, using it for proprioceptive feedback has proven more difficult. In a single monkey in our lab, ICMS in area 2 of S1 biased the perception of the direction of a coincident bump in a direction predicated by the preferred direction (PD) of neurons recorded on the stimulated electrodes. In three other monkeys, the bias direction could not be predicted. The difference between touch and proprioception could be due to the topographical organization of the two areas. While touch has a distinct somatotopy, proprioceptive cortical maps do not, as receptors from many muscles need to be mapped onto the two-dimensional surface. Without a well-defined somatotopy, ICMS may activate neurons with very different encoding properties, resulting in perceived hand movements in unpredictable directions or even discordant effects at the hand and elbow. To explore the effect of topography, we used a topographical variational autoencoder trained to regenerate arm joint velocities via an 80x80 cortical map that included lateral inhibition, as we have done previously. This resulted in clusters of neurons with similar PDs, something like S1. We probabilistically activated neurons as a function of distance and hijacked the firing rates of activated neurons. We decoded joint velocities from cortical activity and used forward kinematics to compute hand cartesian velocities. We read out the effect of ICMS as the difference between hand velocity with and without ICMS. If the direction of this difference-vector was within 45° of the electrode's PD, we considered the effect to be predictable. We stimulated 300 randomly chosen electrodes with amplitudes from 15 μA to 40 μA. The percentage of electrodes with a predictable effect decreased from ~60% to ~40% with increasing magnitude, although the magnitude of the effect was quite small at small currents. In an effort to increase the magnitude of the effect while retaining its predictability, we stimulated sets of four electrodes with similar PDs simultaneously, each with 15 μA. Across 300 groups, the percentage with predictable effects was 70%, and the magnitude of the effect was nearly twice that of single-electrode stimulation at the same total current. With this model, we will explore the efficacy of various stimulation strategies for providing robust proprioceptive feedback.

Title: Myoelectric Closed-Loop Autoregressive Models for Predicting Ankle Kinetics and Kinematics Across Mobility Tasks

Authors: *J. J. EGANHOUSE[1], S. A. BEARDSLEY[2];
[2]Dept. of Biomed. Engin., [1]Marquette Univ., Milwaukee, WI

Abstract: Numerous techniques have been proposed for controlling active lower limb prostheses during walking, however, predictive control systems that function across mobility tasks remain underdeveloped. The purpose of this study is to develop a closed loop predictive model that uses current muscle activity to predict future ankle angle and moment over time and across mobility tasks for use in an active transtibial prostheses. Kinematic, kinetic, and electromyography (EMG) data of lower limb movement obtained from six healthy ambulators was used to train a closed-loop nonlinear autoregressive (NARX) model to predict ankle angle and moment in response to changes in EMG during level (over ground) walking, stair ascent and stair descent (LW, SA, SD). Training data was assembled into 10 sets of LW, SA, and SD trials and separate NARX models were trained for each subject using a 10-fold cross-validation to characterize generalized performance across mobility tasks. All NARX models were configured with a 58.3 ms prediction interval, 120 ms sampling window, and 16 hidden units based on prior exploratory testing of the network structure. Batch training was used to ensure that models were trained on entire trials rather than randomly selected time points across trials. NARX model performance was characterized based on the type of feedforward input provided to the network which included: 3D shank velocity, and EMG signals obtained from the tibialis anterior, medial, and lateral gastrocnemius muscles (TA, MG, and LG respectively), and their combinations. Following training, the average root-mean-square errors (RMSE) of the model prediction across tasks varied with the type of input. RMSE for EMG only was 4.92° ± 1.394° and 0.154 ± 0.044 Nm/Kg, for shank velocity only was 2.93° ± 0.69° and 0.121 ± 0.0301 Nm/Kg, and for EMG plus shank velocity was 2.37° ± 0.58° and 0.084 ± 0.026 Nm/Kg . While network prediction of ankle angle and moment based on 3D shank velocity was generally better than EMG-only inputs, networks that combined 3D shank velocity and EMG inputs produced the best overall performance. The closed-loop model performance indicates that prior *estimates* of joint kinematics and kinetics can reliably predict gait when combined with external input(s) that convey user intent. Shank velocity input stabilized recurrent estimates of joint dynamics during cyclic movement, whereas EMG inputs improved prediction for transitions between walking conditions, where feedback of noncyclic user intent was most relevant. The results suggest that a NARX model combining shank velocity and EMG input could provide robust predictive control for use in active transtibial prostheses.

Title: Volitional Modulation of Temporally Precise and Structured Spiking Pattern in Motor Cortex

Authors: *Y. NING[1,2], T. ZHENG[1,2], G. WAN[2], S. ZHANG[1,2];
[1]Dept. of Biomed. Engin. and Instrument Sci., [2]Qiushi Acad. for Advanced Studies, Zhejiang Univ., Hangzhou, China

Abstract: One of the most concerned and debated issues in neuroscience is how neurons communicate and convey information through spikes - firing rates or precise timing. There is accumulating evidence in favor of temporal coding. However, these pieces of evidence come dominantly from the sensory system. Little evidence is found in the motor cortex. Abundant studies have revealed the role of the motor cortex in driving muscles, which are often framed as a low-pass filter. Besides, the noisy nature of spiking time is inferred from the huge success of decoding kinematics by applying the Poisson rate code. These prevalent views underscore the validity and feasibility of coding with precise timing between neurons in the motor cortex. In this study, we designed a novel Brain-machine interface(BMI) paradigm, under which precisely timed spiking activity in the primary motor cortex (M1) was volitionally and robustly generated. We highlighted the feasible neural implementation of precisely timed spiking in the motor cortex that is hard to find and analyze under natural movements. Besides, we found the temporal offsets between the selected neurons were not uniformly distributed in the window of [0 15]ms defined by the BMI decoder. On contrary, neurons fire in smaller temporal offsets with higher probability, which further validates the temporal precision carried out in M1. To further understand how neurons in M1 can exhibit this temporally precise and structured pattern, we assigned pairs of neurons with various distances in between to be the “direct neurons” and then characterized the dynamics of “indirect neurons”. We found that traveling waves propagate through an area larger than the minimal area covering the “direct neurons”. Besides, the component of the propagation vector aligning to the “trigger-target” vector is larger than the component being perpendicular to that. Therefore, the traveling waves may serve to synchronize the neural activity of the recording sites. It was further supported by the finding that rats with longer distances between direct neurons performed worse than those with shorter distances. In addition, pronounced high gamma oscillation(60~90Hz) phase-locking to the discharging of direct neurons was found. High gamma oscillation phase locking has long been considered to arise from local E-I balance. This E-I balance may help to fine-tune the temporal structure by creating the “opportunity window”. In conclusion, our results suggest, in the primary motor cortex, temporal fidelity can be accomplished through the interplay between the global flow of excitation and local E-I balance.

Title: Minimally-invasive restoration of vision using photothermal stimulation of retinal neurons

Authors: *J. NIE[1], K. EOM[2], H. ALGHOSAIN[1], G.-M. GERBAKA[1], C. LANGEVIN[1], A. NEIFERT[1], X. GUO[1], V. COLVIN[1], J. LEE[1];
[1]Brown Univ., Providence, RI; [2]Pusan Natl. Univ., Pusan, Korea, Republic of

Abstract: Age-related macular degeneration is an incurable eye disease leading to blindness due to photoreceptor degeneration. The current clinical retinal prosthetics to restore vision in blindness have too low resolution (worse than 20/200, legal blindness) to improve patients' daily-life functionality, and require complicated and often risky implantation surgery. Here, our study aims to prove a concept in blind model mice to restore higher resolution vision with a minimally-invasive approach with photothermal stimulation of retinal neurons. This novel approach has a potential of remotely activating retinal neurons with single-cell resolution, without either genetic manipulation or stem cell treatment. We intravitreally delivered Thy-1 antibody-coated gold nanorods (Thy-1-AuNRs) specifically targeting retinal ganglion cells (RGCs) and then stimulated RGCs with near-infrared (NIR) light, based on the well-studied phenomena of surface plasmon resonance and its photothermal effect. To validate the efficacy of this approach in blind Rho^{P23H} mice, we used single-cell fluorescent Ca^{2+} imaging *ex vivo* and electrophysiology *in vivo*. When we illuminated an NIR laser beam (780-nm wavelength, 15-μm beam diameter, 10-ms pulse, 33 Hz, 0.9-s duration) on individual cells of Thy-1-AuNR-delivered retinal explants, RGCs exhibited significant Ca^{2+} responses (0.16±0.04 % dF/F, n=163) while sham-delivered mice did not. In Thy-1-AuNRs-injected mice, visual cortical neurons were activated by NIR single-spot laser of retinal neurons (780-nm, single 100-ms pulse, 50 trials averaged), producing evoked potentials of 44.4±8.8 μV (n=9), but sham-delivered mice did not respond to NIR light. The amplitude of the NIR-evoked potentials was similar to visually evoked potentials in wild-type mice (49.4±14.2 μV, n=9; p=0.12). We proved the concept of activating retinal neurons with the minimally-invasive photothermal approach both ex vivo and in vivo. The result opens a possibility of restoring vision with an ideal pixel pitch (30 μm) while covering the macular visual field (10°) at an effective refresh rate (10 frames per second).

Abstract: Speech is the most effortless, personal, and efficient mode of communication for almost every person. For individuals with severe paralysis who have lost the ability to speak, brain-computer interface (BCI) technology designed to restore communication has the potential to drastically improve their autonomy and quality of life. Remarkable progress has been made with existing communication BCI approaches, enabling users to type out intended messages letter-by-letter. A complimentary approach to restore communication to paralyzed individuals may be to decode speech directly from their brain activity as they attempt to speak. As part of a clinical trial, we implanted a custom 128-channel, high-density electrocorticography (ECoG) array over the surface of the speech motor cortex of a person with anarthria (loss of the ability to articulate speech) and spastic quadriparesis caused by brainstem stroke. We then collected brain activity as the participant attempted to say or silently mime a variety of utterances. Using deep artificial neural networks and natural-language models, we show that the participant's attempts to speak can be detected from brain activity and decoded into text in real time. We also characterize spatial, temporal, and spectral features of the cortical activity during the participant's attempted speech. Using brain activity collected over the course of more than 80 weeks, we show that chronic ECoG activity and discriminative spatial maps were relatively

stable throughout the study, facilitating consistent decoder performance without daily or weekly model recalibration. Our findings demonstrate that functional cortical representations of speech were present in a person after over 15 years of anarthria, enabling real-time text decoding directly from neural activity as the person attempted to speak using a clinically viable long-term neural interface.

Title: Simulating the effect of asynchronous phosphene stimulation on artificial vision

Authors: N. MEITAL-KFIR, *J. S. PEZARIS;
Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: Electrical micro-stimulation techniques used in visual prostheses are designed to restore visual functions following acquired damage or disease of the eye. Induced focal percepts, known as phosphenes, are achieved by applying localized electrical pulses to the visual pathway in a location that bypasses the impaired site. A given electrode elicits a single phosphene with a fixed receptive field. A complex artificial percept is achieved by coordinated electrical stimulation of multiple electrodes which translates the visual scene into an artificial percept made of a collection of individual phosphenes.Stimulation applied across a set of electrodes can take place simultaneously or may involve some form of temporal spread, resulting in asynchronous electrical pulses. The spatiotemporal pattern of activation across electrodes will determine the quality of the artificial percepts. Here, we describe an experiment to explore the temporal relationships between individual phosphenes and the impact of the electrical pattern on object binding and perception. We hypothesize that synchronous electrical stimulation will facilitate object perception as compared to asynchronous. A model system with sighted subjects, using virtual reality technologies, will be used to simulate how sight would appear to blind individuals with a visual prosthesis. We will assess the effect of temporal desynchronization of phosphene presentation on visual acuity in a simple sentence reading task based on the MNREAD test. Reading speed and accuracy will be tested at varying font sizes and under varying levels of phosphene temporal noise. The results of this study will be fundamental for

developing an efficient temporal pattern of stimulation and for the creation of functional prosthetic vision.

Title: Multi-electrode stimulation evokes consistent spatial pattern of phosphenes and improves phosphene mapping in blind subjects

Authors: *D. OSWALT[1], W. H. BOSKING[1], P. SUN[2], S. NIKETEGHAD[3], M. ARMENTA SALAS[4], U. K. PATEL[5], J. D. DORN[6], N. POURATIAN[7], M. BEAUCHAMP[1], D. YOSHOR[1]; [1]Neurosurg., Univ. of Pennsylvania, Philadelphia, PA; [2]Baylor Col. of Med., Houston, TX; [3]Bioengineering, Univ. of California Los Angeles, Panorama City, CA; [4]Neurosurg., UCLA, Los Angeles, CA; [5]Second Sight Med. Products, Inc., Sylmar, CA; [6]Second Sight Med. Prod, Sylmar, CA; [7]Neurosurg., Univ. of Texas, Southwestern, Dallas, TX

Abstract: Visual prostheses are envisioned to operate by combining phosphenes produced by stimulation of individual electrodes to produce a percept of an image. This strategy requires efficient and reliable methods for mapping individual phosphenes. We examined different mapping techniques in two blind subjects (BS1 and BS2) who are participants in the clinical trial for the Orion visual cortical prosthesis. Two fixation strategies were tested. For unimanual fixation, subjects placed their left index finger on a tactile fixation point. For bimanual fixation, subjects overlaid their right index finger atop their left index finger on the tactile fixation point. Two mapping strategies were tested. For absolute mapping, a single electrode was stimulated on each trial while for relative mapping, dynamic sequences of stimulation were delivered to three to five electrodes on each trial. Precision was quantified with 2DRMS. Bimanual fixation resulted in improved precision (lower 2DRMS) in phosphene localization compared to unimanual fixation (BS1: 4.0±2.6^o vs. 19±4.7^o, $p < 0.001$; BS2 4.1±2.0^o vs. 12±2.7^o, $p < 0.001$). Multi-point relative mapping had similar baseline precision as absolute mapping (BS1: 4.7±2.6^o vs. 3.9±2.0^o; BS2: 4.1±2.0^o vs. 3.2±1.1^o) but improved significantly when trial-to-trial variations were removed, revealing a consistently perceived and reported visual pattern across trials and sessions. The types of trial-to-trial variation observed were translational, rotational, and scaling variations, with translational errors accounting for a majority of the incongruity. Multi-point

sequences can capture basic retinotopic organization of visual cortex but tend to regularize distance between perceived phosphenes. Fitting a logarithmic map to these data can address this issue and generate a final map estimate. Relative mapping methods, combined with bimanual fixation resulted in the most precise and consistent estimates of phosphene location.

Title: Modeling activation of early visual cortex and visual percepts produced by multi-electrode stimulation

Authors: *W. BOSKING, D. OSWALT, D. YOSHOR;
Neurosurg., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Electrical stimulation of single electrodes implanted in visual cortex produces perception of a small flash of light known as a phosphene. Visual cortical prostheses (VCPs) are envisioned to operate by stimulating many electrodes at once to evoke perception of an image. However, in practice, results of multi-electrode stimulation have been difficult to predict. We developed a pipeline to predict the cortical activation and phosphenes that result from simultaneous multi-electrode stimulation. Our simulation framework builds on our previous model for predicting phosphene size based on current amplitude and the location of the electrode in the map of visual space (Bosking et. al., 2017). We expand on that model by simulating the resulting cortical activation produced by each electrode within a flat-map of the V1-V3 complex (Schira et. al., 2010). For each electrode, we assume a 2D-Gaussian profile of cortical activation. The center of each activation profile in visual space is set by the receptive field location for each electrode. The overall cortical activation for simultaneous stimulation of a group of electrodes is then calculated by linear addition of the activation profiles resulting from each electrode.This framework can be used to explore and predict the visual percepts evoked by VCPs with different implementations. For example, an array with a specific number of electrodes, and inter-electrode spacing, can be placed at a desired location over a portion of V1-V3. An input image can then be

fed to the model, simulating input from a camera to a VCP based on an array of this geometry. The stimulation current used for each electrode is set based on the gray scale value at each point in the image. Output from the model then provides a visualization of how the activation of each electrode ultimately leads to a full pattern of activity distributed over early visual areas, and to the visual percept predicted in response to the input image. Our model can be used to demonstrate the importance of balancing electrode spacing and stimulation currents for optimum performance of future VCPs. The equations used to predict cortical activation for each electrode, or the rules governing summation across electrodes, are modifiable to allow for flexibility in predicting visual percepts.

Title: Stability of phosphene thresholds and locations for a long-term cortical visual prosthesis - 3-year measurements with the Orion system

Authors: M. ARMENTA SALAS[1], U. K. PATEL[2], S. NIKETEGHAD[1], J. S. BELL[1], A. A. BARI[1], R. J. GREENBERG[3], D. YOSHOR[4], J. D. DORN[2], N. POURATIAN[5];
[1]Neurosurg., Univ. of California Los Angeles, Los Angeles, CA; [2]Second Sight Med. Products, Inc., Sylmar, CA; [3]Alfred Mann Fndn., Valencia, CA; [4]Neurosurg., Penn Med., Philadelphia, PA; [5]Neurolog. Surgery, UT Southwestern, Dallas, TX

Abstract: For the development of long-term visual prosthesis, it will be important to determine the safety and functionality of the system. After the pioneering work of Dobelle et al (2000) and Schmidt et al (1996), recent human clinical trials in and outside the U.S have started re-addressing these key questions. However, it will also be crucial to determine whether the systems can reliably generate visual percepts (i.e. phosphenes) after years of implantation. The Orion Early Feasibility Study sponsored by Second Sight (NCT03344848) has participants implanted for over three years, which allows us to start addressing some of these long-term stability questions. To test the system's ability to induce phosphenes, we measured thresholds at defined clinical time points (1, 6, 12 and 24/36 months) in the enabled electrodes, and semi-periodically for a subset of electrodes in four of the six subjects. These four subjects were recruited, implanted, and tested at the UCLA site. We used a modified binary-search algorithm to estimate thresholds, with the same stimulation parameters across subjects. We also captured the

phosphene locations at different time points, to evaluate whether the spatial map or the size of the phosphenes shifted over time. We were able to determine thresholds, at either 20 or 120 Hz, in most of the electrodes across all subjects (99.8%). There was a significant increase in thresholds from the first measurements to the last ones ($p < 0.01$), but phosphenes were still elicited within the system's stimulation ranges. The phosphene locations were mostly stable, although there was inter-session variability ($\mu_{shift} = 8°$, C.I. 0.6°). However, the gross locations within the upper and lower visual field were stable across most subjects. Three subjects had a significant increase in phosphene size from the first mapping measurements to the last one ($p < 0.001$). This increase correlated with the increase in thresholds ($\rho = 0.64$, $p < 0.001$), like that reported in sighted subjects (Bosking et al, 2017). These results are encouraging, since they highlight the ability to elicit phosphenes up to 3 years after device implantation, and well within safe stimulation parameters and the system's stimulation capabilities. Furthermore, the phosphenes are most likely perceived in the same location across the visual field, which means that once a map is determined from an initial fitting it could be sufficient for long-term use. Future experiments should address how video-mode functionality varies over time, and which behavioral or attentional aspects might affect this performance.

Abstract: In the last decades, the fascinating opportunity to communicate artificially with the brain using peripheral nerve stimulation (PNS) have been extensively explored in people with sensory-motor deficits. The use of innovative neural interfaces, enabling the interaction of robotics devices (e.g., limb prostheses) with the human somatosensory system, allows to restore the complex sense of touch and proprioception in people suffering from limb loss. These artificial sensory feedback was then successfully implemented in bionic prostheses and exploited by the users to accomplish different sensorimotor tasks with higher performance compared to conventional no-sensorized prostheses. In particular, multiple TIMEs (Transversal Intrafascicular Multichannel Electrode) have been implanted in the sciatic nerve of transfemoral amputees and utilized to restore sensory feedback in neuro-robotic leg prostheses. Although the provided benefits could have a tremendous potential impact on the patients' quality of life, they are strongly dependent by the electrodes and sensations stability mainly connected to the bio-integration of this neurotechnology over time. To this aim, here we unveil the characteristics of the artificial sensations restored using intraneural stimulation and we report the mechanisms of how they evolve during 3-month implants in human peripheral nerves. To do so, we assessed the electrically-evoked sensations of 3 transfemoral amputees implanted with multiple TIME in their tibial nerve. Firstly, we characterized in detail the perceptual thresholds, the sensation locations and qualities evoked by the neural stimulation at the brain level. Then, we evaluated the bio-integration of the device considering the time evolution of the evoked-percepts and their complex relationships, together with the tissue reactions and the electrode failures. The results of the neural stimulation collected during the months of implants together with the human nerve histologies and the electrode post-explant analyses allowed us to model the phenomenon using advanced computer simulations (Hybrid modelling). We considered both morphological and biophysical aspects of an human-machine connection exploiting neural interfaces and neuromodulation. Our results provide a comprehensive assessment of polyimide-based intra-neural electrode functionality, stability, and bio-integration and open a realistic pathway to refine and disseminate such implants in long-term clinical applications in humans. These neuroscientific evidences allow to optimize the neuroprosthetic device for the next applications.

Abstract: Restitution of the sense of proprioception to amputees is recognized as one of major challenges in the field of neuroprosthetics. Proprioception is essential in maintaining balance and performing motor tasks without visual aid: its absence limits the performance of the prosthetic users, their confidence, and ultimately increases the cognitive load required for the movement. Previous studies were successful in restoring tactile sensations through electrical nerve stimulation, but unfortunately reliable restoration of proprioception has never been achieved. We hereby propose a framework for the electrical stimulation of the peripheral nervous system leveraging experimentally validated models to elicit a physiological-like activity of muscle spindle afferents for different muscles simultaneously. In particular, a musculoskeletal model coupled with a Ia Prochazka muscle spindle transducer model modified to fit experimental human data is used to estimate the expected natural activity of muscle spindle afferents. The neurostimulation policy to replicate it is optimized by a computational model which estimates the effect of electrical nerve stimulation on each axon of the target nerve. A degree of complexity of anatomical reconstruction is higher of previously published models, including a complete 3D model of the nerves of interest of subjects with transfemoral amputation. The proposed stimulation system is evaluated against traditional methods for proprioception restoration such as linear charge modulation for knee angle encoding. The linear charge stimulation induces a response of muscle spindle afferents which is considerably different from the natural activity. The proposed solution is able to replicate the recruitment rate and frequency of the estimated physiological activity in terms of population average, with the limitation of synchronous activation as opposed to natural asynchronous point processes. We ultimately propose how we envision the system being implemented in the next generation of lower-limb neuroprostheses and show how it can be applied with minimal effort in other scenarios as for upper-limb prostheses.

Title: The effects of chronic cannabidiol (CBD) use in adolescent female mice on the prevalence of anxiety symptoms

Authors: *C. RECHSTEINER, E. MARTIN, T. LEAK, A. LACROSSE;
Northern Michigan Univ. Departments of Biol. and Psychology, Marquette, MI

Abstract: Cannabidiol (CBD) is a non-psychoactive compound derived from the cannabis plant, *Cannabis sativa.* Previous research has shown CBD's wide ranging therapeutic effects from antidepressant, antipsychotic, and anti-anxiety studies to preventing social-recognition deficit in an Alzheimer's disease model. However, there remains limited literature examining the effects of CBD treatment on anxiety levels in adolescent females. This is an important oversight as females have higher rates of diagnosed anxiety disorders compared to males. Furthermore, the effects from discontinuation of chronic CBD use has yet to be studied. Therefore, this *in vivo* study examines the effects of chronic oral consumption of CBD oil on anxiety symptoms with an adolescent, female mouse model. The current study also measures the effects of cessation from chronic CBD treatment on anxiety levels. We hypothesized that CBD use will decrease anxiety in adolescent users, and that the cessation of CBD use will potentiate levels of anxiety. In order to test our hypothesis, mice were divided into two groups, the CBD treatment group (n = 7) and a control group (n = 8). Based on the treatment group, mice received cheese containing 5 mg/kg CBD dissolved in olive oil or cheese containing olive oil only for 14 days to represent chronic use. Following treatment, all mice received cheese containing only olive oil for 10 days to represent discontinuation from treatment. The behavioral assays used in this study are the open field test and the elevated plus maze in order to measure anxiety symptoms in the mice at baseline (prior to beginning any treatment), after 14 days of chronic treatment, and again after CBD treatment was discontinued. All behavior data was digitally recorded and analyzed using an interrater reliability score of .80 or higher. Results indicate a greater decrease in anxiety symptoms in CBD treated mice compared to the control group after 14 days of treatment and after discontinuation. This suggests that CBD may have a lasting anxiolytic effect on adolescent, female mice. Future studies will investigate the significance of underlying neuronal changes due to CBD treatment in key brain regions relating to anxiety and cognitive ability in adolescent male and female mice.

Title: Evaluating the effects of glyphosate consumption on grooming behavior in rats

Authors: M. GONZÁLEZ-PEDRAZA, A. FIGUEROA-PÉREZ, M. CÁCERES-CHACÓN, H. HADDOCK-MARTÍNEZ, O. MARTÍNEZ-GUZMÁN, M. RIVERA-LÓPEZ, ***D. SIERRA-MERCADO**;
Anat. & Neurobio., Univ. of Puerto Rico Sch. of Med., San Juan, PR

Abstract: Glyphosate is the active ingredient in several commercial herbicides. Though initially considered safe for mammals, recent reports suggest that glyphosate administration at unusually high doses increases anxiety-like behaviors. However, few studies have evaluated the neurobehavioral effect of glyphosate exposure at the low concentration levels that the Environmental Protection Agency considers safe for human consumption. Grooming behavior, one of the most frequently performed behaviors in rodents, has been proposed as a measurement for states of generalized anxiety. Thus, we hypothesized that prolonged exposure to levels of glyphosate thought to be safe for humans will increase general anxiety-like behavior observed as abnormal grooming behavior in rats. To test this hypothesis, male Sprague Dawley Rats (n=13) had access ad libitum to drinking water containing glyphosate at a dose of glyphosate considered safe (2.0mg/kg) for 16 weeks, whereas control rats received filtered drinking water. After glyphosate exposure, rats were recorded in their home cage for 5 minutes. Videos were scored for total time spent grooming, as well as distance traveled and time where the rat was immobile. Preliminary data shows that glyphosate exposure does not affect the total number of grooming bouts (glyphosate: 0.67, control: 3.50; p=0.1268). Interestingly, however, glyphosate exposure decreased total distance traveled (glyphosate: 9.73, control: 15.79; p=0.0318) and increased the total time immobile (glyphosate: 429.30, control: 329.10; p=0.0364. Future directions include assessing the brain tissue for changes in biomarkers of neuronal activity in the bed nucleus of the stria terminalis, a brain region implicated in anxiety-like behaviors. The results of this study will allow us to elucidate the potential neurotoxic effects that glyphosate consumption may have on the brain, and how these effects could manifest as behaviors in rats.

Title: Role of kappa opioid system in stress-induced anxiety-like behaviors in females

Authors: *A. KHURANA, C. BOUARAB, A. POLTER;
The George Washington Univ., Washington, DC

Abstract: Women are twice as likely as men to be diagnosed with a mood or anxiety disorder. Given that stress plays a significant role in the development of these disorders, sex differences in the response to stress are likely to be a critical factor in the enhanced vulnerability of females to these pathologies. Across both human populations and animal models, males and females exhibit divergent responses to stress at all levels, from molecular signatures to behavioral adaptations. Sub-chronic variable stress (SCVS) is a model of depression and anxiety in which female mice develop anhedonia and anxiety-like behaviors, but males do not.
Dysregulation of the mesolimbic reward circuitry is implicated in the pathophysiology of stress-related illnesses such as depression and anxiety. Dopaminergic (DA) neurons in the ventral tegmental area (VTA) are a major target of stress. Previous work has shown that acute stress leads to a days-long activation of kappa opioid receptors (KORs) in the VTA. We hypothesize that similar changes may underlie the female-specific behavioral deficits induced by SCVS. If this hypothesis is correct, pre-stress treatment with NorBNI (10mg/kg, ip) would prevent the stress-induced behavioral deficits observed in females. To test this, we used both male and female C57Bl/6J mice at 8-weeks old in a SCVS protocol (n=9 per group). Using dark-light box to assess anxiety-like behavior, we first confirmed that SCVS causes an increased latency to enter the light compartment in female mice only. Interestingly, this deficit is prevented by a pre-treatment with NorBNI. Next, we will inject the NorBNI post-stress to see if it can reverse this anxiety-like behavior in females. Together, this data indicates the important role of the kappa opioid receptor in the development of maladaptive behavioral responses in female mice.

Title: Sex-specific effects of ventral hippocampal Egr1 expression on neuronal transcriptional programs and behavior

Authors: *D. ROCKS[1], I. JARIC[1], E. PURISIC[1], E. GALLO[1], J. M. GREALLY[2], M. SUZUKI[2], M. KUNDAKOVIC[1];
[1]Fordham Univ., Bronx, NY; [2]Ctr. for Epigenomic, Dept. of Genet., Albert Einstein Col. of Med., Bronx, NY

Abstract: Women have a two-fold increased risk for developing anxiety and depression disorders compared to men. Due to exclusion of female subjects from animal studies of the brain and behavior, the biological basis for this phenomenon is unknown. Clinical and epidemiological evidence indicate fluctuating ovarian hormones contribute significantly to this female-biased risk. Previously, we demonstrated that anxiety-like behavior changes in female mice over their estrous cycles. In our examination of the molecular basis for this behavioral phenotype, we demonstrated, for the first time, estrous-cycle dependent regulation of neuronal chromatin accessibility and gene expression in the ventral hippocampus, a brain region critical to emotion regulation and anxiety-like behavior in rodents. Analyses of these data indicated that Egr1, an estrogen-responsive immediate early gene product, is a putative regulator of these hormone-dependent changes in neuronal chromatin accessibility and gene expression within females. Here we aim to determine whether ventral hippocampal Egr1 expression mediates estrous-cycle dependent changes in chromatin accessibility, gene expression, and behavior. By measuring the behavior of female mice across the four phases of the estrous cycle, we found that females in the high-estrogenic (proestrus) phase have lower anxiety indices compared to females in the other, low-estrogenic phases. Serum estradiol levels positively correlate with a low-anxiety behavioral measure, further supporting an anxiety-reducing effect of estrogen. We also observed cycling expression of Egr1 and its putative target gene, Darpp-32, in the ventral hippocampus of females over the estrous cycle. In order to mechanistically link Egr1 expression to behavior, we delivered an adeno-associated virus carrying Egr1 into the ventral hippocampus of ovariectomized (OVX)-female and intact-male mice and performed anxiety- and depression-related behavioral tests. Without viral manipulations, we found that OVX females behave similarly to low-estrogenic (diestrus) females and exhibit higher anxiety indices compared to high-estrogenic (proestrus) females. Remarkably, overexpression of Egr1 in the ventral hippocampus of these OVX females reduces anxiety- and depression-related behavior and reproduces a proestrus-like behavioral phenotype. Our findings were sex-specific as we observed no behavioral changes in male animals. These results link Egr1 expression to estrous cycle-dependent gene regulation and behavioral plasticity and establish a foundation for the development of sex-specific treatments for anxiety and depression.

Title: Viral infection of hypothalamic circuits: Implications for post-viral syndromes

Authors: *C. NIEMEYER[1], J. HASSELL, Jr[1], L. MERLE[1], B. BAXTER-BOLT[1], A. BUBAK[1], W. COLLOTY[1], D. RESTREPO[2], M. NAGEL[1];
[1]Univ. of Colorado Denver Sch. of Med., Aurora, CO; [2]Cell & Dev. Biology, Neurosci. Program, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Renewed interest in the biological basis of post-viral syndromes (PVSs) has emerged during the COVID-19 pandemic because many individuals complain of persistent symptoms, including fatigue, anxiety, depression, and sleep disorders, which significantly affect quality of life. PVSs can also occur with other viruses, and interestingly, many of these symptoms can arise from hypothalamic dysfunction, leading to neuroendocrine, autonomic, and neurobehavioral changes. Understanding how viruses disrupt hypothalamic circuits to produce persistent clinical symptoms can potentially guide new therapies to prevent and treat specific features of PVSs. HSV-1 encephalitis (HSE), the most common cause of viral encephalitis, has been associated with PVSs, and can affect the hypothalamus. In humans with HSE, hypothalamic inflammation may be present; in HSV-1-infected rodents, viral antigen in the hypothalamus is seen and disruption of the hypothalamic-pituitary-adrenal axis is observed. However, detailed studies on how HSV-1 affects the hypothalamus, which can serve as a basis for how other viruses affect this structure and associated functions, are lacking. Here we investigate the pattern of viral antigen and the pattern of immune response in within the rostral caudal extent of the brain following intranasal inoculation of HSV-1 (10^5-10^6, McKrae strain) in C57bl/6 mice. We found the presence of HSV-1 DNA in the olfactory epithelium, olfactory bulb, and trigeminal ganglia, identifying possible routes of entry to the brain. We found striking specificity for subnuclei in the hypothalamus (bilateral dorsomedial, lateral hypothalamus, and paraventricular nuclei). Furthermore, we find extensive HSV-1 antigen in brainstem regions that project to hypothalamic subnuclei, including nucleus of the solitary track, and area postrema, suggestive of possible routes of infection to hypothalamic subregions. We also found extensive activation of iba-1 positive microglia in associated HSV-1 infected regions. Our anatomical results raise questions of whether functions associated with these infected hypothalamic regions are disrupted (including mood, appetite, sleep, and thermoregulation) and whether direct virus infection and/or

neuroinflammation are major contributors to pathology. Understanding mechanisms by which viruses affect hypothalamic circuits that may contribute to specific features of PVSs will provide the rationale for development of prognostic, preventive and treatment strategies.

Title: Glyphosate increases anxiety-like but not fear-like behaviors in rats

Authors: *M. CACERES-CHACON, A. FIGUEROA-PEREZ, H. HADDOCK-MARTINEZ, S. RODRIGUEZ-ROSADO, G. HERNANDEZ-BUSOT, M. RIVERA-LÓPEZ, O. MARTÍNEZ-GUZMAN, D. SIERRA-MERCADO;
Anat. and Neurobio., Univ. of Puerto Rico Sch. of Med., San Juan, PR

Abstract: Glyphosate-based herbicides (GBH) are the most commonly used herbicides worldwide. Glyphosate was initially considered safe for mammals because it acts by inhibiting a metabolic route not present in mammals. However, recent studies in rodents have shown that exposure to GBH at relatively high doses causes increased anxiety-like behavior. The Environmental Protection Agency has established a chronic reference dose for glyphosate of 2.0mg/kg daily, based mainly on toxicological studies that did not include behavioral assessments. Therefore, we aimed to evaluate the effect of prolonged oral consumption of GBH-contaminated drinking water on anxiety-like behavior. Furthermore, given the similarity in the neural circuit involved in anxiety-like behaviors and fear, we aimed to evaluate the effect of GBH on fear-like behaviors. To achieve this, rats were given a target dose of 2.0mg/kg daily of GBH in their drinking water. Control rats were treated in the same manner but received filtered drinking water. Of note, there were no differences in neither the amounts of water consumption, nor body weight between the groups ($p>0.05$). We assessed for anxiety-like behavior after 4

weeks of exposure using the open field test. No difference was observed in the amount of time spent in the center (control: 49.01, GBH: 47.68; p = 0.9051), or the number of entries into the center (GBH: 17.62, control: 17.33; p=0.9463). After 10 week of exposure, anxiety-like behavior was reassessed in the elevated plus maze where GBH caused a decrease in the amount of time spent in the open arms (GBH: 45.36, control: 103.7; p=0.0086), as well as a decrease in the number of entries into the open arms (GBH: 4.39, control: 9.50; GBH: 4.39; p=0.0214). Furthermore, we reassessed for anxiety-like behaviors after 14 weeks using the light/dark box. Interestingly, GBH reduced the percent of time spent in the light (control: 13.03, GBH: 3.32; 0.0173), suggesting that glyphosate may have a time dependent effect on anxiety-like behavior at low doses. Lastly, after 16 weeks of exposure, animals underwent delayed auditory fear conditioning and extinction. Contrary to our hypothesis, no differences in fear expression were observed during conditioning or extinction. Future directions include assessing other emotional memories and performing immunohistochemistry on brain regions involved in anxiety-like behaviors.

Title: Mice with chronic, but not acute gut inflammation display generalized fear upon resolution of disease.

Authors: *C. E. MATISZ, M. PATEL, N. HONG, R. J. MCDONALD, A. J. GRUBER; Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Chronic inflammation in the body is a risk factor for mood disorders. This is particularly evident in inflammatory bowel diseases (IBD), which are highly comorbid with anxiety and other disorders, even during periods of IBD remission. A frequent feature of anxiety disorder is heightened threat assessment in benign contexts. Here, we test how the duration of gut inflammation evoked by dextran sodium sulfate (DSS) in mice affects such generalization using a fear to context paradigm. We found that neither an acute (5 days) or chronic (3x5 days) course of DSS-induced IBD affected learning or discrimination of safe/threating contexts at peak of disease. After remission of IBD symptoms one week later, however, the chronically-treated

animals exhibited equal amounts of freezing in both contexts. Their freezing behaviour was equivalent to other groups in the shock-associated context, but was greater in the benign context than other groups. Interestingly, all groups showed a preference for the benign context over the shock context. These data suggest that the repeated DSS treatment induced a generalization of fear to the benign context, even though learning & preference were intact.

Title: A streamlined approach to routine staging of the estrous cycle in behavioral studies

Authors: *G. M. RAIMONDI, A. K. ENG, M. A. BRITTING, M. P. KENNY, L. E. OSTROFF;
Univ. of Connecticut, Storrs, CT

Abstract: The amygdala is a central mediator of emotional responses, and the lateral amygdala (LA) circuit that underlies aversive auditory Pavlovian conditioning is among the most well-studied brain systems. However, decades of literature on its structure and function have focused largely on male subjects. Studies of sex differences have produced inconsistent results, especially when the female reproductive (estrous) cycle is taken into account. Estrous effects on fear- and anxiety-like behaviors have been reported, which makes the cycle a potential source of variability, but because tracking methods are subjective and not standardized, conflicting results are common between studies. We systematically compared several methods for monitoring the estrous cycle in rats, with the goal of finding a simple, reliable means of accounting for it in behavioral experiments such as Pavlovian conditioning. The 4-day cycle is traditionally divided into four stages of varying length that are defined by the appearance of vaginal epithelial cells. This method proved capricious; variability was high and some animals did not have regular cycles. Alternative methods such as vaginal resistance were unreliable. Rats are nocturnal, so the most variable phases of the cycle, which occur during the day, may not be relevant to behavior. Comparison across the light cycle revealed that samples taken in the dark cycle were extremely reliable, with nearly all rats having consistent 4-day cycles. This greatly simplified the tracking procedure, as only the most obvious day, the day of ovulation, needs to be detected. In addition, the common practice of excluding animals with irregular cycles was unnecessary. Using this

tracking method, we compared Pavlovian conditioning in males (n=24) and females (n=60) across the cycle, with all experiments performed in the dark. Relative to males and females on other days, females on the third day of the cycle showed less freezing behavior during training and testing. Quantification of c-Fos labeling after testing revealed that in males and females with equal freezing, females had more c-Fos cells in the intercalated cells of the amygdala but not in the LA. Although tracking the estrous cycle may not be necessary, it allows the cycle to be eliminated as a confound when sex differences are found, as in our c-Fos results. Overall, our approach is easier and less subjective than older methods and may allow improved reproducibility without undue effort in behavioral studies where the estrous cycle is of concern.

Title: Neural representations for distinct stress coping strategies in the rat

Authors: *G. RICHTER-LEVIN[1], C. MA[2], L. JING[3], L. XU[2];
[1]Univ. Haifa, Haifa, Israel; [2]Kunming Inst. of Zoology, Kunming, China; [3]Univ. of Haifa, Haifa, Israel

Abstract: Coping with stress is characterized by high individual variability, which is often attributed to either genetic background differences, sustained environmental conditions, or a combination of both. However, the neural mechanisms underlying coping style variability are yet poorly understood. Here we examined the impact of a single extended emotional challenge on coping style variability, and the associated involvement of the hippocampus, medial prefrontal cortex (mPFC) and periaqueductal gray (PAG). Sprague-Dawley rats (n = 170) were trained in an extended two-way shuttle avoidance (eTWSA) task for 7 days, and daily avoidance rates were measured. Forced swim test, elevated plus maze or Morris water maze were tested before or after eTWSA exposure. Excitotoxic lesion of the hippocampal dentate gyrus (DG) was performed by Ibotenic infusion. Transient pharmacological blocking of DG, mPFC or PAG was performed by

muscimol or CNQX+TTX infusion. Exposing rats to eTWSA was found to lead to naturally-developing dichotomous, not continuous, coping styles, we termed ‘Active’ or ‘Passive’. Prior emotional responses did not predict the developing coping style. Active coping was associated with beneficial outcomes including antidepressant effects and improved spatial learning. Passive coping led to impaired spatial retrieval. Active coping was abolished by lesioning or pharmacological blocking of the DG. Passive coping was prevented by blocking mPFC or PAG. A single exposure to a significant emotional challenge can lead, in otherwise healthy individuals, to dichotomous development of an active or passive coping style, with distinctive neural correlates, relating to emotional vulnerability or resilience.

Title: A signaled locomotor avoidance action is fully represented in the neural activity of the midbrain tegmentum

Authors: S. HORMIGO, B. SHANMUGASUNDARAM, J. ZHOU, ***M. CASTRO-ALAMANCOS**;
UConn Hlth. Sch. of Med., Farmington, CT

Abstract: Animals, including humans, readily learn to avoid harmful and threatening situations by moving in response to cues that predict the threat (e.g., fire alarm, traffic light). During a negatively reinforced sensory-guided locomotor action, known as signaled active avoidance, animals learn to avoid a harmful unconditioned stimulus (US) by moving away when signaled by a harmless conditioned stimulus (CS) that predicts the threat. CaMKII-expressing neurons in the pedunculopontine tegmentum area (PPT) of the midbrain locomotor region have been shown to play a critical role in the expression of this learned behavior, but the activity of these neurons during learned behavior is unknown. Using calcium imaging fiber photometry in freely behaving mice, we show that PPT neurons sharply activate during presentation of the auditory CS that predicts the threat - before onset of avoidance movement. PPT neurons activate further during the succeeding CS-driven avoidance movement, or during the faster US-driven escape movement. PPT neuron activation was weak during slow spontaneous movements but correlated sharply with movement speed and, therefore, with the urgency of the behavior. Moreover, using optogenetics, we found that these neurons must discharge during the signaled avoidance interval

for naive mice to effectively learn the active avoidance behavior. As an essential hub for signaled active avoidance, neurons in the midbrain tegmentum process the conditioned cue that predicts the threat and discharge sharply relative to the speed or apparent urgency of the avoidance (learned) and escape (innate) responses.

Title: Assessing Combinatorial Effects of HIV Infection and Former Cocaine Dependence on Cognitive Control Processes: A Functional Neuroimaging Study of Response Inhibition

Authors: *K.-M. WAKIM-TAKAKI[1], E. G. FREEDMAN[1], M. TIVARUS[2], A. HEINECKE[3], J. J. FOXE[1];
[1]Neurosci., [2]Imaging Sci., Univ. of Rochester, Rochester, NY; [3]Neurosci., Maastricht, Maastricht, Netherlands

Abstract: Individuals with a diagnosis of co-morbid HIV infection and cocaine use disorder are at a higher risk of poor health outcomes. Active cocaine users, both with and without HIV infection, show clear deficits in response inhibition and other measures of executive function instrumental in maintaining drug abstinence --a factor which may complicate treatment. Neuroimaging and behavioral evidence indicate normalization of executive control processes in former cocaine users as a function of the duration of drug abstinence, but it is unknown to what extent a co-morbid diagnosis of HIV affects this process. To this end, we investigate the combinatorial effects of HIV and cocaine dependence on the neural substrates of cognitive control in cocaine-abstinent individuals with a history of cocaine dependence. Blood-oxygen level dependent signal changes were measured as 86 participants performed a Go/NoGo response inhibition task while undergoing functional magnetic resonance imaging (fMRI). Four groups of participants were selected based on HIV and cocaine-dependence status. Participants affected by both conditions demonstrated the lowest response accuracy of all participant groups. In a region of interest analysis, this reduced task performance was coupled with left putamen and midline-cingulate hyperactivation during response inhibition relative to participants with only one

condition. Results of a whole-brain analysis indicate response inhibition-related hyperactivation in the bilateral supplementary motor area, right hippocampus, bilateral superior temporal gyrus, right sensory association area, and right visual-motor area. These results indicate complex and interactive alterations in neural activation during response inhibition and highlight the importance of examining the neurocognitive effects of co-morbid conditions.

Title: Simultaneous, real-time, pharmacokinetic and pharmacodynamic (behavioral) measurements of psychoactive drugs in the brains of awake, ambulatory rats

Authors: *J. GERSON[1], K. HONEYWELL[2], N. EMMONS[3], J. GIBSON[3], K. PLAXCO[3], T. E. KIPPIN[3];
[1]Psychological and Brain Sci., [2]UC Santa Barbara, Santa Barbara, CA; [3]Dept Psycholol gical and Brain Sci., Univ. California, Santa Barbara, Santa Barbara, CA

Abstract: Psychoactive drugs exert their behavioral effects via concentration-dependent actions upon neural circuits. However, to date, the temporal resolution with which we can measure these compounds is *orders of magnitude* too slow to capture the concentrations associated with altered physiological processes. Thus motivated, our group has recently developed a new technology, electrochemical aptamer-based sensors (E-AB sensors) that can detect physiologically relevant concentrations of specific drugs *in-situ,* in awake, freely behaving animals. Procaine and cocaine are two psychoactive compounds that, although similar in their chemical structure, elicit opposing behavioral effects when administered. By adapting a previously presented aptamer we have improved the sensitivity of our E-AB sensor to both drugs by an order of magnitude, as well as enhanced drift characteristics observed in vivo. Here, we tested this new technology on rats that have been administered procaine intravenously and measured the in-brain concentrations of this drug while performing concurrent locomotion and physiological monitoring. We successfully measured procaine concentrations every 10 s in real-time and generated subject-specific full pharmacokinetic profiles which are compared to the pharmacodynamic (behavioral) profile. Increases in procaine concentration coincide with

decreased locomotion. We also show in vitro data suggesting a route forward for the detection of cocaine at physiologically relevant concentrations in rats. In conclusion, we have developed a novel, potentially revolutionary, technology that can measure the pharmacokinetics of psychoactive drugs within the brains of awake, freely behaving animals.

Title: Local field potential oscillatory dynamics in prelimbic cortex to nucleus accumbens core circuitry after extended access cocaine self-administration and prolonged abstinence

Authors: *M. L. NGBOKOLI, L. P. EDWARDS, R. M. CARELLI;
Univ. of North Carolina At Chapel H Behavioral Neurosci. Program - Psychology Dept., Chapel Hill, NC

Abstract: Individuals with a substance use disorder often show increased rates of drug craving and seeking following abstinence from drug use. Further, neuroadaptations occur including changes in local field potential (LFP) activity that result from repeated drug use and abstinence. Work from our lab has shown that abstinence from cocaine self-administration results in a dampening of activity in several reward-related areas including the prelimbic cortex (PrL) and nucleus accumbens core (NAc core). Further, our recent work has also shown that transcranial alternating current stimulation can reverse cocaine-induced neural reductions in PrL-NAc core coherence and restore cocaine related deficits in behavioral flexibility. Here, we investigated the effects of extended access cocaine self-administration (6 hr/d for 2 weeks) and prolonged (1 month) abstinence on resting state (spontaneous) LFP activity using electrophysiological methods. Adult, male Sprague Dawley rats were trained to self-administer cocaine (n=10, 0.33 mg/inf, 6 h per session) or water (n=3) during 14 daily sessions, followed by 30 days of experimenter-imposed abstinence. LFP activity in the PrL and NAc core was recorded for 15 minutes at 3 different timepoints: before self-administration training began, after self-administration training was complete but before abstinence, and immediately following prolonged abstinence. Behavior was recorded during self-administration and in two extinction

sessions, one that occurred immediately after self-administration training, and the second after 1 month cocaine abstinence. Preliminary behavioral data indicates that cocaine rats exhibited a significant escalation in drug taking when comparing days 3 and day 14 (t_9= 2.902, p= 0.0175), and showed increases in extinction presses after prolonged abstinence. Preliminary LFP data suggests that rats with a history of cocaine exhibited an overall reduction in resting state PrL to NAc core coherence immediately following self-administration compared to controls. Ongoing studies are increasing the number of control (water) rats and examining relationships between LFP signaling and aspects of behavior such as escalation and incubation of drug seeking. Collectively, these data will provide insight into how a history of extended access cocaine self-administration and prolonged abstinence may alter LFP oscillatory firing dynamics within the PrL to NAc core circuit.

Title: Cerebellar correlates of the transition from goal-directed behaviors to habits

Authors: *P. IBÁÑEZ-MARÍN[1], R. REDÓN-CLOFENT[1], H. GONZÁLEZ-GARCÍA[1], A. SANCHEZ-HERNANDEZ[1], J. GUARQUE-CHABRERA[1,2], M. MIQUEL[1,2];
[1]Psychobiology, Univ. Jaume I, Castelló de la Plana, Spain; [2]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Previous studies have demonstrated the ability of addictive drugs to create an imbalance between flexibility and repetition of behavioral patterns that can be biased towards incentive habits, becoming insensitive to devaluation. Our group found that the establishment of cocaine-induced incentive memory increases neural activity in the cerebellar cortex and cerebellar deep nuclei as well as the expression of perineuronal nets (PNNs) which are specialized extracellular matrix structures that stabilize synapsis. In the present research, we wonder whether a treatment with cocaine or alcohol in different phases of the learning process will increase insensitivity to reward devaluation and thus to facilitate the transition from goal-directed behavior to habit in natural rewarded behaviors. We also aimed to explore the cerebellar

correlates of this transition. Cocaine was administered every two days in ascending doses (2, 4 & 10 mg/kg; intraperitoneal injection (IP)) for 7 weeks. Different groups of adult male rats were exposed to intermittent voluntary alcohol consumption in ascending concentrations too (2,5, 5 & 10%) for 12 weeks. Animals were exposed to drug treatments before or after instrumental learning. Control groups were treated with saline or consumed water, respectively. Rats were trained in operant boxes to consume two kind of palatable pellets (banana and chocolate) in a random ratio schedule (RR10), then rewards were devalued by 1h of prefeeding and sensitivity to reward devaluation was assessed under extinction in two tests of 5 min. At the end of the last extinction test, rats were perfused and cerebella were processed for cFos and WFA immunofluorescence. Cocaine-treated animals maintained goal-directed patterns in all the conditions despite saline-treated rats showed insensitivity to reward devaluation when instrumental learning occurred before IP administration. However, in the alcohol groups (treatment before and after learning) a tendency towards insensitivity was observed. Related to cerebellar correlates, we found a reduction of the number of PNNs in lobule VIII of the cerebellum in alcohol pretreated rats. In conclusion, both alcohol groups showed a tendency to insensitivity to devaluation, but only saline treated rats exhibited this tendency when the treatment is administered after the learning process. On the other hand, cerebellar cFos and PNN expression depend on the drug and the cerebellar region evaluated.

Title: Cocaine experience alters discrete aspects of risky decision-making within the Balloon Analogue Risk Task

Authors: *M. C. HILLMAN, E. C. WARNOCK, K. A. SILETTI, M. NAVARRO, K. T. BROWN, M. P. SADDORIS;
Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: The decision to endure risk in order to obtain reward progresses through a series of discrete cognitive processes: reward valuation, risk assessment, and feedback integration to update future expectations. While optimal decision making requires dynamic updating of anticipated costs and rewards, each facet of the decision is vulnerable to corruption, such as

impulsivity driven by prior long-term experience with drugs of abuse. Here, rodents complete the Balloon Analogue Risk Task (BART) to evaluate these discrete elements of risk-taking behavior and their vulnerability to prior life experiences, namely drugs and stress. In the BART task, when animals engage with a lever of learned reward probability, they can press that lever multiple times to cache sucrose pellets, with the knowledge that over-exploitation of the lever on any given trial can lead to a "bust", wherein all rewards are lost. Moreover, animals can choose between two levers of different reward and risk contingencies (i.e. "risky choice") and then press that chosen lever to their desired amount (i.e. "risky action").
While the neural circuitry underlying risky decision-making is known to include prefrontal cortical projections to the dorsomedial and ventral striatum (i.e. nucleus accumbens), differentiation in activity across the different aspects of the decision (e.g. risky choice versus risky action) remains poorly understood. Moreover, cortico-striatal activity can undergo dramatic remodeling within abstinence from drugs of abuse, such as cocaine, creating vulnerability to poor impulse control and risky behaviors. Here, animals self-administer cocaine (0.5 mg/kg/infusion) or saline over 14 short-access (2 hour) sessions and are then forced into home-cage abstinence. Animals are then trained to press one of two levers to obtain 40 mg sucrose pellets before receiving implants of electrophysiological arrays within prefrontal cortex and striatal areas. In male (but not female) rats performing our BART task, cocaine experience enhanced risky decision-making and correlates with differences in neural encoding within cortico-striatal circuitry.

Title: Reduced GIRK channel activity in prelimbic pyramidal neurons impairs extinction of cocaine-induced conditioned place preference in male, but not female, mice.

Authors: *T. ROSE, K. D. WICKMAN, E. MARRON;
Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Drug-induced neuroadaptations in the mPFC have been implicated in addictive behaviors. Repeated cocaine exposure has been shown to increase pyramidal neuron excitability in the prelimbic (PL) region of the mouse mPFC, an adaptation attributable to a suppression of $GABA_B$ receptor-mediated signaling through G protein-gated inwardly rectifying potassium/K^+ (GIRK) channels. Prior work in our laboratory found that selective suppression of GIRK channel activity in PL pyramidal neurons in drug-naïve mice enhanced the motor-stimulatory effect of cocaine, without affecting basal activity. The goal of this exploratory study was to examine the impact of GIRK channel plasticity in PL pyramidal neurons on affective and reward-related behaviors. Specifically, we used a viral GIRK channel ablation approach involving drug-naïve adult (7-8 wk) $Girk1^{fl/fl}$ mice and intra-PL delivery of viral Cre or control vectors to selectively reduce GIRK channel activity in PL pyramidal neurons. The behavioral impact of this manipulation was assessed in the elevated plus maze (EPM), forced swim test (FST), and cocaine-induced conditioned place preference (CPP) paradigm. GIRK channel ablation did not impact innate avoidance behavior in the EPM (male: p=0.177, n=16; female: p=0.963, n=9-14) or behavioral despair in the FST (male: p=0.533, n=16; female: p=0.881, n=9-14). While this manipulation did not alter the acquisition of cocaine-induced CPP (male: p=0.402, n=11-12; female: p=0.435, n=8-9), it impaired the extinction of cocaine-induced CPP in male (p=0.0098, n=11-12), but not female (p=0.166, n=8-9), mice. This finding suggests that cocaine-evoked GIRK channel plasticity in PL pyramidal neurons may facilitate prolonged drug-seeking behavior in male mice.

Title: The mPOA modulates sex differences in neural and behavioral responses to cocaine

Authors: *J. MARTZ, A. VASQUEZ, J. M. DOMINGUEZ;
The Univ. of Texas at Austin, Austin, TX

Abstract: Males and females respond differently to drugs of abuse; this difference is in part due to the influence of gonadal hormones such as estradiol. The medial preoptic area (mPOA) in the hypothalamus is an important integrator of neuroendocrine signaling and a key regulator of both natural and drug-related reward. While the mPOA is a sexually dimorphic structure and implicated in several behavioral sex differences, whether it is involved in the regulation of sex

differences in cocaine response remains unclear. To investigate this, we examined sex differences in cocaine-induced locomotion and neural activation in the mPOA of male and naturally-cycling female rats. We found a correlation between cocaine-induced locomotion and neural activation in the mPOA of both males and females. However, this relationship was only present in females in high estradiol phases of their estrous cycle, but not in females in low estradiol phases of their cycle. Using iontophoretic injections of the retrograde tract tracer Fluoro-gold into the ventral tegmental area (VTA) of male and female rats, we also explored possible sex differences in neural projections from the mPOA to the mesolimbic reward system. In particular, we analyzed sex differences in estrogen-receptor containing efferents. Results indicate that while projections from the mPOA to the VTA were comparable between males and females, projections that contained estrogen receptors were significantly greater in females than in males. Taken together, these findings further point to the mPOA as an important regulator of endocrine-mediated sex differences in cocaine response.

Title: Housing environment affects anxiety-like behaviors but not cocaine-induced sensitization in female and male mice

Authors: A. SHAPIRO, V. KIMBLE, I. KEREN, S. NOBOA SALOBO, R. DIVEKAR, M. GIRONTA, M. J. KIM, J. WILHELM, *C. R. MCKITTRICK;
Drew Univ., Madison, NJ

Abstract: Environmental conditions have been shown to have a significant impact on behavior and mental health. In humans, social isolation and chronic psychosocial stress are risk factors for substance use disorders and for affective disorders such as anxiety and depression whereas environments providing social support and cognitive enrichment have been shown to ameliorate some of these adverse effects. Similar outcomes have been observed in animal models; however, the majority of these studies have been conducted only in male subjects. We investigated the effect of housing conditions on behavioral responsiveness to cocaine and on anxiety-like behavior in both female and male mice. Adult C57BL/6J mice were housed in environments that varied in social structure and cognitive enrichment: Impoverished (IE: individually housed with a single compressed cotton bedding sheet), Standard (SE: same-sex groups of 4 with aspen bedding and modest enrichment), or Enriched (EE: same-sex groups of 4 with aspen bedding, with multiple enrichments changed twice weekly). Animals were introduced to their respective

housing conditions 4 weeks prior to behavioral testing. For the sensitization study, locomotor activity was monitored in an 0.5 m^2 chamber for 10 minutes before and 50 minutes after i.p. administration of either saline or 20 mg/kg cocaine. On d0 of the sensitization protocol, half of the animals received saline and half received cocaine; all animals received cocaine on d7, d14 and d28 following the initial session. Locomotor sensitization was observed in all groups, with distance traveled increasing progressively with repeated intermittent administration of cocaine; however, there was no effect of environment or sex. Anxiety-like behaviors were assessed in the elevated plus maze (EPM) after animals had been drug-free for over one week. Behavior in the EPM was significantly affected by environment but not by prior cocaine exposure. Total distance traveled and distance traveled in the closed arms was significantly greater in the IE group compared to the EE group. The effect was greater in males than females, although there was more variability among the males, likely due to the fact that several male SE and EE groups had to be separated due to fighting. The observation that housing environment affected anxiety-related behaviors but not the sensitization response suggests that these behavioral processes involve distinct neural pathways. In addition, the robust behavioral sensitization to cocaine exhibited by both female and male mice supports the routine inclusion of females in studies of substance-use disorders.

Title: Behavioral implications of cell-specific knockdown of D2 receptors on the cocaine response and the vulnerability for developing addictive-like behaviors

Authors: E. M. MURRAY, R. BOCK, A. MASKERI, I. BLEIMEISTER, M. BOCARSLY, V. A. ALVAREZ;
Lab. on Neurobio. of Compulsive Behaviors, Natl. Inst. of Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Cocaine is a monoamine transport blocker, which has shown to increase dopamine within the striatum. Dopamine in the striatum is important for motivation, motor function, and reinforcement. The actions of dopamine in the striatum are mainly driven by two types of receptors: D1 and D2. Clinical imaging studies showed that chronic cocaine abusers have lower levels of D2 receptor (D2R) availability within the striatum. A few studies showed that stimulant

abuse also correlates with low levels of D2R availability in the midbrain region. It is not yet clear how the D2R expressed in striatum or the midbrain contribute to cocaine taking behavior and the vulnerability to develop compulsive-like behaviors. Previous work using transgenic mouse models have shown that deletion of D2R within the striatum produces different behavioral outcomes, sometime even opposite effects, compared to D2R deletion in the midbrain. However, patients suffering from substance use disorders display lower levels rather than complete loss of D2R function, so knockdown of D2R is a more realistic manipulation which better mirrors the observations in the clinical condition. We hypothesize that lower levels of D2R in the striatum and the midbrain drive different alterations to the synaptic connectivity throughout the basal ganglia, which contribute to selected changes in cocaine driven behaviors. We also speculate that low levels of D2R in both striatum and midbrain might synergize to produce a vulnerable phenotype to cocaine abuse. The goal of this project is to test these hypotheses and dissect out the contribution of the D2R in the striatum and the midbrain to the behavioral response to cocaine. We generated transgenic mice with low levels of D2R in either the striatum (striatum-D2HET), the midbrain (auto-D2HET), or both (double-D2HET). We tested a battery of striatal-controlled behaviors and the response to cocaine. We also conducted intravenous cocaine self-administration (IV-SA) and compared the behavior among these three genotypes and littermate controls. Our data so far shows that mice with auto-D2HET and striatum- D2HET often display opposite changes in dopamine-related and cocaine-related behaviors. We also found that double-D2HET often compensate better than the region specific HETs and they show no evident alteration. Double-D2HET resemble auto-D2HET alterations on some behaviors while they mimic phenotype of striatum-D2HET on other behaviors. Completion of this project will give us a better understanding of the unique contributions of striatal and midbrain D2R to dopamine-dependent behaviors and the response to cocaine to better inform new treatment for substance use disorders.

Title: Wild type and trpc4 knockout rats show no effect of cocaine on performance of reversal learning, while amphetamine disrupts reversal performance of both groups

Authors: *W. D. KLIPEC, B. POHL, M. VORHIES, L. GUCK, S. SEETHAMRAJU, M. JOHNSON, M. GEREAU, D. SHIVAPUJA, C. VARGAS, S. ABDULLAHI, J. MARTIN; Psychology & Neurosci., Drake Univ., Des Moines, IA

Abstract: Previous research in our lab showed that the deletion of the *trpc4* gene produced a brain-wide elimination of TRPC4 channels, including those within a subpopulation of TRPC4-bearing dopamine neurons in the ventral tegmental area (VTA). That research also showed that the *trpc4* knockout rat (KO), compared to normal (WT) rats exhibit reduced cocaine self-administration and reduced cell firing rates in VTA dopamine neurons, with no differences in simple or complex reversal learning using food or water rewards. More recently, we found that acute cocaine administration produces a significantly greater dose-dependent increase in early responding (impulsivity) in WT compared to KO rats maintained on a DRL reinforcement schedule. Here, we examined the effects of acute cocaine and amphetamine administration on the performance of a Y-maze reversal task, by switching between running toward the lighted alley and reversing to running to the unlighted alley. In Experiment 1, the effects of cocaine (0, 5, 10, and 15mg/kg, i.p.) on KO and WT rats were tested after a series of four reversals. We found no difference between KO and WT rats in the acquisition of the reversal task, or disruption in performance at any dose. To determine if the lack of a disruption in performance was due to overlearning the reversal, we conducted Experiment 2, using different KO and WT rats, administering both acute cocaine (0, 5, 10, and 15mg/kg, i.p.) and d-amphetamine (0, 1, 2, 3 and 4mg/kg, i.p.), tested after one reversal. Once again, we found no differences between KO and WT rats in the acquisition of the reversal task, or disruption in performance at any dose of either drug; however, amphetamine produced a significant increase in errors for both KO and WT rats. These results replicate the finding that KO and WT rats do not differ in learning a reversal task. Importantly, these results also show that the reduction in cocaine self-administration and increased impulsivity on the DRL task in KO compared to WT rats are specific to those tasks and do not represent a more general disruption of learning or performance. The finding that amphetamine but not cocaine disrupts performance in both KO and WT rats is interesting and warrants further research. In conjunction with our previous research, these findings suggest a potentially important role for the TRPC4 channels in cocaine addiction and dopamine disorders.

Title: Isoform-selective PI3-kinase inhibition confers partial resilience to cocaine cessation-induced anxiety-like behavior

Authors: *B. R. BARBEE[1,2,3,4], S. L. GOURLEY[1,2,3,4];
[1]Grad. Program in Mol. and Systems Pharmacol., Emory Univ., Atlanta, GA; [2]Pediatrics and Psychiatry, Emory Univ. Sch. of Med., Atlanta, GA; [3]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [4]Children's Healthcare of Atlanta, Atlanta, GA

Abstract: Phosphoinositide 3-kinase (PI3K) is a multi-subunit signaling complex that phosphorylates phosphoinositides, membrane-embedded second messengers that are critical for synaptic and structural plasticity of neurons. Cocaine potentiates PI3K-Akt-mTOR cascade activity, and this activation persists beyond the period of drug exposure. The PI3K p110β isoform is neuronally enriched and able to control PI3K signal propagation, allowing for manipulation of PI3K activity in a more targeted manner than broad-spectrum PI3K inhibition. Cessation of cocaine use triggers anxiety-like behavior in humans and rodent models, and anxiety can be a causal factor in relapse. Here, we used viral-mediated gene silencing to reduce expression of p110β in the dorsomedial prefrontal cortex (dmPFC). Isoform-selective PI3K inhibition mitigated anxiety-like behavior triggered by acute cocaine. Interestingly, however, a history of repeated cocaine exposure occluded this resilience, presenting an opportunity to compare immediate-early gene expression between cocaine-vulnerable and cocaine-resilient mice. We examined 22 brain regions and found that resilient mice - those displaying less anxiety-like behavior - displayed lower immediate-early gene expression in the claustrum and lateral hypothalamus. We next found that chemogenetic stimulation of the claustrum induced anxiety-like behavior. Future studies will determine whether suppressing p110β in the dmPFC combats anxiety-like behavior via connections with the claustrum. Our findings suggest that isoform-selective PI3K inhibition mitigates cocaine cessation-elicited anxiety-like behavior, likely via coordinated brain regions and circuits.

Title: Modulation of cocaine self-administration behaviors with nicotine co-administration in rats

Authors: *M. H. DAWES, P. M. ESTAVE, S. ALBERTSON, S. R. JONES;
Wake Forest Univ. Sch. Med., Winston Salem, NC

Abstract: Prevailing preclinical models of cocaine use have not resulted in an FDA-approved treatment for cocaine use disorder, potentially due to a focus on cocaine use in isolation. It is known that clinical populations with cocaine use disorder are predominately polysubstance users, with high co-use of cocaine and nicotine. Nicotine has been shown to increase cocaine potency and enhance the reinforcing effects of cocaine, suggesting that examination of the combined use of cocaine and nicotine may provide a more translational model for cocaine use disorder. Prior studies suggest that non-contingent nicotine exposure is not sufficient to alter cocaine self-administration in rats; therefore, this experiment looked to examine if concurrent, co-administered cocaine and nicotine would increase responding for long access cocaine self-administration. Male Sprague Dawley rats were trained to self-administer either a concurrent combination of cocaine and nicotine (0.375 mg/kg/infusion cocaine + 0.03 mg/kg/infusion nicotine) or cocaine alone (0.375 mg/kg/infusion). After completing acquisition (defined as 2 consecutive days of 20 infusions), rats were tested on a long access, fixed ratio 1 schedule of reinforcement (6 hour sessions, unlimited infusions). Unexpectedly, rats self-administering combined cocaine and nicotine responded significantly less than rats self-administering cocaine alone during both acquisition and long access schedules. Further, rats with a history of concurrent cocaine and nicotine did not self-administer nicotine alone under the same long access self-administration conditions. Together, these data highlight the importance of nuance in nicotine self-administration paradigms, particularly context and environmental cues, and suggest that current widely-used preclinical models of cocaine administration may not fully recapitulate cocaine use in clinical populations.

Title: N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline potentiates cocaine-induced locomotor activity in preweanling rats: role of 5-$HT_{1A/1B}$ receptors

Authors: A. TERAN, J. A. M. ROBINSON, G. I. RAMIREZ, C. G. KATZ, ***S. A. MCDOUGALL**;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: In adult rats and mice, dopamine (DA) receptor inactivation causes predictable behavioral effects. For example, the locomotor-inducing actions of D2 receptor agonists are almost completely eliminated if adult rats are pretreated with the peptide-coupling agent *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ). In preweanling rats, on the other hand, EEDQ does not attenuate the locomotor activating effects of D2 receptor agonists like *R*-propylnorapomorphine (NPA). More surprisingly, systemically administered EEDQ actually potentiates the cocaine-induced locomotor activity of male preweanling rats. Specifically, cocaine produces significantly more locomotor activity in EEDQ-treated male preweanling rats than vehicle-treated rats. It is uncertain why EEDQ leaves the NPA-induced locomotor activity of preweanling rats unaffected, while potentiating cocaine-induced locomotor activity, but the answer may involve serotonin (5-HT) system functioning. Specifically, NPA is a selective agonist at D2 receptors, whereas cocaine increases synaptic levels of both DA and 5-HT by blocking monoamine transporters. Two experiments were conducted to assess 5-HT involvement in this psychopharmacological effect. First, we extended previous findings by determining whether EEDQ potentiates the cocaine-induced locomotor activity of female preweanling rats. To this end, preweanling, adolescent, and adult female rats were pretreated with vehicle or EEDQ (7.5 mg) 24 hr prior to a test day injection of saline or cocaine (15 mg/kg). Second, to assess the importance of serotonergic involvement we examined whether EEDQ potentiated the locomotor activity produced by RU 24969 (a 5-$HT_{1A/1B}$ receptor agonist) and/or quinpirole (a D2/D3 receptor agonist). Results showed that EEDQ attenuated the cocaine-induced locomotor activity of adolescent and adult female rats, while potentiating the locomotor activity of female preweanling rats. EEDQ also potentiated the locomotor activity of preweanling rats treated with RU 24969+quinpirole, but not RU 24969 or quinpirole alone. These data indicate that EEDQ's ability to potentiate the cocaine-induced locomotor activity of preweanling rats is only manifested after co-activation of D2 and 5-HT_{1A}/$_{1B}$ receptors. If only DA receptors are stimulated (i.e., using NPA or quinpirole), a potentiated locomotor response is not evident. When considered together, these results show that preweanling and adult rats respond in a qualitatively different manner to EEDQ, and these age-dependent differences involve both DA and 5-HT system functioning.

Title: Investigating the role of medial prefrontal cortex inhibitory neurons in attentional engagement

Authors: *B. FERGUSON[1], R. KADURU[2], J. R. HUGUENARD[3];
[1]Neurol., [2]Stanford Univ., Stanford, CA; [3]Dept Neurol & Neurolog. Sci., Stanford Univ. Sch. Med., Palo Alto, CA

Abstract: Disrupted attention presents as a comorbidity across several disease states, including but not limited to schizophrenia, autism, depression, bipolar disorder, Alzheimer's disease, and epilepsy. These impairments often persist even when hallmark symptoms respond to treatments. Thus, identifying neuronal circuits linked to successful and dysfunctional attention represents a significant public health concern. Attention is comprised of certain component processes, including sustained attention, selective attention, and attentional flexibility. The initial focusing of attention, precludes engagement of other components making it an important building block of many of our more complex behaviors. To explore this, we developed a protocol to capture this phenomenon in mice, referred to here as attentional engagement. Food-restricted mice were trained to initiate trials by nose poking in a center port and learned that responding correctly to a visual cue presented in one of two locations would result in a food reward. Using pseudorandom variation of cue lengths, we obtained a psychometric curve where intermediate cue lengths had variable detection rates that revealed relevant circuit components. With a combination of fiber photometry, optogenetics, and electrocorticography, we observed that the medial prefrontal cortex (mPFC) subserves attentional engagement with different neuronal subtypes playing distinct roles in specific task epochs. Dampening mPFC activity via chR2-mediated activation of VGAT-expressing neurons impairs performance during cue presentation, but not during the response period. Additionally, we determined that accuracy was linked to increases in cue-evoked parvalbumin-expressing interneuron activity, while somatostatin and vasoactive intestinal peptide-expressing neurons provide important error signals. Finally, electrocorticography of local field potentials indicated that increases in gamma oscillations help facilitate making the correct choice. Future directions involve investigating the contribution of long-range inputs to the mPFC, and their role in coordinating activity in distinct mPFC neuronal subtypes during attentional engagement.

Title: Distinct coordinated activity patterns in the mPFC for exploratory versus defensive behaviors

Authors: *G. SHAH[1], J. POPOVITZ[3], S. P. MYSORE[2], H. M. ADWANIKAR[2]; [2]Psychological and Brain Sci., [1]Johns Hopkins Univ., Baltimore, MD; [3]GenEdit, San Francisco, CA

Abstract: Exploratory and defensive behaviors form a fundamental component of the behavioral repertoire of animals. Yet, how they are differentially signaled in neural representations remains largely unknown. To date, the dominant finding is the presence of individual neurons (or groups) that are selective for exploratory states versus for defensive states in the medial prefrontal cortex, (as well as the amygdala and the ventral hippocampus). The complexity of such affective states, multimodal characteristics of mPFC neurons and variability in single neuron selectivity suggests additional insights may be gained from investigating the coding by coordinated neural activity patterns - an approach that has proved effective in studies of other encoding problems in neuroscience. To test this, here, we examined the coordinated activity vectors of simultaneously imaged neural ensembles in mPFC of mice as they engaged in exploratory versus defensive behaviors in a variety of standard assays – the zero maze, plus maze and open field test. We measured neural activity in 100s of mPFC neurons using a miniature fluorescence microscope, and longitudinally tracked their Ca^{2+} dynamics as they traversed the exploratory or defensive zones of these paradigms. Our data reproduce the classic result that subsets of individual neurons are selective for these zones. Notably, however, they show that coordinated activity vectors of simultaneously imaged neurons (in n-d space) are distinct between the exploratory versus defensive behavioral states, with the cloud corresponding to exploratory zones being denser (more stereotypical patterns). These results are not accounted for purely by selectivity of individual neurons. Moreover, this representation in joint neural activity is maintained stably when animals are re-exposed to the assays (across weeks; unlike selectivity of individual neurons), and is consistent across assays (unlike selectivity of individual neurons). Surprisingly, sub-ensembles of neurons that are not individually selective also show these robust distinctions for the two behavioral zones in their coordinated activity. Results reveal a neural code in the mPFC that reliably signals the exploratory versus defensive behavioral states differentially, is stable across days, and is generalizable across behavioral paradigms.

Title: Corticotropin-releasing factor (CRF) acts within the mediodorsal thalamus to impair sustained attention.

Authors: *S. K. COOKE[1], S. E. NICOL[1], R. C. SPENCER[2], C. W. BERRIDGE[1];
[1]Univ. of Wisconsin Madison, Madison, WI; [2]Psychology, Univ. of Wisconsin, Madison, WI

Abstract: The prefrontal cortex (PFC) supports a variety of cognitive processes that guide goal-directed behavior. While PFC-dependent cognitive dysfunction is associated with multiple behavioral disorders, the treatment of this dysfunction is impeded by a limited understanding of the neural mechanisms underlying PFC-dependent cognition. Corticotropin-releasing factor (CRF) neurons and receptors are found in the PFC. However, their role in cognition has only recently begun to be examined. In prior studies we demonstrated that chemogenetic activation and inhibition of CRF neurons in the caudal dorsomedial PFC (dmPFC) of rats impairs or improves, respectively, working memory. These actions were dependent on local PFC CRF receptors, consistent with working memory impairing and improving actions of caudal dmPFC CRF receptor activation or inhibition, respectively. Additional studies demonstrated that activation/inhibition of caudal dmPFC CRF neurons also impairs/improves sustained attention. However, in contrast to working memory, this action was not dependent on PFC CRF receptors. Collectively, these observations indicate that PFC CRF neurons modulate distinct cognitive processes via divergent projection pathways. To date, the terminal fields involved in the sustained attention-modulating action of PFC CRF neurons are unknown. To initially approach this issue, we used an AAV5 viral vector system to express eGFP selectively in caudal dmPFC CRF neurons and examined the distribution of labeled axons outside the PFC. We observed particularly dense collections of varicosity-containing fibers in the medial and lateral aspects of the mediodorsal thalamus (MD) as well as the medial posterior parietal cortex, regions previously implicated in the regulation of attention. As a first step in determining whether either of these regions might contribute to the sustained attention actions of caudal dmPFC CRF neurons, we examined the effects of CRF infusion into these regions in animals engaged in an operant-based signal detection task of sustained attention. 500 nl infusions of CRF (50-250 ng) into the lateral MD elicited a dose-dependent impairment in sustained attention, as did inactivation of this region with the GABA-A agonist, muscimol (75 ng). Ongoing studies are examining the sustained attention actions of CRF infusions into the medial MD. In contrast to that seen in the MD, muscimol or CRF infusions into the parietal cortex had no significant effects on sustained attention. These results indicate the MD may be a site of action in the sustained attention impairing effects of caudal dmPFC CRF neurons. Future experiments will test this hypothesis.

Title: Imaging sensory responses in the intermediate and deep layers of the superior colliculus

Authors: *A. BANERJEE[1], S. P. MYSORE[1,2];
[1]Dept. of Psychological and Brain Sci., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The superior colliculus (SC) is a major sensorimotor hub in the vertebrate midbrain. Particularly, the intermediate and deep layers (SCid), which encode topographic maps of multisensory and motor space, are critical brain circuits involved in spatial target selection. However, an understanding of cell type-specific neural representations underlying SCid function is lacking because work to date has primarily employed electrophysiological techniques to measure SCid neural responses. Here, we present cellular-resolution calcium imaging of sensory responses in the mouse SCid using the *nVoke* microendocsope (Inscopix, Inc.). We first characterize visual response properties of CaMKII-positive neurons in SCid, and then investigate population-level signatures of stimulus competition by imaging SCid responses to distant competing stimuli. These results not only demonstrate the feasibility of imaging large-scale neural responses in SCid in a cell-type specific manner, but also shed light on the nature of competitive interactions underlying spatial stimulus selection in mammalian SCid.

Title: Neuroestrogen regulation of inhibitory synaptic transmission in genetically-identified auditory neurons

Authors: *H. KANG[1], L. REMAGE-HEALEY[2];
[1]Neurosci. and Behavior Program, [2]Psychology and Neurosci., Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: A prominent neuromodulator system found in forebrain auditory circuits of vocal learners such as humans and songbirds is neuronal aromatase, which provides locally-synthesized estrogens ('neuroestrogens'). In songbirds, local neuroestrogens fluctuate in the forebrain in response to song, and modulate neuronal firing states to shape song-evoked responses and auditory learning. However, the synaptic mechanisms and network motif that underlies these rapid actions are still unclear. To address this gap, we used a combination of cell-type specific viral vectors and whole-cell voltage clamp electrophysiology to investigate the synaptic mechanisms that account for acute neuroestrogen actions in songbird auditory forebrain. Specifically, we identified inhibitory synaptic transmission onto principal excitatory neurons as a primary target of neuroestrogen modulation. These findings and the results of ongoing experiments are thus far consistent with the hypothesis that neuroestrogens acutely modulate inhibitory synaptic transmission by regulating GABAergic input onto both excitatory and inhibitory cell types. Definitive evidence for how neuroestrogens specifically modulate genetically-identified targets of inhibition will clarify the mechanisms underlying neuroestrogen regulation of sensory processing in a vocal learning species. Furthermore, the principles extracted from this circuit modulation mechanism could then be applied to understand the neuromodulation of cortical sensory processing in other species and brain regions. Support from NIH R01NS082179.

Title: A midbrain inhibitory nucleus controls distracter suppression for spatial attention

Authors: *N. B. KOTHARI[1], W.-K. YOU[1], Q. ZHANG[1], S. LOGGIA[2], S. P. MYSORE[1]; [1]Johns Hopkins Univ., Baltimore, MD; [2]NEI, Bethesda, MD

Abstract: Selective spatial attention is the ability to preferentially process the highest priority (most important) spatial location, while simultaneously ignoring competing distracters. The neural circuit mechanisms underlying distracter suppression and target selection for spatial attention, however, are unknown. Here, in freely behaving mice engaged in a touchscreen-based primate-like task of visuospatial attention (Flanker task), we demonstrate that a midbrain inhibitory nucleus, called the pLTN (periparabigeminal lateral tegmental nucleus) controls distracter suppression. The pLTN, which consists of parvalbumin expressing (PV+) neurons, receives topographically organized input from the midbrain sensorimotor hub, the superior colliculus. In PV-cre mice trained on the flanker task, we expressed the cre-dependent DREADD, h4MD(Gi), bilaterally in pLTN. We found that inactivation of pLTN through CNO administration severely disrupted attentional target selection in the flanker task and produced hyper-distractibility. In addition, it also caused loss of reliability in selecting the attentional target by attenuating the categorical nature of psychophysical response curves measured as a function of relative priority between the target and flanker. Because our task design dissociates the locus of attention from the locus of behavioral report, we were able to rule out deficits of motor selection as an explanatory factor. Moreover, administration of CNO during target-alone trials did not alter performance, ruling out purely sensory deficits as an explanatory factor. Administration of saline instead of CNO to these animals does not alter target selection. The observed deficits in distracter suppression for target selection in the absence of purely perceptual deficits establish the midbrain pLTN as a critical hub for the control of distracter suppression for selective spatial attention.

Title: Identifyingnatural transitions from goal-directed to habit-like performance during sensorimotor learning in mice

Authors: *S. MOORE[1], Z. WANG[1,2], K. KUCHIBHOTLA[1,3];
[1]Psychological and Brain Sci. Dept., [2]Neurosci. Res. Undergraduate Program, [3]The Solomon H. Snyder Dept. of Neuroscience, Sch. of Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Animals use different decision processes to efficiently adapt to complex environments. When operating in a goal-directed mode, animals deliberate amongst alternatives in a slow and cognitively demanding process. As the statistics of the environment become predictable, animals can shift to a faster and more automatic habit mode. The nature and timescale of the transition from goal-directed to habit-like performance during learning, however, remains poorly understood. Studying this transition is crucial for understanding adaptive behaviors and it may add to our knowledge of disorders like addiction and OCD. During learning, a challenge to identify the decision process (goal-directed vs habitual), is that the decision itself is a hidden variable that is not behaviorally observable. For one, performance outcomes (action rate and accuracy) are often similar when using either decision process. Secondly, in commonly used water-restriction paradigms, an animals' drive is based on a biological *need* linked to survival (hydration), so animals exhibit constantly high action rates (due to elevated motivation) and gradually improve accuracy (due to learning). We hypothesized that by shifting an animals' motivation from a *need* (for survival) to a *preference* (for palatability), we could use action rate variability as a behavioral indicator of goal-directed performance (highly variable) versus habit-like performance (stable) without impacting accuracy. Here we leveraged a recent protocol in which mice get *ad libitum* access to water with citric acid (CA), a non-palatable substance that fulfills the need for hydration. We compared CA mice with mice under two different water restriction protocols. All groups were trained in an auditory go/no-go task in which mice learned to lick in response to a tone to obtain a water reward and withhold licking in response to another tone to avoid a timeout. Our data shows that mice acquired task contingencies at similar rates in all three groups. Interestingly, throughout training, most CA mice initially showed high action rate variability, regularly shifting from epochs of high engagement (high action rate) to low engagement (low action rate). With time, CA mice exhibited an abrupt reduction in action rate variability, suggesting a shift to habit-like performance. This shift was not evident in water restricted mice. We are currently using pupillometry to link changes in action rate during the goal-directed phase with a standard biomarker of arousal. These data suggest that the transition from goal-directed to habit-like performance during learning is abrupt and may result from a winner-take-all decision process.

Title: Using overtraining to abbreviate tests of attentional set-shifting

Authors: T. S. KNOTT[1], E. M. BOWMAN[1], V. J. BROWN[1], S. DEIANA[2], M. VON HEIMENDAHL[2], *D. S. TAIT[1];
[1]Sch. of Psychology and Neurosci., Univ. of St Andrews, St Andrews, United Kingdom; [2]CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co.KG, Biberach, Germany

Abstract: The rodent intradimensional (ID)/extradimensional (ED) attentional set-shifting task has been used for over two decades to assess behavioral flexibility. However, a drawback of the classic ID/ED task is that there are seven learning stages, requiring three pairs of unique exemplars. It has previously been observed that overtraining improves reversal learning in multidimensional stimulus discriminations, with evidence suggesting this is due to increased attentional allocation to the predictive (relevant) stimulus dimension (Dhawan *et al*, 2019, *Behav. Brain Res*., 363**:** 45-52). If so, then it should be possible to assess attentional set-shifting using overtraining on a single stage to facilitate set-formation, substituting four of the usual seven stages. To investigate this, we inhibited medial prefrontal cortex (mPFC) function—a brain region implicated in mediating behavioral flexibility (Birrell & Brown, 2000, *JNsci*, 20:4320-4324). Twelve adult male Lister hooded rats received inhibitory designer receptors exclusively activated by designer drugs (DREADDs; AAV5-hSyn-hM4D(Gi)-mCherry—Bryan Roth, Addgene) bilaterally into mPFC. mPFC inhibition via the expressed receptors was induced by i.p. administration of Compound 21 (C21; 3mg/kg). Rats completed the standard 7-stage ID/ED task twice, following vehicle or C21 administration; and a 4-stage task, consisting of a compound discrimination, a reversal, a novel compound discrimination where the rewarded dimension was switched to the previously irrelevant, then a final reversal, four times: twice with thirty additional trials after reaching criterion (6 consecutive correct trials) in the initial compound discrimination, and twice without the additional trials, with vehicle or C21, in a pseudorandom order. Consistent with previous findings, mPFC inhibition impaired ED learning in the 7-stage task. In the 4-stage task, overtraining improved reversal learning performance and slowed learning when the rewarded dimension switched. Learning at that stage was slowed further by mPFC inhibition, but only when the rats were overtrained. Overall, our results indicate that overtraining to a compound stimulus drives focus to the relevant dimension, and that a subsequent stage where a shift is required is functionally equivalent to the ED stage of the classic 7-stage ID/ED test. In both the classic ID/ED task, and the abbreviated task, shifting performance was impaired by mPFC dysfunction. It is thus possible to reduce the number of task stages required to measure set-shifting.

Title: Rats adapt decision thresholds based on reward manipulation in an evidence accumulation task

Authors: *G. A. KANE[1], B. B. SCOTT[2];
[2]Psychological & Brain Sci., [1]Boston Univ., Boston, MA

Abstract: Animals, including humans, exhibit speed-accuracy tradeoffs in decision-making: the more time they spend deliberating or accumulating evidence, the more accurate their decisions, but at the cost of time and future opportunities. Finding the appropriate balance between speed and accuracy is critical for maximizing reward rate, but the neural mechanisms of choosing when to decide are not well understood. To determine whether rats could serve as a model to study the neural mechanisms of speed-accuracy tradeoffs, we investigated how rats choose to trade speed for accuracy in response to different task demands in a pulse-based evidence accumulation task. Rats self-initiated trials by nose poking in a center port and were then shown a series of light flashes in ports on their left and right according to a Bernoulli process (a weighted coin flip). Light flashes continued until rats executed a decision by nose poking in the left or right port. Rats were rewarded for choosing the side with the greater flash probability. Rats (n=9) were tested in their home cage with access to the task 24 hr/day; we collected an average of 1638 (st. dev. = 500) trials per rat per day using mild food restriction and 10% sucrose as reward. The most effective manipulation to encourage slower responses was to alter the reward landscape: in some conditions, rats were offered larger rewards for waiting longer to respond. In these conditions, rats not only exhibited slower responses, but also greater accuracy, suggesting that they accumulated more evidence while waiting. Accumulation to bound models fit to individual rats' behavioral choices and response times revealed that, in these conditions, rats exhibited a greater decision threshold (they required more evidence to commit to a decision), with no change in the rate at which rats accumulated evidence or in their non-decision time (time not related to evidence accumulation, such as the time to prepare and execute motor responses). Overall, these findings indicate that rats adapt their speed-accuracy tradeoff to task demands, providing a high-throughput model to study the neural mechanisms of adapting decision boundaries.

Title: Rational inattention in mice

Authors: *N. GRUJIC, J. BRUS, D. BURDAKOV, R. POLANIA;
Swiss Federal Inst. of Technol. Zurich, Zurich, Switzerland

Abstract: Behavior exhibited by humans and other organisms is generally inconsistent and biased, and thus is often labelled irrational. However, the origins of this seemingly suboptimal behavior remain elusive. We developed a behavioral task and normative framework to reveal how organisms should allocate their limited processing resources such that there is an advantage to being imprecise and biased for a given metabolic investment that guarantees maximal utility. We trained mice to perform a novel choice task requiring them to make decisions based on ordinal comparisons of orientation stimuli spanning the whole sensory space. Additionally, we introduced trial-to-trial variability in the reliability of sensory stimuli and controlled the prior distribution of the sensory inputs in terms of presented orientations. During the experimental timeline, mice went through different novel stimulus-reward association environments. This allowed us to model the allocation of sensory resources across the orientation stimulus space in each stimulus-reward environment, and check whether it complies with the predictions of rational inattention theory.
We found that mice act as rational-inattentive agents by adaptively allocating their sensory resources in a way that maximizes reward consumption in each stimulus-reward association environment. Surprisingly, perception to commonly occurring stimuli was relatively imprecise. However, this apparent statistical fallacy implies "awareness" and efficient adaptation to their neurocognitive limitations. Interestingly, distributional reinforcement learning mechanisms efficiently regulate sensory precision via top-down normalization. Furthermore, we found that arousal systems, as tracked by pupil size, contain information about reward expectancy of orientation stimuli in a given sensory-reward association environment.
These findings establish a neurobehavioral foundation for how organisms efficiently perceive and adapt to environmental states of the world within the constraints imposed by neurobiology.

Title: Model-free and model-based components of reinforcement-learning differentially mediate reversal learning in the rat

Authors: *S. GROMAN[1,2], S. L. THOMPSON[2], D. LEE[3,4], J. TAYLOR[5];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Psychiatry, Yale Univ., New Haven, CT; [3]Neurosci., Yale Sch. of Med., New Haven, CT; [4]Johns Hopkins Univ., Baltimore, MD; [5]Psychiatry, Yale Univ. Sch. Med., New Haven, CT

Abstract: Reversal-learning paradigms have been extensively used to investigate flexible decision making in normal and abnormal states. However, our understanding of the mechanisms of reversal-learning remains limited. Differences in reversal learning performance have been attributed to impairments in value updating, state learning, and belief updating, but how these reinforcement-learning mechanisms relate to one another is not known. To elucidate those relationships, we assessed decision-making processes in both a three-choice, probabilistic reversal learning (PRL) task and in a multi-stage decision-making (MSDM) task in the same adult, male rats. Computational approaches were used to quantify value updating and state transitions in individual rats so that parameter values could be compared between the two decision-making paradigms. We find that reversal-learning performance is correlated with the prospective evaluation of reinforced actions (e.g., model-based learning) and, specifically, with the detection of the state transition between the acquisition and reversal phase. Retrospective evaluation (e.g., model-free learning), however, was related to differences in the degree to which action values were updated following rewarded and unrewarded outcomes. These data provide the direct evidence that model-free and model-based learning influence distinct aspects of adaptive choice behavior in a reversal-learning paradigm and showcase the independent of value updating from state detection. We then examined how these model-based and model-free computations could explain the reversal-learning impairments we have observed in rats following drug self-administration. We found that cocaine-induced reversal-learning deficits were due to selective impairments in the ability of animals to detect a state transition, whereas value updating following the state transition was not affected by cocaine self-administration.

Together, these data provide new insights into the reinforcement-learning computations that mediate flexible decision making in normal and pathological states.

Title: Sex differences in learning from exploration

Authors: E. KNEP[1], C. CHEN[1], B. A. EBITZ[2], *N. GRISSOM[1];
[2]Neurosci., [1]Univ. of Minnesota, Minneapolis, MN

Abstract: Sex-based modulation of cognitive processes could set the stage for individual differences in vulnerability to neuropsychiatric disorders. While value-based decision making processes in particular have been proposed to be influenced by sex differences, the overall correct performance in decision making tasks often show variable or minimal differences across sexes. Computational tools allow us to uncover latent variables that define different decision making approaches, even in animals with similar correct performance. Here, we quantify sex differences in mice in the latent variables underlying behavior in a classic value-based decision making task: a restless 2-armed bandit. In this task, animals chose from two options, each of which was associated with certain reward probabilities that changed randomly and independently over time. To maximize rewards, animals had to balance between exploiting a known good option with exploring better alternatives. While male and female mice had similar performance on reward acquisition, we found that they achieved this performance via different patterns of exploration by fitting a Hidden Markov model and reinforcement learning models. Male mice tended to make more exploratory choices overall, largely because they appeared to get "stuck" in exploration once they had started. Female mice tended to explore less, but they learned more quickly during exploration, indicated by elevated win-stay and lose-shift behaviors during exploratory trials. Together, these results suggest that sex exerts stronger influences on decision making during periods of learning and exploration than during stable choices. The neural mechanisms of exploration are thus poised to confer sex-modulated variability in cognition and potentially sex-modulated vulnerability to neuropsychiatric diagnoses.

Title: Near-optimal time investments under uncertainty in humans, rats, and mice

Authors: *T. OTT[1], P. MASSET[2], M. BOSC[3], J. SANDERS[3], A. KEPECS[1];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Harvard Univ., Cambridge, MA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Our scarcest resource is time. Humans and other animals must allocate their time on a vast number of different activities - from reading a paper, pursuing a degree, or foraging for food. Optimal, utility-maximizing, behavioral strategies must balance expected future gains with irrecoverable time investment. However, humans and other animals often succumb to a variety of cognitive biases that lead to suboptimal returns such as considering sunk costs when investing time to obtain future rewards. Comparative studies across species are important to understanding the evolutionary origins of irrational behavior. Here we re-examine the question whether humans, rats, and mice are able to invest their time optimally. First, by developing computational task models, we re-interpret previous reports that humans, rats, and mice succumb to the sunk cost fallacy as optimal behavior when the precise value of choices is uncertain (Sweis et al., 2018, Science). Our results demonstrate the importance of experimental control over the decision maker's reward uncertainty. Second, we behaviorally tested how optimal humans, rats, and mice invest time by controlling their uncertainty in obtaining future rewards. This allowed us to evaluate whether subjects scaled investment decisions in proportion to their confidence in obtaining a reward. Human or animal subjects committed to one of two choice alternatives with ambiguous sensory evidence, which enabled us to infer the subjects' confidence in making a correct choice. After making a choice, subjects invested time in their decision by waiting for randomly delayed reward for correct choices. We predicted optimal time investment for each trial using a statistical model of confidence and a non-parametric estimate of the subjects' mapping function between confidence and time investment. Crucially, this approach allowed us to isolate the contribution of confidence to investment behavior. Humans, rats, and mice invested time close to optimal model predictions, i.e., with low confidence noise, demonstrating that all species appropriately use sensory evidence to adjust investment behavior. In humans, explicit confidence reports predicted time investment, suggesting shared mechanisms for verbal and non-verbal confidence-guided behaviors. Our results demonstrate that humans, rats, and mice are

efficient economic agents, who optimize investment decisions by leveraging their sense of confidence in uncertain environments.

Title: Production of central tendency effects in interval timing tasks via reinforcement learning

Authors: *N. CHIULLI[1], G. KANE[2], B. B. SCOTT[3];
[1]Boston Univ. Undergraduate Program In Neurosci., Boston, MA; [2]Ctr. for Systems Neurosci., [3]Psychological & Brain Sci., Boston Univ., Boston, MA

Abstract: In interval time estimation and reproduction tasks, during which participants are asked to reproduce a range of time intervals over the course of many trials, participants exhibit a central tendency effect: their responses are biased toward the mean of previous sample times. Current literature suggests this behavior is an adaptive basis due to an awareness of and compensation for endogenous timing uncertainty (noise in the estimation of elapsed time); in other words, because the estimation of elapsed time is imprecise, estimates are combined with the prior expectation built from experience over multiple past trials to reduce uncertainty. While this hypothesis is widely accepted, other possible contributing factors have not been sufficiently ruled out. As the central tendency bias improves reward rate, we explored whether this effect could also be achieved by agents that seek to maximize reward using model-free reinforcement-learning (i.e. without knowledge of their endogenous timing uncertainty). We first used a discrete time Q-Learning algorithm in which, given a state (noisy sample interval), the model chose from a set of possible reproduction times and received reward based on how similar the chosen reproduction time (plus noise in the reproduction of the time interval) was to the sample interval. Similar to models that explicitly account for endogenous timing uncertainty, this Q-learning model with no knowledge of timing uncertainty exhibited a central tendency effect, and the central tendency bias grew with greater timing uncertainty. Next, we replicated these effects using an Actor-Critic model in which sample and reproduced times were mapped onto a continuous function rather than chosen from predetermined bins. The achievement of this behavior via model-free reinforcement learning algorithms indicates that it is possible to learn the actions (i.e. reproduction times) that maximize reward without explicit knowledge of

endogenous timing uncertainty. Future studies in humans and animals will be required to determine the extent to which these effects are due to awareness of and compensation for endogenous timing uncertainty or model-free reward maximization.

Title: A Deep Neural Network Model Adapts Flexibly to Different Opponent Strategies in a Competitive Game

Authors: *M. OSTROW[1], R. YANG[2], H. SEO[3];
[1]Neurosci., Yale Univ., New Haven, CT; [2]Brain and Cognitive Sci., MIT, Boston, MA;
[3]Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: In social interactions, theory of mind (ToM) is thought to be an inference in which an agent learns a model of other agents' intentions, goals, and reward function in order to predict future actions. ToM also allows for agents to generalize to novel social interactions. ToM has been modeled at the algorithmic level, with explicit modules that represent the postulated cognitive components of ToM. However, these models offer only limited insights into the potential neural mechanisms underlying ToM, largely due to the lack of linking hypotheses to the activity of complex neural networks. Recent applications of artificial neural networks (ANNs) in neuroscience research have shown that ANNs learning complex cognitive tasks often exhibit the spatiotemporal features similar to the neural activity observed in the brain, suggesting that ANNs might be a useful tool to understand how ToM might emerge in the distributed activity of biological neural networks. Here, we explore the potential of artificial neural networks to provide novel insights into the neural mechanisms underlying ToM.
Using a deep reinforcement learning actor-critic algorithm, we trained a recurrent neural network (RNN) to play a two-player competitive game against multiple opponents who generate their actions according to a set of higher-order strategies. We used a meta-learning approach inspired by past models of the prefrontal cortex as performing meta-reinforcement learning. We focused on two questions. *First*, can the network learn to play adaptively against a wide variety of opponents in its training set, and can it generalize to novel strategies of similar subtypes? *Second*, does adding an auxiliary task to model the opponents' action enhance the network's ability to adapt and generalize?

After training over one hundred different RNNs for between 300,000 and 3 million iterations to ensure significance of our results across random seeds and hyperparameters, we found that despite a lack of explicit ToM, the network can generalize well to new opponents. We next provided the models the ability to develop a rudimentary form of ToM by requiring it to make a prediction of the opponent's choice on each iteration of the game. Adding the explicit task did not significantly improve the network's ability to generalize. Our results demonstrate that RNNs can learn the strategies of the opponents in order to adaptively play a competitive game. They also suggest that explicit modules of ToM may not further enhance the network's ability to meta-learn and generalize in our present task. In future studies, we hope to further understand the potential neural mechanisms underlying ToM computations by analyzing network dynamics.

Title: Does pre-stimulus EEG power redict cognitive processes in perceptual decision making

Authors: *Q. SUN[1], M. D. NUNEZ[2], J. VANDEKERCKHOVE[1], R. SRINIVASAN[1]; [1]Dept. of Cognitive Sci., Univ. of California, Irvine, Irvine, CA; [2]Dept. of Psychological Methods, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: EEG activity prior to the onset of a stimulus may reflect different cognitive components of preparatory brain activity relevant to subsequent perceptual processes. 48 subjects performed a two-alternative forced-choice task by discriminating whether a Gabor patch presented with noise is high or low spatial frequency. Task difficulty was manipulated by the difference in spatial frequency (perceptual evidence) between the two choices. Participants performed the task in blocks of trials at 3 levels of difficulty (spatial frequency difference). A cue interval containing visual changing noise starts from 0.5 to 1.0 second before a stimulus onset. Response times increased as task difficulty increased. A standard Hierarchical Drift Diffusion Models (HDDM) were fitted using choice accuracy and reaction time to obtain estimates of the rate of evidence accumulation (drift rate) and the boundary separation between two choices. Hierarchical model parameters were estimated for each participant per condition, and showed that drift decreased as the task difficulty increased. Desynchronization in EEG oscillations was investigated using 5 frequency bands: theta (3-5Hz), low alpha (7-9Hz), high

alpha (11-13Hz), low beta (15-21Hz), and high beta (23-29Hz). Relative power of each frequency band was calculated by the ratio of the power of each electrode per trial to its corresponding baseline. Correlation matrices (channel x time) for each frequency band were generated by calculating the Pearson correlation coefficient between model parameters and relative power of every subject per condition, at each channel and each time point. Pre-stimulus interval is defined as 300ms prior to stimulus onset. Our results suggest that pre-stimulus alpha power reflects condition effects of drift rate, such that alpha power increases with task dmatlab.matifficulty as drift rate decreases. Correlations of boundary and EEG power in theta, low alpha, and high beta bands during pre-stimulus intervals primarily reflect individual differences, as these correlations show consistent patterns across conditions. These results provide a new perspective to use neural correlates to interpret diffusion model parameters. Preparatory activity in the prestimulus determines the rate of evidence accumulation and decision caution in perceptual decision making tasks.

Title: High-density OLED-on-CMOS devices for implantable hyperlocal optogenetic stimulation in-vivo

Authors: *A. TAAL[1], I. UGUZ[1], S. HILLEBRANDT[2], C. MOON[2], C. KEUM[2], J. CHOI[1], E. POLLMANN[1], M. GATHER[2], K. SHEPARD[1];
[1]Electrical Engin., Columbia Univ., New York, NY; [2]Sch. of Physics and Astronomy, Univ. of St. Andrews, St. Andrews, United Kingdom

Abstract: The ability to precisely map neural circuits and to selectively manipulate region of interest is critical to understanding brain function. To that end, optogenetics has emerged as a great candidate due to its excellent spatiotemporal resolution and cell-specific targeting. Combined with simultaneous recordings of responsive neuronal micro circuitries, optogenetics manifests itself as a powerful tool for feedback regulated manipulation of particular brain regions and neural pathways. While these feedback loops are well-understood at the brain surface, the complexity of integration has obstructed such experiments in the deep brain. Accessing the deep

brain in a highly localized fashion for simultaneous stimulation and recording has thus remained elusive. We have been exploring fully implantable optoelectronic devices exploiting advances in complementary metal-oxide-semiconductor (CMOS) microelectronics and advanced heterogeneous integration as a means of accessing deep brain structures, bringing advantages over techniques using optical fibers or GRIN lenses. Here, we present an implantable CMOS shank probe containing 1024 organic light emitting diodes (OLEDs) on a 25-µm pitch. The OLEDs are fabricated directly on top of the CMOS integrated circuit, matching approaches used in advanced display technologies. Each of four 6-mm-long shanks carry 256 OLEDs, emitting 25nW per OLED from an active area of 400µm^2. The CMOS pixels support repetition rates beyond 50kHz and allow stimulation of the surrounding neural tissue with arbitrary patterns of individually addressable OLEDs over an area of 3200x800µm. Neurons as far as 50µm away can be reached, bringing the total addressable volume up to 0.1mm^2. To record the corresponding neural response, we combine the CMOS shank with a transparent electrode array (32 electrodes spaced at a 50-µm pitch) fabricated with 100-nm-thick PSS:PEDOT electrodes and indium-tin-oxide interconnect on a 4-µm-thick parylene substrate. The 20-by-20-µm electrodes have an impedance of 100KOhm at 1kHz with a baseline noise of 6.5µV rms over the 10Hz-to-3kHz band. During optogenetic stimulation, we observe artifact-free recording, which is not typical of electrical approaches In our experiments, we demonstrated optogenetic stimulation from the OLEDs by implanting them in the CA1 of Channelrhodopsin transgenic mice. We successfully manipulated neural populations down to single neuronal level and observed the effects of stimulation in real time. By adjusting the power of OLEDs, we seek to precisely control the field of stimulation and induce hyperexcitability in local populations.

Abstract: Investigating the network dynamics of neuronal populations in the cortical areas involved in vision with photostimulation is one of the hot topics of the past few years. However, measurement protocols, visual paradigms, and experimental scenarios have all been restricted by the technological constraints of conventional microscope systems. Here we present a novel, 3D acousto-optical scanning-based photostimulation equipment which enables ms resolution precise temporal control of activity patterns at the level of individual neurons. To demonstrate the efficacy of the system we used it to replay activity on a set of neurons found to be responsible for coding certain visual stimulation. For performing this first we used fast multilayer acousto-optical frame scanning, which enables recording the activity of arbitrary cortical layers sequentially with high speed (40Hz with 512x512 pixel resolution, in a 500x500 µm areas). By this, we can follow the activity of hundreds of cells in multiple (3-11) areas of the cortex. Next, we developed novel analytic software modules to automatically detect responding neurons and to define among the acquired cell-level activity patterns those that are involved in the perception of specific visual stimuli (i.e., representing a latent task variable of a task). Optical stimulation is presented with a custom virtual reality system that provides binocular depth-perception and a fully immersive experience for small head-fixed. Finally, we photostimulate hundreds of somata simultaneously with 3D imaging. For precise temporal control of the activity on the cells selected to be stimulated we developed novel driver electronics of the AO system allowing us to arbitrarily modulate the stimulating laser intensity with a granularity of 30 µs. The achievable temporal resolution of the activity playback was found to be 100 ms, however, note that this is not limited by the stimulation method itself, but by the precision of the activity detection which was measured with GCaMP6f. Using this system, we showed that we can effectively stimulate and measure up to 250 cells simultaneously or can replay precise temporal dynamics on up to 20 cells with 100 ms temporal resolution.

Title: A flexible origami opto-electro array for in vivo optogenetic stimulation and electrophysiology recordings from dorsal root ganglion

Authors: *Y. GONG, W. LI;
Michigan State Univ., East Lansing, MI

Abstract: Developing a tool to better understand the relationship between spindle length-sensitive afferents from hip muscles and both interlimb coordination and gait selection is an active area of biomedical microelectrochemical systems research. Future tools must be flexible and configurable, given the evolving understanding of both neuroscience mechanisms and clinical outcomes. We describe a thin-film, three-dimensional (3D) opto-electro array with 4 addressable microscale light-emitting diodes for surface illumination of dorsal root ganglions (DRGs) and 9 penetrating electrodes for simultaneous recordings of light-evoked DRG activities. Emerging optogenetic stimulation provides distinct advantages over electrical stimulation, such as cell-type specificity, sub-millisecond temporal precision, rapid reversibility, and suppressed electrical artifacts. Importantly, using the origami design concept, the array can be fabricated directly on a silicon wafer in a two-dimensional (2D) configuration, which can transform into a 3D structure by folding. The device fabrication involves multiple steps of polymerization, photolithography, thermal evaporation of metal, wet etching of metal, and plasm etching of polymer. Polyimide is chosen as the substrate and packaging material, and a Ti/Au stack is used to form conductive patterns, e.g., electrodes, traces, and contact pads. During device release, the penetrating microelectrode probes were gravitational and buoyant lifted into a vertical position, and maintained vertically relying on both the plastic deformation of their base hinge regions and base package material. Currently, we have completed device fabrication, and will assemble the device with an external electronic headstage and test the integrated system in cat models to validate its capability for optogenetic stimulation and electrophysiology recordings from DRGs. This work will pave the way for neuroscience research of reversible modulation of proprioceptive afferent activities. The tool could also be used for delivering proprioceptive feedback to limb prosthetic users and/or patients with sensory neuropathies in the future.

Title: Flexible Parylene photonic optoelectrodes for high-resolution neural recording and stimulation

Authors: *J. W. REDDY, M. YUAN, V. JAIN, Z. AHMED, M. CHAMANZAR;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: High resolution light delivery deep into the brain tissue with high spatial resolution, as well as collocated electrophysiology recording for local neural circuit interrogation are essential tools for experimental neuroscience. Optical techniques such as optogenetics or structural and functional imaging enable cell-type specific neural circuit analysis. Implantable photonic waveguide arrays can passively confine and guide light to target regions in the brain. Modern multimodal, microfabricated neural probes integrate light delivery and electrical recording functionality in a small footprint to minimize tissue damage. Flexible, polymer material platforms are preferred for chronic experiments to minimize damage to tissue due to tethering forces and micromotions. Here, we demonstrate a novel multimodal neural probe architecture consisting of flexible, biocompatible Parylene photonic waveguides for optogenetic stimulation and collocated recording electrodes for simultaneous electrophysiology readout. The Parylene photonic waveguides are broadband and operate over a wide range of wavelengths (λ; = 450, 532, 633, 680 nm). The input/output coupling via integrated micromirrors enables illumination volumes normal to the probe surface, collocated with the recording volume. We demonstrate 1.3 cm neural probes with 1-6 individually-addressable optical waveguide and 1-6 recording electrode channels in a linear array with 200 micrometer pitch along the probe shank. The 9 micrometer diameter electrodes show an impedance of 4.5 MOhm at 1 kHz, which is reduced to 106 KOhm at 1 kHz via PEDOT:PSS electroplating. We demonstrate compact optical packaging with optical fiber arrays and bare chip vertical cavity surface emitting laser (VCSEL) diodes, and electrical packaging with commercial neural amplifier headstages (Intan RHD2132). In vivo implantation of the flexible probes is demonstrated via attachment to a tungsten microwire shuttle using the polyethylene glycol (PEG) bioresorbable coating. The probe functionality is validated in vivo in mice.

Title: Response characteristics of hybrid optogenetic and electrical stimulation in rat peripheral motor nerves

Authors: E. M. MORAVEC[1,2], A. S. PAVLENKO[1], *J. WILLIAMS[1,3,2];
[1]Biomed. Engin., Marquette Univ., Milwaukee, WI; [2]Biomed. Engin., [3]Neurosurg., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Optogenetic stimulation of peripheral motor nerves is a promising alternative to electrical stimulation for reanimating paralyzed muscles. This technique allows motor nerves to be stimulated with light after using a viral vector to induce expression of light sensitive ion channels, or opsins, along the nerve. Optical stimulation offers advantages over functional electrical stimulation including natural muscle recruitment order and stimulation target specificity. However, it is not as well characterized as electrical stimulation and suffers from challenges that may impact its clinical viability. The level of opsin expression and inherent opsin kinetics limit the strength of muscle responses to optical stimulation as well as the frequency at which these responses can be maintained. Improvement in both areas is essential for producing functional movements with optical stimulation. To address these issues, this study aimed to characterize EMG responses to optical stimulation, optimize optical stimulation parameters, and enhance optical EMG responses with subthreshold electrical stimulation. We injected the tibialis anterior muscle of rats with an adeno-associated virus (AAV) carrying the gene for channel rhodopsin (ChR2), and used stimulation of the corresponding peroneal nerve as the basis for the experiments. First, we found that EMG response latency after optical stimulation was a function of the intensity of optical stimulation but was not dependent on optical pulse width. Second, we found that optical stimulation intensity and pulse width also impacted EMG coupling to optical pulses at higher pulse train frequencies. Finally, subthreshold electrical stimulation paired with optical stimulation was able to modify EMG responses to both a single optical pulse and high frequency pulse trains, though the effect of combining these two modes of stimulation was highly dependent on their relative timing. The results of this study highlight unique challenges of optical stimulation while also providing pathways to address these issues so that optical stimulation may become a clinically viable option for muscle stimulation.

Abstract: The ability to selectively perturb and record hundreds to thousands of neurons across large brain circuits can provide the technological ground for innovative experimental tools to study brain circuits in health and disease. Although optogenetics is nowadays a widely used technique to study brain circuits by selectively controlling the activity of neurons through the expression expression of light-modulated opsins, electrode technologies for sub-millisecond recordings of light-evoked activities are typically limited to a few tens of neurons. With respect to conventional Si-probes realized only by MEMs processes, the recent introduction of implantable active neural probes based on microstructured monolithic complementary metal-oxide semiconductor (CMOS) devices (i.e. NeuroPixels, NeuroSeeker and SiNAPS) is opening new perspectives by enabling to scale up by several orders of magnitude the number of recorded neurons within and across multiple brain circuits. To this aim, previously reported studies have demonstrated the possibility of combining Neuropixels recordings with optogenetic stimulation of both excitatory and inhibitory neural populations in vivo. However, SiNAPS probes are built on a radically different circuit architecture that has not been shown yet in combination with optogenetic light stimulation. SiNAPS neural probes are based on a modular on-chip circuitry architecture and on DC-coupled front-ends. Rather than integrating front-end amplifiers at the base of the probe,as in NeuroPixels and NeuroSeeker, our SiNAPS probes integrate front-ends underneath each single electrode. This one-to-one correspondence between electrodes and amplifiers allows continuously recording at sub-millisecond resolution from all the integrated electrodes while defining an architecture that simplifies the realization of probes with different layouts and number of recording sites. Initially demonstrated with a 512 electrode single-shank probe layout, we recently presented a 4-shank version with 1024 electrodes (electrode pitch 28 µm) that was realized in standard 180 nm CMOS technology by “copy and paste” the basic circuit modules. Here, we will present and discuss first results obtained by combining optogenetics with electrical recordings using a 4-shank SiNAPS probe with 1024 simultaneously recording electrodes. Specifically, our preliminary recordings report light-evoked neural activity and confirm the possibility of exploiting SiNAPS probes for investigating optogenetic response dynamics with a large spatial coverage, both at the single-neuron and large-scale network level with an unprecedented spatiotemporal resolution.

Title: Closed-loop optogenetic control of single unit phase locking to network oscillations in behaving mice

Authors: *Z. CHRISTENSON WICK, P. A. PHILIPSBERG, S. I. LAMSIFER, T. SHUMAN; Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The precise timing of neuronal spiking relative to the brain's endogenous oscillations (i.e., phase locking) has long been hypothesized to coordinate cognitive processes and maintain excitatory-inhibitory homeostasis. Though its causal role has never been tested, disruptions in phase locking have been described in several neurological diseases with associated cognitive deficits, including epilepsy. We predict that this loss of phase locking may prevent maintenance of excitatory-inhibitory homeostasis and exacerbate pathological neuronal activity such as seizures. Further, we predict that disruptions in phase locking may prevent effective information transfer between regions. We developed a closed-loop optogenetic system to bidirectionally control the phase locking of hippocampal neurons to ongoing endogenous theta oscillations. We performed in vivo silicon probe recordings in male and female head-fixed control and epileptic mice navigating a virtual track, identified the baseline phase preference of parvalbumin- or somatostatin-expressing interneurons within the hippocampus, and applied our closed-loop system to phase lock their spiking to the trough or peak of hippocampal theta. This closed-loop system uses real-time signal processing to detect the target phase and deliver bidirectional photo-manipulation within milliseconds; it is capable of targeting any phase of theta with high precision. Using this system in awake, behaving mice, we have altered the phase locked firing of hippocampal interneurons and have preliminary data suggesting that altering their phase locking may impact epileptiform activity. This closed-loop system outperforms existing tools and will enable us to continue investigating the causal role of precise single-unit phase locking to network-wide oscillations with many versatile applications.

Title: Hippocampal Power Spectrum Responses to Irregular Optogenetic Stimulation Parameter Spaces

Authors: *E. R. COLE[1], T. E. EGGERS[2], N. G. LAXPATI[2], M. J. CONNOLLY[3], M. C. GOMBOLAY[4], R. E. GROSS[2];

Abstract: Introduction: Brain stimulation has become a fundamental tool for treating and understanding the mechanisms of neurological diseases, such as Parkinson's disease, epilepsy, and more. One key challenge in delivering effective brain stimulation is choosing the stimulation parameters (such as the amplitude, frequency, contact configuration, and pulse width) that induce a desired change in symptoms, behavior, or neural activity. Most clinical and translational studies use constant-frequency pulses of stimulation, but recent evidence suggests that irregular temporal stimulation patterns can produce unique changes in neural activity and also lead to better therapy in various clinical applications. Here, we comprehensively evaluate several optogenetic stimulation parameter spaces, report their differing effects on hippocampal LFP spectral activity, and present a machine learning strategy using Bayesian optimization to select parameters that induce a desired multi-band change in the power spectrum.
Methods: Sprague-Dawley rats (N=4) were prepared for pan-neuronal excitatory optogenetic stimulation via adeno-associated virus in the medial septum (hSyn-ChR2) and 16-channel LFP recording in the hippocampus, and we swept the following parameter spaces with grid and random search (>1000 trials per subject): Standard pulse train: Constant-frequency pulsatile stimulation.Nested pulse train: Pulsatile stimulation modulated by a slow on/off period.Sinusoid: Sinusoidal time-series of light power.Summed sinusoid: Sum of two different-frequency sinusoids.Poisson: Pulsatile pattern with an inter-pulse interval drawn from a Poisson distribution.
Results: Via dimensionality reduction analysis, we show that these parameter spaces produce similar effects on low gamma (32-50 Hz) activity, with key differences in driving theta (4-10 Hz) activity and modulating the combination of low and high-frequency activity throughout the power spectrum. We compare these induced spectral patterns to LFP activity recorded during two natural conditions (exploratory and quiescent behavior), and describe two strategies to represent the complete power spectrum as a single objective function for shaping multispectral neural responses: by computing hand-crafted features or learning features through dimensionality reduction on the power spectrum, then quantifying a distance metric between induced and desired features.
Conclusion: The results of this comprehensive evaluation of various parameter spaces can preliminarily guide the selection of stimulation parameters based on spectral biomarkers in translational and clinical applications.

Title: The role of the anterior insular cortex to dorsolateral striatum in modulating binge alcohol consumption

Authors: *D. HAGGERTY, B. MUÑOZ, B. ATWOOD;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Many drugs of abuse, including alcohol, affect neurotransmission in the dorsal striatum by altering glutamatergic signaling. For example, alcohol specifically ablates long-term synaptic depression (LTD) at glutamatergic synapses in the dorsolateral striatum (DLS). This specific type of LTD is mediated by μ-opioid receptors (mOP-LTD) exclusively on inputs from the anterior insular cortex (AIC). However, the behavioral effects of mOP-LTD and other types of drug-induced synaptic plasticity changes at AIC inputs to the DLS remain unknown. Here we show that photoexcitation of AIC to DLS projecting neurons alter consumption of binge-like levels of alcohol during Drinking in the Dark. Using wireless, in-vivo, closed-loop optogenetics to photoexcite AIC terminals in the DLS during alcohol consumption behaviors, we describe how modulating DLS inputs from the AIC can alter alcohol drinking behaviors, drinking microstructure, and decrease alcohol consumption levels across six weeks of Drinking in the Dark. Furthermore, photoexciting AIC inputs into the DLS only altered synaptic plasticity at AIC-DLS synapses that had been exposed to alcohol, not water during Drinking in the Dark sessions. These findings suggest that AIC to DLS projecting neurons may be uniquely sensitive to alcohol induced synaptic plasticity changes that correlate with alterations in alcohol consummatory behaviors. This work also indicates that insular cortex synapses in the DLS may be key drug targets for affecting the development of alcohol-induced neuroadaptations.

Abstract: Establishing causal links between specific patterns of neural activity, sensory computation, and behavior requires the ability to simultaneously monitor and manipulate neural activity with cellular resolution. Systems that combine 2-photon calcium imaging and targeted photostimulation provide such an approach. These all-optical approaches require co-expression of a calcium indicator and a potent, soma-targeted excitatory opsin construct. This has so far been achieved in the mammalian brain through viral transduction. However, this invasive procedure results in focal, variable expression that often becomes toxic over time. To overcome these challenges, we developed and validated a Cre-reporter mouse ('Ai203') that conditionally expresses a soma-localized opsin, ChroME, fused directly to GCaMP7s. 1- or 2-photon illumination of expressing neurons *in vitro* and *in vivo* produces powerful activation comparable to viral expression. The novel soma-enriched, membrane-bound GCaMP7s is a potent calcium-sensing tool that provides sensitive measurements of neural activity. Mice expressing Ai203 in cortical excitatory neurons have normal visual responses in V1 neurons and normal performance in a cortex-dependent operant visual task, indicating that transgenic expression of the opsin and GCaMP7s does not compromise circuit function. Additionally, we demonstrate that the Ai203 line is useful for high-throughput, high-resolution 2-photon synaptic connectivity mapping. This new transgenic line will facilitate the study of neural circuits by providing a flexible, convenient, and stable expression mechanism for combined optogenetic manipulation and functional imaging of large neural populations.

Title: Novel biocompatible probe design for optogenetics

Authors: *M. ANDERSEN[1,2], L. WALLMAN[2], L. PETTERSSON[2], O. KIEHN[1], J. SCHOUENBORG[2,3];
[1]Dept. of Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [2]Neuronano Res. Center, Dept. of Exptl. Medicine, Lund Univ., Lund, Sweden; [3]NanoLund, Lund Univ., Lund, Sweden

Abstract: Optogenetics has increased our knowledge of neural network function by its ability to selectively manipulate well-defined neuronal populations. However, reaching deep brain nuclei with light is difficult because of scattering and absorption of the emitted light, which makes implantation of optical fibers necessary. The implantation of stiff and rigid materials like glass and metal in the nervous system is known to result in a loss of nearby neurons and glial responses resembling infarct-like reactions, which likely strongly affects neuronal activity. It would therefore be valuable to develop highly flexible probes for optogenetics that can be used in combination with long-lasting electrophysiological recordings. The aim of the present work was thus to develop an implantable and biocompatible light guide in polydimethylsiloxane (PDMS) and to evaluate its light transmission properties and effects on the brain tissue in rats. We have designed and tested a mono-fiber pulled vertically from PDMS. The fiber was pulled from a drop of semi-cured Sylgard 184 (3:1 ratio) at room temperature. We focused on two diameters: 75 µm and 120 µm. Any desired diameter is, however, possible to construct using our method. The developed PDMS fibres were compared with optic glass fibers with respect to tissue reactions and neuronal responses to light in virally channelrhodopsin (ChR2) transfected rat hippocampus *in vivo*. Using immunohistochemistry of the implanted site we show an improved biocompability of PDMS over glass (core: pure silica (105µm), cladding: fluorine-doped silica (10µm)) of equal size fibers with respect to a lower ED1 staining close to the implant. Using extracellular acute recordings, we demonstrate that the developed single layer PDMS fibers (using the tissue as cladding) transmit enough light to activate ChR2 and generate action potentials in rat hippocampus *in vivo*. Our development and demonstration of *in vivo* functionality of highly biocompatible optical fibers provides the opportunity to deliver light with less damage to the area of interest. When combined with biocompatible recording electrodes and

transgenic technology these PDMS optical waveguides gives the ability to perform longitudinal single unit recordings from phototagged neurons in nearly intact areas.

Title: Maternal intake of Ganoderma tsugae benefits in brain development and cognitive function of the offspring in Sprague-Dawley rats

Authors: *C.-Y. TSENG;
Biomed. Engin., Chung Yuan Christian Univ., Chungli City, Taiwan

Abstract: Maternal malnutrition, exposure to environmental hormones, heavy metals, or environmental pollutants cause damage to fetal brain development. Antioxidants, anti-inflammatory agents, and nutraceuticals have been shown to protect or mitigate the adverse factors affecting maternal and child health. Our previous research showed that *Ganoderma microsporum* immunomodulatory proteins reduce the impacts of exposure to $PM_{2.5}$ during pregnancy in Sprague-Dawley (SD) rats on their offspring's brain development through immunomodulation. However, most of the literature focuses on how to reverse or prevent abnormal brain development, and few scholars explore whether these anti-inflammatory/antioxidants or nutraceuticals would benefit fetal brain development, promote neurogenesis, and improve nerve function? Humans may have retained attitudes about this research because of safety concerns during pregnancy, but literature search engines show few along with animal studies. Therefore, this study plan to take the lead in evaluating whether supplementing nutraceuticals during pregnancy can improve fetal brain development and nerve function. We adopted *Ganoderma tsugae* (GTDE) in this study, which has the best antioxidant function in Reishi, a typical and traditional Chinses medicine. We applied less than a thousand times the dose of no observed adverse effect levels of GTDE (200 μg/kg) during pregnancy. We found that maternal gavage of GTDE effectively enhances the rat fetal cortical neurogenesis, especially in the lateral ventricular/ventricular zone. The mRNA PCR microarray analysis of the fetal cortex shows nine genes that significantly increased due to maternal exposure to GTDE, including Bmp8a, Drd2, Egf, Gdnf, Hes1, Ndp, Pax2, Pax3, and Sox2. These genes play essential roles in neurogenesis. Moreover, the maternal application of GTDE promotes the

cognitive function of the offspring from working memory analysis. Here we present the first report showing that low doses of *Ganoderma tsugae* can effectively promote fetal brain development and offspring's cognitive function.

Title: Myomegalin regulates Hedgehog pathway by controlling PDE4D at the centrosome

Authors: *J. ZHANG[1], H. PENG[1], A. YA[1,3], W. MA[1], S. VILLA[1], S. SUKENIK[2], X. GE[1]; [1]Mol. and Cell Biol., [2]Chem. and Chem. Biol., Univ. of California, Merced, Merced, CA; [3]Mol. and Cell Biol., Dartmouth Col., Hanover, NH

Abstract: Mutations in the Hedgehog (Hh) signaling are implicated in birth defects and cancers, including medulloblastoma, one of the most malignant pediatric brain tumors. Current Hh inhibitors face the challenge of drug resistance and tumor relapse, urging new insights in the Hh pathway regulation. Our previous study revealed how PDE4D (Phosphodiesterase 4D) controls global levels of cAMP in the cytoplasm to positively regulate Hh signaling; in the present study we found that a specific isoform PDE4D3 is tethered to the centrosome by myomegalin, a centrosome/Golgi associated protein. CRISPR knockout of Myomegalin dislocates PDE4D3 from the centrosome, leading to local PKA over-activation and inhibition of the Hh signaling, leaving other PKA-related pathways unaffected. Targeting a FRET (fluorescence resonance energy transfer) based PKA sensor, AKAR4, to the centrosome, we detected a constitutively high local PKA activity, suppressing the Hh signaling activity. Myomegalin loss suppresses the proliferation of granule neuron precursors, and blocks the growth of medulloblastoma in mouse model. Our findings specify a new regulatory mechanism of the Hh pathway, and highlight an exciting therapeutic avenue for Hh-related cancers with reduced side effects.

Title: Is the effect of serotonin on neurogenesis concentration dependent?

Authors: *A. AGYEMANG, B. S. BELTZ, P. CHAVES DA SILVA, A. EDWARDS; Neurosci. Program, Wellesley Col., Wellesley, MA

Abstract: Is the Effect of Serotonin on Neurogenesis Concentration Dependent?August Agyemang, Barbara Beltz and Paula Chaves da Silva*Wellesley College, 106 Central Street, Wellesley, Massachusetts, 02481vagyeman@wellesley.edu***Abstract**Adult neurogenesis, a process observed in both vertebrates and invertebrates, is the birth and integration of new neurons in the adult brain. In many crustaceans, including crayfish, neurogenesis occurs throughout life. Newborn neurons are produced by progenitor cells that congregate in a neurogenic niche. These cells proliferate, and descendants travel to proliferation zones in cell clusters 9 and 10 (CL9 and CL10) that innervate into the olfactory and accessory lobes. The niche progenitor cells originate from an extrinsic source. Studies indicate that the immune system supplies hemocytes that replenish these cells. Thus, the factors that affect the immune system, such as diet, exercise, and neurotransmitter activity, also affect neurogenic activity in the niche. One such neurotransmitter, the monoamine serotonin (5-HT), has been identified as a regulator of neurogenesis. 5-HT influences the attraction of hemocytes to the niche as well as the proliferation of the precursor cells in CL10. Serotonin (5×10^{-9}M)results in an increase in hemocyte counts in the blood and niche cell counts compared with control conditions. With knowledge of this interaction, this study investigates the effects of varying concentrations of serotonin on the early stages of neurogenesis *in vivo*; total hemocyte counts (THC), the total number of niche cells, and the number of proliferating cells in the niche will be assessed. *Procambarus acutus* crayfish were incubated in different concentrations of5-HT, [5×10^{-10}M, 5×10^{-8}M, 5×10^{-6}M], for 36 hours.Additionally, the animals were injected with bromodeoxyuridine (BrdU), a proliferation marker, 12 hours after incubation. We hypothesize that as 5HT concentration increases, so will neurogenic activity in the niche.These studies will test whether serotonin influences the crayfish niche in a concentration-dependent manner.

Title: Il10 and inflammatory resolution are critical element of photoreceptor regeneration in zebrafish

Authors: *M. NAGASHIMA, P. F. HITCHCOCK;
Univ. of Michigan Dept. of Ophthalmology and Visual Sci., Ann Arbor, MI

Abstract: In the retina of zebrafish, acute inflammation is required to initiate reprogramming and proliferation of the intrinsic stem cells, Müller glia. Reprogrammed Müller glia divide asymmetrically to produce retinal progenitors, which rapidly proliferate and differentiate to replace the ablated neurons. Chronic inflammation, however, is detrimental. Mechanisms governing the resolution of inflammation during the regeneration of photoreceptors remain to be elucidated. Il10 is a classical anti-inflammatory cytokine that plays a critical role in resolving inflammation and promoting wound healing. In this study, we examine the expression and function of il10 in the zebrafish retina following the death of photoreceptors. We also assess how dysregulation of inflammatory resolution affects multi-step process of retinal regeneration. Following photolytic lesion, *il10* is significantly upregulated by 2 days post lesion and returns to baseline by 5 days. In the absence of Il10, expression of the pro-inflammatory cytokines, tnf-a, tnf-b, and il1b, are significantly elevated. These data are consistent with that il10 is a potent anti-inflammatory cytokine and indicate that Il10 suppresses the production of pro-inflammatory cytokines following acute death of photoreceptors. At 5 to 7 days post lesion, when in wild-type animals photoreceptor progenitors exit the cell cycle, proliferation in the il10 mutants remains significantly elevated. These results suggest that il10-mediated inflammatory resolution determines the magnitude of proliferation among the Müller glia-derived progenitors following the acute death of photoreceptors.

Abstract: In zebrafish, visual system growth and development is a life-long process. Specialized stem cell niches established early in eye and brain development support life-long growth of each retina and corresponding optic tectal lobe. Coordinated growth of these tissues ensures that accurate retinotopic mapping is maintained as new neurons are added as the visual system grows. Studies of adult fishes have provided evidence that survival, proliferation, and differentiation of cells in the optic tectum is correlated with retinal innervation, raising the possibility that retinal axons provide crucial information to control stem and progenitor cell behaviors in the optic tectum. To explore how retinal innervation influences optic tectum growth in larval zebrafish, we examined brains lacking innervation from (i) both eyes as a result of the *lakritz* mutation and (ii) one eye as a result of surgical eye removal, and then compared them with wild-type larvae with two eyes. We observed elevated cell death in non-innervated and denervated optic tecta lobes only after 6 days post-fertilization (dpf). In addition, we uncovered that optic tecta lacking innervation contained fewer *sox2+* stem cells and a smaller proportion of proliferating progenitors. To test how much light-evoked retinal activity contributes to proliferation and survival in the optic tectum, we reared fish from 1-9 dpf in the dark and then asked how optic tectal cells in innervated and non-innervated tecta behave. We found that innervation was still able to promote survival and proliferation, albeit to a lesser extent, when fish were reared in the dark. Taken together our data led us to examine whether trophic factor(s) were being provided by the optic nerve, irrespective of light-evoked retinal activity. Combining bulk RNA-Sequencing and candidate gene approaches, we identified innervation-dependent Wnt/B-catenin pathway activity in larval zebrafish optic tecta, raising the possibility that a Wnt, may travel along the optic nerve and serve as a trophic cue for tectal stem and progenitor cells.

Title: Age-related distribution of oligodendrocytes in the brain of the male japanese quail (curtonix japonica)

Authors: *A. M. SHEHU[1,2], P. MAZENGENYA[3,1], P. NKOMOZEPI[4], A. O. IHUNWO[1]; [1]Sch. of Anatom. Sci., Univ. of the Witwatersrand, Johannesburg, South Africa; [2]Human Anat., Federal Univ. Dutse, Jigawa, Nigeria; [3]Col. of Med., Ajman Univ., Ajman, United Arab Emirates; [4]Human Anat. and Physiol., Univ. of Johannesburg, Johannesburg, South Africa

Abstract: Gliogenesis involves the generation of new glial cells (astrocytes and oligodendrocytes) from neural stem cell or progenitor cells (NSPC) in both developing and adult individuals. Oligodendrocytes are cells accountable for myelin production and responsible for maintaining the electrical impulse through the myelin sheath in neuronal axons. However, there is a paucity of literature on the life history changes in the expression of oligodendrocyte transcription factor 2 (OLIG2) in the avian species. We use myelin silver stain and oligodendrocyte transcription factor 2 (OLIG2) to study the distribution of oligodendrocytes, and in the juvenile, sub-adult and adult brain. The results showed that the myelin stain exhibited an increase in the density of myelinated fibres as development progresses but showed a decline in the adult brain. There was a high density of positive Olig2 immunoreactivity (OLIG2-ir) in the white matter and fibre tracts (optic tectum, optic tract, anterior and posterior commissure and tectal ventricle) arranged in rows while those found in the grey matter are scattered (pallium, Subpallium and hippocampus). A few moderate OLIG2-ir were observed in the caudal area of the ventricular zone. The density level of the OLIG2-ir oligodendrocytes in the quail brain corresponds to the regions where the myelination level is on the high. The presence of OLIG2 in the Japanese quail brain indicates that the protein plays a critical role in the production, development and differentiation of oligodendrocytes. In conclusion, the three week juvenile and six week sub-adult stages presented the highest density and more regions for oligodendrocytes progenitor cells. The oligodendrocytes transcription factor 2 in the Japanese quail brain similarly decline with post-hatching age.

Title: Hippocampal neural stem cell proliferation and survival are increased in the adult brain during a viral infection

Authors: *M. N. CHANDWANI[1], Y. S. KAMTE[1], M. E. HEMERSON[2], L. A. O'DONNELL[1]; [1]Dept. of Pharmacol., Duquesne Univ. Grad. school of Pharmaceut. sciences, Pittsburgh, PA; [2]High Point Univ., High Point, NC

Abstract: Viral infections in the adult central nervous system (CNS) can cause physiological changes despite successful viral control. Neural stem cells (NSCs) may be altered during an infection either by direct infection and/or the anti-viral immune response, potentially contributing to changes in neurological function. To define the components of the anti-viral immunity that regulate NSCs, we utilized a mouse model of CNS measles virus (MV) infection. In this model, human CD46+ (a MV receptor) is expressed only on mature neurons, restricting MV to neurons and sparing the NSCs from infection. Using this model, we are assessing the effects of the anti-viral immune response on NSC activity in the adult brain in the context of successful control of the virus. Two-month-old mice were infected with MV, and flow cytometry was conducted at 7 and 60 days post infection (DPI) to quantify the NSC, neuronal, and glial populations. NSC numbers (Nestin+) increased at 7 and 60 dpi in the hippocampus. NSC proliferation (Nestin+BrdU+) trended towards an increase during and after infection, implying long-term changes in NSC activity. Mature neurons (βIII-tubulin+) were reduced at 7 dpi, possibly due to infection-mediated cell death, but then recovered to basal levels by 60 dpi. Neurogenesis (Doublecortin+BrdU+) was increased in the hippocampus at 7dpi, which may account for the recovery of mature neurons at 60 dpi. NSC proliferation and neurogenesis increased at 7 dpi in the SVZ, but both proliferation and neurogenesis were reduced at 60 dpi compared to uninfected controls. Thus, hippocampal NSC activity was increased at 7 and 60 dpi, whereas SVZ NSC activity was increased at 7 dpi but was reduced at 60 dpi. The SVZ has a higher viral load as compared to the hippocampus at 7 and 60 dpi, which could be driving these region-dependent differences in the outcome in NSCs. Immune cells such as microglia, T-cells, and B-cells were increased early in infection (7 dpi); however, only resident memory cytotoxic T-cells remain at 60 dpi after the infection is resolved. In the absence of the adaptive immunity (CD46+/Rag2-KO), NSCs increased during infection similarly to CD46+ mice. Microglia were upregulated in both CD46+ and CD46+/Rag2KO mice, and positively correlate with hippocampal NSCs and negatively correlate with the SVZ NSCs, suggesting that microglia may regulate NSC activity during infection. Current studies address the role of microglia in modulating NSC activity *in vivo* and *in vitro.* We are also assessing the long-term effects of the infection on learning and memory. These studies emphasize that NSCs experience enduring changes due to a successful anti-viral immune response in the adult brain.

Abstract: Preterm birth, especially prior to 34 weeks of gestation, is associated with disrupted development of the central nervous system and is a leading cause of childhood disability. The lower hippocampal volumes of children that were born preterm are of clinical interest because of the association with varying degree of memory impairment. We explored the molecular and cellular mechanisms of the lower hippocampal volumes using preterm pigs delivered via C-section at day 105 of gestation (91% of term and relevant to 32-week preterm infants) and reared in NICU settings for 10 days to term equivalent age. Newborn term pigs served as controls. Each experimental group included n=8 animals of both sexes. Ki67+ progenitors and Prox1+ neuronal populations were identified in the hippocampal dental gyrus by immunohistochemical staining and counted using unbiased stereological method. The numbers of Ki67+ and Prox1+cells in the dental gyrus of preterm pigs were decreased compared to control pigs. Proliferation of neural progenitors in the hippocampus of preterm pigs was reduced as well. The disturbances in dental gyrus neurogenesis may contribute to the long-term memory impairment. Importantly, the reduced neurogenesis in preterm pigs occurred without the presence of necrotizing enterocolitis or other diseases that frequently occur after preterm birth and are known to indirectly disrupt brain development. Our findings highlight the preterm pig as a translational model to study the consequences of premature birth on brain development, the underlying molecular mechanisms, and interventions aimed to mitigate the disrupted development and long-term disabilities. Title: Subventricular neural progenitor cells differentation is modulated by taurine via gaba receptors interaction

Authors: *N. GUTIÉRREZ[1], E. GRIEGO[1], E. J. GALVAN[1], L. OCHO-DE LA PAZ[2]; [1]CINVESTAV Sur, Mexico City, Mexico; [2]Facultad de Medicina, UNAM, Mexico City, Mexico

Abstract: Neurogenesis occurs throughout mammals' lives, in the regions composed of the hippocampal subgranular zone and the subventricular zone (SVZ) of lateral ventricles, and multiple extrinsic factors regulate this process. Taurine, a neuroactive factor, plays a central role in the proliferation, differentiation, and migration of neural progenitor cells. However, the mechanism of action of taurine is not well understood. Thus, we explored the effect of taurine on the differentiation process of SVZ neural progenitor cells through the interaction with GABA receptors. Immunofluorescence assays were performed on cells isolated from SVZ of CD1 mice (P8) in the absence or presence of taurine. Our results show that neural progenitor cells express Sox-2 and Nestin, both progenitor cell markers; however, no signal for DCX was observed, confirming that cells obtained from the SVZ are neural progenitors. In cultures exposed to differentiation conditions with taurine, the number of DCX+ cells was increased. Morphometric analysis revealed a significant difference in cell morphology. Compared to control and GABA-treated cells, taurine-treated cells exhibited a significant number of secondary and tertiary neurites, increased dendritic branching, and marked complexity in dendritic arborization. Taurine actions were sensitive to picrotoxin, indicating active participation of $GABA_A$ receptors. Also, we measured the electrophysiologic properties of the control, GABA-, and taurine-treated cells with patch-clamp whole cell recordings. Taurine-treated cells developed an electrophysiologic behavior (passive and active properties) akin to central neurons. Our results provide information regarding the role of taurine as a morphogen in the neurogenic processes throughout the interaction with GABA receptors and their role as a central player in the maturation processes of NPCs into functional neurons. This work represents an advance in the morphometric effect and suggests a functional effect of taurine in the neuronal differentiation process.

Abstract: Multiple genes that incur an increased risk of an autism diagnosis have been identified, however, some are still without studied animal models to uncover their impact on brain function. As more genes that contribute to autism are studied, distinct cellular hubs have been identified, including synaptic dynamics, nuclear regulation and cellular signaling. The latter is of particular interest, as there are several monogenic syndromes caused by genes implicated in autism, with known cellular signaling pathways that could be manipulated in future therapeutic approaches. One such syndrome, DeSanto-Shinawi syndrome (DESSH), is caused by mutations in the WW domain-containing adapter with Coiled Coil (*Wac*). Through its protein domains, *Wac* has been shown to positively regulate MTOR activity, one of the main signaling hubs that harbors many other genes implicated in autism. Wac can also mediate events within the nucleus. However, the function of *Wac* in the brain has not been studied.
We generated a conditional deletion of *Wac* in brain inhibitory cortical interneurons (CINs), a critical cell type known to be impacted by MTOR activity and implicated in autism. Our data reveal a critical role for *Wac* in regulating the proper number of CINs that populate the developing and adult cortex, with distinct impacts on different CIN subgroups. In addition, we found evidence for changes in brain excitability and neuron morphology that could underlie some of the cognitive symptoms associated with DESSH. Overall, our results provide a new genetic mouse model to study potential inroads into DESSH and cellular hubs implicated in autism biology.

Title: Differentiation of HT22 cells, an immortalized hippocampal-derived neuronal cell line, increases degrees of neuronal characteristics

Authors: E. FARRELL[1], J. CLARK[2], M. HORN[1], J. VALADEZ[1], C. WILLIAMS[2], *G. M. BEAUDOIN, III[3];
[1]Biol. and Neurosci., [2]Biol. and Chem., [3]Trinity Univ., San Antonio, TX

Abstract: HT22 cells are an SV40 transformed, immortalized mouse hippocampal neuron cell line. They are commonly used to study glutamate induced toxicity. Because they are immortalized, HT22 cells act very differently from true hippocampal neurons. HT22 cells have been used in multiple studies under the assumption that they operate similarly to primary cultured neurons, but that assumption may be invalid. We are characterizing the neuronal qualities of HT22 cells that are grown with sera and after switching to a neuron supporting media with N2 or B27 supplements. Additionally, the effects of nerve growth factor (NGF) and retinoic acid (RA) to further induce and support neuronal characteristics is being tested. The media supplements N2 and B27 are consistently used in the culturing of primary neurons and the differentiation of immortalized neurons. NGF has been shown to induce differentiation and structural changes in HT22 cells into neuronal cells. RA has been shown to regulate the CaMKIIα promoter. Differentiation is characterized via a variety of metrics. Activity of a late stage neuronal differentiation promoter, CaMKIIα, is assessed via expression of green fluorescent protein (GFP) and measured via confocal imaging. Because CaMKIIα is a neuron-specific promoter, quantifying its expression across differentiation conditions provides insight into how neuronal the cells become. Complexity of cell morphology, through extension of neurites, is evaluated via neurite analysis methods, including sholl analysis and tip counting. Cell cycle progression and apoptosis/necrosis levels are quantified using propidium iodide and annexin V staining and analyzed via flow cytometry. These cell cycle analyses are performed because differentiated neurons exhibit higher levels of apoptosis and are mitotically arrested. Finally, the maturation of a stable hyperpolarized membrane potential and expression of voltage-gated ion channels is assessed through electrophysiological recordings. Overall, results indicate that HT22 cells differentiated with a combination of N2 supplement, RA, and NGF show the highest degrees of neuronal characteristic when compared to undifferentiated cells. Additionally higher rates of apoptosis have been observed in cells differentiated with B27 supplement alone, however, rates of apoptosis appear to decrease with the addition of NGF and RA.

Title: Transcriptional and epigenetic regulation of neuronal differentiation and function reveals key epigenetic phenomena

Authors: *Y. ZHOU, S. RASHAD, K. NIIZUMA;
Tohoku Univ., Sendai, Japan

Abstract: Neuronal differentiation is a complex process. Although transcriptomic changes may be one of the key factors contributing to this complexity, a comprehensive analysis of transcriptomics and post-transcriptomics, including RNA stability, alternative splicing, and RNA binding proteins (RBPs) during this process is rarely explored. In order to decipher the whole landscape of transcriptomics and post-transcriptomic regulation underlying neuronal differentiation *in vitro*, we performed RNA sequencing and bioinformatic analyses on neural-like cells from SH-SY5Y human neuroblastoma cells, induced by retinoic acid and BDNF. Well-differentiated SH-SY5Y cells exhibited extensive neurite outgrowth and connections, and express mature neuronal markers. 728 differentially expressed genes (DEGs) were identified in differentiated cells compared to undifferentiated cells and Gene Ontology (GO) analysis revealed most DEGs were enriched in synaptic signaling and cell morphogenesis pathways, which was consistent with morphological changes of differentiated cells. At the RNA stability level, GO analysis showed a number of pathways including electron transport chain and glutathione metabolic process were differentially regulated. Mature neurons are known to be highly sensitive to oxidative stress. Our results suggest that this heightened sensitivity is regulated at the RNA stability level, and in return mRNA modifications and translation, rather than the transcriptional level. Differential exon usage analysis revealed enrichment in cellular component morphogenesis and cell junction organization, which was in line with DEGs enriched pathways. However, further analysis of local splice variants (LSV) showed splice type specific gene enrichment patterns that may affect neuronal function via distinct LSV dependent mechanisms. Importantly, genes with retention intron, alternative 5 and 3 prime splicing site exclusively clustered in the translation and translation initiation pathway, implicating the potential effect of AS on translation following neuronal maturation. Splice motif analysis was able to reveal enriched motifs for RBPs that regulate various splice types and can be further correlated to distinct functions or expression of these RBPs in neuronal differentiation and maturation. This study systematically explores the transcriptomics, epigenetics, and potential post-transcriptomics during neuronal differentiation, indicating an important role of RNA stability and AS in regulating neuronal differentiation and neuronal function and behavior, which can be a new insight into the molecular mechanism of neuronal differentiation.

Title: Dopaminergic interneuron diversity is restricted by the Kinase LKB1

Authors: *R. MACKIN, J. LIANG, C. BURGER, M. SAMUEL;
Baylor Col. of Med. Dept. of Neurosci., Houston, TX

Abstract: The mammalian central nervous system is comprised of thousands of distinct neuronal types, but even neurons within apparently uniform populations can display key functional differences. In particular, subtypes of dopamine neurons modulate circuits supporting motor function, cognition, and vision, and dysfunction or loss of these cells is associated with cognitive defects. Understanding what restricts the formation of closely related dopaminergic neurons may shed light on the unique susceptibility of subsets to disease. Using the murine retina, we show that the serine-threonine kinase LKB1 acts as a restrictive cue that limits dopaminergic neuron diversity. In wild type animals, dopaminergic amacrine interneurons are sparse, reside only in the inner nuclear layer, and are OFF laminating cells, responding to light decrements. Removing LKB1 from the retina markedly and specifically increases the numbers of dopaminergic amacrines (DACs) but not other amacrine cell types. Corresponding alterations in DAC cell body and synapse lamination accompany these changes. Subsets of newly generated DACs reside in the ganglion cell layer but retain amacrine cell markers and send neurites to the ON sublamina. DAC cellular and laminar alterations persist into adulthood. This process appears to be intrinsic to AC precursors, as removing LKB1 from AC fate specified cells but not from other neurons produces similar results. Together, these data suggest that a kinase cascade controlled by the serine-threonine LKB1 initiates neuron subtype specification and migration to restrict the development of diverse dopamine neuron subsets. Further, because newly generated ON DACs appear alike in many respects to their OFF laminating counterparts they may constitute a newly formed dopaminergic paramorphic pair.

Title: Scanning the RCOR1 corepressor on active chromatin: Is it actually a silencer of neuronal genes?

Authors: C. A. RIVERA[1,2,3], H.-G. LEE[1,2], A. LAPPALA[1,2], V. NOCHES[3], M. OLIVARES-COSTA[3], M. SOJBERG[3], J. T. LEE[1,2], *M. E. ANDRES[3];

Abstract: The transcriptional corepressor RCOR1 (CoREST) is recruited by the transcription factor REST to silence neuronal genes in non-neuronal tissues and neural stem cells. RCOR1 constitutes a chromatin-modifying complex as it allows the LSD1 and HDAC1/2 enzymes to erase transcriptionally-permissive histone modifications such as H3K4me2/1 and acetylation. We hypothesized that this complex must be actively acting in heterochromatin regions. Thus, we tested this hypothesis using bioinformatics, chromosome modeling, high-resolution microscopy, and biochemical studies in non-neuronal cells. Paradoxically, metagenomic analyses of RCOR1 chromatin occupancy showed exclusion of RCOR1 peaks from heterochromatin and enrichment at transcriptionally active chromatin of highly expressed genes. Furthermore, biochemical fractionations and high-resolution microscopy showed that RCOR1 was mainly enriched in euchromatin regions governed by histone acetylation. We also explored molecular mechanisms to characterize the role of RCOR1 in active regions by following its impact on transcriptional dynamics on short time scales, leading us to propose that RCOR1 has a novel and non-canonical role as a transcriptional dampener in euchromatin domains.

Abstract: Competing genetic programs underlie the generation of neuronal subtypes of the mammalian central nervous system. To date, the extent to which extrinsic cues influence these programs remains unknown. Using medial ganglionic eminences (MGEs), which give rise to populations of interneurons (INs) of different developmental timelines, we modeled the contribution of the environment in shaping and maintaining neuronal identity. First, we transplanted mouse MGE progenitors into 2D and 3D mouse and human cortical, MGE and thalamic co-culture models, including dissociated cells, organoids, organotypic and conditioned cultures. We detected different proportions of somatostatin (SST) or parvalbumin (PV)-positive IN descendents across models. We discovered that transplantation into 3D models of human, but not mouse, corticogenesis leads to the accelerated and efficient differentiation of PV-positive INs in a nonautonomous manner. We observed additional aspects of PV-identity, including increased soma size, the upregulation of molecular markers of PV maturation, the repression of SST-specific markers and the establishment of perineuronal nets. Finally, transplantation of early postmitotic SST-positive interneurons into human cortical organoids reprograms the molecular signature of transplanted INs to PV. Altogether, our work supports a model of multipotent progenitors in the MGE, whose cell bias is defined and refined by the environment.

Title: The transcription factor Satb2 mediates differentiation and circuit integration of pyramidal neurons in CA1

Authors: *M. HANSON, P. NAGARAJAN, J. WESTER;
Neurosci., Ohio State Univ., Columbus, OH

Abstract: Hippocampal pyramidal cells (PCs) in CA1 are essential for learning and memory. These cells can be parsed into deep (near stratum oriens) and superficial (near stratum radiatum) sublayers, each with distinct morphologies and intrinsic membrane properties. Furthermore, PCs in CA1 form biased circuits with local inhibitory interneurons. In particular, deep cells receive stronger inhibitory postsynaptic currents (IPSCs) from parvalbumin-expressing (PV+) basket cells than superficial cells. The mechanisms that regulate the differentiation of PCs into deep or superficial subtypes are currently unknown. Here, we test the hypothesis that the transcription factor *Satb2* is critical for differentiation of PCs in CA1. *Satb2* is necessary for the specification of neocortical pyramidal cell types and is preferentially expressed in superficial PCs of the hippocampus. We used the Emx1-cre mouse line to conditionally knock out (cKO) *Satb2* from pyramidal cells during early development (E10). We then used whole-cell patch clamp recording in acute hippocampal slices of juvenile mice to investigate differences between deep and superficial PCs and how early loss of *Satb2* altered their developmental trajectories. Among superficial PCs, we found that conditional *Satb2* knockout resulted in an increase in voltage sag and concomitant depolarization of the resting membrane potential. This depolarization of superficial PC membrane potential significantly reduced the difference between deep and superficial cells observed in control mice. To test biases in PV+ basket cell input, we further crossed our mice to a PV-tdTomato reporter line and performed paired whole-cell recordings between identified deep and superficial pyramidal cells and PV+ basket cells. Strikingly, we found that loss of *Satb2* abolished the bias in PV+ basket cell input strength to deep versus superficial PCs, as the amplitude of IPSCs observed in superficial cells increased to match those recorded in deep cells. Our data show that *Satb2* is necessary for the differentiation of CA1 PCs and their integration into circuits with local inhibitory interneurons dependent on their subtype identity.

Abstract: Neurogenesis is influenced by both internal and external cues during brain development and the addition of new neurons postnatally. These intrinsic and environmental factors shape neurogenesis partly through the modulation of local network activity, which in turn releases several neurotransmitters and growth factors. An important consequence of this activity-induced neurogenesis is illustrated in epilepsy where seizure-induced neurogenesis participates in the progression of epilepsy and the behavioural comorbidities. The lack of accessibility to the human brain at the cellular and molecular levels *ante mortem* impedes our understanding of the exact mechanisms of activity-induced neurogenesis, which could help identify mechanisms of epilepsy and potential targets for its treatment. Using cerebral spheroids derived from a human induced pluripotent stem cell line, we investigated the effect of increased neuronal activity on neurogenesis. We hypothesized that, when subjected to the pro-epileptic drug 4-aminopyridine (4AP), cerebral spheroids would demonstrate increased neurogenesis. Here, we show that 4AP increases neuronal activity but does not elicit seizure-like events in 3-month-old cerebral spheroids as measured with multi-electrode arrays, calcium imaging and expression of activity-dependent genes known to be dysregulated in human epileptic tissue. However, an increase in new neurons and a decrease in new glial cells formed after 4AP exposure is observed, suggesting that activity-induced neurogenesis can be recapitulated in human cerebral spheroids. We then explored a potential mechanism for this activity-induced neurogenesis by measuring the expression of several microRNAs that are involved in neurogenesis and dysregulated in epileptic tissue. We identified a decrease in the expression of miR-135a, a miRNA previously implicated in exercise-induced neurogenesis. MiR-135a is predicted to regulate the SMAD2/3 and BDNF pathways, and therefore represents a promising candidate for the regulation of activity-induced neurogenesis. Together, the results of this study suggest that cerebral spheroids are a suitable model to study some aspects of activity-induced neurogenesis, a phenomenon previously described in only the postnatal brain of humans and other animals.

Title: Molecular and morphological heterogeneity of immature neurons within the human paralaminar amygdala

Authors: *C. E. PAGE[1], S. BIAGIOTTI[1], M. A. NASCIMENTO[2], S. F. SORRELLS[1]; [1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Neurolog. Surgery, Univ. of California San Francisco, San Francisco, CA

Abstract: The amygdala is central to processing emotional stimuli and volumetric changes in amygdala nuclei are hallmarks of both neurotypical development and neuropsychiatric disorders. In humans, the amygdala increases in total volume and neuron number during childhood. We recently characterized a novel form of neurodevelopment in the paralaminar nuclei (PL) of the amygdala where a population of immature neurons delay their maturation and may contribute to postnatal amygdala growth. These immature neurons are found at all ages (birth-77 years), though the majority develop into excitatory neurons during childhood and adolescence (birth-19 years). When immature, they are small, have compacted chromatin, and express the immature markers doublecortin (DCX) and polysialylated neural cell adhesion molecule (PSA-NCAM), which they stop expressing as they mature. During this investigation we also noticed diversity in morphology and marker expression among these cells. The majority of immature PL neurons are connected to large axonal projections which we mapped across the medial temporal lobe. In addition, a small subset are not connected to projections and instead have migratory morphology. As they mature, PL neurons express markers indicative of several different neuronal identities, suggesting additional heterogeneity in the types of neurons formed or possibly different stages of their maturation. We also re-analyzed single nuclei RNA-sequencing (snRNA-seq) data from amygdala samples at 4-15 years of age and find additional evidence of heterogeneity of the immature population. Within the cluster of immature neurons from these samples we further identify five distinct subpopulations. We conclude that, rather than being a homogenous population, some immature neurons in the human PL develop into projection neurons while others retain a migratory phenotype, and different subsets express distinct molecular markers.

Understanding the heterogeneous identities of these neurons is essential for gaining insight into their neurotypical function and potential alteration in neuropsychiatric disease.

Title: Presence and possible function of miRNA-8 in the echinoderm radial nerve cord

Authors: *Y. MIRANDA-NEGRON[1], A. MORALES-RIVERA[2], E. QUESADA-DIAZ[2], R. GARCIA-ROSARIO[2], S. CRUZ-GONZALEZ[2], J. E. GARCIA-ARRARAS[3];

Abstract: For decades, scientist have employed extensive resources to elucidate important gene regulators involved in the process of nerve tissue regeneration. Regenerative competent organisms have been studied to learn how to overcome the regeneration limitations present in mammals. One of these organisms is our model system, the sea cucumber, *Holothuria glaberrima*. Here we explore the possible role of miRNA-8 as a molecular driver involved in the regeneration of the radial nerve cord (RNC) of this echinoderm. MicroRNA-8 (miRNA-8) has been shown to be responsible for cell proliferation, neuroblast transition and differentiation to neuron-like cells in the nervous system of various animal species. We now report the identification of an echinoderm miRNA-8 homolog stem-loop in transcriptomes of *H. glaberrima*. The sequence is highly similar to that of the sea urchin *S. purpuratus* showing 82% (61/74) identity. Moreover, a comparison of the holothurian miR-8 stem-loop with that of the human miR200a sequence showed 58% (54/93) identity and two possible mature miRNAs sequences with an identity of 77 % to miR-200a and 86% to miR200c of humans. Using RNA sequencing techniques and a novel *in vitro* protocol of RNC explants we show that miRNA-8 is differentially expressed in the holothurian RNC following injury. Changes in miRNA-8 take place during the period that corresponds to the dedifferentiation of radial glia-like cells, the initial process in the regeneration of the holothurian nervous system. Ongoing experiments are focused on the knockdown of miRNA-8 in the RNC explants as to determine its role during

regeneration. The effect of miRNA-8 depletion is being determined by cellular proliferation, dedifferentiation, and apoptosis analyses. Our results using this miRNA-RNAi technique will provide important technical and theoretical information on the role of miRNA-8 and toward explaining the amazing regenerative capacities of echinoderms.

Title: Representation of mPFC axonal efferents in the thalamic nucleus reuniens in a rodent model of FASD

Authors: *I. SMITH, Z. GURSKY, A. KLINTSOVA;
Univ. of Delaware, Newark, DE

Abstract: Alcohol exposure (AE) during the prenatal period can result in fetal alcohol spectrum disorders (FASDs), a prevalent yet completely preventable developmental disorder. One of the prominent deficits of FASDs is impaired executive functioning (EF). Spatial working memory (SWM), an integral part of EF, relies on the coordination of activity between the medial prefrontal cortex (mPFC) and hippocampus (HPC) by the thalamic nucleus reuniens (Re), a structure that has been shown to be damaged following high-dose binge AE in a rodent model of third trimester alcohol exposure (Gursky, Savage, & Klintsova, 2019). Layer 5 mPFC neurons do not project directly to HPC, but rather communicate with the HPC via a disynaptic pathway where they first synapse with neurons in Re, and axons of those neurons go on to make contacts with CA1 neurons in HPC. This experiment investigated the effect of binge AE (5.25 g/kg/day, two doses 2 hours apart) during postnatal days 4-9 (PD4-9) on prefrontal axonal projections to Re in male and female Long Evans rat pups. Between PD 42-49, 400 nL of a fluorescent anterograde viral tracer (AAV5-CAG-tdT) was infused into the left mPFC of AE rats (n=10) and sham intubated (SI) rats (n=7). After three weeks survival on PD70, animals were perfused, and brains were extracted and postfixed followed by sectioning on cryostat in preparation for fluorescence microscopy. Hoechst33342 was applied to stain cell nuclei in order to locate areas of interest. Unbiased stereology was performed using the StereoInvestigator software (MBF Biosciences) to estimate injection volume, Re volume (Cavalieri probe), and cumulative length

of mPFC-originating axonal terminals within Re (Spaceballs probe). No significant main or interaction effects of sex were found, thus data were collapsed across sex for remaining analyses. Independent samples t-tests revealed significant main effects of postnatal treatment on Re volume [$t_{15} = 2.372$, $p = 0.0315$] and cumulative length of mPFC-originating axon terminals in Re [$t_{14} = 3.198$, $p = 0.0064$]. AE reduced the cumulative length of mPFC-originating axon terminals in Re, as well as overall Re volume. This ongoing experiment will help to better understand the structural basis for how AE effects mPFC-Re-HPC connectivity and subsequent EF deficits associated with FASDs. This study is supported by NIAAA1 R21 AA026613-01 and 1 R01 AA027269-01 to AYK.

Title: A running start: histologically exploring the therapeutic potential of adolescent aerobic exercise to recover corpus callosum myelination after prenatal alcohol exposure

Authors: *E. K. BRENGEL, K. A. MILBOCKER, G. L. LEBLANC, A. Y. KLINTSOVA; Psychological & Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Fetal Alcohol Spectrum Disorders (FASD), a group of related developmental disorders caused by prenatal alcohol exposure (AE), are reported in 1 of every 20 live births in the U.S. (May et al., 2014). Prenatal AE may result in a range of physical, cognitive, and behavioral symptoms including a deficit of executive function, for which the heavily myelinated interhemispheric fibers of the corpus callosum (CC) are critical. Myelination of the central nervous system occurs throughout life via the production and growth of oligodendrocytes. AE-induced disruption of CC myelination, which continues into adolescence, has been observed in clinical and preclinical studies (Newville et al., 2017; Gautam et al., 2014). Conversely, upregulation of CC myelination has been observed in response to aerobic exercise in adolescence (Tomlinson et al., 2018). This study utilizes immunohistochemistry (IHC) of brain tissue samples to investigate the effects of developmental AE and an adolescent wheel-running intervention (WR) on oligodendrocyte-lineage cell quantity in CC in a preclinical rodent model of FASD. Male and female Long-Evans rat pups received AE via intragastric intubation (5.25 g/kg/day) on postnatal days (PD) 4-9 during the brain growth spurt, a time of rapid

neurodevelopment that occurs during the third trimester of the human pregnancy. Sham-intubated controls underwent identical procedures without liquid administration. On PD 30-42, half of all rats were housed in cages with free access to WR; the other half remained socially housed in standard cages. Brains were perfused on PD42 with 4% paraformaldehyde and collected for IHC. Tissue was stained with CC1-Alexa Fluor594 antibodies (Millipore, OP-80; ThermoFisher, A21203) for quantification of mature oligodendrocytes (mOL) in 40 μm coronal sections using microscopic imaging and unbiased stereology (MBF SteroInvestigator). One-way ANOVA of preliminary data collapsed across treatment and sex groups demonstrates that there is no significant effect of WR intervention on mOL quantity in CC ($F_{1,16} = 0.045$, $p = 0.840$, n = 8-12). The sample will be expanded to eight groups ($n = 12$) to allow for analysis of WR, AE, and sex as independent variables. In addition, the CC oligodendrocyte precursor population, which is most immediately upregulated by aerobic exercise, is being quantified. Alongside IHC approaches, our lab obtained Diffusion Tensor Imaging scans before and after WR to assess changes to CC myelination longitudinally (submitted as a separate abstract). Taken together, these findings will help elucidate the mechanisms by which CC development is disrupted by AE and may be rescued by adolescent aerobic exercise.

Title: Spatial working memory is impaired in adult male and female rats after binge alcohol exposure in a third - trimester model of FASD

Authors: *S. KIM, A. Y. KLINTSOVA, A. L. GRIFFIN;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Alcohol exposure (AE) during pregnancy is known to affect executive functioning later in life, including working memory (WM). In rodents, spatial WM is dependent upon the medial prefrontal cortex (mPFC) and hippocampus (HC). Previous work has demonstrated that these two structures are vulnerable to AE during the brain growth spurt, which occurs during 3rd trimester of human pregnancy and the first two postnatal weeks in rodents. Our lab has shown that thalamic nucleus reuniens (Re) is damaged in a rodent model of human 3rd trimester AE. We have also demonstrated that Re is critical for mPFC-HC oscillatory synchrony and spatial

working memory (SWM). The current study investigated the effects of early AE on delay dependent SWM ability in adulthood in male and female rats. We predicted that AE would lead to SWM impairment as WM demand increased.
Alcohol was administered on postnatal days 4-9 (PD4-9) as ethanol solution in milk formula in a dose 5.25 g/kg/day via intragastric intubations in a binge manner (AE group). Control animals were intubated without liquid (sham intubated (SI) group). Both male and female rats were included in the study. On PD90, rats were trained on a continuous alternation (CA) T-maze task. Upon reaching a choice accuracy criterion of 80% on CA for two consecutive days, we introduced increasing delays between trials (DA) in order to enhance SWM demand. The rats underwent 6 DA sessions, consisting of 12 each of 10-second (s), 30 s, and 60 s delay trials given in a pseudorandom sequence.
Our results show that male and female animals in both AE and SI groups learned the CA task at similar rates: no sex difference was observed. However, on the DA task, the SI group showed consistent improvement across sessions on the 30-s delay trials, whereas the AE group did not (postnatal treatment x day interaction: $F(5,195)=2.70$, $p = .02$). For the 10 s delay trials, both AE and SI groups showed improvement across days (main effect of day: $F(5,195)=7.93$, $p < .001$), whereas for the 60 s delay trials, both groups performed uniformly poorly across days. There was no main effect of sex ($F(1,37)=.029$, $p=.479$)
These findings support the hypothesis that binge AE during the brain growth spurt produces SWM deficits that depend on the level of SWM demand. This study will lead to a better understanding of the impact of HC-Re-mPFC circuitry damage due to developmental AE on cognitive function later in life.

Title: Running to Repair: Does aerobic exercise intervention in adolescence mitigate the effect of prenatal alcohol exposure on myelination?

Authors: *K. MILBOCKER[1], G. L. LEBLANC[1], E. K. BRENGEL[1], S. K. HEKMATYAR[2], C. F. FERRIS[3], A. Y. KLINTSOVA[1];
[1]Psychological and Brain Sci., [2]Ctr. for Biomed. and Brain Imaging, Univ. of Delaware, Newark,

DE; [3]Dept Psychology, Northeastern University, Ctr. for Translational NeuroImaging, Boston, MA

Abstract: 1 in 20 infants born annually in the U.S. has been exposed to alcohol prenatally which could produce cognitive deficits categorized as Fetal Alcohol Spectrum Disorders (FASD) (May et al., 2018). Cognitive processing impairments resulting from corpus callosum (CC) abnormalities including reduced axonal myelination are well-described in adolescents with FASD (i.e., Wozniak et al., 2019; Jacobson et al., 2017). Mammalian CC myelination, which begins in childhood and continues into adolescence, is imperative for optimizing axonal conduction and cognitive processing capacity. Diffusion tensor imaging scanning and immunocytochemical analysis were used to investigate the effects of: 1) prenatal AE and 2) exercise, a stimulator of myelinogenesis, in adolescence on CC myelination in a rodent model of FASD. Male and female Long-Evans pups were AE via intragastric intubation twice daily (5.25 g/kg/day) or served as sham-intubated controls during the rodent brain growth spurt (Dobbing & Sands, 1979). From PD 30-42, half of all rats had free access to running wheels for aerobic exercise while the second half remained in the homecage (n = 8-12, counterbalanced for sex/postnatal treatment group/intervention group). Scans were acquired twice longitudinally (PD 30 and 42) in all rats to assess alterations to CC myelination within-subject. Following scanning, tissue was collected for quantification of oligodendrocyte lineage cells and concentration of myelin basic protein in CC. Histological results will be presented at this meeting in the poster by Brengel et al. Longitudinal analysis of scan data shows that forebrain and CC volume increase between PD 30 and 42 ($F_{1, 75} = 29.0$, $p < .001$) and exercise stimulates forebrain growth. Cross-sectional analysis at each time point shows that AE significantly reduces CC volume compared to controls ($p < .01$). Since the effect of postnatal treatment on CC volume is mediated by forebrain volume, it is likely that AE and exercise intervention have opposing effects on CC growth across adolescence. Further, it was observed that radial diffusivity, interpreted as a noninvasive measure of myelination, decreases with age in CC ($p < .01$) as expected. However, radial diffusivity remains higher in AE rats compared to controls at both time points ($p < .01$), ultimately decreasing to pre-exercise (control) levels by PD 42. These findings confirm that the trajectory of CC myelination is delayed in cases of late term prenatal alcohol exposure. Adolescent exercise intervention supports whole and regional brain growth but has not been shown to mitigate alcohol-induced alterations to myelination using longitudinal neuroimaging.

Title: The consequence of patient-derived anti-NMDA receptor autoantibodies in neural circuit development and subsequent behavior

Authors: *J. ZHOU[1], A. GREENFIELD[2], R. LOUDERMILK[2], C. BARTLEY[2], B. TRAN[2], H. WANG[2], M. WILSON[2], S. PLEASURE[2];
[1]Univ. of California San Francisco, San Francisco, CA, CA; [2]Univ. of California, San Francisco, San Francisco, CA, CA

Abstract: Anti-NMDA receptor autoantibodies cause severe behavioral deficits and prominent abnormal movements in pediatric patients, indicating disruption of sensory-motor circuits. A key structure for integrating sensory-motor information is the callosal connection between primary somatosensory cortices (S1). We have demonstrated that genetic disruption of NMDA receptor and antibody-mediated loss of function lead to defects in the somatosensory callosal projection in mice. We showed that disruption of axon guidance functions of the EPHRIN-B/EPHB pathway due to loss of NMDAR is the likely mechanism of this phenotype (Zhou et al., *eLife*, 2021). To further address whether exposure to patient-derived anti-NMDA receptor autoantibodies during callosal development disruptes callosal connectivity in S1, we generated anti-NMDA receptor monoclonal antibodies from the cerebrospinal fluid (CSF) of an anti-NMDA receptor encephalitis patient and identified two mAbs against two different subunits of NMDA receptor - mAb1 is against the NR2A subunit, mAb3 is against the NR1 subunit. Injections of either of these antibodies during callosal development in mice disrupts the ordered somatosensory callosal circuit. Injection of mAb1 caused small changes in the callosal projection but injection of mAb3 caused dramatically increased callosal innervation in the somatosensory cortex. Most interestingly, the disruption of a developmentally patterned circuit by the two patient-derived anti-NMDA receptor autoantibodies causes sensory-motor deficits in fine movement when these mice grew to adulthood. In particular, mAb3-treated mice show much worse performance in sensory-motor coordination tasks than mAb1-treated mice. This is the first demonstration that sensory-motor circuit deficits caused by patient-derived autoantibodies during development, cause subsequent sensory-motor behavior deficits in adulthood. This is relevant to the effects of this syndrome in pediatric and newborn patients and may also shed light on the protracted neurocognitive deficits experienced by anti-NMDA receptor encephalitis patients even after resolution of the acute phase of the illness.

Title: Neonicotinoid insecticides cause long-lasting neurobehavioral effects following embryonic exposure in zebrafish

Authors: *A. B. HAWKEY, Z. R. HOLLOWAY, E. D. LEVIN;
Duke Univ. Med. Ctr., Durham, NC

Abstract: Neonicotinoid compounds are commonly used insecticides which have become increasingly popular following growing concern for older generations of insecticides, such as organophosphates. As with other replacement compounds, these insecticides were introduced to provide an effective alternative with reduced health risks for non-target species. However, like nicotine and organophosphates, neonicotinoids exert their toxicity through well-conserved agonistic actions at nAChR. Given the established neurotoxicity of nicotine and other cholinergic toxicants, particularly during development, developmental neurotoxicity studies are needed to identify the nature and persistence of neonicotinoid toxicity in vertebrate species. The current study was performed to evaluate the neurobehavioral toxicity of two neonicotinoid insecticides using developing zebrafish as a model system. Fertilized zebrafish eggs were placed into glass petri dishes and exposed to vehicle (0.1% DMSO), clothianidin (CLO) (1-100uM) or dinotefuran (DIN) (1-10uM) from 5-120h post-fertilization. Neurobehavioral tests were conducted at larval (6 days), adolescent (10 weeks), and adult ages. Although these compounds produced no significant behavioral impairments in larval fish, phenotypic changes emerged over development. A low concentration of CLO (1uM) led to reduced anxiety-like diving in the novel tank test in adolescence, while the highest concentration (100uM) produced enhanced anxiety-like diving in adulthood. When tested in adulthood, developmental exposure to the highest concentration of CLO caused reduced locomotor activity in the novel tank overall, prior tap in the tap test, and in the predator avoidance assay, as well as increased avoidance of a fast predator cue. DIN exposure during early development produced no significant effects on behavior in adolescence. When the fish were tested in adulthood, the lower DIN concentration (1uM) caused enhanced diving responses in the novel tank, while both concentrations (1-10uM) caused reduced locomotor activity during the initial minutes of the predator avoidance test. These data suggest that neonicotinoid insecticides may carry some of the same risks for vertebrates posed by other classes of insecticides, and that these risks may include adverse neurobehavioral outcomes that emerge later in life. This work was supported by the Duke University Superfund Research Center (ES010356).

Title: Deciphering the neuronal role of the WASH complex and its influence on cognition and movement

Authors: *J. L. COURTLAND[1], T. W. A. BRADSHAW[2], G. WAITT[3], E. J. SODERBLOM[3], T. HO[3], A. RAJAB[6], R. VANCINI[4], I. KIM[7], S. H. SODERLING[5];

Abstract: Multiple neurodevelopmental and neurodegenerative disorders are driven by disruptions in intracellular trafficking between organelles in neurons. One branch of this trafficking network, the endo-lysosomal pathway, is thought to tightly regulate many neuronal processes, including the dynamic recycling of synaptic receptors and the homeostatic regulation of membrane lipid composition. This idea is supported by numerous accounts of human neurological diseases that develop from the disruption of endo-lysosomal processes. In particular, mutations in subunits of the endosomal WASH complex, Strumpellin and SWIP, are implicated in motor and cognitive disorders, but the cellular etiologies of these associations are unknown.To explore the role of the WASH complex in neurons, we first sought to identify the molecular interactors of WASH in mouse brain. We utilized *in vivo* BioID (iBioID) to delineate the neuronal WASH complex proteome in wild-type mouse brain, revealing a rich network of endosomal proteins. Comparison of this network to previously reported WASH interactors in other cell types demonstrated the conservation of WASH function in endosomal trafficking within the mouse nervous system. Then, to uncover how dysfunction of endosomal SWIP leads to disease, we generated a novel mouse model of a human *WASHC4*$^{c.3056C>G}$ mutation. We performed quantitative spatial proteomics analysis of SWIP^{P1019R} mouse brain, which demonstrated that this mutation destabilizes the WASH complex and causes significant perturbations in both endosomal and lysosomal pathways. We then utilized cellular and histological analyses to confirm that SWIP^{P1019R} results in an endo-lysosomal disruption *in vitro*

and *in vivo*. We also found indications of neurodegeneration in SWIP^{P1019R} mice that appeared selective for the motor cortex. To determine if these structural changes produced functional effects in SWIP^{P1019R} brain, we conducted behavioral assays in wild-type and mutant SWIP^{P1019R} littermates at adolescence and adulthood. These studies revealed that SWIP^{P1019R} not only impacts cognition, but also causes significant progressive motor deficits in mice. By analyzing human SWIP^{P1019R} patient data, we found that this *WASHC4* mutation produces similar movement deficits in humans. Combined, our research provides the first molecular analysis of WASH complex function in the mammalian nervous system, and supports the model that WASH complex destabilization, resulting from SWIP^{P1019R}, drives cognitive and motor impairments via endo-lysosomal dysfunction in the brain.

Abstract: Neonatal hydrocephalus presents with various degrees of neuroinflammation and long-term neurological deficits in surgically treated patients, provoking a need for additional medical treatment. We previously reported elevated neuroinflammation and severe

periventricular white matter damage in the *progressive hydrocephalus* (*prh*) mutant which is caused by a point mutation in the *Ccdc39* gene. These mutants exhibit ependymal cilia defects and altered cilia-mediated cerebrospinal fluid flow and develop into severe hydrocephalus within the first postnatal week. In this study, we demonstrate that suppression of microglial activity using the anti-inflammatory small molecule, bindarit, significantly inhibits white matter edematous injury and supports neural cell maturation of the early postnatal *prh* brain. Bindarit treatment inhibited nuclear localization of p65 in amoeboid-shaped *P2ry12+* microglia and upregulation of pro-inflammatory genes including *Ccl2, Ccl3, C3aR, Tyrobp, Trem2, Tlr4* and *Cd86*. While bindarit only mildly reduced the ventricular volume, it greatly improved microglial morphology, myelination, interneuron morphogenesis, and vascularization of the *prh* mutant. In addition, the treatment attenuated thinning in cortical layers II-IV and supported excitatory synapse formation in the *prh* mutants, while protecting the ramified-shaped homeostatic microglia from cell death in the developing cortex. These data implicate the active involvement of pro-inflammatory microglia in the developmental defects observed in neonatal hydrocephalic brains. Collectively, we revealed that suppressing microglial-induced inflammation is crucial for supporting white matter and neuronal maturation in neonatal hydrocephalus.

Title: Fgf13 regulation of postnatal cortical development and function

Authors: *S. LIN[1], A. GADE[2], H. WANG[2], A. RAJADHYAKSHA[1], G. S. PITT[2];
[2]Cardiovasc. Res. Inst., [1]Cornell University: Weill Cornell Med. Col., New York, NY

Abstract: Fibroblast growth factor homologous factor 13 (FGF13) is a non-canonical member of the fibroblast growth factor (FGF) superfamily that is not a secreted growth factor and functions intracellularly. Long-studied for its role in regulating voltage-gated sodium channels in brain and

heart, the full complement of FGF13 molecular functions is undefined. C**linical studies revealed that patients with disruptions or mutations in the *Fgf13* gene have early onset cognitive impairment and febrile seizures. FGF13 also has two major alternatively-spliced isoforms in the cortex, one which is predominantly expressed in excitatory and the other in inhibitory cells.** To study cell-type specific FGF13 expression in the cerebral cortex, I generated mice lacking FGF13 throughout CamkIIα-expressing glutamatergic or *Gad2*-expressing GABAergic interneurons. Mice heterozygous for *Fgf13* in interneurons suffer epileptic seizures, consistent with the human phenotype, and hemizygous knockout mice die perinatally. Mice with *Fgf13* deficiency in glutamatergic cells exhibit behavioral abnormalities but survive through adulthood. To further define the functional roles of FGF13, I conducted a battery of behavior assays to identify differences between knockout mice and wildtype littermates. My findings reveal distinct roles of *Fgf13* in the two cell types, likely mediated by distinct molecular mechanisms. **These data show that differential regulation of *Fgf13* via alternative splicing generates distinct proteins with different neuronal functions.**

Title: Maternal restraint stress during pregnancy increases neonatal status epilepticus severity in rats

Authors: *D. A. CRUZ ROJAS[1], K. P. RAMOS RIERA[1], L. BELTRAN PARRAZAL[2], C. MORGADO VALLE[2], M. L. LOPEZ MERAZ[1];

Abstract: Evidence suggests that stress during pregnancy promotes acute and long-term consequences in offspring, which include molecular, cellular, and behavioral alterations. The goal of this study was to evaluate the effect of maternal restraint stress during pregnancy on neonatal *status epilepticus* (SE) in rats. Gestational stress was induced by immobilization of pregnant Wistar rats from gestation days 12 to 20 during two 2 h sessions, twice a day (stress rats, n = 4); control rats (n=4) were kept in standard housing conditions. The body weight and height of pups were evaluated from postnatal day (P) 3 to P7. In P7, SE was induced with the

lithium-pilocarpine model (LiCl 5mEq/kg, i.p.; pilocarpine hydrochloride 320mg/kg, s.c.). The behavioral evaluation was performed considering a modified scale to that described by Torolira et al. (2019): Stage 1 = motor hyperactivity, head, and forelimbs clonus; stage 2 = Clonic activity with loss of posture and rotational movements; stage 3 = sustained generalized seizures, running, and vocalization. The results showed that the neonates from stressed mothers (n = 31) showed a lower weight [males: 10.85 ± 0.80 g; females: 10.48 ± 0.82 g) and length [males: 6.55 ± 0.25 cm; females: 6.42 ± 0.30 cm] than those from control mothers (n = 20) [males: 13.94 ± 0.95 g and 7.22 ± 0.43 cm, respectively; females: 13.18 ± 1.05 g and 7.58 ± 0.54 cm, respectively]. Males born from stressed mothers (n=18) showed decreased latency to stage 1 (10.71 ± 1.63min), stage 2 (15.42 ± 1.90min) and stage 3 (15.77 ± 1.77min) seizures compared with those born from control mothers (n=14; 17.78 ± 1.80min, 35.58 ± 6.48min, 39.48 ± 10.22min, respectively). Males from stressed mothers also had a higher frequency of stage 1 (29.82 ± 5.05) and stage 3 (17.67 ± 3.72) seizures, and longer duration to stage 3 seizures (2.73 ± 044min) than control males (14.69 ± 4.23, 5.45 ± 1.77 and 1.32 ± 0.40min, respectively). Regarding female pups, those born from stressed mothers (n=13) showed decreased latency to stage 2 seizures (16.69 ± 2.94min) compared with control females (n=11; 30.81 ± 7.68min). In addition, female pups from stressed mothers showed increased number (33.54 ± 6.08) and duration of stage 2 seizures (0.40 ± 0.08min), as well as longer duration of stage 3 seizures (2.98 ± 0.76min) when compared with female control rats (12.45 ± 2.0, 0.15 ± 0.02min and 0.92 ± 0.35min, respectively). In conclusion, maternal restraint stress during pregnancy affects pup development and increases the severity of neonatal SE.

Title: Pv^+ interneurons are non-cell autonomously dysregulated in cerebral cortex with conditional knock-out of Depdc5 in pyramidal neurons.

Authors: *T. YANG, S. HU, M. KAO, W.-Z. CHANG, Y. WANG;
Univ. of Michigan, Ann Arbor, MI

Abstract: MTOR-related malformation of cortical development (MCD) is the most common cause of medically refractory epilepsy in children. It is still unclear which cell subtypes with MTOR hyperactivation contribute to the pathogenesis and epileptogenesis of MCD. Clinical and experimental data have suggested that MTOR hyperactivation in dorsal progenitors-derived cells, but not ventral progenitors derived interneurons, generates pathognomonic cellular changes, overall cortical overgrowth, and severe epilepsies. However, studies have also reported impaired inhibitory pre-synaptic transmission as well as the reduction of interneuron number in MTOR-associated MCD, raising a critical question how genetically intact interneurons are impaired. In this study, we used *Depdc5* conditional knockout mice lines to show that *Depdc5* deletion in cortical dorsal progenitor, but not in ventral progenitors, is necessary and sufficient to generates thickened cortex, cytomegalic neurons, and severe epileptic seizures. Astrocytes-specific deletion of *Depdc5* failed to produce these pathognomonic features of MTOR-related MCD. We further found that perineuronal nets (PNN) and parvalbumin (PV) + interneuron (IN) are impaired non-cell autonomously through microglial-mediated neuroinflammation in a response to the downregulated microglial inhibitory molecule, CD200, and the severely disrupted homeostasis in mutant cortical excitatory neurons. Therapeutically, treatment with Everolimus restored both cell-autonomous pyramidal neuron and non-cell autonomous PV+ IN impairments, and rescued severe seizures, suggesting critical roles of PV+ INs in the epileptogenesis of MTOR-related MCD.

Title: Brief synaptic inhibition persistently interrupts firing of fast-spiking interneurons

Authors: *S. CHAMBERLAND, M. HANANI, R. EGGER, E. R. NEBET, S. B. LARSEN, K. EYRING, R. W. TSIEN;
New York Univ. Sch. of Med., New York, NY

Abstract: Input-output operations performed by neurons rely on their ability to integrate synaptic activity with their intrinsic electrical properties, a process thought to be constrained by the duration of synaptic events. At variance with this classical view, we find that the sustained firing of CA1 hippocampal fast-spiking (FS) parvalbumin-expressing interneurons (PV-INs) is persistently interrupted for several hundred milliseconds following brief GABAAR-mediated

inhibition. A single presynaptic neuron could interrupt PV-INs, occasionally with a single action potential (AP), and reliably with brief bursts of APs. Experiments and a computational model revealed that the persistent interruption of firing maintains neurons in a depolarized, quiescent state through a cell-autonomous mechanism dependent on an inactivating $K_v1.1$-mediated current and largely inactivated Na^+ channels. Strikingly, interrupted PV-INs are highly responsive to Schaffer collateral inputs, with subthreshold stimuli at rest becoming suprathreshold during the interruption. We show that the persistent interruption of firing represents a powerful disinhibitory mechanism that favors spike generation in CA1 pyramidal cells. Overall, our results demonstrate that neuronal silencing can far outlast brief synaptic inhibition owing to a well-tuned interplay between neurotransmitter release and postsynaptic membrane dynamics, thus impacting circuit function.

College, Huazhong Univ. of Sci. and Technol., Wuhan, China; [4]Inst. for Translational Brain Research, Fudan Univ., Shanghai, China

Abstract: The electrophysiological properties of neurons strongly determine information processing in the networks they form. Usually these properties are extracted from in vitro recordings from animals, especially rodents. However, the ultimate goal is to understand how human neurons work. The problem is that, for obvious reasons, there are only rare recordings from human neurons. In this work, have studied the electrophysiological properties of pyramidal and fast spiking interneurons in Layers 2/3 of the human temporal lobe. Whole-cell patch clamp recordings were obtained from human cortical L2/3 neurons collected from 21 pyramidal cells from 7 males and 10 females and from 9 interneurons from 5 males and 4 females. A total of 491 traces were used for the analysis.
We first compared our data with the few electrophysiological features available from published datasets recorded from the same region (Deichter et al. 2017, Chameh et al. 2021, Berg et al. 2020 and Beaulieu-Laroche et al. 2018), and confirmed that they are consistent with those extracted from our traces. We then analysed several features, and we found statistically significant differences between males and female pyramidal neurons for the resting membrane potential (M: -68.530 ± 4.966 mV, F: -71.731 ± 3.017 mV, p = <0.001), the mean firing frequency (M: 28.743 ± 17.343 Hz, F: 39.246 ± 29.009 Hz, p=0.032), the instantaneous frequency of first ISI (M: 90.593 ± 48.082 Hz, F: 156.567 ± 108.828 Hz, p= <0.001) and the minimum voltage between spikes (M: -54.823 ± 4.036 mV, F: -51.637 ± 8.241 mV, p=0.004). For interneurons, features that significantly differ between males and females were the resting membrane potential (M: -65.806 ± 4.502 mV, F: -73.883 ± 4.562 mV, p = <0.001), the mean frequency (M: 87.386 ± 52.759 Hz, F: 58.523 ± 50.696 Hz, p=0.025) and the input resistance (M: 70.020 ± 55.934 MΩ, F: 185.999 ± 159.454 MΩ, p = <0.001). Females pyramidal neurons showed higher mean frequency and input resistance compared to males, whereas female interneurons showed lower mean frequency compared to males. Preliminary results also suggest that some of the features changes with age. These results are the first assessment of electrophysiological features of fast spiking interneurons of the human temporal cortex. They are being used to implement detailed biophysical models of L2/3 temporal cortex neurons and interneurons able to reproduce the intrinsic variability of excitability exhibited by these cells.

Title: Diurnal variation in parvalbumin interneuron excitability in mouse prefrontal cortex

Authors: *J. BURNS[1], Y. H. HUANG[2], C. A. MCCLUNG[3];
[2]Psychiatry, [1]Univ. of Pittsburgh, Pittsburgh, PA; [3]Psychiatry, Univ. of Pittsburgh Med. Sch., Pittsburgh, PA

Abstract: Approximately twenty-four hour rhythms in behavior and physiology are widely conserved across the species and can be observed at the cellular and molecular level as changes in gene expression and cellular function. Previous studies in the prefrontal cortex (PFC) have shown that parvalbumin (PV) interneurons, which play a key role in regulating the excitation/inhibition balance and have been implicated in cognitive function, display diurnal changes in both PV expression and perineuronal nets (PNN). Given that studies have also found changes in PV cell excitability linked to PNN presence and overall diurnal changes in the excitation/inhibition balance have been observed in other cortical regions, we investigated diurnal changes in PV cell excitability, membrane properties, and the excitatory drive to these cells. Male and female adult G42 mice were sacrificed at ZT 5-6 or 17-18 (lights on ZT 0) and slices were prepared for whole cell patch electrophysiology. PV cells in the medial PFC were selected for recording. Excitatory drive was measured as spontaneous excitatory postsynaptic currents to PV cells in the presence of picrotoxin. To measure PV cell excitability and membrane properties, current pulses were injected via the recording electrode (500ms; -60 to 300pA); responses were averaged across 3 repeats. We find that PV cells show reduced excitability in the dark phase, with fewer action potentials per current injection as well as diurnal variation in membrane properties. These changes in PV cell excitability may have a profound impact on the overall excitation/inhibition balance of the PFC. Moreover, PV cells have been heavily implicated in psychiatric diseases and previous research in our lab has shown robust circadian reprogramming of the transcriptome in the PFC in schizophrenia. Therefore, through better understanding the normal diurnal changes in the physiology of these cells, we may gain insight into how these processes are disrupted in disease.

Title: Biophysical alterations dampen excitability of cortical PV interneurons and contribute to network hyperexcitability in early Alzheimer's

Authors: *M. J. M. ROWAN[1], J. DIMIDSCHSTEIN[3], V. J. OLÁH[2], A. M. GOETTEMOELLER[2];
[1]Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA; [2]Cell Biol., Emory Univ. Sch. of Med., ATLANTA, GA; [3]Broad Inst., Cambridge, MA

Abstract: AD is characterized by synaptic dysfunction and degradation, ultimately resulting in memory loss and dementia. The molecular and cellular mechanisms responsible for the initiation of this neurodegenerative progression remain poorly understood. A prevailing theory underlying the etiology of AD is that toxic, protein-rich accumulations result in neuronal death and eventual cognitive decline. However, increasing evidence from both human clinical trials and animal models suggests that these aggregates are not the causal determinates of disease initiation. Thus, uncovering alternative molecular and cellular mechanisms involved in the initiation of neurodegeneration is crucial. A guiding concept for this study is that circuit overexcitation may act as an initial determinant of future neurodegeneration in AD. Prior studies have uncovered that cortical overexcitation and intermittent epileptiform discharges emerge in the pre-plaque stages of AD. Multiple studies now suggest that this circuit overexcitation is due to changes in action potential (AP) firing of GABAergic inhibitory interneurons. 'Fast-spiking' parvalbumin (PV) interneurons appear to be particularly vulnerable to changes in AP firing in human APP (hAPP)-expressing mouse models. However, the molecular and biophysical mechanisms responsible for these changes remain largely unexplored. Here we used a novel, PV-specific AAV labeling technique, to perform targeted whole-cell patch clamp recordings in pre-plaque 5xFAD mice and controls. We found that the AP firing was severely dampened in cortical PV neurons from 5xFAD mice. PV-neuron specific qPCR found no changes in the mRNA levels of several Kv and Nav channels necessary for AP firing at this stage. However, outside-out patch clamp recordings uncovered significant alterations in the biophysical properties of Kv3 channels from 5xFAD mice. Using dynamic clamp and biophysical models, we found that the observed modifications in Kv3 channel activity could fully recapitulate changes in AP firing and waveform observed in 5xFAD mice. This study indicates that direct ion channel modulation precedes changes in gene expression, which is sufficient to modify AP firing in GABAergic interneurons in an early-stage hAPP model.

Title: Examining mechanisms of human APP expression on AP firing in cortical GABAergic interneurons

Authors: *A. M. GOETTEMOELLER, M. J. M. ROWAN;
Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Alzheimer's Disease (AD) causes a neurodegenerative cascade resulting in severe memory loss in elderly patients. To date, effective preventative interventions remain elusive. Current treatments often focus on amyloid plaques; however, plaque pathology occurs relatively late in the disease. New studies from AD patients and mouse models have identified cortical hyperexcitability prior to amyloid accumulation or plaque pathology. Hyperexcitability, which is associated with neuronal and synaptic pathology, is typically prevented by inhibition from local-circuit GABAergic interneurons. Interestingly, recent literature has shown that distinct interneuron subtypes are functionally impaired at this early phase in APP-expressing mouse models, including 'fast spiking' parvalbumin (PV) interneurons. Preliminary studies from our group also show altered PV interneuron firing in young 5xFAD mice before plaque formation. Together, this suggests that PV interneurons become dysfunctional independent of extracellular amyloid accumulation during AD. Here we utilized an AAV viral approach to express human APP (hAPP) and several of its downstream products in the cortex of adult wild-type or PV-Cre mice. Using ex-vivo patch-clamp electrophysiology, we observed altered firing phenotype in PV interneurons following short-term viral induction of WT hAPP, which mirrored findings from pre-plaque 5xFAD mice. These findings suggest that abnormal hAPP processing or expression, independent of extensive amyloid accumulation, represents an alternative cellular mechanism responsible for cortical circuit hyperexcitability observed in early AD.

Title: Dysfunction of novel low-threshold spiking hippocampal interneuron in Fragile X syndrome

Authors: *L. T. HEWITT, G. J. ORDEMANN, D. H. BRAGER;
Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: Fragile X syndrome (FXS) is the most common inherited form of intellectual disability and the leading monogenetic cause of autism. FXS patients exhibit an increased incidence of sensory hypersensitivity, epilepsy, and anxiety in tandem with other cognitive impairments. Recent data suggests that dysfunctional inhibitory/excitatory balance in the brain may be a major contributor to the debilitating cognitive deficits in FXS. Previous studies, focused almost exclusively on excitatory pyramidal neurons, identified multiple impairments of voltage-gated ion channels in the hippocampus of the *fmr1* knockout mouse. Whether there are similar ion channel changes in hippocampal inhibitory interneurons remains largely unknown. Hippocampal interneurons can be classified based on firing pattern: fast spiking (FS) and low-threshold spiking. We recently showed that low-threshold spiking interneurons in the CA1 stratum oriens form two distinct groups based on interspike interval and subthreshold properties (Hewitt et al., 2021). Voltage clamp recordings revealed that the density of the hyperpolarization non-selective cation channel (I_h) was significantly different between the two populations. We refer to these two groups as oriens-lacunosum moleculare (OLM) and Low-Threshold High I_h (LTH) cells (Hewitt et al., 2021). We made whole-cell current clamp recordings from FS, OLM, and LTH neurons in hippocampal slices from adult wild type and *fmr1* knockout mice. We found no differences in subthreshold properties or action potential frequency for FS and OLM cells between wild type and *fmr1* KO mice. By contrast, resting membrane potential was depolarized and input resistance was lower in *fmr1* KO LTH cells. Additionally, action potential frequency was decreased in the *fmr1* KO compared to wild type LTH cells. Consistent with a potential difference in I_h, the effect of the h-channel blocker ZD7288 on input resistance was significantly larger in *fmr1* KO LTH cells compared to wild type. Given the diversity of interneuron function between subtypes, these results suggest aberrant properties of LTH cells may alter hippocampal function in FXS.

Title: Long lasting reduction of intrinsic excitability in O-LM interneurons is mediated by endocannabinoid dependent up-regulation of Kv7 channels

Authors: *S. INCONTRO, M. SAMMARI, *N. ANKRI, M. RUSSIER, J. FANTINI, D. DEBANNE;
Aix-Marseille Univ., Marseille, France

Abstract: KCNQ-Kv7 potassium channels are found at the axon initial segment of pyramidal neurons where they control cell firing and resting membrane potential. While Kv7 channel redistribution along the AIS has been demonstrated in homeostatic plasticity, their contribution to functional plasticity is still unclear. We show here for the first time that induction of long-term synaptic depression (LTD) in oriens lacunosum moleculare (O-LM) interneurons results in the synergistic expression of long-term depression of intrinsic excitability (LTD-IE) mediated by a gain of function of Kv7 channels. Both LTD and LTD-IE were found to involve endocannabinoid biosynthesis for their induction. Stimulation of CB1 receptor induced pre-synaptic LTD whereas direct interaction of endocannabinoids with post-synaptic Kv7.2/3 channels induced LTD-IE, thus showing the importance of lipids in the regulation of Kv7 channels. Using electrophysiology combined with pharmacological tools, cell biology, molecular modeling and microtensiometry, we demonstrate the direct activation of Kv7 channels by endocannabinoids. The long lasting reduction of the intrinsic excitability can have important consequences on the role of O-LM interneurons in the feedback inhibition and in the control of hippocampal network activity.

Abstract: The mammalian brain is a highly heterogeneous tissue that is composed of a diverse collection of neuronal and non-neuronal cell types that vary in function and composition across different regions of the brain. Single-cell genomics methods are rapidly expanding our definition of cell types as well as our knowledge of their properties and functions. However, how these cell types change with age is not yet fully understood. Here we present a comparison between old and young adult mice via single cell transcriptomics. Our dataset contains 820,560 aged (18 month) and 364,644 young adult (2 month) cells analyzed by single-cell RNA sequencing on the 10x v3 Genomics platform. This dataset spans 16 different brain regions, including areas within the isocortex, hippocampal formation, cerebral nuclei, hypothalamus, midbrain, and hindbrain. Upon label transfer from previous RNA-seq datasets, we detect diverse cellular subclasses across all 16 regions including both neuronal and non-neuronal types. When equivalent subclasses are compared in young adult and aged animals for differentially expressed (DE) genes, we find more DE genes in non neuronal compared to neuronal cells. These non-neuronal subclasses include astrocytes, microglia, oligodendrocytes, vascular/leptomeningeal cells, endothelial cells, and smooth muscle cells. We find expected gene ontology (GO) terms enriched among DE genes in certain non-neuronal subclasses, including enrichment of adaptive immune response terms across microglial populations, and axon and myelin sheath related-terms across oligodendrocyte populations. We also find enrichment of a wide range of GO terms across different neuronal populations, including terms specific to synaptic structure, axonogenesis, mitochondrial function, respiration, and others. Overall, we observe that changes in the molecular landscape of the aged brain vary widely at the cellular subclass level, with the greatest number of genes and GO terms changing in non-neuronal types. As analysis of this tremendous dataset progresses, we will continue to uncover novel insights about specific cell types and regions of the mammalian brain.

Abstract: Association of Single nucleotide polymorphisms ARMS2-rs 10490924, RAD51B-rs8017304 and VEGF-rs 699947 and their protein levels in Age Related Macular Degeneration. Priya Battu[a], Kaushal Sharma[a], Manjari Rain[a], Ramandeep Singh[b], Akshay Anand[a#]a.Neuroscience Research Lab, Department of Neurology, Post Graduate Institute of Medical Education and Research, Chandigarhb.Advanced Eye Centre, Post Graduate Institute of Medical Education and Research, ChandigarhAge-related macular degeneration is a neurodegenerative retinal disease affecting the elderly worldwide. Single nucleotide polymorphisms have been implicated in this disease, but studies in the context of these SNPs in the Indian population are lacking. Also, how protein levels of the studied genes vary with the genotype remains elusive in AMD. In this study, we have investigated whether SNPs in ARMS2-rs 10490924, RAD51B-rs8017304 and VEGF-rs 699947 and their protein levels are associated with AMD in the Indian population. A case-control study consisting of 265 AMD patients and 78 unaffected was conducted at Advanced Eye centre PGIMER, Chandigarh. ELISA was used for the estimation of proteins in the serum of the participants. Taqman genotyping assay was used for SNP genotyping of the samples. We found that the TT variant of the ARMS2 genotype was significantly associated with AMD (p=.001). But for the other two genes, we did not find any significant differences. Also, the levels of ARMS2 and VEGF were increased in AMD compared to controls.Whereas, RAD51B levels were decreased in AMD as compared to controls. Hence, we conclude that TT is a risk variant for AMD in our studied population and varying levels of these proteins among the cases and controls show that these proteins might be implicated in the pathophysiology of AMD.
Conflict of interest: NoneEthical Statement: The study was conducted after taking approval from Institute ethical committee, PGIMER, Chandigarh, India.

Title: Histone H2A ubiquitination resulting from Brap loss of function connects multiple aging hallmarks and accelerates neurodegeneration

Authors: *Y. FENG[1], C. LOWE[1], Y. GUO[2], A. A. CHOMIAK[2], Y. HONG[3], E. S. MONUKI[4]; [1]Uniform Services Univ. of the House Sci., Bethesda, MD; [2]Northwestern Univ., Chicago, IL; [3]Univ. of Turku, Turku, Finland; [4]UC Irvine Sch. of Med., Irvine, CA

Abstract: Aging is an intricate process that is characterized by multiple hallmarks including stem cell exhaustion, genome instability, epigenome alteration, impaired proteostasis, and cellular senescence. While each of these traits is detrimental at the cellular level, it remains unclear how they are interconnected to cause systemic organ deterioration. Here we show that abrogating Brap, a BRCA1 associated protein important for neurodevelopment, results in cellular senescence with persistent DNA double-strand breaks and elevation of histone H2A mono- and poly-ubiquitination (H2Aub). The high H2Aub initiates histone proteolysis, leading to both epigenetic alteration and proteasome overflow. When these changes occur in mice carrying Brap deletions in the brain, they promote neuroinflammation, impair proteostasis, accelerate neurodegeneration, and shorten lifespan. We further show H2Aub is also increased in human brain tissues of Alzheimer's disease. These data together suggest that chromatin aberrations mediated by H2Aub act as a nexus of multiple aging hallmarks.

Title: Age-related DNA methylation signatures in the dorsal hippocampus of male and female mice

Authors: *C. A. CHINN[1], H. REN[2], J. MORIVAL[2], Q. NIE[2], M. A. WOOD[3], T. DOWNING[2]; [1]Neurobio. and Behavior, [2]UC Irvine, Irvine, CA; [3]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: DNA methylation is a well-characterized epigenetic modification involved in numerous molecular and cellular functions. Methylation patterns have also been associated with aging mechanisms. However, how DNA methylation patterns change within key brain regions involved in memory formation in an age- and sex-specific manner remains unclear. Here, we performed reduced representation bisulfite sequencing (RRBS) from mouse dorsal hippocampus - which is necessary for the formation and consolidation of specific types of memories - in young and aging mice of both sexes. Overall, our findings demonstrate that methylation levels within the dorsal hippocampus are divergent between sexes during aging in genomic features correlating to mRNA functionality, (particularly in 3'UTRs) and in gene regulatory elements. In transcription factor binding site motifs, we found hypomethylated regions to have a neural activity related signature (AP-1, FOS/JUN), in contrast to hypermethylated regions, which contained transcription factors significant during developmental processes. These results define age-related changes in the methylome across genomic features and build a foundation for investigating potential target genes regulated by DNA methylation in an age- and sex-specific manner.

Title: Crest: a keystone regulator in nucleosome remodeling and histone acetylation in memory formation and aging

Authors: *F. GARCIA, R. G. SERRANO, E. KRAMER, M. WOOD;
Univ. of California, Irvine, Irvine, CA

Abstract: One hypothesis proposed to underlie age-dependent cognitive decline and memory formation impairment is that the epigenome becomes altered with age, leading to alterations in gene expression required for long-term memory processes. Recent studies have highlighted a transcription factor, CREST (Calcium RESponsive Transactivator), as a keystone coordinator of two different epigenetic mechanisms, histone acetylation and nucleosome remodeling. CREST has two distinct domains, one of which binds CBP (CREB-Binding Protein, a potent histone

acetyltransferase) and the other BRG1 (Brahma related gene 1, an ATPase and main enzymatic component of BAF nucleosome remodeling complex), leading to the coordination of histone acetylation and nucleosome remodeling. Surprisingly, there is almost nothing known about the role of CREST in synaptic plasticity and memory. Mutations in the human *Crest* gene give rise to Amyotrophic lateral sclerosis (ALS; aka Lou Gehrig's disease), which is a progressive nervous system disease. My research will test the hypothesis that CREST is essential for adult- and age-dependent memory formation, synaptic plasticity, and activity-dependent gene regulation. To test this hypothesis, we have generated both *Crest*-FLOX and *Crest* heterozygous knockout genetically modified mice, as well as adeno-associated viruses (AAVs) that express wildtype CREST, or mutants of CREST. We characterized hippocampal long-term potentiation (LTP, a form of synaptic plasticity), long-term memory, and gene expression during the consolidation phase of memory formation. In addition, using a computational screening of motifs in CREST peptide, we found a candidate phospho-Tyrosine conserved in mouse and human mapping to the proximity of residues necessary for CREST-CBP interaction, which may provide insight into how CREST is regulated. Lastly, using RNA seq data generated by the U-54 MODEL-AD initiative here at UCI, we found that *Crest* mRNA expression is progressively decreasing over the span of of the aging mouse hippocampus, suggesting a potential age-dependent mechanism by which reduced CREST expression leads to memory dysfunction. Together, completion of these studies will determine whether CREST regulates synaptic plasticity and memory formation and age-related cognitive decline along with a means of understanding how CREST may be responding to activity-dependent regulation via the coordination of histone acetylation and nucleosome remodeling.

Title: 17b-estradiol regulates mir-9-5p and mir-9-3p stability and function in the aged female rat brain.

Authors: *M. LINSCOTT[1], C. KIM[1], S. FLURY[1], M. ZHANG[1], T. R. PAK[2];

Abstract: The “timing hypothesis” speculates that the ovarian hormone 17β-estradiol (E_2) is neuroprotective within a narrow window of time following menopause, suggesting that there is a biological switch in E_2 action that is temporally dependent. Our previously published work suggests that microRNAs (miRNAs), a class of small non-coding RNAs, can post-transcriptionally regulate many mRNA targets and therefore could underlie this temporal switch in E_2 action in the aging female brain. Specifically, we found that the ability of E_2 to regulate miRNAs in aged rats was dependent on the length of time between ovarian hormone depletion (via ovariectomy) and the subsequent timing of replacement E_2 treatment. However, while E_2 treatment upregulated levels of mature miR-9-5p and miR-9-3p in the rat hypothalamus, the primary and precursor levels remained unchanged, suggesting that this upregulation was not mediated by an increase in transcription. Here, we focused on mir9-5p and mir-9-3p, miRNAs derived from the same primary transcripts which our previous work found to be differentially regulated by E_2 in the hypothalamus and hippocampus of aged female rats. Therefore, we hypothesized that E_2 maintains miR-9-5p and -3p transcript levels by altering either their stability or activity. To study the stability of miRNA in aged female brain, we developed biochemical assays in cell lines and in rat brain tissue lysate. Interestingly, we found that E_2 treatment stabilized miR-9-3p, but not miR-9-5p, in the rat hypothalamus and this stabilization was dependent on age of treatment. Through polysome fractionation experiments, we found that E_2 was able to shift polysome loading of miRNAs, which repressed translation of the predicted mRNA targets. Moreover, miR-9-5p and -3p transcripts appeared to occupy different fractions of the polysome profile, indicating differential subcellular localization. Together, these studies demonstrate the significance of a miRNA-mediated switch that coordinates the neuroprotective effects of E_2 in the aged female brain.

Title: Absolute quantification and functional analysis of hippocampal phosphorylated ERβ amino acid residues in a menopause model.

Authors: *S. FLURY[1], M. ZHANG[1], C. KIM[1], W. C. CHUNG[2], J. KIRK[1], T. R. PAK[1]; [1]Loyola Univ. Chicago, Chicago, IL; [2]Biol. Sci., Kent State Univ., Kent, OH

Abstract: Menopause, characterized by a depletion of circulating 17β-estradiol (E2), can coincide with serious symptoms, particularly neurological. This can range from memory problems to mood alterations, such as an increase in anxiety and depression. Hormone therapy (HT) can be used to alleviate the symptoms of menopause. However, the time post menopause in which HT is implemented greatly alters efficacy of the treatment. This clinical observation raised the possibility that estrogen receptor (ER) signaling could be altered through changes in the receptor itself following long periods of estradiol deprivation and/or increasing age. ERβ is known to mediate E2 effects on anxiety, therefore we hypothesized that age and length of E2 deprivation differentially alter phosphorylated ERβ in the brain leading to changes in ERβ function. In this study we used absolute quantification mass spectrometry (AQUA-MS) to quantify the levels of phosphorylation at four ERβ residues; S105, S176, S200 and Y488. AQUA-MS quantification was performed using human hippocampal samples (21-83 years old) as well as hippocampal samples from our rat model of menopause. We observed that absolute phosphorylation levels were similar at all of the sites in human and rat models. Specifically, S105 was highly phosphorylated regardless of E2 treatment or age; S176 phosphorylation was decreased by age alone; S200 was lowly phosphorylated and further decreased by age in humans and E2 deprivation in rats, respectively, and Y488 levels were moderate and unaltered by age or E2. To address the functional consequences of ERβ phosphorylation, we used electrophoretic mobility shift assays (EMSA) and dual luciferase assays in combination with phospho-mimetic and phospho-nulls for each residue. The EMSA results showed that the phosphorylation status of ERβ S176 and S200 greatly inhibited receptor binding to DNA. Moreover, ERβ function at minimal promoters was not always consistent with what we predicted from the DNA binding, suggesting that the proteins recruited to ERβ upon DNA binding are altered based on phosphorylation status. To our knowledge, this is the first study to map absolute quantification of phosphorylated ERβ at specific amino acid residues in the brain. Further, we demonstrate changes across the lifespan and propose functional changes in ERβ signaling that could impact the success of HT in postmenopausal women.

Title: Non-cell-autonomous intestinal occluding junction modulation in aging and disease

Authors: C. SESSIONS, K. PAULEY, ***A. SALAZAR**;
Christopher Newport Univ., Newport News, VA

Abstract: Aging is a process marked by a continuous decline in multiple physiological functions. Intestinal barrier function, for example, is tightly linked to longevity in *Drosophila melanogaster* and other organisms. We have previously shown that altered expression of occluding junctions in the guts of fruit flies can lead to various hallmarks of aging, including modulation of intestinal homeostasis, variations in microbial dynamics, changes in immune activity, and alterations in lifespan. Loss of a specific occluding junction, Snakeskin (Ssk), leads to rapid and reversible intestinal barrier dysfunction, altered gut morphology, dysbiosis, and a dramatically reduced lifespan. Remarkably, restoration of Ssk expression in flies showing intestinal barrier dysfunction rescues each of these phenotypes previously linked to aging. Intestinal up-regulation of Ssk protects against microbial translocation following oral infection with pathogenic bacteria. Furthermore, intestinal up-regulation of Ssk improves intestinal barrier function during aging, limits dysbiosis, and extends lifespan. Additionally, perturbing barrier function in the gut has non-cell-autonomous impacts, including alterations in the brain and muscle. Moreover, these analyses add more information about the impact of the gut on tissue outside the gut and begin to address communication between the gut and the brain and muscles in disease models. These findings indicate that intestinal occluding junctions may represent prolongevity targets in mammals, in addition to their possible roles in intestinal dysfunction, aging, and disease.

Title: Maintenance of axonal morphology during aging is regulated by the microtubule cytoskeleton

Authors: *R. GOSLING, N. SANCHEZ-SORIANO;
Inst. of Systems, Mol. and Integrative Biol., Univ. of Liverpool, Liverpool, United Kingdom

Abstract: Axons are cable-like projections of neurons that electrically wire the nervous system. Although microscopic in diameter, these slender structures can extend up to a metre long and

often need to be maintained throughout the lifetime of an organism. This makes them particularly vulnerable to the pathological processes of ageing and neurodegenerative disease (ND), yet the mechanisms driving these are not fully understood. Axon morphology, structure and physiology are reliant on densely packed parallel bundles of microtubules (MT) within the axonal core. Not surprisingly, dysfunctional MT networks are strongly linked with neurodegeneration. In addition, deterioration of axonal MT bundles has been observed in the ageing primate brain. All these cumulative findings have prompted us to propose that aberrant MT regulation during ageing may drive age-related neuronal deterioration. We use *Drosophila melanogaster* to investigate MT regulation in mature axons, and to understand how this process changes during ageing. We have identified an array of MT regulators necessary for the maintenance of MT bundles in axons and synapses from mature neurons within the adult brain. Excitingly, their manipulation leads to structural axonal and synaptic defects which are characteristic of the ageing brain. Moreover, we find that the activity of several MT regulators decreases with age and that boosting some of these factors not only improves MT decay but also axonal and synaptic atrophy during ageing, thus suggesting that aberrant MT regulation is a key factor in age-dependent neuronal decay.

Abstract: The prevalence of Alzheimer’s Disease (AD) is rapidly increasing in the US with an expected 14.8 million cases by 2050. Evidence suggests that risk factors for AD include both heritable and non-heritable environmental components. Recently, pesticides have gained much

attention as environmental toxins due to the potential hazard they pose to human health. Glyphosate, the active ingredient in the broad-spectrum herbicide Roundup, is the most heavily applied pesticide worldwide. The recent rise in glyphosate application to corn and soy crops has a strong, positive correlation with increased death rates due to AD and other dementias. Notably, glyphosate has been shown to cross the blood-brain barrier (BBB) *in vitro* but has yet to be verified *in vivo.* Additionally, its potential detrimental effects on AD-related pathologies remain elusive. Here, we examined whether glyphosate crosses the BBB in both male and female 4-month-old C57/bl6 laboratory mice. Mice received either 125, 250, 500 mg/kg/day of glyphosate or a vehicle control via oral gavage for 14 days. Post-mortem brain tissue analysis revealed that glyphosate infiltrated brain tissue in a dose dependent manner. We then analyzed brain expression levels of tumor necrosis factor α (TNFα), a key inflammatory cytokine that is elevated in peripheral tissue following glyphosate exposure. Notably, TNFα has been shown to induce cell death and exacerbate amyloid-β plaque burden in the brains of mouse models and patients with AD. Our data shows a significant upregulation of TNFα in brain tissue post glyphosate exposure. Future work will focus on examining whether glyphosate exposure exacerbates cognitive deficits and associated AD neuropathology in mouse models of AD. Thus far, this data highlights the need for further exploration into the long-term consequences of glyphosate exposure in relation to AD and has broad implications regarding the health of the general population.

Abstract: Tau hyperphosphorylation and neurofibrillary tangle formation contribute to the extensive neuronal death in Alzheimer's disease (AD) and related tauopathies. Recent work has identified that tau acetylation promotes tau phosphorylation. Tau acetylation at lysine 280 (K280) has been shown to be a prominent site resulting from increased expression of the lysine acetyltransferase p300. The exact upstream mechanisms mediating p300 expression remain elusive. Additional work suggests that dysregulation of epigenetic proteins may contribute to acetylation and hyperphosphorylation of tau. Here we identified Retinoblastoma-binding Protein 7 (Rbbp7), the histone-binding subunit of the Nucleosome Remodeling and Deacetylase (NuRD) complex, as an upstream mediator of tau acetylation. Rbbp7 chaperones chromatin remodeling proteins to their nuclear histone substrates, including histone acetylases and deacetylases. Rbbp7 binds to p300, suggesting a role in modulating tau acetylation. We interrogated Rbbp7 in post-mortem brain tissue, cell lines and mouse models of AD. We found reduced Rbbp7 mRNA expression in AD cases, a significant negative correlation with CERAD (neuritic plaque density) and Braak Staging (pathogenic tau inclusions) and a significant positive correlation with post-mortem brain weight. We also found a neuron-specific downregulation of Rbbp7 mRNA in AD patients. Rbbp7 protein levels were significantly decreased in 3xTg-AD (12 month) and PS19 (8.5 month) mice compared to respective NonTgs, but no decreases were found in APP/PS1 (12 month) mice lacking tau pathology. Interestingly, tau acetylated at lysine K280 was observed in 2-month-old PS19 mice, preceding tau phosphorylation; significant reduction of Rbbp7 in PS19 mice compared to NonTg also occurs at 2 months of age, corresponding with early changes in tau acetylation. Rbbp7 deficiency, tau acetylation at K280 and hyperphosphorylation of tau at Ser202/Thr205 (AT8) were evident in the older PS19 mice. This suggests that Rbbp7 downregulation and tau acetylation at lysine K280 may be early events in tau pathogenesis. In vitro, Rbbp7 overexpression rescued TauP301L-induced cytotoxicity in immortalized hippocampal cells and primary cortical neurons. In vivo, hippocampal Rbbp7 overexpression rescued neuronal death in the CA1 of PS19 mice. Mechanistically, we found that increased Rbbp7 reduced p300 abundance, tau acetylation at lysine 280 and tau phosphorylation at AT8 and AT100 sites. Collectively, these data identify a novel role of Rbbp7, protecting against early events in tau pathogenesis, and highlight its potential as a therapeutic target in AD and related tauopathies.

Abstract: Alzheimer’s Disease (AD) rates are rising as the aging population increases. Dietary nutrients play a key role in mediating mechanisms associated with body and brain function. Choline, a nutrient found in common foods is required to produce acetylcholine, a neurotransmitter responsible for memory and muscle control. Choline also builds cell membranes, donates methyl groups for epigenetic mechanisms that regulate gene expression, and reduces homocysteine (Hcy), a toxic amino acid. Elevated Hcy is linked to health issues such as obesity, impaired glucose metabolism, and cardiac pathology, which are all risk factors for AD. While humans and rodents can produce endogenous choline, these levels fail to meet bodily demands, requiring dietary consumption. In 1998, the U.S. established an adequate intake (AI) of daily dietary choline for adult women (425mg/day) and men (550mg/day). However, epidemiology studies show that ~90% of Americans fail to reach the daily AI. Thus, it is imperative to determine whether choline deficiency at adulthood increases body dysfunction and AD risk. Here, we placed the 3xTg-AD mouse model of AD and NonTg controls on a diet that was either choline normal (ChN) or deficient (Ch-) from early adulthood throughout life (3-12 months of age). Mice were assessed for motor function using the rotarod task at 10 months of age followed by a glucose tolerance test to assess glucose metabolism. Heart, liver and brain tissue were subsequently harvested to assess metabolic and neuropathological changes with choline deficiency. The Ch- diet induced motor deficits, increased weight significantly, and impaired glucose metabolism in both 3xTg-AD mice and NonTg, with 3xTg-AD Ch- mice showing greater deficits. Additionally, we found evidence of cardiac pathology and fatty liver disease in the Ch- diet groups. In 3xTg-AD mouse brains, a Ch- diet elevated the levels of toxic oligomeric and insoluble Amyloid-ß (Aß) levels in the hippocampus and throughout the cortex. Collectively, these results highlight that a choline deficient diet could be a risk factor for motor

deficits, metabolic dysfunction and subsequent AD and suggest that simply modifying one's diet to include adequate choline is critical to offset the risk of developing these pathologies.

Title: Preclinical evaluation of drug treatment options for sleep-related epitleptic spiking in Alzheimer's disease

Authors: N. JIN, I. GUREVICIENE, ***H. TANILA**;
Univ. Eastern Finland, Kuopio, Finland

Abstract: *Aims.* Epileptic spiking without motor manifestations can be found in 30-50% patients with early AD. This number may still be an underestimate as this spiking occurs almost exclusively during sleep and may limit to the deep temporal lobe. Further, AD patients with subclinical epileptiform activity have about twice faster cognitive decline during a follow-up of 3-5 years (Vossel K et al. Ann. Neurol. 2016; Horvath A et al., EEG Clin Neurophys. 2021). Treating epileptic spiking during sleep may thus offer a way to slow down AD progression, but so far there is no published clinical study on the topic, calling for preclinical testing to guide the choice of optimal drug treatments.
Methods. Ten male APP/PS1 mice (3-5 months) were implanted bilaterally with cortical screw electrodes and hippocampal staggered triple wire electrodes to record local field potentials. Sleep was monitored by overhead video-recording and neck EMG wire electrodes. We tested the standard AD-drugs donepezil and memantine as well as anti-epileptic drugs levetiracetam and lamotrigine that have been recommended as drugs of choice in AD patients with epilepsy, In addition, we assessed amyloid-beta reduction by the gamma-secretase inhibitor semagacestat and anti-inflammatory approach with the tetracycline derivative minocycline at doses with no overt motor manifestations. The analysis focused on hippocampally generated giant spikes and was done within-subject in reference to a repeated vehicle injection.
Results. Preliminary data suggest that levetiracetam decreases while lamotrigine unexpectedly

increases sleep-related giant spikes in APP/PS1 mice. Other tested drugs seem to have no significant effect.

Title: Characterization of interneuronal activity in living APP/PS1 mice using genetically encoded calcium indicators

Authors: *M. ALGAMAL[1], A. N. RUSS[2], L. OBAID[3], B. J. BACSKAI[5], K. KASTANENKA[4]; [1]Neruorology, [2]Neuorology, [3]Neurol., [4]Massachusetts Gen. Hosp., Charlestown, MA; [5]Dept Neurol., Mass Gen. Hosp., Charlestown, MA

Abstract: Alzheimer's disease (AD) is characterized by neuronal network dysfunction. Alzheimer's patients exhibit disruptions in neuronal activity that have been linked to cognitive decline. Similarly, amyloidosis animal models, including APP/PS1 (APP) mice, show amyloid-beta-induced aberrant neuronal activity. However, the mechanism underlying these aberrations is not understood. Here, we explored the relationship between amyloid-beta and calcium transients of excitatory neurons as well as two major classes of inhibitory interneurons, parvalbumin and somatostatin interneurons. To this end, the genetically encoded calcium indicator GCaMP6s was targeted to excitatory cortical neurons through CAMKII promoter in 8-12 months-old APP mice and age-matched non-transgenic littermates (WT). Similarly, jGCaMP7s was targeted to parvalbumin or somatostatin interneurons in the somatosensory cortices using Cre-Lox technology with viral delivery. A month later, cortical neurons were imaged through cranial windows under anesthesia using high-resolution two-photon microscopy. The spontaneous calcium transients in distinct neuronal populations were monitored and compared between genotypes. Analysis of calcium events revealed that parvalbumin interneurons are hypoactive, while somatostatin interneurons were moderately hyperactive in APP relative to WT mice. In addition, all neurons, regardless of class, showed disrupted neuronal synchrony in APP relative to WT mice. Finally, proximity to amyloid-beta plaques correlated with neuronal activity in excitatory and somatostatin interneurons. Thus, amyloid beta differentially affects calcium transients of distinct cortical neuronal populations and ultimately leads to network failure in Alzheimer's disease.

PV interneurons are hypoactive in APP/PS1 mice

Title: Unbiased proteomic analysis reveals dietary choline deficiency-induced changes to neurodegeneration-relevant pathways in 3xTg-AD mouse model of Alzheimer's disease

Authors: *S. TALLINO[1,3], A. DECKER[1], N. DAVE[1], J. SANDLER[2], T. KARR[2], R. VELAZQUEZ[1,3];
[1]ASU-Banner Neurodegenerative Dis. Res. Ctr., [2]Biosci. Mass Spectrometry Facility, Arizona State Univ. Biodesign Inst., Tempe, AZ; [3]Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: Alzheimer’s disease (AD) is an increasingly prevalent and costly health burden, creating an urgent need for mechanistic insight into modifiable environmental risk factors, such as diet, to offset disease. The dietary nutrient choline is found in a variety of foods; while adequate intake values were established in 1998, recent reports suggest 90% of Americans do not

meet these requirements. Choline plays an integral role in diverse neurodegeneration-relevant pathways such as acetylcholine biosynthesis, myelination, synapse formation, neurogenesis, and epigenetic modification. Thus, inadequate dietary choline may be a potential risk factor for AD. Here, we investigated hippocampal proteomic alterations induced by choline deficiency in the 3xTg-AD mouse model of AD and nontransgenic (NonTg) controls to identify molecular pathways linking diet to AD pathology. 3xTg-AD and NonTg mice were fed either a choline-normal (ChN) or choline-deficient (Ch-) diet from 3 to 12 months of age (n=4 animals per genotype per diet). Hippocampal tissue was harvested and label-free quantitation (LFQ) was performed using high-resolution mass spectrometry. LFQ revealed significant changes in relative protein abundance in 3xTg-AD and NonTg mice as a result of Ch- diets (>4,500 proteins identified). In particular, feeding 3xTg-AD mice Ch- diets resulted in significant changes in relative abundances of 491 proteins compared to 3xTg-AD mice on ChN diets (2-fold change; FDR <0.05). Of proteins with decreased abundance, gene set enrichment analysis (GSEA; hypergeometric test) using STRING (v11.0) revealed significant enrichment of tau-family protein pathways (FDR <0.03) as well as in pathways related to mitochondrial RNA processing (FDR <0.04) and scaffold protein binding (FDR <0.004); of proteins with increased abundance, we observed significant enrichment of pathways related to cytoskeletal organization and binding (FDR <0.004) as well as myelination and calcium homeostasis (FDR < 0.05). Similarly, comparison between NonTg mice showed the Ch- diet resulted in significant protein abundance changes in 202 proteins (2-fold change; FDR <0.05). Of proteins with decreased relative abundance, GSEA revealed significant enrichment of neurogenesis, neurodevelopment and metabolic pathways (FDR <0.05); myelination and vesicular transport pathways were significantly enriched amongst the proteins with increased relative abundance (FDR <0.05). Collectively, these results highlight that inadequate dietary choline alters AD-relevant biochemical pathways in the hippocampus of NonTg mice as well as in 3xTg-AD mice and may be a modifiable risk factor in AD.

Abstract: Epigenetic dysregulation has been identified as a mechanism contributing the pathogenesis seen in Alzheimer's Disease and a related class of disorders known as the tauopathies. Chromatin remodeling complexes, such as the Nucleosome Remodeling and Deacetylase Complex (NURD), contribute to epigenetic regulation. NURD and other complexes, contain retinoblastoma binding (Rbbps) proteins, which act as chaperones and make histones available for modification. Recently, we identified Rbbp7 as a mediator against tau pathology observed in Alzheimer's disease (AD) and related tauopathies. We found evidence that rescuing Rbbp7 in the PS19 mouse model of tauopathies reduces tau acetylation of lysine K280 and phosphorylation of Ser202/Thr205 (AT8). Notably, Rbbp7 and Rbbp4, share 92% homology, are expressed in many shared chromatin remodeling complexes implicated in diseased aging and neurodegeneration. Given the homology of Rbbp4 and Rbbp7, we examined their mRNA expression levels in AD post-mortem brain tissue and aged-matched controls. We used two cohorts of post-mortem brain tissue obtained from the Arizona Study of Aging and Neurodegenerative Disorders/Brain and Body Donation Program. Cohort one included a total of 56 brain samples of young (n = 21, M = 35.4yrs), aged (n = 18, M = 80.7yrs) and AD (n = 17, M = 86.7yrs) patients, and the area examined was the entorhinal cortex (ENT). Cohort two included a total of 187 brain samples (n = 89 AD, M = 84.7yrs; n = 98 age-matched controls, CTL, M = 85.0yrs), and the area examined was the middle temporal gyrus (MTG). The ENT and MTG were selected because these two brain regions are affected in AD; brain samples underwent microarray analysis to identify mRNA expression differences. Subject age, gender, and postmortem autopsy intervals were not significantly different per groups. Quantitative analysis revealed that Rbbp4 is significantly upregulated in the ENT of patients with AD relative to young and aged controls. In the MTG, we found increased Rbbp4 mRNA expression in AD patients compared to controls. Further analysis of MTG tissue showed a significant positive correlation between Rbbp4 mRNA expression with neuritic plaque density in AD brains, but a non-significant positive correlation between Rbbp4 and Braak staging. Interestingly, we found that Rbbp4 and Rbbp7 are negatively correlated in AD post-mortem brain tissue, illustrating that as Rbbp4 goes up, Rbbp7 goes down. Collectively, these results highlight a potential association of Rbbp4 in AD related pathologies.

Title: Reduced striatal gray matter volume and apathy in Alzheimer's disease: a meta-analysis and experimental confirmation

Authors: *S. CHAUDHARY, S. ZHORNITSKY, H. CHAO, C. VAN DYCK, C.-S. LI;
Yale Med. Sch., New Haven, CT

Abstract: Abstract: Affecting nearly 70% of patients with Alzheimer’s Disease (AD), apathy is associated with higher morbidity and reduced quality of life. Basal ganglia, anterior cingulate and orbitofrontal cortical atrophy is noted in association with the severity of apathy. However, the findings varied across studies and it remains unclear whether subdomains of apathy may involve distinct neuroanatomical correlates. We thus performed a literature search and meta-analysis of the extant findings. The results of a total of six eligible studies of 184 AD and 56 healthy controls (HC) showed convergence toward smaller basal ganglia volumes in AD. To replicate these findings, we recruited 19 patients with AD or mild cognitive impairment (MCI) and 25 age- and gender- matched healthy controls (HC) for T1 weighted anatomical magnetic resonance imaging. Apathy was assessed using apathy evaluation scale (AES) with the sub-domains - cognitive, behavioral and emotional apathy - separately scored. We performed voxel-based morphometry to examine the gray matter volumes (GMV) of the putamen, caudate and nucleus accumbens in region of interest analyses. The analysis revealed right putamen atrophy to be significantly ($p<0.05$ FWE-corrected, small volume correction) associated with higher apathy, especially the total, behavioral, and emotional AES scores. The association remains significant even after controlling depression as assessed by Beck Depression Inventory II (BDI). However, after controlling both BDI and Mini Mental State Examination (MMSE, cognition) scores, right putamen GMV was significantly associated with only the emotional AES subscore. The findings suggest potential influence of depression and cognition in apathy. Right putamen atrophy may be a neural marker of behavioral and emotional apathy. A larger sample size will be needed to further confirm these preliminary findings.

Title: Altered basal forebrain activity during recurrent patterns of brain activity in 4-month-old TgF344-AD rats

Authors: M. VAN DEN BERG, M. ADHIKARI, M. VERHOYE, *G. A. KELIRIS;
Biomed. Sci., Univ. of Antwerp, Wilrijk, Belgium

Abstract: Alzheimer's Disease (AD) is a severe neurodegenerative disorder that leads to brain network dysfunction and cognitive decline. Changes in functional networks at symptomatic stages of AD can be captured using resting state fMRI (rsfMRI) in patients and animal models. In this study, we used a rat model manifesting the full-spectrum of human AD-pathology to identify if spatiotemporal network alterations are present at an early, pre-symptomatic stage of AD. RsfMRI data were collected from four-month-old TgF344-AD (TG) rats (N=15) and wildtype (WT) littermates (N=11) on a 9.4T preclinical MRI scanner. Preprocessing included normalization, filtering and global signal regression. Recurrent, quasi-periodic patterns (QPP) of whole brain activity during a time window (3.6 seconds/6 image volumes) were extracted from the group-level image series[1]. The resulting QPPs were hierarchically clustered based on spatiotemporal similarity to identify robust clusters and their highest occurring QPPs (rQPPs). Cluster-averaged occurrence rates and voxel-wise activations of matched rQPPs were compared between groups using a two-sample t-test. QPP analysis resulted in two clusters of QPPs per group involving two anti-correlated RS networks, the lateral cortical network and the default mode network. Cluster wise-occurrence rates were significantly lower for both clusters in TgF344-AD animals ($p= 0.0427$ & $p= 0.0449$). Spatially, the co-activation of the basal forebrain (BFB) and the cingulate cortex was significantly reduced in the TG rats. The BFB is an important orchestrator of whole-brain network activity [2], and is one of the first regions affected by AD in humans[3]. Alterations in BFB activity might contribute to differences in whole-brain spatiotemporal properties of QPPs as is observed in this study. Spatiotemporal changes in QPPs together with altered 'orchestrating' BFB activity could be a potential signature to identify early onset changes at the network level. Further histological analysis will be performed to gain more insight into the disease-mechanisms driving the changes in QPPs.

Title: Investigating whether fractional anisotropy is associated with reduced reaction time cost on an attentional control task

Authors: N. S. MCKAY[1], A. DINCER[1], V. MEHROTRA[1], ***D. A. HOBBS**[1], A. J. ASCHENBRENNER[1], D. BALOTA[1], R. C. HORNBECK[1], J. HASSENSTAB[1], J. C. MORRIS[1], T. L. S. BENZINGER[1], B. A. GORDON[2];
[1]Washington Univ. in St Louis, St Louis, MO; [2]Washington Univ. in St Louis, Saint Louis, MO

Abstract: Background Previous research has shown that with age and disease, the integrity of white matter (WM) structures can decline. One such measure of WM integrity is fractional anisotropy (FA), where lower values are often associated with disrupted WM. Similarly, previous work has highlighted that attentional control also declines with age and disease. It was therefore of interest to investigate whether FA was associated with cognitive ability in an aging population. To assess this, we derived a measure of attentional control performance from the Consonant-Vowel, Odd-Even (CVOE) task.
Methods246 participants aged 42-87 years (*M* = 69, *SD* = 8.5), who were enrolled in studies at the Knight ADRC, were included in this analysis. Participants were classified as cognitively normal (CDR = 0, *n* = 185), or cognitively impaired (CDR > 0, *n* = 61). All participants completed an MRI and the CVOE task. Tract-Based Spatial Statistics (TBSS) were run on FA

maps calculated for the participants. We used reaction time (RT) cost, the burden caused by the most difficult aspects of this task, as our behavioral measure of interest. This measure was calculated as the difference between RTs within pure vs mixed trial blocks.
ResultsUsing TBSS, we found that the relationships between FA and RT-cost were significantly different for each group (Figure 1). More specifically, we found no relationship between RT-cost and FA in our cognitively normal individuals ($r = 0.14$, $p = 0.052$; Figure 2). In contrast, we do observe a significant negative relationship between RT-cost and FA in our cognitively impaired individuals ($r = -0.64$, $p < 0.01$; Figure 3).
ConclusionOverall, we found a strong relationship between WM integrity and cognitive performance, as measured by the CVOE task. That is, as integrity becomes more compromised, participants become slower at the task when in the mixed versus the pure blocks within the CVOE task. Importantly, this relationship is only observed for individuals that are cognitively impaired. Taken together, our results add to a body of literature that report a relationship between WM integrity and cognitive performance, but hint that further development of more sensitive cognitive tasks may be needed to fully understand this relationship.
Figure 1. TBSS relationship between fractional anisotropy and reaction time cost for our two groups (CDR = 0, CDR > 0).
Figure 2. Scatterplot depicting the relationship between fractional anisotropy and reaction time cost in individuals who are cognitively normal (CDR = 0).
Figure 3. Scatterplot depicting the relationship between fractional anisotropy and reaction time cost in individuals who are cognitively impaired (CDR > 0).

Title: Affective behavioral phenotyping and imaging functional network connectivity in Alzheimer’s disease mouse models

Authors: *M. GRUDNY, M. FEBO;
Psychiatry Dept., Univ. of Florida, Gainesville, FL

Abstract: Apathy presented as impaired motivation and reduced affective expression, is commonly diagnosed in patients with dementia, including Alzheimer's disease (AD). Evidence suggests that in the initial pre-cognitive stage of Alzheimer's disease the communication between brain areas involved in reward and memory processing becomes dysregulated. Extracellular plaque deposits of the β-amyloid peptide (Aβ) are a primary pathological hallmark used to diagnose and characterize AD, however the role of this pathology in the affective symptoms of AD is not fully understood. The present preliminary study investigated affective behavioral phenotypes exhibited by amyloidosis mouse models and expands on prior magnetic resonance imaging (MRI) studies examining functional and structural brain abnormalities in mouse models of AD. Specifically, the behavioral phenotypes were investigated with an open-field test, sociability and preference for social novelty test, and sucrose preference test. Young (5-7 m.o.) male and female 5XFAD, CRND8, and their sex- and age- matched wildtype counterpart mice (BxD, B6, B6D2F1/J, and B6C3F1/J) were tested. One-way ANOVA indicated a strain x mutation effect in total distance ($p < 0.05$) and margin distance ($p < 0.05$) during open field between B6C3F1/J and CRND8 mice. Additionally, One-way ANOVA indicated a strain x strain effect in total distance ($p < 0.05$) and margin distance ($p < 0.05$) between BxD 5XFAD and CRND8 mice. The unpaired t-test did not indicate any difference in social interaction and recognition between wildtype and 5XFAD mice on a BXD background. One-way ANOVA indicated a strain x strain effect in sucrose preference ($p < 0.001$) between B6 and BxD mice and a strain x strain effect in sucrose preference ($p < 0.05$) between B6 and 5XFAD mice. These results suggest that even at an early timepoint, prior to significant Aβ burden and cognitive impact, CRND8 mice have significantly increased locomotion, primarily in margin distance traveled. This effect is seen when comparing to B6C3F1/J and 5XFAD mice. Sucrose preference was significantly elevated in B6 mice when compared to both BxD and 5xFAD mice. There was no effect observed in the sociability or preference for social novelty in these mice. However, the lack of effect observed in this task could be caused by the early time point of this study. Overall, these behavioral results show that there is some differential impact of Aβ mutations and background genetics dependent on the phenotype observed. Additionally, these mice were scanned using functional MRI and will be longitudinally studied at an aged time point to discern the impact aging and Aβ pathological progression has on brain function.

Title: The neural basis of spectral prosody in avian vocal duets

Authors: *A. LEMAZINA, L. TROST, M. GAHR, S. HOFFMANN;
Behavioural Neurobio., MPI for Ornithology, Starnberg, Germany

Abstract: Turn-taking requires participants to control and adjust their vocal production in regards to conversation cues received from a partner. It has been suggested that birds pay attention to the prosodic structure to coordinate their song. We hypothesize that prosodic cues, such as changes in the “intonation pattern” of song elements, facilitate duet coordination by predicting the boundaries of the partners‘ turns. In songbirds, vocal production is controlled by an interconnected network of brain nuclei, the so-called vocal control system. One of these nuclei, HVC, plays a crucial role in arranging individual vocal emissions into sequences. We hypothesize that if prosodic cues are used by songbirds in vocal turn-taking, the production of song elements that differ in prosodic pattern should be controlled differently by HVC. To tackle these questions, we used duet singing White-browed Sparrow Weavers (*Plocepasser mahali*) as animal model. Pairs of *P. mahali* sing antiphonal duets by precisely alternating their vocalizations. We recorded the individual vocal and HVC activity in both partners of duetting pairs, and found that *P. mahali* duet songs are indeed organized into spectral prosodic patterns. The maximum frequency contour of male birds’ song syllables could be classified either as rising (R) or as falling (F) pattern. The pattern of the maximum frequency contour of female birds' song syllables could also be divided into two groups: low (LM) - and high (HM) - frequency modulated syllables. Based on these prosodic patterns, we constructed a markov chain for each individual song to determine if there are underlying duetting rules to guide the turn-taking in the duet song. Female prosodic types LM and HM showed greater than expected transition probabilities to male prosodic types R and F, respectively. In addition, we found that in male *P. mahali*, HVC activity was different depending on the prosodic pattern of produced syllables. Median spike time relative to syllable onset was significantly higher in F-type syllables than in R-type syllables. This indicates, that the right HVC is active later during the production of F-type syllables than during the production of R-type syllables. While in R-type syllables, maximum frequency is rather low at the beginning of the syllable, in F-type syllables, maximum frequency is rather low at the end of the syllable. Given that low frequencies are produced by the right syrinx, lateralization of vocal motor control might explain our observations. Our study demonstrates the existence of spectral prosodic cues in birdsong and suggests song lateralization as the underlying neural mechanism for prosody generation.

Title: Context-dependent control of singing behavior in wild nightingales (Luscinia megarhynchos)

Authors: *G. COSTALUNGA, D. VALLENTIN;
Max Planck Inst. for Ornithology, Seewiesen, Germany

Abstract: Adapting vocal outputs depending on different contexts is an essential feature of learned interactive vocal exchanges, like complex human conversations. Like humans, songbirds are one of the few vocal learning animals. Among them, nightingales are an exceptional example performing sophisticated interactive singing with conspecifics. Every night during their breeding season, male nightingales sing hundreds of different songs engaging in vocal duels against conspecifics to defend territories and attract females. This vocal sparring consists of epochs of turn-taking and overlapped singing with a rival. Additionally, nightingales are able to perform song-matching, listening to and repeating the song sung by their opponents. Although the naturalistic vocal behavior of nightingales is well described, if and how these birds are able to adjust vocal strategies while singing against different opponents remains unknown. To tackle this question, we conducted field experiments exposing wild nightingales to playbacks of an unknown conspecific (CON playback) and of the bird's own songs (BOS playback). We investigated the temporal aspects of the bird's responses to the two playback contexts. The duration of the songs produced by the birds remained unaltered, however the birds increased gap durations and reduced song frequency when exposed to the BOS playbacks. Moreover, we found that nightingales changed the timing of their singing behavior by reducing the number of overlapping songs and the number of consecutive overlaps when exposed to the BOS playbacks compared to the CON playbacks. We then analyzed the song-matching proficiency in the two playback conditions. We found that the birds increased their song-matching behavior while singing against their own songs compared to the CON playbacks. Interestingly, we observed that nightingales were also able to anticipate the upcoming playbacks while counter-singing against the BOS playbacks. The rate of anticipations and matches were higher than the expected chance level based on their song repertoire size. In both conditions, the duration of matches and anticipations of the birds were correlated with the duration of the target songs of the playbacks. Taken together, these results show that nightingales are able to adjust their vocal outputs depending on the context. The birds adapt their temporal performance by changing the timing of their songs in respect to the vocal partner' singing behavior and adjust the content of their responses by singing context-specific songs imitating and anticipating the simulated opponent. Our findings reveal a novel form of context-dependent flexibility in birds' singing behavior.

Title: Chunks of birdsong: Zebra finch motor thalamus preferentially activates HVC neurons representing the onset of song elements

Authors: *F. W. MOLL[1], A. CORREDERA ASENSIO[1], D. KRANZ[2], M. A. LONG[1];
[1]Neurosci. Inst., NYU Sch. of Med., New York, NY; [2]Harvard Univ., Cambridge, MA

Abstract: Thalamic input to forebrain motor centers has been shown to be essential for the execution of simple movements, but its role in more complex behaviors is poorly understood. We explore this issue in the context of the zebra finch courtship song, a well-studied skilled motor behavior consisting of a learned, stereotyped sequence of typically 3-7 syllables approximately 200 ms in length that function as the minimal effective 'chunk' of singing behavior. The song is represented on a moment-to-moment basis by a sequence of sparse activity in the forebrain premotor circuit HVC which receives input from the motor thalamic nucleus Uvaeformis (Uva). Previous lesion studies have indicated that Uva is necessary for singing, but the precise role of Uva in song production remains undefined. Two main models have been proposed: (1) Uva is part of a distributed feedback loop in which rapid cycling of activity through several brain regions is necessary to advance the song on a moment-to-moment basis. (2) Song-relevant sequences are mediated by local interactions within HVC, initiated by inputs from thalamus.

To address these models, we perturbed either HVC or Uva activity in singing birds using bilateral electrical stimulation. In both cases, most stimulation events resulted in song truncations. In stark contrast to HVC stimulation, which is capable of stopping the song at arbitrary moments, Uva stimulation led to selective truncation of the song at syllable boundaries. This result suggests that thalamic activity may be critical for the initiation of syllables.

To test this idea, we asked whether Uva preferentially targets a functional subgroup of HVC neurons active at the beginning of syllables. Using in vivo calcium imaging, we identified a small set of HVC cells reliably activated by focal Uva stimulation and designated them as putative thalamorecipient neurons. We then measured the activity of these neurons during singing. We found that most of putative HVC thalamorecipient neurons became active at the beginning of song elements, suggesting a wiring scheme favorable of thalamic activation of forebrain circuity capable of driving behaviorally-relevant vocal chunks. Taken together, our results indicate that thalamic inputs can provide important temporal structure for skilled motor performance.

Title: Understanding the song-production pathway using sleep replay

Authors: *M. ELMALEH[1], F. MOLL[2], D. KRANZ[4], A. CORREDERA ASENSIO[1], M. A. LONG[3];
[1]NYU Langone Med. Ctr., New York, NY; [2]Neurosci. Inst., NYU Sch. of Med., New York City, NY; [3]Neurosci. institute, NYU Sch. of Med., New York, NY; [4]Neurosci., Harvard Univ., Boston, MA

Abstract: Complex behaviors often require the coordination of multiple brain regions, complicating our ability to determine the contribution of local network mechanisms to their execution. During song production in the zebra finch, premotor sequences within the forebrain region HVC may result from some combination of local connectivity or long-range inputs originating from the motor thalamus (nucleus uvaeformis, or Uva). Because lesions to either structure abolish song vocalization, we examine network 'replay' activity during sleep using high-density recording methods and can reconstruct precise song related events. Sleep replay slows when HVC is cooled, demonstrating that it provides temporal structure for these events. Surprisingly, we find that reconstructed sleep sequences continue to span the duration of the song following Uva lesions, supporting a model in which local HVC connections are sufficient to propagate these dynamics. Additionally, we perform simultaneous bilateral recordings which reveal that, while the two hemispheres are precisely coordinated during song production, the cortical regions of this pathway can operate independently during sleep. Because Uva is the only site of bilateral feedback in the song-production pathway, the import of thalamic input during song may be to coordinate the local premotor sequence propagating networks. Our results highlight the power of examining offline activity for studying behaviorally relevant circuit organization.

Title: Inhibitory regulation of vocal timing: Integrating auditory-evoked and vocal-premotor activity in the songbird forebrain.

Authors: *J. BENICHOV[1], P. NORTON[2,3], M. PEXIRRA[1], S. SCHREIBER[2,3], D. VALLENTIN[1];
[1]Max Planck Inst. for Ornithology, Seewiesen, Germany; [2]Inst. for Theoretical Biol., Humboldt Univ., Berlin, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany

Abstract: The ability to regulate vocal timing is a fundamental aspect of communicative interactions for many species, including conversational speech among humans. During these interactions, the production of vocalizations is often influenced by perceived acoustic signals from other individuals. Little is known, however, about the neural circuitry that enables incoming auditory information to affect if and when a vocal reply is produced. To approach this problem, we generated a spiking network model informed by behavioral and electrophysiological data from zebra finches engaged in call-response interactions. The model incorporates the activity of single neurons in the forebrain vocal premotor nucleus HVC prior to vocal production and in response to call playbacks. By simulating the interplay between premotor and auditory-evoked activity, the model accounts for experimentally-induced changes in call timing and predicts that two patterns of inhibition can regulate vocal-motor responses to a heard call. In one regulatory scenario, the strength of production-related premotor inhibition translates into plasticity in vocal response delays. In the other scenario, fast transient interneuron activity in response to auditory input results in the active suppression of call production while a call is heard. The model provides a parsimonious framework by which auditory-vocal transformations can give rise to social coordination in the form of vocal turn-taking. More broadly, it highlights multiple roles of local inhibition within a sensorimotor circuit for behavioral modulation at different time scales.

Title: Neural mechanisms for the robustness of the timing network in songbird HVC against cooling

Authors: *A. KHARE, D. M. SEDERMAN, D. Z. JIN;
Dept. of Physics, Pennsylvania State Univ., University Park, PA

Abstract: Understanding the robustness of neural computation against perturbations such as temperature fluctuations is important for systems neuroscience. Birdsong in the zebra finch has exquisite timing features, controlled by an ultra-sparse sequential bursting of projection neurons in the premotor nucleus HVC (proper name) [1]. Experimental and modeling works suggest that a feedforward network within HVC generates sequential bursts [2]. Focal cooling of HVC slows down the song [3]. The effect of temperature on any biological process is quantified using a Q10 temperature coefficient. Most cellular and synaptic processes have Q10 values close to 2.0, and cooling by 10 degrees Celsius typically leads to a 100 percent change in time constants. In contrast, cooling HVC by 10 degrees Celsius in the zebra finch slows down the song only by 30 percent (Q10 ~ 1.3). Hence the burst sequence in HVC is much more temperature resilient than the cellular processes. This difference in Q10's of the song tempo and the cellular and synaptic processes led to a dilemma: Can a network entirely localized within HVC generate timing signals that are more robust against cooling than the cellular and synaptic processes? [3] Here we resolve this problem by computational modeling of a feedforward network within HVC and testing this model for temperature changes. An important aspect of our work involves incorporating axonal delays [5]. Signal transmission along the axons takes up a significant part of the network activity. Unmyelinated axons in HVC, like many such axons across species [6], should have a Q10 of approximately 1.25. This contributes significantly to the temperature robustness of the network. Moreover, our analysis of a single neuron's dynamics shows that the spike responses of HVC projection neurons have a Q10 smaller than the cellular and synaptic Q10's. A combination of these two aspects leads to a Q10 close to 1.3-1.5 for burst propagation time in the network. We also propose how a significant drop in the firing rate of inhibitory neurons could further lower the network Q10. Our work shows that local neuronal networks can be robust to temperature changes, despite higher sensitivity of cellular and synaptic processes to temperature.

Title: Vocal motor commands engage respiratory brainstem dynamics for call production in songbirds

Authors: *E. A. KISH, K. YACKLE, M. S. BRAINARD;
UCSF, San Francisco, CA

Abstract: Some of the evolutionarily oldest behaviors are generated by rhythmic central-pattern generators (CPGs) in the brainstem and spinal cord. Complex behaviors driven by evolutionarily newer brain regions like the cortex and midbrain often build on these simpler rhythmic behaviors, turning simple behaviors like walking and breathing into complex ones like dancing and vocalizing. Vocalization is a complex behavior used by many species for communication. Vocal motor commands from cortex and midbrain generate sound through vital respiratory machinery, such as the diaphragm and larynx, that is otherwise under the control of CPGs in the respiratory brainstem. Studying how vocal motor commands are coordinated with the ongoing dynamics of the respiratory brainstem can give us a deeper understanding of how descending motor commands interact with CPGs to produce complex behaviors. Bengalese finch calls provide a unique opportunity to study how vocalizations are coordinated with respiratory dynamics since they are produced one at a time, allowing the close study of how individual vocal commands interact with ongoing respiratory dynamics. By pairing audio recordings of vocalizations with air sac pressure recordings of breathing, we found that calls can interrupt breathing at any phase of the respiratory cycle. This indicates that the call-motor command can overcome the ongoing dynamics of the respiratory brainstem. Moreover, calls reset the respiratory rhythm, which means that calls directly interact with the respiratory CPG. Using electrical stimulation of midbrain vocalization nucleus DM to evoke calls, we discovered that the generation of the call respiratory waveform is dependent on a dynamical system. Moreover, our preliminary results from electrical stimulation of the respiratory brainstem indicate that a dynamical system in the respiratory brainstem is sufficient to produce an expiratory vocalization following a large inspiration evoked by electrical stimulation of the respiratory brainstem. Finally, we found evidence that local respiratory dynamics are not just driven by call commands but can also exert influence on call timing. We found a bias of call timing with respect to the respiratory cycle, in that calls are more likely to occur during the inspiratory phase of breathing. Taken together, these results show that top-down motor commands generated by the midbrain can override pre-existing brainstem respiratory dynamics to generate calls, but these local brainstem dynamics can in turn influence the production and timing of calls. Other complex behaviors may similarly depend on a precise interplay between top-down motor commands and local CPG dynamics.

Title: Extreme fine motor control of birdsong by recruiting the smallest, weakest and fastest motor units.

Authors: *I. ADAM[1], A. MAXWELL[1], H. ROESSLER[1], E. B. HANSEN[1], M. VELLEMA[2], J. BREWER[1], C. P. ELEMANS[1];

Abstract: Songbirds are an excellent model system to understand the acquisition and maintenance of auditory guided fine motor skill learning, however very little is known about the motor pool controlling the muscles of the vocal organ, the syrinx. The control resolution of all animal behavior is set by the smallest possible force step when recruiting the muscles involved in that behavior. This in turn depends on the number of motor units (MU), their size distribution as well as their muscle-specific force. To measure the MU size distribution, we developed and applied a new method using spatiotemporally resolved calcium imaging on cross-sections of intact and living syrinx muscles. Additionally, we determined how force drives fundamental frequency (f_o) using an in vitro syrinx preparation. Combining both data sets with measurements of muscle stress allowed us to determine the control resolution of f_o, an important vocal parameter, in zebra finches. We show that the syrinx motor pool is made up of extremely small MUs, 40-50% of MUs innervated 3 muscle fibers and 13-17% even consisted of only one single muscle fiber. In combination with the lowest specific stress known in skeletal vertebrate muscles (5 mN/mm^2), we found that the major muscle controlling f_o is equipped with small force steps of 50 mHz to 7.3Hz per MU. In conclusion, the song system possesses the highest possible control resolution in vertebrates. We suggest that this evolved in response to strong selection on finely graded vocal output. We furthermore propose that high-resolution control was one of the features contributing to the successful radiation of songbirds by expanding their vocal space allowing for diversification of song ultimately leading to speciation.

Title: Dynamical system model for the neural activity of singing canaries (Serinus canaria)

Authors: *A. AMADOR[1,2], C. T. HERBERT[1,2], S. BOARI[1,2], G. B. MINDLIN[1,2];

Abstract: Vocal production in songbirds is a key topic regarding the motor control of a complex, learned behavior. Birdsong is the result of the interaction between the activity of a neural network specifically dedicated to song production and learning (known as the “song system”), the respiratory system and the vocal organ. These systems interact and give rise to precise biomechanical motor gestures which result in song production. Telencephalic neural nuclei play a key role in the production of motor commands that drive the periphery, and while several attempts have been made to understand their coding strategy, difficulties arise when trying to understand neural activity in the frame of the song system as a whole. In this work, we report neural additive models embedded in an architecture compatible with the song system to provide a tool to reduce the dimensionality of the problem by considering the global activity of the units in each neural nucleus. This model is capable of generating outputs compatible with measurements of air sac pressure during song production in canaries (*Serinus canaria*). In this work, we show that the activity in a telencephalic nucleus required by the model to reproduce the observed respiratory gestures is compatible with electrophysiological recordings of single neurons in freely behaving animals.

Title: Neural reinstatement reveals divided organization of fear and extinction memories in the human brain

Authors: *A. C. HENNINGS[1], M. MCCLAY[2], M. R. DREW[3], J. A. LEWIS-PEACOCK[4], J. E. DUNSMOOR[5];
[1]Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX; [2]Univ. of California, Los Angeles, CA; [3]Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX; [4]Psychology, Univ. of Texas at Austin, Austin, TX; [5]Psychiatry, UT-Austin, Austin, TX

Abstract: Neurobiological research in rodents has revealed that competing experiences of fear and extinction are stored as distinct memory traces in the brain. This divided organization is adaptive for mitigating overgeneralization of fear to related stimuli that are learned to be safe, while also maintaining threat associations for unsafe stimuli. Whether a similar division exists in the human brain remains unclear. Here, we used a hybrid form of Pavlovian conditioning with an episodic memory component to identify overlapping multivariate patterns of fMRI activity associated with the formation and retrieval of fear versus extinction. In healthy adults (N=24), distinct regions of the medial PFC and hippocampus showed selective neural coding for fear and extinction memories. Specifically, the vmPFC showed specificity for extinction memories, while the dACC displayed specificity for fear memories. This dissociation was absent in participants with PTSD symptoms (N=24). Like healthy adults, individuals with PTSD did display reinstatement of fear memories in the dACC. However, extinction memory reinstatement was also observed in the dACC, representing a misallocation of extinction memories. Similar to the double dissociation observed in the mPFC of healthy adults, we also observed a double dissociation in fear and extinction reinstatement along the long axis of the hippocampus. Specifically, the anterior hippocampus exhibited selective reinstatement of extinction memories while the posterior hippocampus exhibited selective fear memory reinstatement. Again, this pattern was dysregulated in individuals with PTSD, such that no extinction memory reinstatement was observed in the anterior hippocampus. The divided neural organization of fear and extinction may support flexible retrieval of context-appropriate emotional memories, while their disorganization may promote overgeneralization and increased fear relapse in affective disorders.

Title: Can you remember the context? Quantification of human context fear conditioning

Authors: *Y. XIA[1,2], J. WEHRLI[1,2], D. R. BACH[1,3,4];
[1]Dept. of Psychiatry, Psychotherapy, and Psychosomatics, [2]Neurosci. Ctr. Zürich, Univ. of Zürich, Zürich, Switzerland; [3]Wellcome Ctr. for Human Neuroimaging, [4]Max Planck UCL Ctr. for Computat. Psychiatry and Ageing Res., Univ. Col. London, London, United Kingdom

Abstract: Contextual fear conditioning is a paradigm commonly used to study aversive learning and the formation of trauma memory in humans. We sought to optimise the quantification of contextual fear memory recall from psychophysiological measures. We first used an existing virtual reality paradigm (Kroes et al. 2017). Participants learned the context-shock association on their first visit; memory retention was then tested one week later under extinction. Measures of conditioning and retention were derived from startle eye-blink responses (SEBR) and autonomic responses, such as skin conductance responses (SCR) and pupil dilation. We first exploratively studied whether memory acquired from this paradigm can be retained for 7 days with N = 23 healthy participants. Although self-reports on valence, arousal and shock expectancy showed successful conditioning and memory retention, model-based analysis of psychophysiological responses did not reveal any differences between the contexts. These negative results were replicated in an independent confirmatory experiment with N = 28 healthy participants. We then adapted a configural fear conditioning paradigm (CFG) using five static room images as conditioned stimuli (CSs; Stout et al. 2019). One of the images (CS+) was reinforced by unconditioned stimulus (US) during memory acquisition with a reinforcement rate of 83%. In two independent experiments with N = 29 and N = 24 healthy human participants, aversive memory was acquired with stronger SCR and pupil dilation responses to CS+ than to CS-. One week later, memory was retained, reflected by stronger SEBR and pupil dilation responses to CS+. Overall, we established a contextual fear conditioning paradigm in healthy humans and verified memory retention over 7 days, based on psychophysiological responses.

Title: Effects of Concussive-like Brain Injury on Fear Behaviors in Rats

Authors: *G. HERNÁNDEZ-BUSOT, M. RIVERA-LÓPEZ, O. MARTÍNEZ-GUZMÁN, M. CÁCERES-CHACÓN, D. SIERRA-MERCADO;
Anat. & Neurobio., Univ. of Puerto Rico Sch. of Med., San Juan, PR

Abstract: Each year 40 million people worldwide suffer from traumatic brain injury, mainly in the form of concussions. Human studies have linked concussions with the development of fear-related disorders such as post-traumatic stress disorder (PTSD). However, the relationship between concussions and fear behaviors remain unclear and animal studies show conflicting results. To evaluate the potential link between concussions and fear behaviors, a biological link must be examined using reliable injury models and behavioral tests. Given that failure to extinguish fear is a hallmark of PTSD, we hypothesized that a concussive brain injury will impair fear extinction using Pavlovian conditioning in rats. To address this gap, rats underwent fear conditioning where they learned that a tone predicts a shock. Freezing behavior to the conditioned tone, an index of fear characterized by lack of movement save those necessary for breathing, was quantified. Afterwards, anesthetized rats received either a concussive-like injury or sham injury. Following recovery from concussive-like injury, rats underwent extinction where they learn that the tone no longer predicts a shock. Results showed no significant difference ($p>0.05$) between concussive-like ($n=9$) and sham ($n=8$) groups, suggesting that concussive brain injury does not affect the ability to extinguish fear. Future studies will aim at examining changes in neuronal activity in brain regions relevant to fear behaviors such as the amygdala using cFos immunohistochemistry.

Title: The role of hippocampal-prefrontal theta oscillations in human contextual fear conditioning

Authors: *I. MARTIN, D. BUSH, J. BISBY, A. CASTEGNARO, R. ADAMS, N. BURGESS; UCL, London, United Kingdom

Abstract: Rodent studies have implicated the hippocampal and medial prefrontal network (HPC-mPFC) in anxiety and spatial fear learning. Both HPC and mPFC theta power, along with HPC-mPFC theta coherence, are increased in anxiogenic environments. Interestingly, however, mPFC theta power is specifically increased in the safe areas of a dangerous environment (Adhikari et al., 2010). These findings may aid in the understanding of underlying mechanisms of anxiety and development of treatments. Thus, we sought to replicate and extend these key findings in humans. We used a magnetoencephalography (MEG) contextual fear conditioning paradigm in which 22 participants were asked to freely navigate to and 'pick' flowers in a circular virtual reality (VR) environment. Flowers in one half of the environment were associated with a 'bee sting' and 50% chance of electric shock . In the other half of the environment, flowers were never associated with a shock. When participants picked a flower, they were asked to rate their expectancy of shock on a scale of 1-10. Given prior findings, we focused our analyses on the longest continuous period of movement towards flowers, and on the theta band. Expectancy ratings were significantly higher in the dangerous half of the environment, showing that participants successfully learned the task contingencies. Based on the grand average power spectrum, and previous literature, we analysed low (2-5 Hz) and high (6-10 Hz) theta bands separately, comparing oscillatory activity between trials in the safe and dangerous halves of the environment. This revealed increased 6-10 Hz power over frontal sensors in the safe half, and increased 6-10 Hz power over middle-temporal sensors in the dangerous half of the environment. Increased theta power in the dangerous half was localized to right hippocampus (rHPC); while increased theta power in the safe half was localized to medial prefrontal cortex (mPFC). Using rHPC as a seed, we examined differences in 6-10 Hz phase coupling and found increased rHPC-dorsolateral PFC coupling in the dangerous half of the environment. Our findings offer important translational support for the roles of HPC and mPFC across rodents and humans in particular that HPC-PFC communication is important in processing danger. Our study is also the first to replicate mPFC theta power increases in the safe areas of dangerous environments in humans. The findings are consistent with recent work describing threat dependent modulation of hippocampal theta power (Khemka et al., 2017) and offer insight into the neural correlates of contextual fear in humans (Suarez-Jimenez et al., 2018).

Title: Anticipatory brain activity during Pavlovian fear conditioning is modulated by the controllability of threat

Authors: *L. R. NELSON[1], A. BOLARAM[1], J. B. PURCELL[1], H. E. DARK[1], D. K. GREY[1], A. J. KNIGHT[2], D. C. KNIGHT[1];
[1]Dept. of Psychology, [2]Physical Med. and Rehabil., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The ability to control the threats we encounter has important implications for resilience to stress. Chronic stress exposure can lead to emotional dysfunction and the development of anxiety disorders. Therefore, examining anticipatory neural responses to controllable versus uncontrollable threats during Pavlovian fear conditioning may provide new insight into the processes underlying emotional dysfunction. We hypothesized the ability to control threat would influence the anticipatory functional magnetic resonance imaging (fMRI) signal response within the amygdala and prefrontal cortex (PFC), which are brain regions that underlie fear conditioning. This study investigated anticipatory neural responses (i.e., conditioned responses; CR) to threats (i.e., unconditioned stimuli; UCS) that were either controllable or uncontrollable using a yoked Pavlovian fear conditioning procedure. Participants (n = 26 [21 females]; mean age = 23.62) were presented visual stimuli (green and yellow squares) as conditioned stimuli (CSs; 8 second duration). One CS (CS+; 20 trials) was always paired (100% pairing rate) with a loud white noise UCS (100dB; 0.5 to 6 second duration). The other CS (CS-; 20 trials) was presented without the UCS (0% pairing rate). The UCS was also presented alone on some trials (20 trials). Stimuli were presented during a Controllable Condition (CC) and an Uncontrollable Condition (UC). During the CC, participants could terminate the UCS by pressing a button, while during the UC, the duration of each UCS was yoked to the UCS durations chosen by a prior participant during their CC. Functional MRI data were collected using a Siemens 3T Prisma scanner and analyzed using Analysis of Functional NeuroImages (AFNI) software. ANOVA revealed that learning-related changes in the fMRI signal response to the CS+ and CS- varied with the controllability of the UCS. More specifically, a significant interaction was observed between CS type (i.e., CS+ versus CS-) and controllability (i.e., CC versus UC) within the amygdala, ventromedial PFC, dorsomedial PFC, ventrolateral PFC, and posterior cingulate. These results suggest that learning-related changes in anticipatory brain activity (i.e., the CR) are impacted by the ability to control impending threats (i.e., the UCS). These brain regions may play an important role during fear conditioning by maintaining

anticipatory representations of control over an impending threat. These findings suggest that threat controllability may impact the way we form associations between a CS and UCS, which could ultimately have implications for the development and subsequent treatment of stress and anxiety-related disorders.

Title: Probing the role of human primary sensory cortex in acquisition and consolidation of aversive memory with transcranial magnetic stimulation

Authors: K. E. OJALA[1], M. STAIB[1], S. GERSTER[1], C. C. RUFF[2], ***D. R. BACH**[3]; [1]Computat. Psychiatry Res., Psychiatric Univ. Hosp. Zurich, Zurich, Switzerland; [2]SNS-Lab, Univ. of Zurich, Zurich, Switzerland; [3]Univ. Col. London, London, United Kingdom

Abstract: Aversive conditioning is often thought to rely primarily on the amygdala with no essential contribution from cortical areas. More recently, however, it emerged that rodents require primary sensory cortex for learning to discriminate complex stimuli that predict threat from those that predict safety. It is not firmly known whether this is also the case for simple conditioned stimuli, and in humans. Here, we used continuous theta-burst transcranial magnetic stimulation (cTBS) to investigate the role of primary sensory cortex in discriminative threat conditioning in humans. Because of its clear lateralisation, we chose the somatosensory domain as a model system. N = 68 participants received cTBS immediately before conditioning in the CS-contralateral (experimental) or CS-ipsilateral (control) hemisphere. They were then trained with simple (location) and complex (location pattern) somatosensory conditioned stimuli (CS) and aversive electric stimulation as US. After overnight consolidation, we measured threat memory retention using fear-potentiated startle. We found that memory retention was attenuated in the experimental compared to the control group. There was no evidence for a difference in this effect between simple and complex stimuli. During initial acquisition, learning was quantified using pupil dilation and skin conductance responses. We found no evidence that cTBS had an immediate effect on initial learning in these measures, or on CS identification. This suggests a stronger effect of cTBS on consolidation than on initial stimulus processing or short-term learning. We propose that non-invasive stimulation of sensory cortex may provide a new avenue for interfering with threat memories in humans.

Title: Neuroticism/negative emotionality is associated with increased reactivity to uncertain threat in the bed nucleus of the stria terminalis

Authors: *S. E. GROGANS[1], J. HUR[3], M. G. BARSTEAD[4], A. S. ANDERSON[5], S. ISLAM[6], H. C. KIM[2], M. KUHN[7], R. M. TILLMAN[1], A. S. FOX[8], J. F. SMITH[1], K. A. DEYOUNG[1], A. J. SHACKMAN[9];

Program, Univ. of Maryland, College Park, MD

Abstract: Neuroticism/negative emotionality (N/NE)—the tendency to experience greater negative affect—is a central dimension of temperament and personality. Elevated N/NE has profound consequences for public health and wealth, drawing the attention of researchers and clinicians. Yet the underlying neurobiology has remained enigmatic. Here, we used a suite of neuroimaging techniques to test the hypothesis that N/NE is associated with heightened reactivity to threat-of-shock in the extended amygdala (EA)—including the central nucleus of the amygdala (Ce) and bed nucleus of the stria terminalis (BST)—in 220 young adults selectively recruited from a pool of nearly 7,000 phenotyped individuals to capture a broad spectrum of N/NE. To clarify specificity, parallel analyses were performed using data from an emotional-faces paradigm. While ‘threatening’ faces are potent triggers of amygdala activity and widely used in on-going biobank projects, they do not elicit robust negative affect and do not represent a trait-relevant challenge. A multiband pulse sequence, best-practice data processing techniques, spatially unsmoothed data, anatomically defined regions-of-interest, and a cross-validated

robust-regression framework enabled unbiased hypothesis testing with unprecedented anatomical resolution. Results revealed that N/NE is associated with heightened BST activation during aversive anticipation (p=0.049), and this association is uniquely evident when the timing of aversive stimulation is uncertain (p=0.004). BST reactivity to uncertain threat remained predictive of N/NE in models excluding BST reactivity to certain threat (p=0.003) or including Ce reactivity to uncertain threat (p=0.002). Other findings suggest that relations between the N/NE phenotype and BST function are indirect and reflect increased threat-elicited arousal (p=0.011). In contrast, N/NE was unrelated to Ce reactivity to threat-of-shock and BST/Ce reactivity to emotional faces (ps>0.05). While it is tempting to treat different 'threat' paradigms as interchangeable probes of brain function, this has rarely been examined. Follow-up analyses revealed no evidence of between-task convergence in the Ce (p>0.05) and marginal evidence in the BST (p=0.059). A large, well-phenotyped sample and pre-registered, best-practices approach enhance confidence in the robustness and translational relevance of these results. Together, these observations have implications for theory and practice and lay the groundwork for the longitudinal and mechanistic studies that will be necessary to determine causation and, ultimately, to develop improved interventions for extreme N/NE.

Title: Predictability and controllability alter neural reactivity to threat

Authors: *A. BOLARAM, J. B. PURCELL, H. E. DARK, D. K. GREY, A. J. KNIGHT, D. C. KNIGHT;
Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Emotional resilience to stressful events depends, in part, on our ability to predict and control threats in the environment. Thus, determining the neural response to predictable and controllable threats, may provide new insights into brain processes that underlie resilience to emotional dysfunction. The present study assessed the functional magnetic resonance imaging (fMRI) signal of participants (N=26, [20 female], Mean Age = 23.62) who completed a differential fear conditioning procedure designed to investigate the neural response to predictable

and unpredictable threats under controllable and uncontrollable conditions. Two visual stimuli (green and yellow squares) served as conditioned stimuli (CSs; 8 second duration) and a loud, 100 dB white noise served as the unconditioned stimulus (UCS; 0.5-6.0 second duration). One CS (CS+) was always (100% pairing rate) paired with the UCS (Predictable threat; 20 trials). The other CS (CS-; 20 trials) was never paired with the UCS (0% pairing rate). In addition, the UCS was presented alone on some trials (Unpredictable threat; 20 trials). Stimuli were presented during both Controllable and Uncontrollable conditions. The color of a UCS expectancy rating bar (blue or red) indicated whether the UCS was controllable or uncontrollable. During Controllable trials participants could terminate the UCS (Controllable threat) by a button press. During Uncontrollable trials the button press did not terminate the UCS (Uncontrollable threat). To ensure UCS durations were equivalent across Controllable and Uncontrollable conditions, the duration of the Uncontrollable UCS was yoked with the duration of a prior participant's Controllable UCS. Skin conductance response and UCS expectancy served as behavioral indices of threat-related processing during the task. Functional MRI data were collected using a 3T Siemens Prisma scanner. Repeated measures ANOVA revealed a significant interaction between predictability and controllability in the threat-related fMRI signal response within the dorsomedial, dorsolateral, and ventrolateral prefrontal cortex, middle and posterior cingulate, and inferior parietal lobule. Follow up analysis revealed that across trial blocks, activity in these regions was greater for predictable threats that were uncontrollable than predictable threats that were controllable. The present findings demonstrate that threat predictability and controllability alters the neural response within brain regions that support emotion regulation processes, which may have important implications for susceptibility/resilience to internalizing disorders.

Title: Cd5 knockout mice exhibit alterations in measures of ethanol sedation and consumption

Authors: *A. J. PAYNE[1,2], J. D. OBRAY[3], B. M. WILLIAMS[2], C. A. SMALL[2], S. M. BAUSERMAN[2], J. T. YORGASON[2], J. G. EDWARDS[2], K. S. WEBER[2], S. C. STEFFENSEN[2]; [1]Noorda Col. of Osteo. Med., Pleasant Grove, UT; [2]Brigham Young Univ., Provo, UT; [3]Med. Univ. of South Carolina, Charleston, SC

Abstract: Cluster of differentiation 5 (CD5) is expressed on the surface of T and a subset of B cells (B1 cells) and is a negative regulatory molecule that alters lymphocyte activation pathways. It has been found that CD5 expression is altered during chronic ethanol (EtOH) use. Specifically, the number of CD5+ B cells is reduced during active alcoholism and returns to normal after withdrawal. Given the apparent sensitivity of these cells to chronic EtOH consumption and the role of some lymphocytes in regulating the development of inhibitory GABA synapses, we assessed the impact of a CD5 genetic knockout (CD5KO) on measures related to EtOH reward and sedation. We found that CD5KO mice display decreased EtOH consumption compared with wild-type C57BL/6J controls in a 24-hour access two bottle choice drinking paradigm. Additionally, CD5KO mice displayed considerable resistance to the EtOH-mediated decrease in locomotor activity at low doses (0.5 - 2.0 g/kg) and EtOH-induced sedation at high doses (4.0 g/kg). We found that there was no difference in spontaneous dopamine (DA) release events between CD5KO mice and wild type controls, and evoked DA release was also measured. Additionally, we found decreased levels of DA transporter (DAT) RNA transcripts in the nucleus accumbens (NAc) in the CD5KO mice. There was no evidence of a CD5-dependent effect in the EtOH-induced inhibition of GABA neuron firing rate in the ventral tegmental area (VTA). These results suggest that CD5KO mice are less sensitive to some of the effects of EtOH and that peripheral neuroimmune mechanisms involving CD5 may be a factor in EtOH consumption and sedation.

Title: The impact of early alcohol exposure and differential rearing on operant responding for alcohol and synaptic plasticity.

Authors: *T. MOSER[1], B. C. HOWATT[1], K. ESCHLIMAN[1], I. MALI[1], S. BOSSMANN[2], M. CAIN[3];

Abstract: The experiences in adolescence can drastically affect how the brain forms in early adulthood. An isolated rearing environment and early alcohol exposure both negatively alter brain development. With either of these experiences, a decrease in synaptic plasticity can occur caused by a concentration change in metabolites (i.e., homoscysteic acid) that cause more neuroinflammation resulting in a reduction of synaptic plasticity. Our current study examines how differential rearing and early alcohol exposure affect alcohol seeking and synaptic plasticity using nuclear magnetic resonance (NMR) to measure markers for synaptic plasticity in adulthood. We hypothesize that enriched rats that have intermittent adolescent alcohol exposure (IAEE) during adolescence will have lower responding for alcohol in an operant paradigm. We also hypothesize that enrichment will have a higher homocysteic acid concentration than standard condition (SC) or isolated condition (IC). In the current study, we raised male and female Long Evans rats in Enriched (EC), SC, and IC conditions during adolescence. During the rearing period, twelve injections of 20% alcohol (w/v; ip) or saline were administered every other day. Rats were then trained to lever press in an operant chamber. After training was completed, rats responded for 10% alcohol on two fixed-ratio (FR-1 and FR-5) schedules and a progressive ratio (PR) schedule. Following a two-week rest period, a challenge injection of alcohol (1.5 g/kg) or saline was administered and blood was collected for a blood alcohol concentration (BEC) quantification and brains were collected for NMR to measure homocysteic acid concentration. The results indicate that enrichment and sex influence responding for 10% alcohol in the operant paradigm; however, IAEE treatment has no effect. Enriched female rats responded the least for 10% alcohol across the different schedules tested with IC and SC female rats responding more. Enrichment decreased the BEC compared to SC and IC rats regardless of sex and prior alcohol exposure. Preliminary results of the NMR imaging suggest that male isolated rats that received an acute injection of alcohol or in the saline control group (alcohol naïve) have lower concentrations of homocysteic acid in the medial prefrontal cortex. In summary, our results indicate that enrichment in early adolescence decreases responding for alcohol on a variety of operant schedules, decreases BEC following IAEE, and helps maintain higher levels of homocysteic acid in the mPFC.

Title: Disturbances in the anatomical location and phenotype of peptide neurons induced by low-dose embryonic ethanol exposure in zebrafish and rats

Authors: *A. D. COLLIER, G.-Q. CHANG, N. KHALIZOVA, N. YASMIN, S. CAMPBELL, M. FAM, S. F. LEIBOWITZ;
The Rockefeller Univ., New York, NY

Abstract: Prenatal alcohol exposure (PAE) is well known to disturb neuronal development and behavior. Previous work from this lab and others has shown in rats and zebrafish that low-moderate concentrations of ethanol exposure during gestation increases the density of neurons expressing the peptides, hypocretin/orexin (Hcrt) and melanin-concentrating hormone (MCH), which are most concentrated in specific areas of the hypothalamus and known to promote alcohol consumption. With studies in rats showing Hcrt neurons under normal conditions to be neurochemically heterogeneous and perhaps functionally distinct based on their anatomical location, we used time-lapse live imaging and brain registration in zebrafish and found embryonic exposure to low-dose ethanol (0.5% v/v) in the water during hypothalamic development (22-24 hours post-fertilization) to increase the dispersion and alter the migration and anatomical distribution of Hcrt neurons, causing more than 25% to be abnormally located. We then laser ablated these Hcrt neurons and found this to block behaviors induced by embryonic ethanol, including increased voluntary ethanol-gelatin consumption, suggesting that these neurons play a role in mediating ethanol-induced behavioral disturbances. We next sought to determine if PAE in rats similarly affects the anatomical distribution of these peptide neurons and also possibly their specific characteristics. We used iDISCO brain clearing with Hcrt and MCH immunolabeling that allows one to examine the total population of these neurons. We found that PAE, at a low-moderate dose (2 g/kg/day) from embryonic day 10 (E10) to E15, increases the density of Hcrt and MCH neurons in hypothalamic areas where they are normally most concentrated, specifically the perifornical lateral hypothalamus, zona incerta and dorsomedial area, but has little effect on the size, shape and number of processes of these peptide neurons. However, analyses of other hypothalamic areas, such as the mammillary nuclei where Hcrt and MCH are not normally detected, revealed populations of both Hcrt and MCH neurons in PAE rat offspring. Moreover, the majority of these abnormally located neurons exhibited altered features, including unusually round somas, small size, and fewer processes, relative to their standard phenotype in areas where they naturally exist. These findings suggest that, in addition to increasing their density in brain areas where they are normally located, PAE alters the anatomical distribution of these peptide neurons and causes some to migrate outside their normal location and have abnormal phenotypes that may contribute to the behavioral disturbances produced in the offspring.

Title: The effects of perinatal sex hormone manipulation on alcohol response following a juvenile traumatic brain injury

Authors: *R. OLIVERIO[1], K. KARELINA[2], R. VELAZQUEZ-CRUZ[2], B. WHITE[2], B. WHITEHEAD[2], Z. M. WEIL[2];
[1]Rockefeller Neurosci. Inst., West Virginia Univ. - PhD In Neuros Neurosci. Grad. Program, Morgantown, WV; [2]Rockefeller Neurosci. Inst., West Virginia Univ., Morgantown, WV

Abstract: Approximately 2.8 million traumatic brain injuries (TBIs) occur each year in the United States, and a large portion of the population affected by these injuries is composed of children. Notably, individuals who suffer from a TBI early in life experience a myriad of adverse risks. For example, women injured in adolescence are more likely to develop an alcohol use disorder in adulthood than women injured at any other developmental stage. We reported similar findings in a preclinical model, wherein female mice injured early in life drank significantly more than uninjured females. However, we did not see this effect in males. Given these sex differences, we aimed to investigate the role of sex hormones in the response to alcohol following a juvenile TBI. We hypothesized that male sex hormones reduced drinking following TBI. Therefore, we manipulated sex hormones in mice perinatally through exposure to androgens in females and gonadectomies in males. We then performed a mild traumatic brain injury at postnatal day 21 using a standard closed-head injury model. In adulthood, we employed additional sex hormone manipulations via gonadectomies in male and female mice. Alcohol preference was then assessed through a conditioned place preference paradigm. Injured female mice for which no sex hormone manipulations were performed developed a conditioned place preference to ethanol, whereas injured females which were provided testosterone perinatally or gonadectomized in adulthood did not. This indicates that sex hormones are involved in the response to alcohol following a TBI early in life.

Title: Receptor Protein Tyrosine Phosphatase β/ζ modulates ethanol effects on hippocampal neurogenesis in male and female adolescent mice but only regulates ethanol intake in male mice

Authors: M. GALÁN LLARIO, M. RODRÍGUEZ-ZAPATA, T. FONTÁN, E. GRAMAGE, M. VICENTE-RODRÍGUEZ, C. PÉREZ-GARCÍA, M. C. OVEJERO-BENITO, J. M. ZAPICO, A. RAMOS, B. DE PASCUAL-TERESA, *G. HERRADON;
Fac. of Pharm., CEU San Pablo Univ., Madrid, Spain

Abstract: Binge drinking causes neuroinflammation and neurotoxicity in the adolescent brain and is highly related to the development of alcohol use disorder (AUD). There is an urgent need to discover new pharmacological targets not only to limit ethanol consumption but to prevent brain damage caused by ethanol in adolescents. Pleiotrophin (PTN) is a cytokine upregulated in the brain after ethanol administration. PTN binds Receptor Protein Tyrosine Phosphatase (RPTP) β/ζ and acts as an endogenous inhibitor of its phosphatase activity. Both, PTN and MY10, a small-molecule inhibitor of RPTPβ/ζ, decrease binge-like ethanol consumption and reward in mice and rats. We hypothesize that RPTPβ/ζ also plays a role in chronic ethanol consumption and in the neural alterations associated with ethanol. To test this hypothesis, male and female adolescent C57BL/6J mice were used in an intermittent access to ethanol (IAE) model using a 2-bottle choice protocol. Before each drinking session, mice received an administration of MY10 (60 mg/kg, i.g.), or vehicle as control, and ethanol consumption was measured. At the end of the 4-weeks IAE protocol, brains were removed for immunohistochemistry analysis of Iba-1 and GFAP in prefrontal cortex and doublecortin (DCX) in dentate gyrus. In acute ethanol experiments, mice were treated with MY10 one hour before the administration of 6 g/kg ethanol (i.p.). Eighteen hours after ethanol administration, brains were dissected and subjected to the same immunohistochemistry analysis. Adolescent male mice treated with MY10 drank less ethanol than controls and showed a reduced preference for the ethanol solution in the IAE model. In contrast, MY10 did not seem to have relevant effects on ethanol intake in female mice. This effect of MY10 was not accompanied by significant alterations in glial responses. In acute ethanol experiments, we observed an overall increased activation of microglia in female adolescent mice, especially in those treated with MY10 and ethanol, suggesting gender differences in RPTPβ/ζ function. Acute ethanol induced a significant decrease on hippocampal neurogenesis in both male and female adolescent mice, which was completely prevented by treatment with MY10 in both sexes. In summary, inhibition of RPTPβ/ζ significantly reduced ethanol consumption in the IAE model only in male mice. RPTPβ/ζ critically modulates ethanol-induced decreases on hippocampal neurogenesis in both male and female adolescent mice.

Title: Withdrawal from oxycodone dependence in mice promotes sex specific increases in alcohol drinking

Authors: A. BOISVERT[1], S. HUITRON-RESENDIZ[2], A. J. ROBERTS[2], *A. KIMBROUGH[1]; [1]Basic Med. Sci., Purdue Univ., West Lafayette, IN; [2]Animal Models Core, The Scripps Res. Inst., La Jolla, CA

Abstract: Substance use disorder (SUD) is a major societal problem throughout the world. In humans, one substance of abuse is commonly used to self-medicate withdrawal symptoms from dependence of another substance of abuse. As such, withdrawal from a specific drug may modulate the intake of another drug to promote excessive use. Preclinical models of self-medication and are not readily available, thus the present study sought to design a preclinical model of self-medication and determine if withdrawal from opioid dependence would modulate alcohol drinking behavior. Mice (n=40) were given daily two-bottle choice (2BC) access for two hours to 15% alcohol and water over two weeks (weeks 1-2) to determine baseline of alcohol drinking behavior. After baseline testing, for one week (week 3) half of the mice (n=20; 10 female, 10 male) were given twice daily injections of oxycodone (12 hours apart; 5 m/kg initially and ramping up to 20 mg/kg in later weeks), while the other half (n=20; 10 female, 10 male) were injected with saline. The following week (week 4), mice underwent 2BC drinking, without daily oxycodone injections. This two-week cycle of oxycodone injections for 1 week, followed by 2BC drinking for 1 week, was repeated for a total of 5 cycles. After the 5th week of 2BC post-oxycodone injections, mice were tested initially after 72 hours of withdrawal for thermal pain sensitivity using the tail-flick test. The mice were tested again after 96 hours of withdrawal, but immediately after a 2BC alcohol session to determine if alcohol could alleviate the presence of heightened pain sensitivity.In females, mice in withdrawal from oxycodone showed a significant increase in alcohol intake compared to mice injected with saline on post oxycodone weeks 3-5. Male mice did not show an effect of oxycodone on alcohol drinking. When tested for thermal pain sensitivity, female mice in withdrawal from oxycodone showed a significantly faster latency to withdrawal their tail compared to saline injected controls. Interestingly, this difference was eliminated after the mice had a 2BC alcohol session prior to testing. Males did not show differences in thermal pain sensitivity across groups. The present study suggests that oxycodone withdrawal promotes alcohol intake in a sex dependent manner. Similarly,

oxycodone withdrawal appears to modulate pain sensitivity in a sex dependent manner that can be alleviated by alcohol drinking. These results suggest females may be more susceptible to excessive alcohol drinking if already dependent on oxycodone. Future studies will explore brain mechanisms involved in the co-use of alcohol and opioids.

Title: Brief-access to ethanol induces an increase in ethanol taste detection threshold without affecting its salient taste quality: a potential role for the insula in escalation of ethanol intake

Authors: *A. MUKHERJEE, M. PALADINO, S. HONEYCUTT, G. LONEY;
Univ. at Buffalo, Buffalo, NY

Abstract: Alcohol use disorder (AUD) is a critical public health concern, characterized by escalating drinking despite adverse outcomes. Preclinical studies demonstrate that animals given intermittent 24-h access to ethanol (EtOH) escalate their intake of EtOH and display blunted sensitivity to quinine-adulteration of EtOH. Previously, we have shown that rats undergoing intermittent brief-access EtOH drinking (10s presentations across 30 min) rapidly escalate EtOH intake and display decreased sensitivity to a quinine (QHCl)-adulteration of EtOH but not sucrose. Here, we examined whether the escalation of EtOH intake following brief-access exposure, and subsequent QHCl-insensitivity, was associated with changes in the psychophysical perception of the taste of EtOH. Briefly, mildly water-restricted EtOH-exposed and naïve rats were trained in a taste-detection paradigm such that they made one operant response when given a taste stimulus (0.4 mM QHCl or 200 mM sucrose) and a separate, distinct operant response when given water. Next, these rats were tasked with detecting various concentrations of EtOH (0.469% to 5%) amongst water trials. Prior brief-access EtOH significantly increased EtOH taste detection thresholds, such that a higher ethanol concentration was required in order for exposed rats, relative to naïve, to reliably distinguish between EtOH and water. In a separate cohort of rats, we examined whether brief-access exposure altered the salient taste quality (i.e. ‘bitterness’ or ‘sweetness’) of EtOH. Here, rats were trained to make one operant response when presented quinine and a separate operant response when presented sucrose. Next, the rats were randomly

given various EtOH concentrations (1.25% to 40%) and their responding on the QHCl ('bitter') or sucrose ('sweet') operandum was measured. Generally, rats reported that the taste of EtOH became more sucrose-like as concentration was increased. Importantly, there were no differences between exposed and naive animals in the perceived taste quality of EtOH. In other words, rats that had escalated their EtOH intake did not find EtOH to taste less 'bitter' or more 'sweet'. As such, the reduced sensitivity to QHCl-adulteration following escalation of EtOH intake is likely not a sensory phenomenon, but a motivational one. Currently we are examining the necessity of the insular cortex (IC) to this escalation of EtOH drinking and change in taste perception with pharmacological and chemogenetic inactivation studies. Furthermore, we are probing the relevant IC-afferents to this escalation, particularly connections with the nucleus of the solitary tract and parabrachial nucleus.

Title: Alcohol intake and preference are regulated by striatal expression of Bmal1 and Per2 in male and female mice

Authors: *N. DE ZAVALIA, S. FERRARO, K. SHÖTTNER, P. SOLIS, G. PARENT, S. AMIR;
Concordia Univ., Montreal, QC, Canada

Abstract: Alcohol use disorders (AUDs) are among the most severe public health problems worldwide and have dramatic consequences for individuals' health and productivity, their families, and society. Drastic differences have been identified between men and women in the propensity for alcohol abuse and their biological response to alcohol. A growing body of literature connects perturbations in circadian rhythms and the genes that control the molecular clock to the development and progression of AUDs. The striatum plays a crucial role in alcohol's reinforcing effects, as well as in the development and maintenance of AUDs. The aim of this work was to study ethanol intake in conditional knock-out mice that lack the *Bmal1* or *Per2* clock gene specifically in the striatum. We created a conditional *Bmal1* or *Per2* knock-out mouse using the Cre-loxP system. *Bmal1* or *Per2 Floxed* mice were crossed to *Gpr88-Cre* mice to specifically knock out *Bmal1* or *Per2* in Gpr88 expressing striatal medium spiny projection neurons (MSN). Twelve-18 week old WT, Knock-out (KO) and Heterozygote (HET) male and

female mice were tested in a 24 h intermittent ethanol (15% v/v) access protocol or sucrose (0.25 or 2% m/v) access protocol. Selective deletion of *Bmal1* or *Per2* mRNA and protein was observed in the striatum of KO mice compared with WT. Deletion of *Bmal1* from MSN disrupted the striatal expression of *Per2* and the clock-controlled gene *Dbp*. The lack of striatal *Bmal1* or *Per2* expression did not affect circadian locomotor activity rhythms and sucrose intake, but it significantly altered voluntary alcohol intake and preference. Strikingly, *Bmal1 and Per2* KO male mice drink significantly more alcohol and have a higher alcohol preference than WT mice (n=10/group, $P < 0.05$). *Bmal1* KO female mice drink significantly less alcohol and have a lower alcohol preference than WT mice (n=10/group, $P < 0.05$). No significant differences in alcohol intake and alcohol preference between *Per2* KO and WT female mice were observed. Interestingly, in both males and females, deletion of one allele of *Bmal1* or *Per2* did not affect alcohol intake and preference. Alcohol behaviour in Gpr88Cre/+ male and female mice was similar to Gpr88+/+ controls. These results demonstrate that a *Bmal1*/*Per2*-dependent mechanism in MSN of the striatum plays a sexually dimorphic role in the control of alcohol intake in mice, conferring protection from excess drinking in males and risk in females. Further studies are being carried out to determine the mechanisms that explain how clock genes exert their protective function and to understand the sex differences observed in this study.

Title: Alcohol activates Rac1 signaling in the dorsomedial striatum and contributes to alcohol drinking behavior in female and male mice

Authors: *Z. HOISINGTON[1], K. PHAMLUONG[1], Y. EHINGER[2], D. RON[3];

Abstract: Alcohol activates Rac1 signaling in the dorsomedial striatum and contributes to alcohol drinking behavior in female and male mice

Zachary W. Hoisington, Khanhky Phamluong, Yann Ehinger, and Dorit Ron
Department of Neurology, University of California San Francisco

The small G-protein Rac1 is a signaling molecule that promotes cytoskeletal rearrangement. We

and others previously showed that alcohol produces alterations in neuronal structure in the striatum [1-3]. We therefore examined the contribution of Rac1 to alcohol-dependent neuroadaptations in the striatum. To do so, mice underwent 7 weeks of intermittent access to 20% alcohol using a two bottle choice paradigm (IA20%2BC) and Rac1 activity was measured. We found that chronic excessive alcohol intake activates Rac1 in the dorsomedial striatum (DMS) and that the activation of Rac1 was maintained after 24 hours of alcohol withdrawal. In contrast, IA20%2BC did not activate Rac1 in the neighboring dorsolateral striatum (DLS). Consumption of 10% alcohol or sucrose did not alter Rac1 activity in the DMS, and the furthermore activity of a closely related small G-protein, RhoB, was unaltered by alcohol in the DMS. We further show that the consequence of alcohol-dependent Rac1 activation in the DMS is the stimulation of LIM kinase (LIMK), and the phosphorylation of its substrate, Cofilin. Next, to examine if Rac1 contributes to alcohol intake, we systemically administered Rac1 inhibitor NSC23766 (10mg/kg) to female and male mice that had undergone 7 weeks of IA20% 2BC paradigm 3 hours before a drinking session. We found that that systemic administration of NSC23766 reduces alcohol but not sucrose intake in female and male mice without altering water intake locomotion, anxiety, or blood alcohol concentration. Together, our data suggest that Rac1 plays a role in cellular and behavioral adaptations that drive and/or maintain alcohol use.

Title: The effects of adolescent social isolation stress on binge drinking and cognitive behaviors in C57BL/6J mice

Authors: *J. LODHA, A. MORGAN, A. B. PAIS, A. C. PAIS, G. ELMISURATI, M. F. MILES, J. T. WOLSTENHOLME;
Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Rationale: Adolescence is characterized by high levels of social interaction and increased risk-taking behavior. Ethanol is one of the most commonly abused substances among adolescents. Due to their increased susceptibility to the rewarding effects and decreased susceptibility to its negative effects, adolescents tend to drink more than adults, often drinking in binges. Disruptions of cortical development by social isolation and/or binge ethanol during this critical period can lead to attention, social, and cognitive deficits later in life, and increase risk for alcohol use disorders. An individual's response to ethanol can be affected by early life stress, social interaction, and sex.
Objectives: Identify long-term behavioral and neurobiological consequences of adolescent social isolation stress and binge drinking in adult male and female C57BL/6J mice.
Methods: Social isolation was used as a social stressor during adolescence. C57BL/6J mice were single or neighbor housed with or without intermittent access to ethanol (2-BC 15% w/v EtOH) from P28-58. In another set of experiments, we used an adolescent (P27-44) drinking in the dark (DID) model (20% v/v EtOH) to test the effects of isolation stress on drinking behavior in single and group housed mice. In a third DID experiment, we modified the neighbor cages by removing the ports so animals could roam freely among the cages. Following DID, mice underwent novel object recognition as adults. BECs were correlated to intake for the DID mice.
Results: Although neighbor housing did not alter drinking behaviors in adolescence or adulthood, it did reduce cognitive deficits compared to single housed mice. Neighbor housing facilitated sharing of nesting material among female mice. During adolescence, neighbor housed ethanol drinkers built their nests significantly further from shared ports compared to water drinkers. In the DID study, socially isolated males and females drank significantly more ethanol than their group housed counterparts when drinking occurred under social conditions.
Conclusions: Social isolation during adolescence leads to cognitive deficits in adult animals, indicative of impairments to the prefrontal cortex. Neighbor housing ameliorated cognitive deficits but did not alter drinking behavior in adolescence or adulthood. In the DID model, social isolation increased adolescent drinking in males and females. Females drank more than males in both the 2-BC and DID models. Further investigation is needed into cognitive deficits following adolescent DID and social isolation, their effects on adult drinking, and underlying morphological and genomic changes in the prefrontal cortex.

Title: The Rewarding Effects of Ketamine are Mediated through Opioid Receptors

Authors: *M. CARLTON[1], M. MICHAELIDES[1,2], J. BONAVENTURA[3,1];
[1]NIH, NIDA IRP, Baltimore, MD; [2]Psychiatry and Behavior, Johns Hopkins Sch. of Med., Baltimore, MD; [3]Departament de Patologia i Terapèutica Exptl., Univ. de Barcelona, Barcelona, Spain

Abstract: In recent years the use of ketamine enantiomers for the treatment of depression has gained traction. Ketamine is a racemic mixture consisting of the R-ketamine and S-ketamine enantiomers. Despite its promising efficacy, ketamine's antidepressant mechanism of action is still under debate. Ketamine's antagonism at N-methyl D-aspartate receptors (NMDAR) cannot fully explain ketamine's antidepressant effects and other putative targets have been characterized (including opioid receptors). Previous experiments from our lab showed that S-ketamine has higher affinity for NMDAR, mu-opioid receptors (MOR) and kappa-opioid receptors (KOR) than R-ketamine. We also showed that rats self-administered S-ketamine but not R-ketamine, and that the opioid antagonist naltrexone partially blocked S-ketamine induced locomotion in mice. To further elucidate the rewarding properties of S-ketamine in a rat self-administration model, we trained Sprague Dawley rats (n=10, 5 male, 5 female) to self-administer S-ketamine on a fixed-ratio schedule (FR1) (0.5mg/kg/infusion, I.V., 1-hour sessions 6 days/week) for a 16-day training phase. We used selective drugs to probe the putative receptor targets involved in S-ketamine seeking behavior. Once the rats were trained and responded steadily for S-ketamine we pretreated them with multiple doses for each of the following drugs: TRV130 (MOR partial agonist, S.C.), buprenorphine (competitive opioid receptor agonist, S.C.), and MK-801 (non-competitive NMDAR antagonist, S.C.) . Our previous PET studies with [^{18}F]-fallypride also indicated a divergence between the dopaminergic actions of S-ketamine and R-ketamine, since R-ketamine was not self-administered, we wanted to test the involvement of dopamine in the self-administration behavior. Hence, we pre-treated rats with the D2-like antagonist Haloperidol (0.1mg/kg, S.C.) and found rats did not change their S-ketamine intake. Instead, rats responded lower when pretreated with partial opioid receptor agonists and MK-801 at doses that did not significantly decrease food intake. These results suggest that binding to both opioid MOR receptors and NMDAR are necessary for the rewarding effects of S-ketamine. This work was supported by NIDA/NIH.

Title: The abuse liability of methadone's enantiomers

Authors: *M. LEVINSTEIN, M. MICHAELIDES;
Biobehavioral Imaging & Mol. Neuropsychopharm., NIH, NIDA IRP, Baltimore, MD

Abstract: Methadone is a synthetic opioid used for chronic pain management and for opioid maintenance therapy; this racemic mixture is comprised of a 50/50 mixture of *d*- and *l*-methadone. Methadone and its enantiomers have nanomolar affinity for the mu opioid receptor; however, these compounds also interact with other receptors, specifically the N-methyl-D-aspartate receptor (NMDAR). Recently, *d*-methadone has gained interest as a potential rapid-acting antidepressant due to its activity at the NMDAR and it is assumed to be less active as an opioid. Here we test the abuse liability of *d*-, and *l*- methadone utilizing pharmacological and behavioral assays. In order to understand the pharmacological effects of these compounds more fully, we first screen them for competitive binding or inhibition against a selected panel of receptors and enzymes, including known targets for addictive drugs and medications. We also investigate the drug abuse related behavior in mice. We first test psychomotor sensitization by repeatedly injecting mice with vehicle, *d*-methadone, or *l*-methadone and measuring locomotor activity for three days. Three days later, we inject all mice with escalating doses of *d*-methadone in a single test session and assessed locomotor activity. Additionally, we test the rewarding effects of *d*- or *l*-methadone using the conditioned place preference (CPP) procedure.

Title: Sex differences in choosing oxycodone over healthy rewards

Authors: V. SCHWABL[1], M. ATUDOREI[1], G. AUGIER[1], *E. AUGIER[2];
[1]Lïnköping Univ., Linköping, Sweden; [2]Dept. of Clin. and Exptl. Med., Linköping, Sweden

Abstract: Use of addictive substances accounts for almost 10% of global disease burden. Opioid misuse in particular has recently become a major concern and a rapidly evolving public health crisis that requires innovative scientific approaches. Oxycodone is one of the most abused prescription opioids, but despite its prevalent misuse, the number of preclinical studies investigating oxycodone-seeking behaviors is relatively limited. Furthermore, opioid use disorder is characterized by a progressive shift of decision making, in which opioids are increasingly chosen over healthy non-drug rewards. Only a subset of people transition from recreational to pathological use. By contrast, in commonly used animal models, nearly all rats learn to self-administer addictive drugs, including opioids and animals have no alternative to drug use.
The primary goal of the present study was therefore to investigate potential sex differences in oxycodone self-administration and choice of oxycodone at the expense of healthy rewards. Using operant conditioning, we first trained male and female rats to self-administer oxycodone orally. We found that males earned more oxycodone reinforcers and showed a higher motivation for oxycodone. Blood oxycodone metabolites concentrations were in addition strongly correlated with oxycodone reinforcers earned during self-administration. Finally, we used an exclusive choice-based method to identify both male and female rats that continue to self-administer oxycodone at the expense of a high-value natural reward, a sweet solution, and found that, in agreement with our previous work with alcohol, only a minority of outbred rats (10% or less) choose oxycodone over an alternative high-value reward.
Together, our results indicate profound sex differences in oxycodone-related behaviors. They also confirm and extend to oxycodone previous data obtained with preclinical choice models.

Title: Peer-induced remifentanil seeking in male and female rats

Authors: *S. MALONE[1], L. HAMMERSLAG[1], M. CARBONE[2], S. DIMEO[1], M. BARDO[1];
[1]Univ. of Kentucky, Lexington, KY; [2]Univ. of Ghent, Ghent, Belgium

Abstract: Re-association with drug-associated peers contributes to relapse in humans, and we have recently found that exposure to cocaine-associated peers triggers reinstatement in rats. Here we extend these findings to opioids by pairing one peer with the fast-acting opioid remifentanil and a different peer with saline. In two experiments, male (n=10) and female (n=11) Sprague Dawley rats (8-9 weeks of age) received 28 days of twice-daily self-administration on a terminal FR5 schedule. Each day, remifentanil (6 µg/kg/infusion) was available during one session in the presence of one same-sex peer (S+) and saline was available during another session in the presence of a different peer (S-). Following extinction, we tested reinstatement to the S+, S-, or no peer; Experiment 2 also included a novel peer. Following pre-training, rats in Experiments 1 and 2 increased active lever pressing for remifentanil but not saline across sessions. Rats also decreased their active lever pressing across extinction. Compared to the no peer condition, rats in Experiment 2 increased active lever pressing in response to the S+, S-, and novel peers; there was no difference between S+, S-, and novel partner-induced active lever pressing. When combining the results from both experiments to power for potential sex differences in peer-induced reinstatement, we found that females consistently pressed the active lever more than males. Furthermore, with both experiments combined, rats increased active lever pressing in response to the S+ and S- partners, with the S+ peer eliciting significantly greater responding compared to the S- peer regardless of sex. Thus, similar to cocaine, these experiments show that re-exposure to a remifentanil-associated peer after extinction elicits greater drug seeking relative to a saline-associated peer in both males and females. However, drug seeking was also triggered by the S- peer and a novel peer, indicative of either stimulus generalization (associative) and/or social facilitation (non-associative).

Title: Examining the effect of neuropathic pain on drug-seeking ensembles in the dmPFC

Authors: *B. C. SARKA[1], Q.-S. LIU[2], C. L. STUCKY[3], S. LIU[1], C. M. OLSEN[4]; [1]Pharmacol. and Toxicology, [2]Dept. of Pharmacol. and Toxicology, [3]Cell Biology, Neurobio. & Anat., [4]Neurosci. Res. Ctr., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Approximately 50 million Americans suffer from chronic pain, and opioids are commonly prescribed for such individuals. While short term use can still pose a risk, those who take opioids for over a year are at an increased risk for long term opioid use. It is not uncommon for patients to require dose increases to maintain analgesic affects because tolerance builds up. Unfortunately, nearly a quarter of chronic pain patients have reported misusing their prescription at some point. We are currently investigating the effect that chronic pain has on drug-seeking behavior at the neuronal level. Drug-seeking behavior is associated with reactivation of an ensemble of neurons sparsely scattered throughout the dorsomedial prefrontal cortex (dmPFC). Prior research has demonstrated that chronic pain leads to an increase in intrinsic excitability of neurons in the dmPFC. We tested the hypothesis that chronic pain would increase oxycodone seeking behavior, and that the pain state would differentially increase intrinsic excitability in dmPFC drug seeking ensemble neurons. TetTag mice were trained to self-administer oxycodone (via intravenous infusion) for 10 days. After 7 days forced abstinence, a drug seeking session (extinction conditions) was performed and the ensemble was tagged. Mice received spared nerve injury (SNI) to induce chronic pain during the period between a first and second seeking session. Shortly thereafter we performed electrophysiology on individual neurons within the dmPFC to assess intrinsic excitability of the drug-seeking ensemble and non-ensemble neurons. Additionally, we compared the two seeking sessions to see if the SNI exacerbates seeking behavior. We have seen mild, insignificant trends in seeking behavior comparing SNI mice compared to Sham. However, the intrinsic excitability of SNI dmPFC neurons differs from Sham dmPFC neurons, and significant differences have been detected between distinct drug-seeking ensemble neurons versus non-ensemble neurons. We are also beginning to look at sex differences, and early data suggests that females may show an increase in neuronal intrinsic excitability compared to males.

Abstract: The genetic basis of Opioid use disorder (OUD) is still largely unknown. Quantitative trait locus mapping in rodent models offers several advantages to human GWAS (controlled sample sizes, controlled environment, within-species gene validation) and can elucidate genetic causes of addiction-relevant model phenotypes. To identify genetic variants of OUD-relevant behaviors in mice, we surveyed 29 strains of mice for strain-specific differences in behavioral responses to the semi-synthetic opioid oxycodone (OXY). Using an OXY conditioned place preference (CPP) experimental design, we found robust strain differences in OXY-induced locomotion, place preference, and state-dependent learning, indicative of causal genetics for these phenotypes. Subsequent haplotype association mapping identified a region on chromosome 17 associated with OXY-induced locomotion containing the candidate gene *Cacna1h*, encoding a voltage-gated calcium channel subunit. We subsequently tested *Cacna1h* knockout (KO) mice on a mixed 129/C57BL/6N background backcrossed to C57BL/6N to the N2 generation (and then subsequently intercrossed) in OXY CPP, in addition to hot plate analgesia, elevated plus maze, and light-dark conflict to assess differential responses to OXY tolerance and withdrawal between genotypes. We did not observe any significant genotypic differences in distance traveled in response to OXY. However, *Cacna1h* KOs with previous OXY history travel shorter total distances during the place preference session. The effect of *Cacna1h* KO was specific to locomotion associated with OXY CPP, as there were no genotypic differences in OXY CPP or state-dependent learning, nor were there any significant differences OXY antinociceptive tolerance or spontaneous withdrawal in the elevated plus maze or the light/dark box. Our negative findings fail to support a role for Cacna1h in opioid addiction model behaviors, with the notable limitation that we have only tested a single genetic background.

Title: Engagement of Beta-Arrestin 2 at the μ-opioid receptor reduces the abuse liability of opioids in mice during operant self-administration

Authors: *L. FELTH, Z. ROSA, S. W. GOODING, J. GIPOOR, A. GAUR, J. WHISTLER; Univ. of California, Davis, Davis, CA

Abstract: In 2019, 500,000 people died as a result of opioid overdose. About 10% of persons prescribed opioids will develop an opioid use disorder (OUD). The explanation for why some individuals transition to misuse of opioids, placing themselves at higher risk for overdose, remains unclear. Despite their significant risks, opioid analgesics, including morphine, codeine, Vicodin and Oxycontin, are still regarded as the gold standard for alleviating pain clinically. All of these drugs exert their analgesic effects through activation of a G protein coupled receptor (GPCR), specifically the G_i coupled μ- Opioid receptor (MOR). When MOR is activated by its endogenous ligand, a regulatory molecule called βeta-Arrestin-2 (βAR2) is recruited to the receptor, causing titration of signal transduction and subsequent internalization and recycling of the receptor. Conversely, when MOR is activated by many clinically relevant opioid drugs, such as morphine, it does not effectively recruit βAR2. The lack of βAR2 recruitment results in receptors remaining present on the membrane without being internalized and recycled back to the membrane. In short, in the presence of endogenous ligand, G-protein signal transduction follows an on/off pattern, whereas in the presence of exogenous drugs signaling remains 'on' and causes homeostatic adaptions, such as cAMP superactivation. This cAMP superactivation has been implicated in neuronal and behavioral plasticity associated with correlates of OUDs seen in mice, including compulsive drug seeking. We hypothesize that effective recruitment of βAR2 to activated MORs will reduce compulsive drug seeking in mice. To investigate this hypothesis, this study utilizes four different genotypes of mice, with varying βAR2 recruitment profiles in response to morphine: WT(poorly recruits βAR2), RMOR (strongly recruits BAR), βAR2-KO (does not recruit βAR2), βAR2-KO/RMOR (does not recruit βAR2). We utilized a novel oral operant self-administration paradigm for 16 weeks to model the transition from impulsive to compulsive drug use. At the end of 16 weeks, operant self-administration was extinguished and reinstatement was assessed to model OUDs. Our results suggest that βAR2 recruitment influences OUDs and that drugs that recruit βAR2 will have a reduced abuse liability.

Title: Identification of novel pain therapies without the side-effect of respiratory depression using phenotype-based drug discovery in larval zebrafish

Authors: S. ZAIG[1], D. SRIKRISHNARAJ[1], C. DA SILVEIRA SCARPELLINI[1], ***G. MONTANDON**[2,1];
[1]Keenan Res. Ctr. for Biomed. Sciences, St. Michael's Hosp., Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction: Opioid drugs produce pain relief as well as respiratory depression which can be lethal with overdose. Opioid overdoses are equally due to the abuse of drugs such as fentanyl or pain killers like oxycodone. During the COVID19 pandemic, the opioid epidemic reached almost 100,000 deaths, highlighting the urgent need to identify pain killers with reduced liability so they can be safely prescribed. However, most pharmaceutical approaches have so far failed due to the complexity of the nervous system and the various phenotypes associated with opioid drugs. Using our newly-developed drug discovery platform in larval zebrafish, we propose to identify new drugs with potent analgesic properties and reduced respiratory liability. **Methods:** Using phenotype-based approaches in larval AB zebrafish *in vivo,* we can quickly and effectively screen new drug compounds to either target respiratory depression or analgesia (*Zaig et al., 2021, eLife*). We first screened customized drug libraries targeting voltage-gated calcium channels and the adenylyl cyclase pathway, which are both known to mediate neuronal inhibition by opioid drugs. **Results:** To test the role of calcium channels, we combined fentanyl and the calcium channel activators nefiracetam (1µM) or FLP-64176 (1µM) with both preventing respiratory depression by fentanyl (1µM). Analgesia by fentanyl, quantified by the escape swimming response to the noxious stimulus formalin, was prevented by FLP-6476. To target the adenylyl cyclase pathway, we combined fentanyl and the phosphodiesterase inhibitors pentoxifylline (50µM), roflumilast (1µM), or dipyridamole (100µM). Pentoxifylline prevented respiratory depression by fentanyl but not roflumilast and dipyridamole. We are also genetically deleting calcium channels and phosphodiesterase molecules using CRISPR-cas9 and are developing opioid withdrawal assays to determine the impact of new drug compounds on opioid addiction. **Discussion:** The successful identification of new drug combinations that can prevent respiratory depression while preserving analgesia suggests that our drug discovery platform in larval zebrafish will substantially accelerate the identification of new opioid drugs with reduced morbidity and mortality. **Acknowledgements:** Research was funded by the St. Michael's Hospital Foundation, the Lung Health Foundation and the J.P. Bickell Foundation. SZ was supported by the Canadian Institutes of Health Research Canada Graduate Scholarship and the St. Michael's Hospital Research Training Centre Scholarship.

Title: Retrieval-related anterior shift is moderated by age and relates to memory performance

Authors: *S. SROKOVA[1], P. F. HILL[3], M. D. RUGG[2];
[1]Ctr. For Vital Longevity, [2]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [3]Dept. of Psychology, Univ. of Arizona, Tucson, TX

Abstract: Cognitive aging is associated with a decline in memory for contextual details of previously experienced episodes. Recent research has shown an increasing interest in a phenomenon termed the retrieval-related 'anterior shift'. The term refers to systematic differences in the localization of neural activity observed at encoding and retrieval, such that retrieval of a perceptual image (e.g., a scene) is associated with a response in category-selective cortex that is localized more anterior than the response elicited when the image is experienced directly. However, both the moderating effects of age on anterior shift and its relationship with memory performance remain unexplored. In the present study, younger (N = 24) and older adults (N = 24) underwent functional magnetic resonance imaging (fMRI) as they completed encoding and retrieval tasks. At encoding, participants viewed words paired with images of faces and scenes. At retrieval, participants determined whether test words were new or old and, if judged old, whether the word had been studied with an image of a face or a scene. Source memory performance - the ability to correctly judge whether a word had been paired with a scene or a face - was lower in the older age group. Turning to the fMRI data, we localized peak scene- and face-selectivity for each individual participant within the face-selective precuneus (PCU) and in three scene-selective (parahippocampal place area [PPA], medial place area [MPA], and occipital place area [OPA]) regions of interest (ROIs). In line with recent research with scene stimuli, we found strong evidence for an anterior shift in the PPA, MPA and OPA. We extended these findings to demonstrate an anterior shift in the precuneus (PCU) for face stimuli, although this effect was observed in older adults only. An age group x ROI ANOVA revealed that anterior shift was larger in older relative to younger adults, and that this age effect did not differ according to ROI. Lastly, the magnitude of the anterior shift in the PPA exhibited a robust negative correlation with source memory performance (after controlling for age), indicating that greater encoding-retrieval displacement of scene-selectivity within the PPA was associated with poorer memory performance. These results shed light on the functional significance of anterior shift in relation to memory success and provide an increased understanding of sources of memory decline in older age.

Title: Effect of context-dependent temporal structure on episodic memory

Authors: *S. COLLIN[1], S. SRIVATSAN[2], A. BEUKERS[2], U. HASSON[2], K. NORMAN[2];
[1]Tilburg Univ., Tilburg, Netherlands; [2]Princeton Univ., Princeton, NJ

Abstract: One of the key objectives of learning is to infer the latent causes of our sensory observations. This concept of latent causes is closely tied to schemas: You make sense of your current sensory observations by inferring that the current event is an instance of a particular kind of schema, which allows you to draw on prior knowledge relating to that schema to make predictions about what will happen next. Theories of schema-dependent memory posit that having a representation of the temporal structure of an event can boost memory for details from that event. However, in the real world, the temporal structure of events is often complex and context dependent. In this study, we investigated how context-dependent temporal structure is represented in the brain during narrative perception, and if and how this relates to memory. We ran a 2-day fMRI-study (N = 40) in which we exposed participants to many unique animated videos of wedding ceremonies with sequences of rituals originating from a novel (fictional) culture, where each video was accompanied by a unique narrative. Each ceremony, despite the regularities in the sequence of rituals, was unique. Participants learned the context-dependent temporal structure of the wedding ceremonies on day 1 and came back on day 2 to watch and recall novel ceremonies. The results, analyzed with multivariate pattern analysis, showed history-independent coding (i.e., only coding for the current event) in lateral occipital and superior parietal regions and history-dependent coding (i.e., coding for the event that is currently shown as well as the preceding event) in medial occipital regions that were both relevant to memory for episodic details of the ceremonies.

Title: Stress-testing the memory system: Inter-item distraction disrupts temporal and semantic organization in free recall

Authors: *R. A. CUTLER[1], N. W. MORTON[2], S. M. POLYN[1];
[1]Psychological Sci., Vanderbilt Univ., Nashville, TN; [2]The Ctr. for Learning & Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: Temporal information situates episodic memories along a personal timeline, while semantic information draws from an existing knowledge store to imbue those episodes with meaning. We present a set of fMRI and behavioral experiments that examine the interactions of temporal and semantic information in memory search. Participants studied lists of 27 items from 3 categories that elicit distinct patterns of brain activity (celebrities, landmarks, objects). Same-category items were presented in blocks of 3 to capture the combined effect of temporal proximity and semantic similarity. During the study period participants were challenged with an inter-item distraction task; *light distraction* was a simple vigilance task while *heavy distraction* was mental arithmetic. We found that heavy distraction disrupted the temporal and semantic organization of recall sequences, suggesting that a demanding task during encoding interferes with a cognitive process that takes advantage of patterns within the list structure. This drop in recall performance was associated with decreased category representation in brain regions that facilitate memory search. Our neural analyses show that increased inter-item distraction can be captured as a decrease in a classifier's ability to decode the category-membership of an item. Distraction also decreases the correspondence between neural patterns and formal models that capture semantic structure. This suggests that increasing the intensity of an inter-item task disrupts a search process that relies on the relational structure of the list to retrieve items from memory. We interpret the behavioral and neural consequences of distraction in terms of a retrieved context model of memory search.

Title: Relating the strength of conjunctive representations to episodic retrieval effects in task-switching

Authors: *B. RANGEL[1], E. HAZELTINE[2], J. R. WESSEL[2];
[2]Psychology, [1]Univ. of Iowa, Iowa City, IA

Abstract: Goal-directed behavior necessitates the combination of external stimuli with appropriate actions and their associated intended outcomes. For example, during the goal-directed behavior of unlocking a door, an external stimulus (door) needs to be paired with an appropriate action (retrieving/inserting the key) and an intended outcome (the opening). Prominent cognitive theories such as the Theory of Event Coding propose that the temporal association of stimulus, action, and outcome representations leads to their integration into a joint episodic memory trace, also known as an "event-file" (Hommel 2009). While the retrieval of such event-files from memory allows for more efficient reactivation of their contained representations when necessary, this retrieval process is automatic, and may not always be contextually appropriate – especially when the environmental contingencies changed. For instance, one may find oneself trying to retrieve the key for a door despite having lost it the day before. In the laboratory, such scenarios are simulated using task-switching paradigms in which contextual task stimuli first cue a task with a preexisting event file, but are then followed by a task conditions that are incommensurate with the action contained in said event file – resulting in a prominent "repetition cost" to reaction time (Hommel et al. 2014; Neill 1997). There is currently ongoing debate about whether this repetition cost is attributable to inhibitory effects (e.g., Mayr & Keele, 2000; Mayr 2002) or indeed due to the retrieval of the event file (e.g., Grange & Kowalczyk, 2017; Grange 2018). Recently, Kikumoto & Mayr (2020) used Linear Discriminant Analysis and Representational Similarity Analysis of Electroencephalography data to produce the first direct neurophysiological evidence for the existence of conjunctive representations (i.e., event-files) in the human brain. Utilizing these methods, we successfully estimated the representational strength of each individual task component (cue/target/response) and their combined conjunctive representation (i.e. the event-file), on a trial-by-trial basis in a sample of N=35 subjects performing a task switching paradigm. A mixed-model analysis demonstrated that event-file strength in a previous trial predicts RT in the current trial when retrieval is prompted by a repeated cue. These results provide the first neurophysiological evidence that the Repetition Cost incurred by incongruent event files can be partially attributed to the retrieval of conjunctive representations - i.e., to the neural representation of past event-files.

Title: Repetition-related memory signals in parietal cortex integrate information about stimulus content

Authors: *Y. ZHAO[1], E. J. ALLEN[4], Y. WU[6], T. NASELARIS[7], K. N. KAY[5], B. A. KUHL[2], J. HUTCHINSON[3];
[2]Psychology Dept., [3]Dept. of Psychology, [1]Univ. of Oregon, Eugene, OR; [4]Psychology, [5]Radiology, Univ. of Minnesota Twin Cities, Minneapolis, MN; [6]Univ. of Minnesota, Minneapolis, MN; [7]Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: When a stimulus from the past is re-encountered, this can elicit increased neural activation relative to a novel stimulus (repetition enhancement) or decreased activation (repetition attenuation). Studies of episodic memory have consistently found that repetition enhancement occurs within parietal cortex and that these enhancement effects are related to behavioral expressions of successful episodic remembering. Repetition attenuation, in contrast, is more typically observed in regions of occipitotemporal cortex and is less consistently related to behavioral expressions of episodic memory. Separately, pattern-based fMRI studies have found that information about the content of stimuli is reflected in both parietal cortex and ventral temporal cortex, but it is less clear how or whether these content representations are integrated with repetition-related memory signals. In the current 7T fMRI study, eight participants performed a continuous recognition task spanning 30-40 fMRI scan sessions and up to 10,000 unique, naturalistic images. We calculated the difference in multivoxel fMRI activations between the first presentation (initial encoding) and second presentation (retrieval) for each stimulus and tested whether these repetition-related differences in activity patterns carried information about the visual content of the image. To quantify the content of each image, we passed the images through VGG16, a convolutional neural network designed for image content classification and detection. We then reduced features from the output layer to 10 PCA dimensions and used ridge regression to test whether repetition-related changes in fMRI activity patterns predicted the PCA content scores. We found that repetition-related differences in medial and lateral parietal cortex predicted image content. Moreover, these predictions were significantly better for hits (correct recognition) compared to misses (failed recognition) indicating that the presence of content information was directly related to successful recognition. Interestingly, repetition-related differences in occipitotemporal cortex also predicted image content, but the success of these predictions were less dependent on successful behavioral recognition. Collectively, our results indicate that repetition-related enhancements which have consistently been observed in parietal cortex directly integrate information about the content of what is being remembered.

Title: Retrieval practice in a recognition memory word pair paradigm

Authors: *A. T. J. CAWLEY-BENNETT[1], D. MINONDO[2], J. R. MANNS[1];
[1]Psychology, [2]Neurosci. and Behavioral Biol., Emory Univ., Atlanta, GA

Abstract: The retrieval practice effect (also termed the testing effect) is a widely-replicated and robust phenomenon demonstrating that retrieving information from memory after recent learning leads to better retention than restudying the information. For example, cued recall (table - _____) of a studied word pair (table - window) leads to better subsequent memory for the target word (window) as compared to restudying the word pair. Several hypotheses have been proposed to explain this effect, yet disagreement overshadows consensus. We sought to address this debate by examining how cued recall retrieval practice affected subsequent memory for both cue words and target words in a study in which the final test consisted of a yes-no recognition memory test of either the cue word or target word contrasted against novel words. Participants were also asked to make confidence ratings for each yes-no judgment. Performance on the final recognition memory test in the retrieval practice condition was compared to performance in a restudy control condition. Existing hypotheses regarding the retrieval practice effect disagree as to whether the subsequent memory benefit should be observed for cue words, for target words, or for both. Preliminary results indicate that cued recall retrieval practice benefitted subsequent memory for both the cue words and target words, although the effect size was smaller for cue words. Planned analyses of receiver operating characteristic (ROC) curves will address for both cue words and target words whether retrieval practice positively impacted the shape of hit rates as a function of false alarm rates as compared to the restudy control condition. The results of the present study have implications for basic memory research on the retrieval practice effect as well as classroom best practices.

Title: Implicit memory for target location facilitates explicit memory-guided attention in real-world sound-clips

Authors: *M. FISCHER[1,2], M. MOSCOVITCH[1,2], C. ALAIN[2,1];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res., Baycrest Ctr. for Geriatric Care, Toronto, ON, Canada

Abstract: What is the relation between awareness, attention, and memory? Long-term memory (LTM) of learned target locations can facilitate target detection. However, it remains unclear what mechanisms enable this perceptual facilitation. We first created long-term associations between audio-clips and the location of an embedded tone. Then, we measured behavioural and neuroelectric activity during a cue-target detection task. An a priori sample size calculation suggested testing a minimum of thirty-two participants in order to achieve an effect size of d = .90.

At learning, thirty-five participants (22 female, M = 22.6 years) were presented with 80 different audio-clips (half included a lateralized pure tone target, referred to as memory trials), and indicated whether the tone was low or high. While the location of the tone remained constant throughout exposure, the frequency of the tone ($500_{Hz}/1_{kHz}$) and the position (i.e., time) of the tone within the audio-clip (1300_{ms}, 1800_{ms}, 2300_{ms}) varied randomly. A surprise memory test followed in which participants were told to press a button as quickly as possible when they heard a *faint* lateralized tone (target), which was present in *all* audio-clips. They also indicated if the clip was (i) old/new; and (ii) if the tone was on left/right/not present when they heard the clip at exposure.

Participants showed good explicit memory for the clip and for the presence/absence of the tone, but *not* for the *specific* location of the tone. They were also faster in responding to the target on memory trials than on trials in which the target was presented for the first time. This benefit in response times coincided with changes in the stimulus-locked sustained potential *prior* to target onset at approximately $800\text{-}1000_{ms}$ and $1800\text{-}2300_{ms}$ over frontal sites.

These findings show that LTM can facilitate signal detection even when there are variations in time and frequency of the to-be-attended material. Furthermore, *explicit* memory for both the clip and the presence or absence of the tone facilitated target detection, an effect that was accompanied by an *implicit* memory of the specific spatial location of the tone.

Title: The role of visual and motor aspects of eye movements in memory retrieval

Authors: *K. TAUB, Y. GOSHEN-GOTTSTEIN, S. YUVAL-GREENBERG;
Tel Aviv Univ., Tel Aviv, Israel

Abstract: Eye movements during memory encoding act as retrieval cues: evidence shows that memory retrieval is improved when eyes are shifted to the same position where they were located during retrieval. However, it is yet unknown which component of eye movements is involved in this effect: the motor component, which is the specific muscle contraction that characterizes each movement performed by the eye, or the sensory component - which is the visual image that falls on the retina. In this research we examined the role of visual and motor aspects of eye movements during memory retrieval, and investigated individual differences in the ability to benefit from these cues. In our experiment (N=72), we dissociated the visual and motor aspects of eye movements during memory encoding and retrieval. In each encoding trial, participants were asked to fixate at one of the four corners of the screen, and then followed a fixation cross to perform two sequential saccades to the left or right, towards the horizontal center. They were subsequently presented with a target word at the final landing position. The trials varied in saccade direction, left or right, and in vertical location, as the horizontal saccades were performed either at the top or bottom part of the screen. During retrieval, participants performed the same task but were also asked to indicate whether the target word was studied or unstudied. Trials were divided into four conditions, with each retrieval trial matching its accompanying encoding trial in: the direction of the saccades (motor-only cue), the vertical location (visual-only cue), both (motor-visual cue) or neither (no-cue). Results showed that while cues were beneficial to memory retrieval compared with the no-cue condition, there was no difference in performance following the appearance of a single cue (either motor-only or visual-only) and the appearance of both cues together (motor-visual cue). Findings also revealed that participants varied in their ability to benefit from eye movements as retrieval cues: while some participants profited from motor and visual cues, others did not. Finally, we found that recognition performance in the motor-only condition was positively correlated across participants with performance in the visual-only condition, even after controlling for memory capabilities. Thus, individuals who tend to benefit from eye movements as retrieval cues, tend to gain from both aspects of these cues (motor and perceptual) to a similar extent. These findings

suggest that the ability to benefit from the encoding-retrieval compatibility of eye movements is an individual ability, which is independent of memory abilities.

Title: Association of the ability to inhibit irrelevant information with alpha activity in the encoding of spatio-temporal information in episodic memory

Authors: *A. POLO-ROMERO[1], U. CABALLERO-SÁNCHEZ[1], D. ZENTENO-MORALES[1], M. MÉNDEZ-DÍAZ[2], O. E. PROSPÉRO-GARCÍA[2], A. E. RUIZ-CONTRERAS[1];

Abstract: Episodic memory is the ability for encoding, storing, and recalling memories that have been personally experienced and that contains a space-time structure. When an event is encoded, decreased alpha-band frequency has been associated with better performance in episodic memory. On the other hand, in attention tasks, decreased amplitude of alpha-band has been associated with selection of information; in contrast, an increase in alpha-band amplitude is associated with the inhibition of irrelevant information. The participation of the selection sub-process of attention within the episodic memory has been reported; however, it is unknown whether the inhibition sub-process ability of attention is associated with the encoding of target information and its spatio-temporal context. Here, we evaluated the potential relationship between alpha activity in the encoding phase of spatio-temporal context of target information in episodic memory with the ability to inhibit irrelevant information. Healthy 22 young volunteers answered an episodic memory task in which target stimuli appeared in specific spatial (up or down) and time (first or second list) context during encoding; this information had to be remembered during the recovery phase. Electroencephalographic activity was recorded during the encoding phase. Complementary, participants answered Eriksen's flanker task. In this task, subjects had to inhibit flanker distractors to answer to target stimulus. Direct correlations were found between the mean amplitude of alpha on the parietal and frontal electrodes during the encoding phase of the episodic memory task, and the percentage of correct responses in the

Eriksen task. Also, inverse correlations were found between the amplitude of alpha and reaction times of type of trial in the Eriksen task. These results, in conjunction with reports in the literature, allow us to interpret that the increase in the amplitude registered during the encoding phase of the episodic memory seems to correspond to an alpha activity associated with the inhibition sub-process of irrelevant information.

Abstract: The risk of Alzheimer's disease increases with age and, after onset, pathology appears to spread or worsen with time. It is not clear why some neural cell populations become vulnerable with age, yet others are resistant. Technological limitations have prevented chronic cellular-level tracking of interconnected brain regions during the many months or years before onset of age-related cognitive defects. To overcome these limitations, we have developed techniques to track electrophysiology of individual neurons in behaving mice, monitor their interactions across brain regions, and determine how they change over long periods of time. We utilized neuron-like electronics enable stable electrophysiological recordings on the scale of one year. We implanted these electronics in the hippocampus of male and female C57BL/6J mice (n=6) and monitored head-fixed running on a ball in virtual reality. We observed the presence of place fields that lasted multiple months. Changing the virtual environment caused the place fields of these cells to remap. A second cohort of THY-Tau22 mice (n = 8) had electronics implanted in the hippocampus and entorhinal cortex and show the ability to record correlated activity of

individual neurons across brain regions. These experiments demonstrate that the use of flexible electronics that do not induce astrogliosis in nearby tissue allows for recording activity of the same neurons over periods longer than months and does not require re-positioning of electrodes or the use of microdrives. Furthermore, these data show the stability of place fields and correlated activity between brain regions for mice running through a virtual maze.

Abstract: The hippocampus plays a vital role in navigation. It is unclear, however, how the hippocampus supports spatial learning over long timescales in complex tasks. One limitation has been the ability to track neural activity for more than a few days or weeks. Even with two-photon imaging, which allows precise anatomical localization of recorded cells, brain deformations make it difficult or impossible to repeatedly image the same plane. Here, we introduce an analysis technique to track calcium activity in large populations at cellular resolution over months of training despite substantial deformations. This technique is composed of two stages: 1) aligning each imaging session to a reference volume, and 2) identifying which cells were recorded on each day, using the reference volume to distinguish unique neurons. Though these processes can be largely automated, manual verification is required to ensure accuracy. To facilitate user inspection of the alignment and cell identification, we have developed a graphical user interface for each stage that allows for rapid verification and correction of the automated procedures. This analysis pipeline has allowed us to measure the activity of ~800 unique CA1 pyramidal neurons across 40 behavioral sessions spanning 90 calendar days. The results of this

analysis are described in a companion poster. We anticipate our technique for tracking large populations could allow for recording longer timescales of activity in other brain areas as well.

Abstract: The hippocampus is critical for navigation and learning goal-directed tasks. Hippocampal place maps form almost immediately in a new environment, but it is unclear whether these maps are sufficient to support behavior, or if instead they must evolve beyond their initial representations. In other words, does the hippocampal map itself need to "learn" something about the environment? To interrogate this possibility, we trained mice on two virtual reality tasks and imaged ~1,000 CA1 neurons during every behavioral session, from first exploration through expert performance. Because the hippocampal tissue gradually changed shape over time, it was impossible to return to the same imaging plane every day. To account for these deformations, we developed a novel analytical technique to track the activity of individual neurons, as described in a companion poster. In the behavioral task, mice learned to associate a water reward with several locations along the track, and their reward anticipation strategies revealed gradual refinement across sessions. Though place cells and reward-associated cells changed in many ways throughout learning, a preliminary analysis revealed that the development of expert behavior coincided with predictive encoding; in both tasks, spatial fields shifted earlier at the precise time when mice began to accurately anticipate reward. This raises the possibility that initial hippocampal place maps are not able to support goal-directed behavior, but rather they must first develop representations that anticipate upcoming environmental features. We further interrogated expert performance using clustering analyses, and we identified discrete reward anticipation strategies that were interleaved throughout behavioral sessions. Preliminarily analyses comparing neural activity across different strategies found that reward-associated cells,

unlike place cells, behaved differently. Reward cell fields tended to shift earlier on traversals with more accurate anticipatory behavior, whereas place cell fields did not. This unexpected distinction implies that reward cells may be more strongly related to prediction of the goal than the general population of place cells. Taken together, our observations are consistent with hippocampal place maps needing to evolve beyond their initial representations in specific ways to facilitate goal-directed behaviors.

Title: Hippocampus as a generative circuit for predictive coding of future sequences

Authors: *Y. CHEN[1], H. ZHANG[1], T. J. SEJNOWSKI[2];
[1]UCSD, La Jolla, CA; [2]Salk Inst., La Jolla, CA

Abstract: Rationale and theory. Neurons in the hippocampus (HPC) CA1 region receive both direct and indirect inputs from entorhinal cortex (EC). Due to synaptic transmission delay, information flow through the indirect pathway via dentate gyrus and CA3 is delayed. The computational principle of this seemingly redundant and asynchronous pathway remains unclear. We propose that the EC-HPC circuit is anatomically wired for training a generative model where the recurrent CA3 network is constantly outputting predicted future states to CA1, a downstream region which then compares that with the actual input from EC and generates prediction errors. In so doing, the transmission delay in the circuit could be canceled out and the internal representation stored in the CA3 recurrent network gets updated. This hypothesis extends the predictive coding regime to the time dimension and can be compared with state space models such as the Kalman filter. Methods and results. We trained a traditional recurrent neural network (RNN) with input and output layers mimicking EC inputs and CA3 output predictions, respectively. The network was trained through back propagation through time in a self-supervised manner such that the CA3 prediction of any future state should match the EC input at those corresponding time points. We used sequential input currents to simulate a rat receiving

location- specific inputs in an environment and random spontaneous currents to mimic the animal's sleeping behavior. In our simulations, the error computing CA1 neurons in the network showed both one-shot activation upon remapping to a new environment and replay of multiple sequences during sleep. When a more realistic grid-cell like EC input was given to the network, the recurrently connected CA3 neurons also showed place fields. In addition, by minimizing future prediction errors, the trained network was more robust to noise interference compared to a conventional loss function that suppresses current prediction errors. Conclusions. These results suggest that the proposed generative model may be a unifying framework to explain how HPC and EC interact to participate in memory formation and spatial localization. Furthermore, this bio-inspired architecture points to a more robust and generalizable RNN training algorithm.

Title: Goal discrimination in hippocampal non-place cells when place information is ambiguous

Authors: *L. ZHANG[1], S. M. PRINCE[3], A. L. PAULSON[4], A. C. SINGER[2];
[2]Coulter Dept. of Biomed. Engin., [1]Georgia Inst. of Technol., Atlanta, GA; [3]Emory Univ., Atlanta, GA; [4]Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. and Emory Univ., Atlanta, GA

Abstract: Memory-guided navigation relies on hippocampal neurons, like place cells, that encode features of the environment. However, little is known about hippocampal place codes when spatial information, like cues, provide ambiguous information about finding goals. Non-place cell activity, pyramidal cells that fire without strong spatial modulation in an environment that are typically ignored, may be well-suited to carry task-relevant non-spatial information. We find that when spatial cues and goal information are conflicting, non-place cell firing distinguishes between ambiguous spatial cues. On correct trials non-place cells had higher firing rates and altered gamma phase modulation at task-relevant cues compared to incorrect trials while place cells showed no such differences. Finally, this goal discrimination in non-place cells

is absent in a mouse model of Alzheimer's disease that has memory impairment. Our findings show that non-place cells differentiate ambiguous goal information that place cells do not and reveal "non-coding" cells have special coding contributions.

Title: Spatially specific, learning-dependent interneuron activity encodes goals

Authors: *N. JEONG, V. P. NGUYEN, S. R. THOMAS, A. C. SINGER;
The Wallace H. Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. and Emory Univ., Atlanta, GA

Abstract: Remembering precise locations of importance in distinct contexts is a key component of spatial memory. Over the past few decades, the hippocampal literature has shown extensive evidence that excitatory pyramidal cells code for various spatially relevant cues. In contrast, inhibitory interneurons have been overlooked and ascribed functions such as balancing global network activity. Evidence linking inhibitory activity to spatial learning has been scarce because interneurons are generally thought to fire action potentials in a spatially uniform manner and are therefore not thought to carry significant spatial information. However, the firing activity of excitatory neurons is under the control of inhibitory interneurons, and therefore interneurons could gate enhanced excitation and information transfer. Such gating would most likely occur in important locations such as rewarded locations during behavior. To test this hypothesis, we recorded from single units in hippocampal area CA3, a region known to be important for developing new spatial memories, in head-fixed mice during spatial learning. Mice learned to lick in specific locations of familiar and novel virtual environments to trigger reward delivery. We found a selective reduction in firing rates of most interneurons as mice reached learned reward zones. The magnitude of this reduction depended on the relative familiarity of the environment and correlated with learning performance as animals learned reward locations in a novel environment. These findings could not be explained by position-related changes in speed or licking behavior. Furthermore, these reductions in interneuron firing did not represent a simple balancing of changes in excitatory activity. Our results demonstrate spatially specific,

learning-dependent interneuron activity and suggest that inhibition plays a significant role in gating spatial information for correct behavioral performance.

Title: Hippocampal place cells use vector computations to navigate.

Authors: *J. ORMOND, J. O'KEEFE;
Sainsbury Wellcome Ctr., London, United Kingdom

Abstract: The hippocampal cognitive map supports navigation towards, or away from, salient locations in familiar environments. One strong candidate for underpinning navigation are the CA1 place cells which provide information about the animal's current location. In open-field foraging tasks lacking a specific goal, place cells provide a non-directional measure of current position. When a goal is introduced, however, place cells become directional and their fields move in the direction of the goal when it is moved. Previous work has shown that cells in the hippocampal formation encode heading towards a goal and other locations in the bat, mouse, primate, and human, but an important caveat about such studies is that the subject usually moves towards the goal whenever possible, precluding full assessment of the neuronal activity in non-goalward directions. We recorded CA1 place cells while rats navigated to a goal on the honeycomb maze. The maze tests navigation via both direct and indirect paths to the goal and allows the directionality of place cells to be assessed at each choice point. A large proportion of place fields (~30%) showed strong directional polarization characterized by vector fields which converged to unique locations, which we termed convergence sinks (ConSinks), distributed throughout the environment. The distribution of these ConSinks was centred near the goal location, and the population vector field also converged there, providing a strong navigational signal. Changing the goal location led to the movement of ConSinks and vector fields towards the new goal. ConSink cells also encoded distance and allocentric direction to their sink positions, indicating that the necessary information for precise navigation to the sinks is encoded by these cells. Directional and distance tuning was broadly distributed, indicating that the ConSink cell population has the information necessary to calculate the goal direction vector from

any location. The directional tuning of the population forms a peak in the goalward direction, and its distribution falls off smoothly with deviation from this direction, except on error trials, when the distribution is disrupted. Animals broadly sample direction relative to the goal, particularly on correct trials, suggesting that they solve the task by identifying the available direction which produces the highest firing rate within the ConSink cell population. ConSink cells, therefore, appear to be an important component of a system allowing flexible navigation towards goal locations.

Title: Multifield and Multiscale Coding of Megaspace by Dorsal and Ventral Hippocampal Place Cells.

Authors: Y. QIN, ***M. CONTRERAS**, C. STERZINAR, B. HARLAND, J.-M. FELLOUS; Univ. of Arizona, Tucson, AZ

Abstract: Animals navigate in familiar and new environments across a range of spatial scales. It is unclear, however, how the mammalian brain forms multiscale representations of complex natural environments, and how these representations are used for implementing successful spatial navigation. We previously recorded wirelessly from dorsal hippocampal place cells while rats performed a goal-oriented spatial task in a large open environment (the megaspace; 5.3 × 3.5 m, 18.6 m2). Rats were trained to follow a small food-baited robot to facilitate high-resolution place cell recordings in the megaspace. We found that place cells within the dorsal CA1 exhibited multiple subfields of different sizes in the megaspace supporting a multi-scale representation of space. Our results demonstrate that each dorsal place cell is active in several sections of the same environment and show that each location of the environment is represented by a unique combination of subfields of different sizes. These results suggest that dorsal hippocampal place cells use a coding scheme that challenges our present understanding of how the hippocampus represents an animal's position in space.
We extended our work by conducting simultaneous wireless electrophysiological recordings from dorsal and ventral place cells while rats perform a rodent version of the traveling salesperson problem (TSP). This allowed us to study whether ventral cells exhibit the same

multifield and multiscale coding scheme as dorsal cells, and to investigate how this dorsoventral coding mechanism may contribute to spatial optimization. The TSP is a spatial optimization task that requires that a subject find the shortest possible route to visit a fixed set of identical reward cups without re-visits. Experiments were also conducted in conditions where the reward locations were differentiated by the presence of small objects (local cues). In this goal directed task, we show that the multiscale and multifield nature of coding is largely conserved in ventral CA1. Additional work is underway to determine if place field locations and place cell firing dynamics are related to the ability of the animal to optimize its trajectory.

Title: Low-dimensional neural manifolds in the hippocampus contain geometric representations of learned knowledge

Authors: *E. H. NIEH[1], M. SCHOTTDORF[1], N. W. FREEMAN[1], R. J. LOW[1], S. LEWALLEN[1], S. KOAY[1], L. PINTO[1], S. C. VENDITTO[1], J. L. GAUTHIER[1], C. D. BRODY[1,2,3], D. W. TANK[1,3,4];

Abstract: Hippocampal neurons encode physical variables such as space or auditory frequency in cognitive maps. In addition, human fMRI studies have shown that the hippocampus can also encode more abstract, learned variables. However, their integration into existing neural representations of physical variables is unknown. Here, we show the integration of physical and learned task variables as smooth gradients on task-specific, low-dimensional neural manifolds, instantiated by the coordinated activity of single neurons. Male and female adult mice (n=7 mice) learned a task traversing the stem of an immersive virtual reality T-maze, while visual cues were presented randomly on the left and right walls. Mice were rewarded for turning to the side that had more cues at the end of the maze. Using 2-photon calcium imaging, we show that

individual dorsal CA1 neurons jointly encode accumulated evidence with spatial position in mice performing this task (n=917 of 3144 total neurons). Nonlinear dimensionality reduction estimated the neural manifold to be approximately 4-6 dimensions. Within this low-dimensional space, both physical and abstract variables were jointly mapped in an orderly fashion, creating a geometric representation that we demonstrate to be similar across animals. Furthermore, using a method combining generalized linear models (GLMs) with hidden Markov models (HMMs), different trials in the task could be clustered into distinct behavioral states. We show that manifolds fit to some clusters of trials better organize behavioral variables, such as accumulated evidence, compared to manifolds fit to all trials in a session. Other clusters have little representation of accumulated evidence, consist mostly of left or right trials, and coincide with poor task performance. These results demonstrate that CA1 neurons can have distinct patterns of neural activity representing different behavioral strategies, i.e. remapping, in animals performing complex decision-making tasks. The existence of multiple behavioral states represented by different neural manifolds suggests that errors independent of trial difficulty seen in various perceptual decision-making tasks, i.e. “lapses”, may correspond to alternate suboptimal strategies, instead of mistakes due to noise or motor errors.

Title: Multiplexed immunofluorescence reveals distinct neuron and astrocyte clusters in the rhesus monkey prefrontal cortex that are differentially altered in normal aging

Authors: W. CHANG[1], M. MEDALLA[1], P. CASTRO-MENDOZA[1], E. MCDONOUGH[2], L. LOWERY[2], M. VARGHESE[3], P. HOF[3], D. E. MEYER[2], ***J. LUEBKE**[1];
[1]Boston Univ., Boston, MA; [2]GE Res., NIskayuna, NY; [3]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Multiplexed immunofluorescence was used to sequentially stain and image 18 biomarkers in tissue microarrays containing PFC sections from young (6.5, 11.7 y.o.), middle-aged (15.3, 17.3, 17.6, 19.2 y.o.) and aged (24.8, 28.4 y.o.) behaviorally characterized rhesus monkeys. Tissue from two additional middle-aged subjects (17.7, 19.7 y.o.), that received daily

dietary curcumin over 3 years, was included to assess whether this compound prevents age-related changes. Cells were precisely localized within gray matter laminae and white matter using machine learning-based segmentation of DAPI images, and classified as neurons or astrocytes using cell type-specific biomarkers.In separate analyses of neurons and of astrocytes, we performed dimensionality reduction and cluster analysis on the cellular intensities of biomarkers known to be closely associated with the aging process. This approach allowed us to identify different subpopulations (clusters) of neurons and of astrocytes that are characterized by distinctive biomarker intensity profiles. Eight out of a total 25 neuronal clusters and 12 out of a total 18 astrocytic clusters incorporate proportions of cells that are either increased or decreased with age (Fisher's exact test, $p<0.05$). For example, "Neuron Cluster 1", characterized by low intensities of 3-nitrotyrosine and amyloid β (Aβ), and high intensities of cleaved caspase-3, TDP43 and TSPO (Mann Whitney U, $p<2.5e-17$), contains significantly higher percentages of the total number of neurons in middle-aged (17.7%) and aged (16%) relative to young monkeys (10%; $p<9e-09$). The percentage of total neurons in "Neuron Cluster 1" (7.2%) of curcumin-treated monkeys is significantly lower than that of middle-aged controls ($p=5.62e-35$). Interestingly, neurons within "Neuron Cluster 1" are preferentially located in the supragranular layers of the cortex ($p=1.36e-24$). As another example, "Astrocyte Cluster 3" characterized by low intensity of Aβ and high intensity of vimentin ($p<0.008$), differs significantly between age groups, with 14.5%, 7.7% and 2.7% of the total number of astrocytes in young, middle-aged and aged respectively ($p<5.12e-5$). "Astrocyte Cluster 3" cells are preferentially localized in the white matter ($p=1.87e-68$). As with "Neuron Cluster 1" curcumin treatment ameliorates the age-related changes to "Astrocyte Cluster 3" ($p=0.006$).These two examples -"Neuron Cluster 1" and "Astrocyte Cluster 3"- are just two of the 43 clusters identified with 6 (of 18) biomarkers. Ongoing analyses will reveal many additional interactions between biomarkers in different cell types, as well as alterations to specific clusters during aging.

Title: Age-dependent changes in the neural coding of the cholinergic basal forebrain during a probabilistic Pavlovian task

Authors: *S. MARTÍNEZ-BELLVER[1,2], A. VELENCEI[1], N. SOLARI[1], C.-H. DE BEVAL[1,3], P. HEGEDÜS[1,4], B. HANGYA[1];
[1]Inst. of Exptl. Med., Budapest, Hungary; [2]Univ. of Valencia, Valencia, Spain; [3]PSL Univ. Paris, Paris, France; [4]Semmelweis Univ., Budapest, Hungary

Abstract: Acetylcholine mediates multitude of cognitive functions including arousal, attention, sensory processing, reinforcement expectation, reward and addiction. The basal forebrain cholinergic input to the cortical mantle plays a central role in the modulation of these cognitive processes. Age-related changes in the morphology of cholinergic neurons has been observed across species, characterized by dendritic, synaptic, and axonal degeneration. However, the link between cholinergic activity during learning and the normal or pathological age-related neurodegeneration is still missing. To clarify the role of the cholinergic basal forebrain in learning during the normal aging process, we performed neuronal recordings in the nucleus of the horizontal limb of the diagonal band (HDB), in head-fixed ChAT-cre mice during a probabilistic auditory cued-outcome task. Animals from 3 to 18+ months of age were injected with an adenoassociated virus carrying channelrhodopsin-2, transfecting cholinergic neurons, allowing us to optically tag them. Animals showed decreased anticipatory licking correlated with aging, being old animals less likely to lick during reward-predicting trials, compared to young ones. Surprisingly, tagged cholinergic neurons in the young animals seemed to respond to the reward but not punish-related cue, whereas in the old animals no response to cue was observed in contrast to the young ones. Additionally, both punishment and reward activated part of the recorded neurons in all the animal groups. We additionally performed fiber photometry experiments with an acetylcholine fluorescent sensor in order to determine the cholinergic influx over the prefrontal cortex and basolateral amygdala, the main cholinergic projections of HDB. Results showed a similar pattern to that observed in the basal forebrain cholinergic neurons. Finally, we managed to modify the associative learning of the Pavlovian task contingencies of 3 months old animals by specifically inhibiting the cholinergic neurons of HDB during the CS presentation. With this paradigm, young animals showed learning deficits similar to those observed by aged animals. Overall, our study reveal new information on the role of the basal forebrain in associative learning, and how this system is affected by ageing.

Title: Reward, sociability, affective behavioral and functional neuroimaging differences in young, middle, and aged C57BL/6J male and female mice

Authors: M. POMPILUS, J. BURAIMA, *M. FEBO;
Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: According to the WHO, mental health conditions affect 15% of adults ages 60 and older and accounts for 6.6% of total disability. These conditions are often underdiagnosed because they occur along with other primary systemic and neurological conditions. More research on the neurobiological regulation of mood and affective states in aging subjects is thus needed. We investigated reward preferences, sociability, and anxiety-like behavior in male and female C57BL/6J mice tested after arrival at 10, 30, and 60 weeks of age. Mice were behavioral assessed using protocols for sucrose preference, social interaction/recognition, open field activity, and contextual fear condition (CFC). Mice were then imaged at 4.7 Tesla under combined dexmedetomidone/isoflurane anesthesia to measure resting state functional connectivity across cortical, striatal, hippocampal, and amygdala nodes. Initial analyses of general locomotor activity in an open field environment indicates that 10-week-old mice had higher levels of horizontal activity than 30- and 60-week-old mice. The total distanced moved during testing showed a similar difference, however, stereotyped activity was not different between the 3 age groups. Interestingly, 10-week-old mice ambulated at much higher levels in the center of the test arena than 30- and 60-week-old mice. We used a 3-day CFC protocol that included a conditioning day, a retrieval day, and a 2nd retrieval day with changes to context. Mice in all age groups acquired tone-shock paired freezing behavior at the same rate and extent on day 1. All mice showed robust conditioned fear to tone alone on day 2, with 60-week-old mice trending towards higher levels of conditioned freezing relative to 10- and 30-week-old mice. On day 3, 10-week-old mice had lowest levels of conditioned freezing in a modified context. Our data suggest that aged (60-week-old) C57BL/6J mice are less active, exhibit anxiety like behavior in an open field, and express higher levels of fear conditioning and more difficulty in suppressing conditioning in a modified context when compared to younger 10-week-old mice. Ongoing analyses will investigate reward preferences, sociability, and functional connectivity in these mice. The present preliminary results show initial evidence of differential expression of affective and cognitive behaviors in aged C57BL/6J mice.

Title: The role of dopamine in age-related changes in regional homogeneity

Authors: *J. H. PARENT[1], C. J. CIAMPA[1], R. M. GARRETT[1], T. M. HARRISON[2], C. N. GORDON[1], W. J. JAGUST[3], A. S. BERRY[1];
[1]Brandeis Univ., Waltham, MA; [3]Helen Wills Neurosci Inst., [2]UC Berkeley, Berkeley, CA

Abstract: Regional homogeneity (ReHo) is an fMRI measure of the nonparametric concordance of neighboring voxel timeseries that has been interpreted to reflect local functional connectivity. Aging is associated with alterations in ReHo, which previous research has associated with accumulation of AD-related pathology and reduced glucose metabolism. However, aging is also associated with changes in the dopamine (DA) system. Given DA's neuromodulatory function and broad innervation of most cortical and subcortical regions, we hypothesized that ReHo would be related to individual differences in DA function in aging. Here, we used [^{18}F]Fluoro-m-tyrosine ([^{18}F]FMT) PET, a measure of DA synthesis capacity, and 3T resting state fMRI to establish relations between ReHo, DA function, and cognition in cognitively normal older adults (OA) (n = 34; 21 females, mean education: 17 mean age: 77 (range = 62-85 years). To limit the possible impact of AD-related pathology, OA were defined as β-amyloid negative via [^{11}C]Pittsburgh Compound B PET. To describe the effect of older age on ReHo, cross-sectional group-level analyses were performed using 29 young adults (12 females, mean education: 16 years, mean age: 25 years (range = 20-35 years)). Analyses relating ReHo to DA and cognition were limited to OA. We found that OA tended to have significantly lower ReHo in cortical regions and higher ReHo in subcortical regions compared to young adults. Next, we tested the relation between ReHo and [^{18}F]FMT net tracer influx (Ki) in a midbrain region of interest (ventral tegmental area/substantia nigra). We found that OA with higher [^{18}F]FMT Ki were those with higher ReHo in prefrontal cortex regions including dorsal anterior cingulate cortex (dACC, r = .379, p=.035). Thus, higher midbrain DA synthesis capacity in older age was associated with "youth like" dACC ReHo patterns. To establish the relevance of relations between [^{18}F]FMT Ki and ReHo to cognition, we tested their independent and combined association with performance on the Stroop task, which is consistently linked with both DA and dACC function. Higher [^{18}F]FMT Ki was associated with better Stroop performance (r=.540, p=.001). However, we did not find a significant relation between dACC ReHo, and Stroop performance (r= .112, p= .534). Lastly, we tested whether [^{18}F]FMT Ki mediated the relation between dACC ReHo and Stroop performance. We found a significant indirect effect of [^{18}F]FMT Ki (mean boostrapped unstandardized β= 2.03, p = .006). Together, this study describes a distributed pattern of ReHo changes in aging and reveals a potential neuromodulatory pathway through which dACC ReHo is related to executive control in OA.

Title: Cortical iron mediates age-related decline in fluid cognition

Authors: *C. M. HOWARD[1,2], S. JAIN[2], A. D. COOK[2], L. E. PACKARD[2], H. A. MULLIN[2], N.-K. CHEN[2], C. LIU[2], A. W. SONG[2], D. J. MADDEN[2,1,3];

Abstract: Brain iron dyshomeostasis disrupts various critical cellular functions and age-related iron accumulation in deep gray matter and sensorimotor regions may contribute to oxidative stress, deficient neurotransmission, and cell death. While recent studies have linked excessive brain iron to cognitive function in neurodegenerative pathology contexts, the role of brain iron accumulation in age-related decline in fluid cognition (encompassing speed-dependent cognitive abilities) remains unknown. We validated age-related accumulation of iron in deep gray matter regions, measured by quantitative susceptibility mapping (QSM), in 67 healthy participants (18-78 years, 35 female), in relation to known histology for these regions. Voxelwise QSM analyses defined cortical regions for which susceptibility was associated with both age and fluid cognition. QSM susceptibility values were negatively associated with fluid cognition in the right inferior temporal gyrus, bilateral putamen, posterior cingulate gyrus, motor, and premotor cortices. These results align with previous literature suggesting that voxelwise QSM methods are valid measures for the detection of age-related differences in brain iron in both cortical and subcortical regions. A mediation analysis indicated that susceptibility in the right inferior temporal gyrus was a significant mediator of the relation between age and fluid cognition. Additionally, age and right inferior temporal gyrus susceptibility interacted to predict fluid cognition, such that brain iron was negatively associated with cognitive decline for adults over 45 years. This novel finding suggests that iron has a mediating role in cognitive decline, is a

critical source of variance in cognitive aging studies, and may be an early biomarker of neurodegenerative disease.

Sci., Natl. Tsing Hua Univ., Hsinchu, Taiwan

Abstract: Normal aging experiences a general decrement in physiological function and cognitive abilities, and the age-related neurocognitive declines is highly variable within the aged population. Previous studies have suggested that Cognitive Reserve (CR) factor such as education could cope with the neurocognitive impairments emerging as a consequence of age-associated brain damage or pathology. Given that age-related and individual differences in neurocognitive function are associated with dynamic processes of the functional brain networks, we hypothesized that CR may involve facilitating age-related changes in flexibility and efficiency of neural networks and individual variations in educational level would be associated with altered functional brain complexity of the aging brain. In this resting-state functional magnetic resonance imaging (rs-fMRI) study, we applied multiscale entropy, cross-sample entropy, and neuropsychological approaches to examine whether and how educational level impacts the complexity of brain function, intrinsic networks, and cognitive ability in healthy aging. The rs-fMRI results showed that, compared with the healthy elder with lower CR, the healthy elder with higher CR presented better performance of executive function, youthful brain entropy and increased efficiency of networks in fronto-parietal (FPN), cingulo-opercular (CON),

and default mode network (DMN). These findings provide neurobiological evidence of CR and suggest that CR may facilitate and scaffold neural networks of the aging brain to act as a protective mechanism.

Title: Cognitive effects of environmental enrichment on aged obese male mice

Authors: *C. C. BAKER[1], L. R. BANNER[2], T. UHLENDORF[3];
[1]Biol., California State University, Northridge, Northridge, CA; [2]Biol., California State University, Northridge, Simi Valley, CA; [3]Cal State Univ. Northridge, Northridge, CA

Abstract: Humans are living longer than ever before. Cognitive impairments are one of the most devastating health challenges that occur with increasing lifespan. Normal aging is associated with atrophy and alterations in hippocampal synapses, plasticity, and spatial memory. Coupled with the increased aging population, approximately 40% of Americans aged 65-74 are obese. Many long-term complications arise in patients with obesity and type-2 diabetes including dementia and Alzheimer's disease. These cognitive effects begin early as they are seen in children and adolescents with type-2 diabetes and a lifetime exposure to obesity could have an additive effect on age-related cognitive decline as has been seen with late life cardiovascular disease. Environmental enrichment has been shown to improve the cognitive decline in in normal aging and Alzheimer's disease. In this study we sought to determine whether environmental enrichment would improve cognition in long-term obese aged C57Bl6/J mice to the same extent it does in control aged mice. Two-month old animals were randomly assigned to standard laboratory mouse cages with either regular chow (RC) or a high-fat diet (HFD). Animals on a HFD developed obesity and elevated blood glucose levels. After 18 months, mice were further randomly assigned into HFD-Control (n=9), HFD-Enrichment (n=8), RC-Control (n=9), and RC-Enrichment (n=11) for two months. Control groups were housed in standard mouse cages while enriched cages were larger and contained a variety of toys rotated on a weekly basis. After two months of enrichment, mice were tested using the Morris Water Maze, Novel Object Recognition, and Elevated Plus Maze. Each trial was filmed and analyzed with tracking software. A decrease in body weigh was seen in both groups in the enriched environment with

the RC animals losing the most weight. Blood glucose levels were also slightly lower in both enrichment groups compared to controls. Although both enriched groups (HFD and RC) showed cognitive improvement over their respective controls, the greatest improvements were seen in the mice on regular chow in the enriched environment. The RC-Enrichment improved their time to the platform in the Morris Water Maze and had a significantly greater exploratory ratio in the Novel Object Recognition compared to all other groups. In the Elevated Plus Maze, both enrichment groups showed a substantial reduction in anxiety (greater number of crossings and more time in open arms), although the RC-Enrichment group showed the greatest changes. Taken together these results may indicate that aging in the context of long-term obesity has a greater cognitive impact than aging alone.

Title: The balance of hippocampal-caudate functional connectivity is altered in older adults

Authors: *M. FREEDBERG[1], R. FOROUGHI[2];
[1]Kinesiology and Hlth. Educ., Univ. of Texas, Austin, TX; [2]Kinesiology and Hlth. Educ., The Univ. of Texas at Austin, Austin, TX

Abstract: The hippocampus and caudate are hubs in the episodic and procedural memory networks, respectively. Aging disproportionately affects episodic memory (memory for personally experienced facts and events) more than procedural memory (memory for skills and habits). This suggests that the hippocampal network is more vulnerable to aging than the caudate one. However, to our knowledge, a direct comparison of age-related changes in hippocampal and caudate network connectivity has not been made. Here, we compared the magnitude and valence of hippocampal and caudate connectivity changes between younger and older adults. We expected to see relatively greater hippocampal network decoupling (i.e., decreases in network connectivity) compared to the caudate network. Single sessions of resting-state fMRI data acquired from younger (18-45 yrs; n = 103) and older (55-75 yrs; n = 125) adults were obtained from the Nathan Kline Institute-Rockland Sample (NKI-RS) repository. Resting-state functional connectivity (rsFC) was measured from the left anterior hippocampus and the head of the right caudate based on their specific roles in episodic and non-motor procedural memory, respectively. Whole-brain hippocampal and caudate rsFC were compared between groups. Statistical significance was set to $p < 0.001$ (FDR-corrected, $q < 0.05$). Examining hippocampal and caudate rsFC separately, we observed that the hippocampus showed significant age-related

decoupling from the medial prefrontal cortex and striatum, while the caudate became disconnected from several subcortical regions, including the striatum and sensorimotor regions. Contrary to our expectations, the caudate showed significantly greater network decoupling compared to the hippocampus, in general. Finally, we also noted a dynamic shift in rsFC between networks: While the hippocampus increased in rsFC with the thalamus, the opposite was true for the caudate. In contrast, we noted that while the caudate significantly increased in rsFC with several frontal areas, such as the dorsal and ventral medial prefrontal cortex, the opposite was true for the hippocampus. Our results challenge the notion that the hippocampus undergoes stronger age-related network decoupling than the caudate and indicate that both networks undergo compensatory shifts: While the hippocampus becomes more associated with the thalamus and less associated with the prefrontal cortex, the opposite is true of the caudate. These results suggest that aging causes a shift in the configuration of each network, including an exchange of network resources.

Title: Norepinephrine possibly mediates the effect of chronic amphetamine on memory performance in aged rats.

Authors: *S. SCOGNAMIGLIO, G. DEZFULI, K. J. KELLAR;
Georgetown Univ., Washington, DC

Abstract: Understanding the neural mechanisms of normal and pathological aging will become increasingly important as the average lifespan continues to rise. Memory impairment is attributed to normal aging processes with the hippocampus and the cerebral cortex playing key role in the encoding and retrieval of memories. Norepinephrine (NE) is an important modulator of memory, especially emotional memory (Tully *et al.*, 2010). Previously, we have demonstrated that acute treatment with amphetamine (0.5mg/kg) enhances memory performance on the novel object recognition (NOR) task in aged Fischer 344 rats, with a reversible and short-term effect on memory performance (Scognamiglio *et al.*, 2021). The purpose of this study was to investigate whether chronic amphetamine treatment has a more robust and possible long-term effect on memory performance in aged rats and whether the effect of amphetamine on object recognition memory is NE dependent. To this end, in the first set of experiments we administered amphetamine for 2 weeks via drinking water at doses of 0.25 mg/kg (week 1) and 0.5 mg/kg (week 2) and tested aged Fischer 344 rats on the NOR task. To determine the extent to which NE

per se influences the cognitive effects of amphetamine, we examined the effects of systemic administration of β and α adrenergic antagonists propranolol, metoprolol, and prazosin prior to the NOR test phase in aged rats chronically treated with amphetamine. Results from the present studies demonstrate: **(a)** aged rats chronically treated with amphetamine display improved object recognition memory compared to acute administration, **(b)** memory performance goes back to baseline 2 months after chronic amphetamine treatment, **(c)** both propranolol and prazosin attenuate the amphetamine effect on cognition while metoprolol completely abolishes amphetamine effects on cognition. An additional goal of this study was to assess the outcome of chronic amphetamine treatment on a cellular level by analyzing dendritic spines in the cerebral cortex and hippocampus. The results will be reported.

Title: Ropanicant (SUVN-911): An orally active neuronal nicotinic acetylcholine α4β2 receptor antagonist for the management of depression

Authors: *R. ABRAHAM, N. GANUGA, R. SUBRAMANIAN, S. PETLU, S. RAVELLA, N. BOGARAJU, V. MIDDEKADI, V. CHOWDARY PALACHARLA, A. MANOHARAN, P. JAYARAJAN, R. NIROGI;
Suven Life Sci., Hyderabad, India

Abstract: Depression is a common and severe psychological condition with change in mood affecting approximately 300 million people worldwide. It is characterized by loss of interest, pleasure, feelings of guilt, low self-worth, low confidence, disturbed sleep or appetite, poor concentration, and is associated with suicidal thoughts. Reports from literature suggest that neuronal nicotinic acetylcholine α4β2 receptor antagonist has antidepressant like activity. Ropanicant is a clinical candidate for the treatment of depression. The pharmacokinetics of ropanicant was assessed. Efficacy of ropanicant in depression was assessed using an olfactory bulbectomized (OBX) Swiss albino mice. OBX mice were evaluated in the tail suspension test. Similarly ropanicant was evaluated in a forced swimming test and brain microdialysis studies. Ropanicant was found to have favorable pharmacokinetics with adequate brain penetration and good oral bioavailability. A reduction in the duration of immobility in the tail suspension test as well as forced swimming test was observed. SUVN-911 produced a significant increase in cortical levels of norepinephrine and altered the expressions of brain-derived neurotrophic factor, indicating the possible neurochemical basis for the effects observed in animal models of

depression. Changes were observed in calcium binding adaptor molecules (Iba1) as well. From the above studies, we conclude that ropanicant may have potential in addressing depression.

Title: Establishing Signature Profile of Muscarinic M4 Selective Molecules by Evaluating their Orthosteric/Allosteric Binding Properties and Biased Signaling

Authors: S. S. PIN, M. TOH, H. N. NGUYEN, P. A. IREDALE;
Cerevel Therapeut., Cambridge, MA

Abstract: The muscarinic M4 receptor is a Gi-coupled G-protein receptor frequently targeted by the pharmaceutical industry for psychiatric disorders such as schizophrenia. The aim of this study is to understand the behavior of M4 receptor in response to the binding and activation by various agonists with distinct chemical structures. Combining classical radioligand binding and modern receptor pharmacology, we have done a comprehensive analysis of known M4 selective molecules at the binding and functional level to determine their preferences for allosteric/orthosteric binding sites, as well as their preferred signaling pathway. Equilibrium binding and full kinetics profiles were determined. Molecules have a broad range of binding affinity and functional potency. At the kinetics level, they have similar k_{off}; the differences in K_d is driven by the various level of k_{on}. Functional profiling was done at the G-protein activating, β-arrestin recruitment, and at the cAMP level. Our results show that M4 agonists have a variety of mode of actions. All have a varying degree of binding affinity to the orthosteric and/or allosteric binding site. Signal transduction can be mediated through the orthosteric as well as the allosteric sites. At the functional level, we evaluated activation of Gαi1, Gαi2, Gαi3, GαoA, GαoB, GαZ, β-arrestin and cAMP accumulation. Agonists have distinct signaling signature profile. Overall, M4 agonists appear to have a variety of unique identities that can be distinguished at the binding

and functional levels. Additional studies are needed to fully understand the clinical implications for each profile.

Title: Cholinergic receptor blockade impairs spatial memory retrieval and minimizes retrieval-induced alterations in matrix metalloproteinase-9

Authors: *M. L. OLSON, B. BADENOCH, M. BLATTI;
Concordia Col., Moorhead, MN

Abstract: Alzheimer's Disease (AD) is associated with a loss of cholinergic function, and the basal forebrain cholinergic system remains the most common target of pharmaceutical treatments for AD. Recently, some have argued that AD may be best characterized as a deficit of memory retrieval; however, research reports investigating the role of the cholinergic system in memory retrieval are often confounded by the fact that they utilize experimental methodologies that fail to fully isolate the retrieval process from acquisition and consolidation processes. Utilizing a methodology which isolates spatial memory retrieval in the circular water maze, we show that the central administration of the cholinergic antagonist scopolamine reliably impairs the retrieval of previously consolidated spatial memories. Matrix metalloproteinase-9 (MMP-9) is a zinc-dependent endopeptidase that regulates the extracellular matrix as well as several other substrates implicated in memory. Using immunoblotting and gelatin zymography, we show that modifications in hippocampal MMP-9 expression are associated with spatial memory retrieval. Further, we provide evidence that the cholinergic system is an important regulator of some of these retrieval-induced changes in MMP-9. These results further elucidate the well-established and important role of MMP-9 in learning and memory and indicate a possible connection between the cholinergic dysfunction and MMP-9 dysregulation that is commonly seen in AD.

Title: Plasticity-related signaling pathways in the medial prefrontal cortex are potential targets of the antidepressant, Vortioxetine, which reverses cognitive impairments associated with androgen deprivation therapy for prostate cancer.

Authors: *A. DORNBUSCH[1,2], A. VAIANA[1,2,3], J. GELFOND[4], T. L. JOHNSON-PAIS[3,5], R. LEACH[3,6], C. RAMAMURTHY[3,7], I. THOMPSON[5,9], D. A. MORILAK[1,2,3,8];

Sci., [5]Dept. of Urology, [6]Dept. of Cell Systems and Anat., [7]Dept. of Med., [8]South Texas Veterans Hlth. Care Syst., UT Hlth. San Antonio, San Antonio, TX; [9]Dept. of Urology, Cristus Santa Rosa Hosp., San Antonio, TX

Abstract: Prostate cancer is one of the most common types of cancer in men. Androgen Deprivation Therapy (ADT) is a first-line treatment for late-stage, metastatic, androgen-responsive prostate cancers. Despite ADT's success to slow cancer growth, there are a number of unwelcome side effects. These include profound cognitive impairment in areas such as executive function, memory, and attention. Further, patients receiving ADT have reduced functional connectivity within the medial prefrontal cortex (mPFC). There are currently no treatment options available to patients that experience cognitive decline. Vortioxetine is a multimodal drug that enhances cognition in patients with major depressive disorder. We hypothesized that vortioxetine might also be beneficial to cognitive decline associated with ADT. We have found that vortioxetine reverses deficits in a rodent model of ADT using surgical castration. Androgen depletion impaired attentional set-shifting, which is mediated in the mPFC. Chronic treatment with vortioxetine (28 mg/kg/day) administered through the diet rescued these deficits (Sharp et al., 2019). Because the androgen receptor is a transcription factor, the impairments seen after ADT are likely related to changes in gene expression. Vortioxetine has also been shown to induce changes in neuroplasticity-related gene expression in healthy rats. It is well documented that castration reduces spine density within the mPFC. Given this, we hypothesized that vortioxetine might reverse cognitive deficits by rescuing plasticity-related gene expression altered by castration. Castrated or intact male Sprague-Dawley rats were treated with vortioxetine or control diet for 17 days. Gene expression in the mPFC was analyzed using a whole rat genome microarray (Agilent). Castration alone significantly altered 1,221 genes within the mPFC (adjusted $p<0.05$). Of the genes altered by castration, many are key for activity-dependent plasticity which may underlie cognition, including Shank1, Akt, MAPK, and CaMKII. Vortioxetine had no significant effect on individual gene expression. However, Ingenuity Pathway Analysis revealed that vortioxetine significantly altered gene clusters involved in

synaptic plasticity (q value<0.05). Preliminary studies are underway to examine changes in the activation state of relevant proteins in the mPFC after castration, as well as chronic vortioxetine treatment. These experiments will provide insight into the mechanisms by which vortioxetine improves cognition after ADT in a rodent model. In conclusion, vortioxetine may be an effective treatment in prostate cancer patients that experience cognitive decline after ADT.

Title: Enduring adverse effects of adolescent cannabis abuse involve kynurenic acid: relevance for the etiology and treatment of cognitive dysfunctions.

Authors: *S. BEGGIATO[1], *L. FERRARO[2], R. SCHWARCZ[3];
[1]Univ. of Chieti, Chieti, Italy; [2]Dept. of Life Sci. and Biotech., Univ. of Ferrara, Ferrara, Italy; [3]Maryland Psychiatric Res. Ctr., Baltimore, MD

Abstract: Cannabis abuse during adolescence is a risk factor for cognitive impairments in psychiatric disorders later in life (Renard et al., 2016). Specifically, early exposure to Δ9-tetrahydrocannabinol (THC; i.e. the main psychotropic component of cannabis) causes enduring cognitive deficits, which critically involve impaired glutamatergic function in the prefrontal cortex (PFC; Zamberletti et al., 2014). Remarkably, these adverse effects are qualitatively very similar to those caused in developing rodents by experimental increases in brain kynurenic acid (KYNA), a neuroactive metabolite of tryptophan degradation (Pocivavsek et al., 2014).To date, the possible causal relationship between cannabinoids, KYNA and cognition has not been investigated in adolescence. We therefore examined the effect of chronic adolescent THC exposure on KYNA levels in the rat brain. Male Wistar rats were chronically treated with vehicle or ascending intraperitoneal (i.p.) doses of THC starting on postnatal day (PND) 35 until PND 45, as described (Zamberletti et al., 2014). In adulthood (PND 75), cognitive assessment (Y-maze) and extracellular KYNA/glutamate levels were measured in the PFC by *in vivo* microdialysis, before and after an acute challenge with L-kynurenine (L-KYN), the biological precursor of KYNA (5 mg/kg; i.p.). By using the selective, brain-penetrable KAT II inhibitor PF-

04859989 (30 mg/kg, i.p., 1 hr prior the Y-maze; Kozak et al. 2014), we then examined whether blockade of KYNA neosynthesis prevents the cognitive impairment. Compared to vehicle-treated controls, extracellular basal KYNA levels were higher in the PFC of adult rats chronically exposed to THC in adolescence ($p<0.01$). No changes were observed in extracellular glutamate levels. Following a challenge with L-KYN, extracellular KYNA levels increased similarly in both groups (i.e. vehicle- and THC-treated; $p<0.001$ and $p<0.01$ respectively). Chronic adolescent THC exposure negatively affected short-term memory (reduced spontaneous alternation) in adult animals ($p<0.001$), while pre-treatment with PF-04859989, which prevented the THC-related KYNA increase ($p<0.01$), partially restored the impairment ($p<0.05$). We conclude that the observed alterations in PFC KYNA signalling might be involved in the cognitive dysfunction induced by the exposure to THC during the adolescence. In the translational realm, these experiments raise the prospect of prevention of KYNA neosynthesis as a promising novel approach to combat some of the detrimental long-term effects of adolescence cannabis use.

Title: Modulation of brain neurotransmitters and BDNF levels by curcumin improves depression and associated pseudodementia in rats

Authors: *S. HAIDER[1], A. AFZAL[1], Z. BATOOL[2];
[1]Univ. of Karachi, Karachi, Pakistan; [2]Univ. of Karachi, Karachi University, Pakistan

Abstract: Rationale Depressive state adversely affects the memory functions, especially in the geriatric population. The initial stage of memory deficits associated with depression is particularly called as pseudodementia. It is the starting point of memory disturbance before dementia. The purpose of this research was to study depression and its consequent pseudodementia. **Material and methods** For this purpose 24 male albino Wistar rats were divided into four groups. Depression was induced by 14 days of chronic restraint stress (CRS) daily for 4 h. After developing a depression model, pattern separation test was conducted to monitor pseudodementia in rats. Morris water maze test (MWM) was also performed to observe spatial memory. It was observed that model animals displayed impaired pattern separation and spatial memory. Treatment was started after the development of pseudodementia in rats.

Curcumin at a dose of 200 mg/kg was given to model rats for one week along with the stress procedure. Following the treatment with curcumin, rats were again subjected to the aforementioned behavioral tests before decapitation. Corticosterone levels, brain derived neurotrophic factor (BDNF) and neurochemical analysis were conducted. **Results** Model rats showed depressogenic behavior and impaired memory performance. In addition to this, high corticosterone levels and decreased hippocampal BDNF, 5-HT, dopamine (DA), and acetylcholine (ACh) levels were also observed in depressed animals. These behavioral biochemical and neurochemical changes were effectively restored following treatment with curcumin. Hence, it is suggested from this study that pseudodementia can be reversed unlike true dementia by controlling the factors such as depression which induce memory impairment.

Title: Cognitive impairments and changes in inflammatory cytokines in a prostate cancer rodent model treated with docetaxel

Authors: *A. ASHER[1], M. GIROTTI[2], A. SHARP[4], D. A. MORILAK[3];
[1]Univ. of Texas Hlth. Sci. Center, San Antonio, San Antonio, TX; [2]Pharmacol., [3]Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [4]Dept of Pharmacol., UT Hlth. San Antonio, San Antonio, TX

Abstract: Prostate cancer (PC) is the most common cancer to affect men, with more than 3.1 million men in the United States having been diagnosed with PC at some point in their lifetime. In fact, metastatic PC is the second leading cause of cancer-related deaths. Mainstay treatment of metastatic PC consists of androgen deprivation therapy and chemotherapy, both of which are associated with cognitive impairments. Microtubule stabilizers, like docetaxel, are often used as chemotherapy for PC. Patients who receive docetaxel as therapy experience difficulties in working memory, cognitive flexibility, and attention. These cognitive changes are accompanied by dysfunction in the prefrontal cortex and hippocampus, but mechanisms underlying these impairments remain unknown. To study possible mechanisms for chemotherapy-induced cognitive impairments, a syngeneic rat model of PC was utilized. Male Copenhagen rats were

implanted subcutaneously with syngeneic Dunning R-3327 G cell tumors or subjected to sham implants, then treated with either docetaxel (3 i.p. injections over 5 days, 6 mg/kg each) or vehicle. Cognitive impairments, specifically in visuospatial memory and cognitive flexibility were assessed using the novel object task and the attentional set-shifting test, respectively. Additionally, an array of inflammatory cytokines were measured in plasma and in medial prefrontal cortex and hippocampus. Preliminary data show that docetaxel reduced discrimination in the novel object task primarily in tumor-bearing rats, with less effect in sham controls. Significant increases in the pro-inflammatory cytokines interleukin-6 and tumor necrosis factor alpha were observed in the plasma of tumor-bearing rats. Moreover, interleukin-6 mRNA was increased in the dorsal hippocampus of tumor-bearing rats compared to sham controls. Ongoing experiments will assess potential disruption of the blood-brain barrier in rats with prostate cancer. Results from this study suggest that peripheral and central inflammatory signaling associated with prostate cancer may increase brain vulnerability to the potentially detrimental effects of docetaxel, contributing to cancer therapy-induced cognitive impairment.

Title: Blockade of the adenosine A2A receptor protects against cisplatin-induced cognitive impairments

Authors: *A. OLIVEROS, M. ABDUR RASHID, K.-H. YOO, A. CORUJO-RAMIREZ, J. TANG, J. HAWSE, D.-S. CHOI, M.-H. JANG;
Mayo Clin. Col. of Med., Rochester, MN

Abstract: Cisplatin, a platinum-based chemotherapy, has been clinically reported to potentiate cognitive impairments, known as chemobrain, and affects approximately 14 million cancer survivors in the United States without a known cure. These cognitive impairments are reported to

occur well-after chemotherapy cessation, thus it is imperative that novel therapeutics against chemobrain are investigated to improve quality of life in cancer survivors. To elucidate the pathological molecular mechanisms by which chemobrain impairs cognition, we have developed a mouse model resembling intermittent cisplatin chemotherapy in humans and performed RNA-seq analysis in the hippocampus, a brain structure critical for learning and memory. Our RNA-seq analysis revealed robust and selective elevations in the adenosine A2A receptor (A2AR) gene in this region. Given that A2AR is known to play a critical role in learning, memory, and neurodegenerative conditions, we hypothesize that A2AR inhibition can prevent cisplatin-induced cognitive impairments. Consistent with our prior results, we observed that cisplatin impairs adult neurogenesis, neuronal morphogenesis of newborn neurons and dendrite spine formation in the adult mouse hippocampus, leading to learning and memory dysfunction as well as increased anxiety. Remarkably, we found that pretreatment with the specific A2AR antagonist Istradefylline significantly prevents the aberrant neuronal and cognitive deficits induced by cisplatin, without promoting tumor growth or interfering with the anti-tumor activity of cisplatin. Mechanistically, we found that cisplatin's neurotoxic effects are cAMP-CREB and ERK signaling dependent in both the mouse hippocampus as well as human cortical neurons derived from iPSCs. Collectively, our results suggest that robust A2AR induction may be a key contributor to cisplatin-induced memory impairments via cAMP-CREB and ERK signaling pathways. Therefore, targeting the A2AR as a novel translational therapeutic target can be efficacious in protecting against cisplatin-induced chemobrain and consequently, have far-reaching synergistic effects on improved quality of life for cancer survivors.

Title: Assessing the effects of different doses of hericium erinaceus dietary supplementation on C57BL/6J mice and its role in cognitive behavior

Authors: *M. N. RODRIGUEZ[1], S. L. LIPPI[2];
[1]Angelo State Univ., Mission, TX; [2]Angelo State Univ., San Angelo, TX

Abstract: Hericium Erinaceus, also known as lion's mane, has shown beneficial neurocognitive and neurobiological effects in both healthy and transgenic mice. It has also shown to lessen anxiety and depression after 4 week consumption in human subjects. Not enough research has been conducted on the effects of lion's mane on healthy mice. It is important to assess the

benefits that Hericium Erinaceus may provide in order to prevent health complications and/or pathological disease. This study served as a baseline for the effects of Hericium Erinaceus Mushroom Mycelium Powder (Host Defense Mushrooms) on Wild-Type mice. Moreover, it was a pilot to an upcoming study assessing the effects of Hericium Erinaceus Mushroom Mycelium Powder (Host Defense Mushrooms) on the tauopathy mouse model. It was hypothesized that mice who received the highest dose of powder (2000 mg) would perform better than those receiving 1000 mg and the control. Twenty-four adolescent C57BL/6J male mice were randomized into 3 groups of 8: One control group and 2 experimental. For 9 weeks, all groups were administered 150 g of wet food every 4 days, while the experimental groups' wet food contained doses of Hericium Erinaceus Mushroom Mycelium Powder (Host Defense Mushrooms). Each Orirat semi-self-contained caging system (Animal Care Systems), housed with 2-3 mice received this. The first experimental group received 1/3 teaspoons of powder containing 1000 mg of Hericium Erinaceus and 825 mg of mycelium polysaccharides, while the second group received 2/3 teaspoons containing 2000 mg of Hericium Erinaceus and 1650 mg of mycelium polysaccharides. All mice were also provided 200 g of dry Teklad pellets ad libitum. Throughout the duration of the study the mice, dry food, and remainder of the wet food were weighed every 4 days to ensure the consumption of the wet food in comparison to the dry food, and to assess weight gain of the mice as a result of maturation along with dietary consumption. Behavior as assessed at 8 weeks through Open Field (OF), Elevated Zero Maze (EZM), and Morris Water Maze (MWM) tests. Trending significance of time spent in the surround ($p = .059$) indicated that mice who consumed 1000 mg of Hericium Erinaceus spent more time in the surround ($M = 152.65$) than mice who consumed 2000 mg ($M = 122.27$). This signifies that those who took a higher dose of Hericium Erinaceus experienced less anxiety. Future analyses of EZM and MWM will be further indicative of the effects of Hericum Erinaceus on the cognitive behavior of Wild-Type mice.

Title: Diethyl (3,4-dihydroxyphenethylamino) (quinolin-4-yl) methyl phosphonate protects against amyloid beta induced defective mitophagy, synaptic damage and cognitive dysfunction

Authors: *C. BOSE[1], M. VIJAYAN[2], P. REDDY[3];
[2]Intrnl. Med., [1]Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Intrnl. medicine, Texas Tech. Univ. Hlth. sciences Ctr., lubbock, TX

Abstract: ABSTRACT: The purpose of our study is to determine the protective effects of the newly discovered molecule DDQ (diethyl (3,4-dihydroxyphenethylamino) (quinolin-4-yl) methyl phosphonate) against mutant APP and amyloid-beta (Aβ) in Alzheimer's disease (AD). To achieve our objective, we used a well characterized amyloid-beta precursor protein (APP) transgenic mouse model (Tg2576 strain). We administered DDQ, a 20 mg/kg body weight (previously determined in our laboratory) intra-peritoneally 3-times per week for 2 months, starting at the beginning of the 12th month, until the end of the 14th month. Further, using biochemical and molecular methods, we measured the levels of DDQ in the blood, skeletal muscle, and brain. Using Morris Water Maze, Y-maze, open field, and rotarod tests, we assessed cognitive behavior after DDQ treatment. Using q-RT-PCR, immunoblotting, transmission electron microscopy, and Golgi-cox staining methods, we studied mRNA and protein levels of longevity genes SIRTUINS, mitochondrial number & length, and dendritic spine number and length in DDQtreated APP mice. Our extensive pharmacodynamics analysis revealed high peak levels of DDQ in the skeletal muscle, followed by serum and brain. Our behavioral analysis of rotarod, open field, Y-maze, and Morris Water Maze tests revealed that DDQ ameliorated cognitive decline (Morris Water Maze), improved working memory (YMaze), exploratory behavior (open field), and motor coordination (rotarod) in DDQ-treated APP mice. Interestingly, longevity genes SIRTUINS, mitochondrial biogenesis, fusion, mitophagy, autophagy and synaptic genes were upregulated in DDQ-treated APP mice relative to untreated APP mice. Dendritic spines and the quality mitochondria were significantly increased in DDQ treated APP mice. Current study findings, together with our previous study observations, strongly suggest that DDQ has anti-aging, and anti-amyloid-beta effects and a promising molecule to reduce age- and amyloid-beta-induced toxicities in AD.

Title: Simultaneous optical imaging of neuronal activity from multiple brain regions in songbirds with a Multiscope.

Authors: J. PENG[1], W. GONZALEZ[1], *Y. SOUDAGAR[2], A. PAPANICOLAOU[2], R. CHRISTO[2], C. LOIS[1];
[1]Caltech, Pasadena, CA; [2]Neurescence US Inc., Rochester, NY

Abstract: Fluorescent imaging of neuronal activity is a powerful method to monitor single-neuron spikes from large numbers of cells over time. Two-photon microscopes (2PM) have high resolution and can image cells deep in the brain. However, 2PM requires the animal to be head fixed, and many animals, such as songbirds, do not perform certain behaviors while head fixed. Miniature implantable microscopes (miniscopes) can be used to image neuronal activity in freely behaving animals. However, miniscopes are relatively heavy (around 2 grams) and bulky, which makes it very challenging to image in young or small animals, or to image simultaneously from 2 or more brain regions in the same animal. In an attempt to overcome the limitations of the miniscopes due to their size and weight, we applied a recently developed multiscope system based on imaging fiber optics, which is much smaller and lighter (less than 0.5 grams) than miniscopes, to study song circuits in songbirds. We have carried out pilot experiments to measure neuron activity in freely behaving zebra finches with calcium sensitive dyes (Oregon green and Cal-520) or GCaMP delivered by viral vectors. The minimal size and weight of the implant has made it possible to simultaneously image both left and right hemispheres in the same animal and image in very young animals (~30 days of age), neither of which has been achieved in songbirds previously. Using the fiber optic multiscope system, we have investigated the activity of neurons in the premotor nucleus HVC in two instances: (a) coordinated activity between the left and right premotor nuclei HVC in freely singing adults, and (b) the responses of neurons in juveniles as they form a memory of the song from their tutors. These preliminary experiments indicate that the fiber optic based mutiscope has the potential to overcome some critical limitations of 2PM and miniscopes to investigate the neuronal basis of behavior in freely moving animals.

Title: In vivo multi-day calcium imaging of hippocampus with miniscopes in freely moving rats

Authors: *H. S. WIRTSHAFTER, J. F. DISTERHOFT;
Northwestern Univ., Chicago, IL

Abstract: Calcium imaging using GCaMP calcium indicators and miniature microscopes has been used to image cellular populations during long timescales and in different task phases, as well as to determine neuronal circuit topology and organization. The hippocampus (HPC) has long been studied with cellular resolution using *in vivo* electrophysiology, but this technique does not allow the same cells to be definitively followed over days, or the visualization of cellular organization within the structure. Because the HPC is essential for many tasks of memory, spatial navigation, and learning, calcium imaging of large populations of HPC can shed new insight on cell changes and organization over time during these tasks.To our knowledge, all reported uses of hippocampal *in vivo* calcium imaging have been done in mouse. However, rats have many basic experimental advantages over mice: they able to do more complex behaviors, more closely mirror human physiology, and are less stressed by handling. Rats are also an advantageous organism to use for calcium imaging: Due to their larger size, rats are able to support larger implants, including a wider diameter imaging lens and a larger camera, thereby enabling the recording of a greater number of cells. Additionally, rats are less prone to post-operative seizures than mice and may be at a decreased risk of seizures after prolonged GCaMP expression as compared to mice. In this poster, we will present the first *in vivo* calcium imaging from CA1 hippocampus in freely moving rats. Using GCaMP7c and the UCLA Miniscope, we will demonstrate that hundreds of cells (mean 226+-90 cells per session) can reliably be visualized and held across weeks using this technique. We will additionally show proof of method by showing that a large number of place cells (>70% of cells) can be recorded on a navigational task involving retrieving food reward on a linear track, and that these place cells are sufficient for decoding animal position.

Pierce Lab., New Haven, CT; [7]Depts. Biol. & Applied Physics, Stanford Univ. Dept. of Biol., Stanford, CA

Abstract: Time-lapse studies of neural dynamics in live animals are crucial toward understanding brain function and plasticity. However, in *Drosophila melanogaster*, long-term recordings of neural spiking have been infeasible, and many cellular electrophysiological properties remain unexplored. To address this obstacle, we used laser microsurgery to create a chronic fly preparation for longitudinal voltage-imaging studies. In combination with recently developed FRET-opsin voltage indicators, this preparation allowed us to perform imaging studies of neural voltage dynamics with single-spike resolution for up to 50 days in adult flies. Using this approach, we systematically and quantitatively characterized spontaneous spiking, stimuli-induced spiking, and learning-induced plasticity over multiple days in 6 subtypes of mushroom body output neurons (MBONs), which are crucial for aversive olfactory conditioning. The MBONs showed diverse spontaneous firing rates and bursting dynamics, revealing heterogeneities across the different MBON subtypes. Further, we observed MBON dendritic spikes, which manifested as a temporally broadened action potentials that backpropagated from the axonal region. Notably, all the MBONs had elevated firing activities during odor presentation, but this odor-induced excitation gradually converted into inhibitory responses after repeated odor exposures, revealing fast neural plasticity during sensory adaptation. After olfactory classical conditioning, some MBONs also selectively decreased their spiking responses to the punishment-predicting odor. This cue-specific depression lasted from 1-48 hr in different subtypes of MBONs as a form of learning-induced distributed neural plasticity in the fly memory system. Overall, our approach for long-term voltage imaging facilitates investigations of neurophysiology and neuroplasticity that were previously challenging in awake behaving flies. Our approach is compatible with a variety of recent optical imaging and optogenetic tools and opens new opportunities to study how individual neurons respond over time to environmental influences and change across the lifespan of adult flies.

Title: Long-term imaging of the ventral nervous system in behaving adult Drosophila melanogaster.

Authors: *L. HERMANS, M. KAYNAK, J. BRAUN, V. LOBATO RIOS, S. GÜNEL, F. AYMANNS, M. SAKAR, P. RAMDYA;
Swiss Federal Inst. of Technol. Lausanne, Lausanne, Switzerland

Abstract: Studying long time-course biological phenomena requires the ability to measure the same tissue repeatedly. In neuroscience, such tools would make it possible to study, for example, long-term memory, brain aging, and neurodegeneration. Here, I will describe a suite of microfabricated technologies that enable long-term, minimally invasive optical recordings of the adult *Drosophila* melanogaster ventral nervous system (VNS)—neural tissues that are functionally equivalent to the vertebrate spinal cord. This consists of a two-component system - a transparent window into the thorax, and an implant that pushes thoracic tissues away from the imaging region of interest. Additionally, we have developed a flexible tethering approach for repeatedly mounting and remounting animals under the 2-photon microscope. Taken together, these tools now open up the possibility of monitoring neural activity, and tissue dynamics in flies over the course of their lifetime. Preliminary results will show the impact of the technology on *Drosophila's* survival and behavior and the loss of sensory neurons following a leg injury.

Title: Calibration of optical measurement of membrane potential in eukaryotic cells

Authors: A. COSTANTINO[1], B. K. PANAMA[2], *M. W. NOWAK[1], R. L. RASMUSSON[2], G. C. L. BETT[2];
[1]Cytocybernetics, Buffalo, NY; [2]Jacobs Sch. of Med., Univ. of Buffalo, State Univ. of New York, Buffalo, NY

Abstract: We developed a method for calibration of optical signals to determine resting membrane potential and action potential (AP) amplitude in mV, for eukaryotic cells. Voltage sensitive fluorescent dyes enable non-invasive observation of APs, but need to be calibrated to provide information about absolute resting potential and amplitude. We used Cytovolt1 (di-4-ANBDQBS) (Cytocybernetics, NY), a voltage sensitive dye that has a much longer lasting stable signal than older dyes such as di-4-ANNEPS. This allows adequate time to permeabilize the membrane and change extracellular $[K^+]_o$ without rundown. We validated a method using a K^+ ionophore and ionic gradients to calibrate optical signals with voltage clamp in HEK293 cells. Cytovolt1 operates via the Stark effect, shifting the emission spectrum in response to membrane voltage (V_m). The emission spectrum is bell-shaped, so we used voltage clamp to verify that the dye response was linear over the physiological range (-80 to +40 mV). We measured changes in fluorescence intensity as a function of the voltage clamp potential, using a 720 nm long pass emission filter and excitation at 660 nm. This relationship was highly linear with deviation from linearity of less than 2% over the range -80 to +40 mV. The linearity of response greatly simplifies our calibration method. The V_m of cells which are dominated by a K^+ conductance will track the K^+ Nernst potential closely. We made HEK293 cell membranes highly permeable and selective for potassium by application of the K^+ ionophore, valinomycin. We then exposed the cells to 10, 25, 60 and 150 mM $[K^+]$. Using the Nernst Equation, these correspond to a V_m of -68, -45, -23 and 0 mV. We calculated the resting V_m of HEK cells as -76 ± 4.9 mV (n=11 cells). The relationship between calculated Nernst potential in the presence of valinomycin showed a linear correlation with changes in fluorescence intensity. To validate these fluorescence-voltage changes in valinomycin treated cells with actual membrane voltages, we correlated the K^+-induced fluorescence changes to fluorescence changes under voltage clamp in single-dye loaded cells in the whole cell patch configuration. Fluorescence measurements were recorded in response to membrane potentials from -80 to +40 mV. The slopes under the two conditions were highly correlated (-0.0051 V/mV (n=6, R^2=0.99) vs. -0.0060 V/mV (n=11, R^2=0.94) for voltage clamp and ionophore experiments, respectively). The close agreement of the ionophore method of calibration vs. voltage clamp validates permeabilization as a method to determine absolute membrane voltage parameters, such as AP amplitude and resting potential, with high accuracy.

Title: Low cost optical multimodal imaging to study neural circuit function

Authors: C. STEFENS[1], L. VANDE PERRE[2], ***J. JOHNSTON**[1];
[1]Univ. of Leeds, Leeds, United Kingdom; [2]Univ. Libre De Bruxelles, Brussels, Belgium

Abstract: We have developed a low-cost solution for wide-field brain imaging that enables simultaneous measurement of activity from different components of a neural circuit along with other experimental or physiological signals. We obtain a field of view of >4.5 mm using optics from a consumer SLR camera. Using open source LED drivers (optostim) we illuminate alternate frames with different wavelengths to achieve imaging rates of 50 frames per second (fps) for 2 channels or 100/n-channels fps for any combination of channels. We demonstrate its utility by combining optical imaging of intrinsic signals with fluorescent imaging of interneurons expressing GCaMP6 driven by the VGAT promoter to image odour evoked activity in the olfactory bulb afferent inputs and periglomerular neurons.

The image shows structural details of the olfactory bulb (green illumination) alongside the response images for afferent input (IOS, far red illumination) and interneuron activity (GCaMP6, blue illumination). The time course of these optical changes are plotted on the right for 3 glomeruli along side the simultaneously recorded respiration signal. We show that in vivo pharmacological manipulations combined with simultaneous measurement of afferent input and interneuron activity provides a powerful means to study feedback circuits within the olfactory bulb.

[1]Martineau & Associates, Inc, Menlo Park, CA; [2]Psychiatry and Behavioral Sci., Stanford University, Beckman Center, Room 201, Palo Alto, CA

Abstract: We present Remanent Imaging (RI): a novel imaging paradigm for next-generation behavioral assays. RI sets the exposure time as the inverse of the frame rate and, when combined with darkfield illumination, allows data-efficient capture and analysis. Our analytics simultaneously reveal individual and population measures from short timescales to sleep/wake daily cycles and potentially to entire organismal lifetimes. Here we present new data from the recording of multiple fish species that demonstrate how RI can be leveraged to identify species-specific locomotion for the automated classification of aquatic research animal species. We will also explore how RI can be combined with computer vision/machine learning techniques to augment performance of this classification.

Title: Unsupervised mouse behavior analysis with self-organizing maps

Authors: *J. TURK[1], M. R. WARREN[1,3], J. P. NEUNUEBEL[2];
[2]Psychological and Brain Sci., [1]Univ. of Delaware, Newark, DE; [3]Emory Univ., Atlanta, GA

Abstract: A major objective of neuroscience is understanding how brain activity gives rise to complex behavior. Animal models are instrumental for investigating this relationship, as we can manipulate and quantify their behavior in controlled settings. Previously, studying behavior involved laborious manual annotation, and was subject to user bias. Newer supervised machine learning techniques have been instrumental, but still rely on human input for training. Therefore, unsupervised machine learning approaches are needed. To address this issue, we applied a computational model to recordings of freely interacting mice (B6.CAST-Cdh23Ahl+/Kjn) in mixed-sex groups (n = 11, 2 males and 2 females per group). To improve training times, we selected an hour-long period for training, after validating that this block contained a representative sampling of behaviors. A supervised approach for automated behavior annotation, JAABA (Kabra et al., 2013), allowed us to first extract discrete instances of social and non-social behaviors. For each frame of video, JAABA calculates a suite of features for each animal, including information about position and movement. We then calculated additional features to capture characteristics of group interactions. With these features and a subset of those from JAABA, we applied a Self-Organizing Map (SOM) (Kohonen, 2001), creating a two-

dimensional representation of the data. To visualize potential clustering, we projected discrete instances of the behaviors extracted by JAABA onto the trained SOM network. Specifically, we separated subsets of our data containing positively identified examples of 12 types of behaviors (e.g., female approaching either male or female, female fleeing male, female investigating either male or female, males fighting, male fleeing male, male approaching either male or female, male chasing female, male chasing male, male investigating either male or female, male mounting female, and walking) and applied hierarchical agglomerative clustering to their projections. We evaluated the clustering using silhouette scores. Scores closer to 1 indicate high-density, well-separated clusters, while scores closer to 0 indicate greater overlap between clusters. When using 12 clusters (one per behavior classified by JAABA), the mean silhouette score was 0.36. However, after tuning the clustering parameters, we found that removing the constraint of using 12 clusters allowed the silhouette score to improve. Our approach may lead to new techniques for unsupervised behavior annotation, thus leading to a potentially more robust quantification of social behavior.

Abstract: Multifunctionality and adaptability are critical for animals to successfully interact with the environment. How do the brain and the body coordinate such multifunctional behaviors? To address this question in the marine mollusk *Aplysia californica*, we are modeling multifunctional feeding behavior, which adapts in response to external sensory cues. Our group previously created a hybrid Boolean/continuous neuromechanical model that could qualitatively reproduce multifunctional *Aplysia* feeding behavior [1]. This previous model was

computationally efficient but lacked many physiological details of the individual neurons and synapses. To assess the effect of neuron dynamics on the simulated behavior, we have translated our Boolean network model into a Synthetic Nervous System (SNS). An SNS is a computational neuroscience model that contains components whose parameters can be set based on actual measurement from neurons.

The SNS network is composed of 3 command-like neurons, 9 interneurons, and 3 motor neurons, similar to the Boolean model [1], but also incorporated intrinsic properties based on a more detailed conductance-based model that was previously published [2]. When simulated without sensory feedback, the model can generate distinct motor patterns somewhat similar to those previously reported in isolated *Aplysia* buccal ganglion [2]. By incorporating feedback from a biomechanical model, the complete simulation with the SNS control can qualitatively reproduce biting (attempts to grasp the food), swallowing (moving the grasped food into the esophagus), and rejection (pushing inedible material out of the buccal mass). Additionally, the SNS can capture post inhibitory rebound and bistability dynamics similar to those observed in the *Aplysia* feeding circuit [2].

The SNS model of *Aplysia* feeding behavior balances biological detail and computational efficiency. The SNS model has a 10-fold simulation time reduction compared with the more complex spiking models of the same circuitry [2]. In the future, we will expand our SNS model to include additional identified neurons and compare model results with animal data. In addition, we are developing optimization and machine learning techniques to tune unknown model parameters. We will also assess the ability of this model to predict animal behaviors and as a robotic controller.

Title: Computational modeling of electrical stimulation of peripheral nerves: A new adaptive meshing technique reduces complexity of realistic large-scale models built from CNN segmentation

Authors: *J. DU[1], A. MORALES[2], J.-M. BOUTEILLER[2], G. LAZZI[2];
[1]USC, San Gabriel, CA; [2]USC, Los Angeles, CA

Abstract: Among different kinds of electrical stimulation to nerves, electrical stimulation of peripheral nerves has long been used and proven effective in many applications. Although numerous modeling studies have emerged in past years to help guide the design in neural stimulation devices and provide safety criteria, most of the studies use either simplified nerve model with homogeneous fascicles or heterogeneous fascicles populated by axons with artificial radii and locations. No peripheral nerve model has yet been capable of capturing all the morphological and structural details of a complex nerve structure.
With the help of high-resolution imaging, realistic computational modeling, machine learning methods and adaptive meshing technique, we developed a multiscale computational model of the sciatic nerve capable of capturing the model's computational complexity within a reasonable range. Utilization of such model aims to help the development of more effective stimulating devices but also more accurate safety criteria that would ensure that stimulation does not induce nerve injury. Model construction involves first performing image segmentation of high-resolution nerve cross-sectional images using a convolutional neural network method and then building realistic peripheral nerve models from the segmentation results. Then in order to keep the 3D heterogeneous nerve model size within a reasonable range, in addition to the multiscale meshing previously developed by our group which can selectively maintain high resolutions at material boundaries and merge inside, we propose another adaptive meshing technique. With our proposed adaptive meshing, a high level of details and fine resolution is maintained near the nerve periphery, in locations proximal to the contact electrode, and the voxel size is increased further away from nerve periphery where fine resolution is unnecessary. Using this methodology, the number of nodes and edges are decreased resulting in decreased computational complexity and reduced simulation runtimes - while maintaining reasonable accuracy.
Results to be presented include the realistic peripheral nerve model construction results, new adaptive meshing technique and its results validation.

Title: Automatic segmentation of corticospinal tract track in patients with brain pathology

Authors: Y. H. MOSHE[1], M. ARTZI[2], *M. TEICHER[1];
[1]Gonda Brain Res. Ctr., Ramat-Gan, Israel; [2]The Sagol Brain Inst., Tel-Aviv, Israel

Abstract: Preoperative white matter (WM) fibers visualization and quantitative assessment can assist in the selection of surgical approach, and setting maximum boundaries for the extent of lesion resection while preserving function. Diffusion tensor imaging (DTI) can be used for WM fibers visualization and quantitative assessment. Currently, reconstruction of white matter tract is heavily rely on manual user intervention and requires prior anatomical knowledge, predefined thresholds Etc. The main limitations of DTI tractography methods, which depend on user intervention, are that they are time consuming, and are heavily prone to Inter and intra rater reliability errors. Recently, TractSeg was proposed as a novel, fully automatic approach for direct WM tract segmentation. TractSeg is based on fully convolutional neural network (FCNN) that directly segments WM tracts in fields of fiber orientation distribution function (fODF) peaks. Although showing promising results for the task of automatic fiber tractography, the implementation of TractSeg for the clinical task as of pre-operative fibers visualization in patients with brain lesion is not straight forward. TractSeg predictive model was trained on healthy subjects, and to relative homogeneous dataset in terms of study population and acquisition parameters.This does not represent the clinical scenario, where there are substantial brain morphological changes due to cerebral pathology, as well as high heterogeneity in terms of data acquisition parameters and data and quality.The aim of this study was to implement and optimize TractSeg tool on extremely large cohort of 675 DTI scans, focusing on the corticospinal tract (CST) segmentation, while tackling with uncertainty in the manually CST labels used for model training. Automatic tool computer aided diagnosis (CAD) tool for identification of the lesion area (target area for resection), mapping WM tracts and identifying the fibers in risk (area for preservation) may promote the approach of personalized medicine in patient's candidate for brain surgery

Title: Benchmarking and scaling of an accurate method for fitting multicompartment models to data

Authors: *A. LADD[1], K. E. BOUCHARD[2], J. BALEWSKI[3], R. BEN-SHALOM[4];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Univ. of California Berkeley, Lawrence Berkeley

Abstract: Effective algorithms for modeling the biophysical properties of a neuron can lead to an overall improved understanding of how ion channel function and dysfunction affects neuronal activity. A challenge in creating these models is determining realistic channel conductances for a wide spectrum of possible neuronal morphological constraints. Here we present an efficient algorithm for the simulation and evaluation of neuronal models and benchmark this algorithm's scaling performance on high performance computing systems.
A common algorithmic approach in generating neuron models are genetic algorithms. The procedure in which the genetic algorithm constructs realistic neuronal models can be broken down into three phases that repeat until a stopping criteria: (1) initialization of a new generation of parameters for the model, (2) simulation of the models with those parameters, and (3) evaluation of those models. The goal of our work was to minimize the amount of time it takes to initialize, simulate, and evaluate one generation. To accomplish this goal, we have developed a genetic algorithm that uses high performance computing (HPC) nodes to maximize the computational efficiency and minimize the run time of the algorithm. To evaluate the benefits of our redesigned genetic algorithm we determined critical aspects of what defines an efficient simulation/evaluation based algorithm for constructing neuronal models. The results show that both simulation of neuronal models and evaluation of resulting voltage traces are computationally costly and that both tasks can potentially act as bottlenecks. We demonstrate how to balance the use of computational resources with simulation problem size. Furthermore, we show that our GPU/CPU based design enables simulating multiple neuronal responses to multiple stimuli with more efficient resource utilization with nominal cost for run time. This analysis demonstrates an opportunity for researchers to advantage using more experimental stimuli in simulation-based neuronal modeling, enabling the development of richer biophysical neuronal models. The analysis also shows how the endeavor of neuronal modeling can benefit from the development of well-designed and efficient software for simulating and evaluating electrophysiological spike traces.
In conclusion, this analysis shows a methodology for benchmarking the performance of simulation based neuronal modeling and provides future directions and considerations for improving algorithmic efficiency and scalability in simulation based neuroscience.

Title: Phase-phase coupling network analysis performed on sEEG recordings

Authors: *M. PARRA[1], A. TEKRIWAL[3], D. R. KRAMER[2], J. A. THOMPSON[4]; [2]Neurosurg., [1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [3]Dept. of Physiol. and Biophysics; Dept. of Neurosurg., [4]Neurosurg., Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Epilepsy is a neurological condition characterized by recurrent seizures that may induce a spectrum of semiologies, caused by excessive, synchronous hyperexcitability in neural activity. Approximately 1/3 of people with epilepsy fail to respond to first line medications and may be diagnosed as treatment refractory. Medical management of treatment refractory epilepsy (TRE) often requires surgical intervention. Recent advances in surgery include novel neuromodulatory interventions for TRE which are predicated on a pathophysiological framework that considers epilepsy as a product of network dysfunction. In this study, we propose to use a novel method, phase-phase coupling analysis, for assessing the network properties of seizure generating brain wide circuits as they shift over time and in response to significant events such as seizures. We introduce a novel exploratory method to analyze phase-phase coupling statistics (PPCS) over a long period of time, using the Hilbert transform, that can be used to generate directed graphs that show the flow of information between areas. We define nodes in this process as each sEEG electrode contact and use a thresholded version of statistically significant PPCS to generate the connections in our network. This process is repeated over discrete timesteps, of 30 second lengths. The result of this analysis is a time varying graph that shows how connections are established and broken over time; revealing whole brain LFP mechanics (<200 Hz). After generating these graphs, we then analyze time periods corresponding to significant events using graph theoretic methods. We analyze the small worldness and centrality measures of the networks generated as a measure to determine deviation from baseline brain activity. Through tracking these larger time-scale network changes, events such as response to medication or shifts in seizure frequency may be able to be monitored. In this study, we propose to use this method to monitor and analyze whole brain activity taken from human epilepsy patients undergoing invasive monitoring for seizure localization, and analyze several days worth of continuous data. Preliminary analysis reveals strong intraregion beta:beta coupling (13-30 Hz), followed by a decrease in this beta:beta coupling in the left orbitofrontal region, over a three hour period. This pattern occurs simultaneously with a gradual increase in high gamma:gamma (>100 Hz) coupling strength in the latter half of this three hour period.

Title: Amortized Bayesian inference of SEEG recordings

Authors: *M. HASHEMI, A. VATTIKONDA1, V. SIP, J. JHA, M. GUYE, F. BARTOLOMEI, M. WOODMAN, V. JIRSA;
Aix-Marseille Univ. Faculté de Médecine de la Timone, Marseille, France

Abstract: Adjusting the stimulation parameters is a key challenge to infer pathological brain networksfrom a large amount of data. Although an efficient Bayesian inversion requires painstakingparameter tuning, the novel methods in deep learning (DL) can efficiently provide theposterior distribution and the relation between model parameters for different observations ofa patient without having to re-run inference, the so-called amortized inference. In this work,we constructed an efficient and accurate method to perform amortized inference for a whole-brain model of epilepsy spread in the context of estimating the brain regional epileptogenicityfrom SEEG recordings. The aim of employing simulation-based-inference (SBI) methodtailored to Bayesian rule, is to perform flexible and efficient inference for complex modelswhen standard methodologies cannot be applied, due to analytic or computational difficulties.The core of the methodology only requires forward-simulations from the computer model,rather than model-specific analytic calculation or exact evaluation of likelihood functionusing MCMC algorithms. Of specific interest is to produce inference for state-space modelsgovern by coupled nonlinear differential equations. One of the goals is to automatically returnthe required (low-dimensional) summary statistics of the observation via ad-hoc DLalgorithms based on a large number of forward-simulations. We demonstrate the efficiencyand accuracy of the training DL such as normalizing flows to automatically infer thedistribution of unknown parameters (the posteriors) of coupled Epileptor model at the whole-brain level given only observed SEEG and prior information. Our results indicated 100%accuracy for the in-silico SEEG recording as generated by virtual brain modeling ofindividual patients. We also investigate the performance of the proposed method againstretrospective data (N=50). The amortized Bayesian framework used in this work proposes anappropriate patient-specific strategy for estimating the epileptogenicity of the brain regions toimprove outcomes after epilepsy surgery.

Title: An eLearning Approach to USV Hand Scorer Training with Acoustilytix: A Web-Based Automated USV Scoring Platform

Authors: *C. DUVAUCHELLE[1], C. B. ASHLEY[2], C. CERVANTES[3], E. C. MACASLAN[2], N. MITTAL[4], S. M. FLEMING[5], J. BAILEY[3], M. D. NIEVERA[3], S. I. SOULEIMANOVA[3], B. NYAOGA[3], L. LICHTENFELD[3], W. MADDOX[6];

Abstract: Ultrasonic vocalizations (USVs) are known to reflect neurotransmitter activity in the ascending limb of the mesolimbic dopaminergic and cholinergic neurotransmitter systems and serve as noninvasive, real-time biomarkers of dopaminergic and cholinergic neurotransmission. In addition to reflecting emotional processing in the limbic system, recent studies have shown USV utility in differentiating between sex and rat strain, transgenerational effects of substance exposure and prediction of future alcohol consumption. Although a valuable experimental tool, collecting and processing USV data is time-intensive and costly, creating a significant bottleneck by limiting researchers' ability to employ fully effective experimental designs, and serves as a barrier to entry for other researchers. We are currently developing Acoustilytix, a web-based automated USV detection and scoring algorithm that is environment- and animal-agnostic. Building upon the fact that some level of hand scoring competency is needed in any USV lab, we describe a new feature that leverages learning science principles to optimize hand scoring training. In brief, trainees are presented, one by one, with a large number of calls (e.g., 1000) which they may examine visually with a spectrogram or auditorily at a reduced rate. For each call, the trainee selects a call category and is given immediate corrective feedback (based on the expert scorer's classification). If in error, the trainee is allowed to make another classification judgement. This process continues until the trainee provides the correct classification for each call. To test the new feature, we asked five individuals who had been give traditional hand scoring training and had been hand scoring USVs for months (6000-31,000 calls classified by each hand scorer) to score a single test file with 1000 calls that had been hand scored by an

expert. We used a kappa statistic to compare each hand scorer with the expert hand scorer and found moderate inter-rater reliability ranging from .30 - .55 with a mean of .42. Next, we asked two individuals with no prior USV hand scoring experience to complete the same training and test and found kappa values of .42 and .47 which are comparable to those of the 5 experienced scorers. Next, we asked the 5 experienced scorers to complete Acoustilytix training and a subsequent test, and found kappa values ranged from .30 - .75 (average kappa = .60). These findings suggest that hand scoring training in which the learner is given immediate call-by-call feedback, and where the teaching signal is based on the call classification from an expert hand scorer leads to more accurate and consistent hand scoring.

Title: A machine learning approach to analysis of skilled reaching behavior in mice identifies behavioral compensation after spinal cord injury

Authors: *N. O'NEILL[1], K. MAH[1], M. MURRY[2], J. L. BIXBY[3], V. LEMMON[4]; [2]Neurosurgery/Miami Project to Cure Paralysis, [1]Univ. of Miami Miller Sch. of Med., Miami, FL; [3]Miami Proj to Cure Paralysis, Univ. Miami, Miller Sch. Med., Miami, FL; [4]Neurolog. Surgery, Univ. of Miami, Miami, FL

Abstract: Injuries to the cervical spinal cord represent around 60% of human spinal cord injuries (SCIs). For these patients, any recovery of arm or hand function is a major priority. Similarities between human and rodent “reach-to-eat movements” mean that analysis of mouse forelimb reaching behavior has potential clinical relevance. While recovery in the single pellet reaching assay is normally measured by successful pellet retrieval, this outcome measure fails to account for compensatory movements that may be used in the task. Our goal was to establish a skilled forelimb reaching task that can be used to distinguish restoration of function from compensation after SCI. We used a machine learning approach to automate the quantitative assessment of videos. Computer vision (DeepLabCut) was used to track individual paw features, allowing for a more refined assessment of reaching behavior after SCI. Kinematic analysis of movements pre- and post-injury illuminated deficits in specific features of the reaching motor pattern (pronation)

that persisted independent of the ability to successfully retrieve pellets. A C5 cervical SCI causes specific deficits in pronation and grasping. To continue retrieving pellets after a loss in those movements, animals can compensate by approaching the pellet with a shallower angle and sweeping across rather than turning the paw over. The change in distance between two points on the paw in the X plane provides a quantitative measure of paw angle (and thus pronation). By plotting this relative distance over the course of an attempt, we can measure the extent of pronation that animals exhibit during a reach. We compared animals from opposite ends of the spectrum with respect to post-injury success at 4 WPI (>35%, or pre-injury levels, vs. complete loss of skill, or <5%). Comparing pronation capabilities between these groups suggests that, despite large differences in retrieval success, the two sets of animals displayed nearly identical deficits in pronation capabilities compared to pre-injury baseline. Our results suggest that, even for an assay requiring fine motor skills, measurements of recovery on a binary (success/fail) scale largely measure an animal's ability to compensate rather than a restoration of normal function in the injured tracts and pathways.

Title: N2A: a language and software tool for large-scale modeling

Authors: *F. ROTHGANGER, *F. ROTHGANGER;
Sandia Natl. Labs., Albuquerque, NM

Abstract: Sharing models and data is a prerequisite for progress toward a full understanding of brain function. The Neuroscience Information Framework (NIF) does this for many forms of descriptive data. Interchange languages such as NeuroML/LEMS provide a simulator-agnostic description of models, and repositories such as NeuroML-DB and ModelDB make them searchable and accessible.
However, exchanging models and data is not sufficient. It is also necessary to assemble those shared models into larger functional units, ultimately reaching the level of an entire nervous system. To create abstract descriptions of function, the modeling system must be capable of crossing all the scale levels, and component models should be expressed in a form suitable for automated analysis.
N2A is an effort toward these challenging goals. It treats models as data rather than code. This declarative approach describes a model as a set of attributes and equations, without specifying a

step-by-step procedure for simulation. It emphasizes the relationships between values within a model and the relationships between models in a larger functional unit.
The declarative approach allows one model to directly extend and modify another, simply by referencing the parent model and declaring new values for specific attributes and equations. A model may also incorporate other models as components, allowing the assembly of arbitrarily deep systems. We will demonstrate an open-source implementation of N2A.

Title: Induced electric fields in the brain exhibit orientation-specific effects on neocortical neurons in awake non-human primates

Authors: *H. TRAN[1], I. ALEKSEICHUK[1], S. SHIRINPOUR[1], B. VAIL[2], D. MAISSON[2], B. VOLOH[2], J. ZIMMERMANN[2], A. OPITZ[1];
[1]Biomed. Engin. Dept., [2]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Transcranial alternating current stimulation (tACS) is a non-invasive method to modulate ongoing neural activity in the brain. Previous work shows that external oscillations entrain neural firing activity in a phase- and dose- dependent manner. Thus, tACS holds promise as a new treatment option for neuropsychiatric disorders characterized by pathological brain oscillations. However, neural responses to oscillating electric fields exhibit large variability. We hypothesize that the neural responses to the external field largely depend on the neocortical column orientations relative to the induced electric fields.
Here, we first perform a computational study to investigate the relationship between 10 Hz tACS and neural entrainment in morphologically realistic neocortical neurons exhibiting ongoing spiking activity (set of 25 cells – 5 cells for each cortical layer). The orientation of the electric field is in the y-axis orientation corresponding to the somato-dendritic axis of pyramidal cells and intensities were between 0.1 mV/mm and 3 mV/mm. Neural entrainment was quantified by computing the phase-locking value (PLV) of spikes times across neurons and field strengths. We found that 1) pyramidal neurons are more entrained than interneurons resulting in a higher phase-locked spiking to the applied oscillation (pyramidal cells n=15, 0.0788 +/- 0.0821 and interneurons n=10, 0.0495 +/-0.0414 at 1mV/mm) and 2) pyramidal cells are more preferentially entrained when parallel to the electric field direction.

Second, we perform in-vivo recordings of single-unit activity in awake non-human primates while applying tACS in 3 orientations (Anterior-Posterior, Left-Right and diagonal orientations) and 2 intensities for each of them (0.4mA and 0.8mA). We record neuronal activities using a 128-channel amplifier at 30 kHz sampling rate with glass coated electrodes. Preliminary findings in one macaque (8 y.o., male) show that neurons (N=159) exhibit significant entrainment to tACS with strong orientation preference (Rayleigh test $p \leq 0.01$).
Overall, these findings advance our mechanistic understanding of tACS effects and highlight the importance of neuronal architecture on the susceptibility to the external electric fields. Highlighting neural directional sensitivity represents a milestone for understanding brain networks interactions.

Abstract: Transcranial Magnetic Stimulation (TMS) is a non-invasive neuromodulation technique commonly utilized in brain research and clinical applications in neuropsychiatric disorders. Despite its widespread use, the underlying neural mechanisms of TMS and how it modulates brain activity is still poorly understood. It has been debated that some of the TMS evoked responses could be the result of peripheral effects rather than direct neural activation. To this end, we recorded brain activity from an anesthetized monkey with implanted electrodes projecting from visual area (V2) to frontal eye field (FEF), secondary auditory cortical (AUD) and temporal (TE) regions in the left hemisphere. The exact locations of electrode contacts were determined by co-registering post- and pre-surgery MR images. Biphasic single-pulse TMS was

delivered over the left hemisphere to 4 different locations. A control stimulation location over the right hemisphere was used to demonstrate spatial specificity. A sham protocol was executed by tilting the coil away from the head to mimic the auditory response. Stimulation intensities were set to 10, 25, 50, 70 and 90% of the maximum stimulator output. We preprocessed the neural data by removing channels contaminated with large noise through visual inspection, removing the TMS and the muscle artifacts (calculated from external EMG data), interpolating, down-sampling to 1 kHz and bandpass filtering at 1-50 Hz. For analysis, we performed time-locked averaging across trials. Cluster based ANOVA test indicated time windows with significantly different amplitudes from 25 - 100 ms ($p < 0.006$) for anterolateral stimulation location and from 25 - 136 ms ($p < 0.001$) for lateral stimulation location. Post-hoc multiple comparisons of the N50 peak of TMS evoked potentials revealed intensity-dependent clusters. Linear regression of N50 with intensity showed a maximum correlation of 0.52 ($p = 5.5\times10^{-12}$) for lateral coil location and 0.37 ($p = 4.0\times10^{-27}$) for anterolateral coil location. The activation region, quantified by the normalized N50 amplitudes per electrode showed movement with the coil location. Furthermore, contacts of AUD electrode in the auditory belt revealed consistent low frequency oscillations in both TMS and sham conditions, which is attributed to the auditory response to the 'click' sound. Our study provides preliminary evidence that the TMS effects are dose dependent, localized and can be separated from peripheral stimulation effects.

Abstract: Neural oscillations reflect and organize brain functions. Transcranial alternating current stimulation (TACS) can non-invasively modulate brain oscillations by entraining neural ensembles to the phase and frequency of the applied current. Thus, TACS presents a versatile tool for basic research and therapeutic applications for "oscillopathies." However, the mechanisms of TACS and their effect on cognition are still incompletely understood. Research in surgical epilepsy patients, who undergo invasive brain recordings, presents a unique opportunity to explore a causal mechanistic link between the modulation of brain oscillations, changes in neurophysiology, and cognitive functioning. Here, we aimed to investigate the causal role of beta oscillations in supporting human cognitive functions. Patients who met clinical guidelines and provided informed consent were implanted with intracranial subdural grids and depth electrodes (100-200 contacts) according to medical needs. The study is conducted in accordance with the Declaration of Helsinki and IRB regulations (University of Minnesota, MN). Intracranial recordings were acquired at a high sampling rate (16 kHz) and dynamic range (24 bits). Participants performed a classical 2-back working memory task while receiving either sham stimulation (passive control), beta TACS at 23 Hz (main condition) or theta TACS at 4 Hz (active control) using bilateral temporal montage. Altogether, five participants performed 45 experimental sessions with different conditions, totaling over 5000 task trials. Generalized linear mixed effect model shows significant effect of stimulation on memory performance: $F(2,5178) = 8.9$, $p = 0.0001$. Post-hoc t-tests reveal significant improvement ($p < 0.05$) following beta TACS in comparison to sham or theta TACS, while theta TACS induced no changes. Bayesian hierarchical diffusion drift modeling of cognitive performance demonstrates an improvement in the quality of the memory process (drift rate *v*, Bayes factor = 3.8). In contrast, there are no changes in the speed-accuracy tradeoff (threshold *a*). Beta TACS improves the memory process in all studied patients with an effect size of Hedges' $g = 0.78$. In invasive brain recordings, we observe a significant and frequency-specific increase in beta oscillations following beta TACS. This significantly correlates with improved working memory performance ($p < 0.05$), providing a mechanistic link from stimulation to behavior. The present findings demonstrate a causal role of beta oscillations in working memory performance and the feasibility of supporting cognitive functions in humans via modulation of beta activity.

Title: Phase-specific modulation of cortical excitability using closed-loop TMS-EEG

Authors: *M. WISCHNEWSKI, Z. J. HAIGH, S. SHIRINPOUR, I. ALEKSEICHUK, A. OPITZ;
Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Transcranial magnetic stimulation (TMS) is able to activate neurons in the motor cortex non-invasively. As such, TMS can be a useful method to promote recovery of motor disorders, for example after stroke. However, due to neurophysiological variability TMS effects differ between and within participants. On source of variability is the phase of motor cortex-related neural oscillations. In this within-subjects, double-blind study, we investigate the role of brain oscillation phase of the motor cortex Mu (8-13 Hz) and Beta (14-30 Hz) rhythm. For this we used a novel closed-loop TMS-electroencephalogram (EEG) system. Phase-specific TMS with our closed-loop system is achieved in two steps. First, during the training phase, specific individual Mu and Beta frequency is determined in a three-minute resting-state EEG. In the second step phase-specific TMS-EEG is applied concurrently. For this, EEG oscillation are read out and the phase is analyzed in real-time. The phase information is forwarded to the TMS and phase-specific pulses are applied. Cortical excitability is tested by measuring the motor-evoked potential (MEP) of the first dorsal interossei (FDI) muscle, at different phases of the Mu and Beta oscillation. For analysis MEPs are normalized to the grand average. Four phases are being explored: the peak, trough, rising-phase, and falling phase. We hypothesized phase-dependent MEP amplitude modulations for both Mu and Beta rhythms. Preliminary results (n = 4) showed that normalized MEPs were largest at the Mu rising phase (1.024 ± 0.018 mV) and smallest at the Mu falling phase (0.938 ± 0.030 mV). In contrast, analyzing MEPs during Beta oscillations revealed that MEPs were largest at the falling phase (1.032 ± 0.016 mV), and smallest at the trough (0.964 ± 0.015 mV). From these data the tentative conclusion can be reached that MEP amplitude modulation is both phase- and frequency-specific, with opposing results for the Mu and Beta rhythm. Our results imply modulation of motor cortex activity may be optimal when phase is considered. Therefore, our results provide valuable insights for clinical application of TMS in rehabilitation of motor-related disorders, such as stroke.

Title: Transcranial alternating current stimulation induces neural entrainment in neuronal network models

Authors: *Z. ZHAO, S. SHIRINPOUR, H. TRAN, A. OPITZ;
Biomed. Engin., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Transcranial alternating current stimulation (tACS) is a non-invasive brain stimulation technique that can modulate ongoing neural activity in the brain by affecting single-neuron spike timing and causing neural entrainment. Thus, tACS may be a promising treatment for neuropsychiatric disorders as well as a useful tool for studying human cognition. However, how the external oscillating electric fields interact with neuronal spiking activity in a neuronal network is still insufficiently understood. Experiments using invasive or non-invasive methods are crucial to address the fundamental questions about the neural responses to stimulation. In addition, computational modeling helps explain the neuronal dynamics observed from recordings by exploring the model parameters and testing hypotheses. We conduct a computational modeling study to investigate the relationship between the electric field and neural entrainment in the coupled population of neurons. Here, we employ a neuron model that consists of two compartments (soma and apical dendrite), which involves the cable equation as well as multiple ionic currents such as Hodgkin-Huxley kinetics. Therefore, we are able to model the effect of the extracellular field on a neuron in a straightforward way. Furthermore, we spatially arrange and connect excitatory and inhibitory neurons to match the realistic neuron distribution in cortical layers. Then, we explore different parameters in this neuronal network, such as types of synapses and synaptic strength to probe how a single neuron and neuronal population respond to the extracellular electric field. We measure the neural entrainment by computing the phase-locking value (PLV) of spike times across neurons with different intrinsic firing rates and electric field strengths. Preliminary results suggest that the excitatory synaptic connection amplifies the entrainment effect on the post-synaptic neurons while the inhibitory synapse reduces the entrainment effect. Investigating the network dynamics will provide additional insights on how tACS affect neuron spiking patterns on the network level. A better understanding of tACS mechanisms of action allows the design of more effective tACS treatment modalities for neuropsychiatric disorders.

Title: Neuron Modeling for Transcranial Magnetic Stimulation (NeMo-TMS) Toolbox

Authors: *S. SHIRINPOUR[1], N. HANANEIA[2], J. ROSADO[3], H. TRAN[1], C. GALANIS[4], A. VLACHOS[4], P. JEDLICKA[2], G. QUEISSER[3], A. OPITZ[1];
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Justus-Liebig-University, Giessen, Germany; [3]Temple Univ., Philadelphia, PA; [4]Univ. of Freiburg, Freiburg, Germany

Abstract: Transcranial Magnetic Stimulation (TMS) of the dorsolateral prefrontal cortex is currently utilized as a non-invasive neuromodulation tool for the treatment of depression. Nevertheless, the basic mechanisms underlying TMS effects at the neuronal level are largely unknown. Since the recording of single-unit activity *in vivo* during TMS is challenging in animals, and typically not possible for humans, computational modeling is an important tool to investigate the neuronal response to TMS. Here, we develop a new multi-scale pipeline (NeMo-TMS) for modeling TMS effects across spatial scales. On the macro-scale, we generate a realistic head model from MRI that includes multiple tissue types (white matter, grey matter, cerebrospinal fluid, skull, and scalp) and use the SimNIBS software to simulate the electric field induced in the brain for a given TMS coil position and orientation using Finite Element Method (FEM). Afterward, simulated electric fields from the previous step are coupled with morphologically realistic neuronal models. These models are solved by discretizing the neuronal branches into small compartments and by numerically solving the cable equation and channel dynamics in the NEURON environment. These neuron-scale simulations allow investigating membrane voltage (depolarization/hyperpolarization), action potential initiation and propagation, field intensity, and orientation necessary for modulating neuron response, etc. Then, we incorporate the membrane voltage data to simulate the calcium concentration induced by voltage-gated calcium-channels at the subcellular scale by solving the calcium dynamics equations. This step is important for understanding neural plasticity due to rTMS protocols. In this study, we also provide results to demonstrate how different neuron types behave distinctly for the same external electric field and therefore make a case for the importance of such multi-scale realistic modeling of neurons. Our pipeline can facilitate research as a tool for hypothesis testing and prediction technique for experiments. Additionally, modeling has the potential to be used for calculating the dose needed for efficient treatment in clinical applications.

Univ. of Denmark, Kgs Lyngby, Denmark

Abstract: Non-invasive brain stimulation (NIBS) is currently being used as a treatment method for psychiatric disorders such as major depression, obsessive-compulsive disorder, and substance use disorder. NIBS is also increasingly utilized as a research tool for causal manipulations of brain activity. Two of its main methods, Transcranial Magnetic Stimulation (TMS) and Transcranial Electric Stimulation (TES) create electric fields in the brain to modulate neural activity. Precise knowledge of these electric fields is crucial for experimental design and choice of stimulation parameters for precise dosing. Computational modeling has been used extensively to predict the induced electric fields. Due to the growing clinical and research applications of NIBS, there is increasing demand in the accessibility of such tools. SimNIBS is one of the leading platforms for NIBS electric field modeling (simnibs.org). In this project, we are increasing the functionality and accessibility of SimNIBS. This includes: 1) Developing automatic non-human primate head segmentation. This will open the SimNIBS tool more researchers interested in translational research. 2) Extending the visualization and graphical interfaces of SimNIBS. This will make the software more user-friendly and bring additional features such as intuitive selection of regions of interest. 3) Improving human MRI segmentation to increase accuracy, speed, and robustness of head model generation. 4) Utilizing software containers to provide simple cross-platform and high-performance access to SimNIBS. 5) Adding functionality to integrate neuronavigation systems with SimNIBS to assist in accurate targeting of the brain and to accurately model test conditions. 6) Generating automated recommendations for optimal coil positions and electrode locations. This will help users plan tailored experimental and clinical setups.Thus far, progress on these updates have resulted in several publications including (Wang et al., NeuroImage, 2021), (Puonti et al., NeuroImage,

2020), and (Saturnino et al., J. Neural Eng., 2021) for items 1), 3), and 6), respectively.Our continued work in these six areas of developments will widen the pool of users such as clinicians, human, and animal researchers to incorporate modeling platforms in their work. Modeling is a crucial part of efforts to understand the NIBS mechanism of action, to translate the experimental findings between animals and humans, and to find the optimal targeting and dosing of brain stimulation. Altogether, these functions will help researchers and clinicians increase non-invasive brain stimulation treatment efficacy.

Title: Effects of repetitive transcranial magnetic stimulation on somatosensory evoked potentials via a miniaturized coil in rats

Authors: *W. JIANG, R. ISENHART, Z. LU, H. XU, J. PACE, D. LEE, C. LIU, D. SONG; USC, Los Angeles, CA

Abstract: While repetitive transcranial magnetic stimulation (rTMS) is a widely-used non-invasive technique for neuromodulation, its underlying neurobiological mechanisms remain unclear. Rodent models are useful tools for elucidating plasticity-like mechanisms of rTMS since they allow simultaneous invasive recording of the neural circuits to monitor the electrophysiological effects of rTMS. However, the lack of small coils suitable for small animal stimulation hinders the rTMS studies in rodent models; Most rodent rTMS studies have used commercially available coils designed for human brain stimulation, which lack stimulation focality. To address this, we have designed, fabricated, and tested a miniaturized TMS coil for rodent experiments. The TMS coil (5 mm outer diameter) was constructed with a C-shaped iron powder core. Insulated copper wires were wound (30 turns) around the core and evenly distributed over its circumference. The magnetic field generated by the TMS coil was measured with a search-coil magnetometer. A maximum magnetic field strength of 473 mT was achieved. The induced electric field was measured with a dipole probe in saline. Maximum electric field (5.2 V/m) was focally created at the center of the coil. To evaluate the effect of rTMS on cortical activities, Platinum-Iridium microelectrodes were implanted in the somatosensory cortices of anesthetized rats (n = 3) to record somatosensory evoked potentials (SSEPs). SSEPs were evoked by electrically stimulating the median nerve of the contralateral forelimb using

subdermal needle electrodes. High frequency (10 Hz) rTMSs were delivered for three minutes above the recording site (1800 pulses). SSEPs were monitored before and after rTMS. Results show that 10 Hz rTMS suppresses the SSEP amplitudes by 33±7% compared to the baseline. SSEPs in the first 5 minutes following rTMS show a slightly decreased latency (91±4%). SSEP amplitudes gradually recover to 85±12% of baseline 10 minutes after rTMS, and 84±14% of baseline 15 minutes after rTMS. The mean latency increases to 107±11% of baseline 10 minutes after rTMS, and 95±3% 15 minutes after rTMS. These results indicate that rTMS (3 minutes, 10 Hz) can effectively modulate SSEPs in rats. The miniaturized TMS coil and the stimulation-recording paradigm described here provide a valuable experimental platform for studying the effect of TMS on brain circuits in rodents. It has the potential to assist the development of novel therapeutic strategies for treating various neurological disorders in humans.

Abstract: Repetitive Transcranial Magnetic Stimulation (rTMS), either at classically-used high intensity (in Teslas, T) or sub-excitation low intensity (μT-mT; LI-rTMS), is used to increase neural circuit plasticity and shows promise in treating human neurological dysfunction. However, the processes activated by magnetic fields at the single neuron level remain largely unknown, preventing the optimization of potentially therapeutic rTMS protocols.
We investigated the impact of continuous focal 10-Hz LI-rTMS on neuronal excitability with in vivo intracellular and electrocorticographic (ECoG) recordings from the primary somatosensory cortex in sufentanil-sedated Sprague-Dawley rats of either sex. Neuronal electrical properties were compared before and after 10 minutes LI-rTMS, so that each neuron was its own internal control. All experiments were approved (APAFIS no. 18003-2019051019017280) and were in accord with the European Union directive (2010/603/EU).

In pyramidal cortical neurons (n=16), this LI-rTMS protocol produced: (1) a large hyperpolarization of membrane potential, (2) a near complete abolition of spontaneous firing and (3) a decreased amplitude of ongoing synaptic events. This alteration of spontaneous activity correlated with significant changes in neuronal membrane excitability, notably a decrease in the input resistance and gradual and persistent increase in the current threshold required to fire cortical neurons.
These findings indicate that a short period of continuous 10-Hz LI-rTMS can strongly, and durably, reduce the membrane and synaptic properties of somatosensory cortical neurons. We are currently further investigating the functional outcome of this time-dependent modulation of cortical excitability by analyzing the ECoG patterns and whisker-evoked sensory responses before and after LI-rTMS.

Title: Transcranial pulse stimulation in Alzheimer´s disease: A global power boost on EEG-oscillations?

Authors: *L. WOJTECKI[1], C. A. TRENADO COLIN[2], C. CONT[3], K. M. ZIMMERMANN[4], N. STUTE[4], A. SCHNITZLER[5];
[1]Heinrich-Heine-Universität Düsseldorf, Duesseldorf, Germany; [2]Saarland Univ., Homburg, Germany; [3]Heinrich Heine Univ. Duesseldorf, Duesseldorf, Germany; [4]Hosp. Kempen, Kempen, Germany; [5]Heinrich-Heine-University Düsseldorf, Duesseldorf, Germany

Abstract: Background: Transcranial Pulse Stimulation (TPS) is a new therapy that uses shockwaves for the treatment of Alzheimer´s Disease (AD). In humans, there is first evidence for beneficial clinical effects after a series of six TPS sessions. Magnetic resonance imaging studies suggest up-regulation of memory networks as well as increased cortical thickness after stimulation. Effects on oscillatory electrical brain activity measured with resting state electroencephalography (EEG) have not been reported so far. **Methods:** A consecutive number of four pilot TPS-treated AD-patients was examined. TPS-naïve resting EEGs were recorded before treatment and compared with EEG-recordings directly after first stimulation. All patients received 4Hz TPS of about 6000 pulses of 0.2 mJ/mm2 (navigated bifrontally, biparietally, bitemporally and praecuneus) using the Neurolith System (Storz Medical). Frontal, parietal, central and temporal channel clusters were analyzed with regard to their alpha, theta delta and

gamma power. **Results:** The immediate effect after TPS on grand-average EEG resting state showed an increase of power in all frequency bands and for total power (Figure), although a significant difference between pre- and post-stimulation was not revealed at each specific band across four patients due to power variability. However, the average power increase was reflected by a power change in each individual patient and by consistent changes across EEG-channels. **Discussion / Conclusion:** Although limited due to a high variability (and possibly due to underpower) we find these pilot measurements remarkable as we see consistent oscillatory changes after one single session of TPS across frequency domains, EEG-channels and patients. More measurements should be added including longitudinal recordings over the treatment course of six sessions with correlations of clinical treatment effects.

Title: Investigating a role for Tcf3/12 during development in the ventral telencephalon and oligodendrogenesis

Authors: *M. TALLEY[1,2], D. NARDINI[1], L. EHRMAN[1], R. R. WACLAW[1];
[1]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Class II pro-neural and pro-glial basic helix-loop-helix (bHLH) transcription factors (TFs), such as Olig2 and Ascl1, are known to be required and sufficient for stem cell differentiation into distinct cell types in the central nervous system. bHLH TFs dimerize in order to bind to DNA and promote those cell fates. Class II bHLH TFs preferentially heterodimerize with class I bHLH transcription factors, also known as E-proteins. E-proteins are thought to be widely expressed, however, their unique function in the developing telencephalon remains largely unknown. In this study, we characterize the expression of all three E-proteins throughout forebrain development, including their expression within the oligodendrocyte (OL) lineage in the postnatal brain. In addition, we generated *Tcf3/12* conditional double knockouts (cdKOs) using *Olig2*$^{Cre/+}$ to understand the requirement of *Tcf3* and *Tcf12* in the ventral telencephalon and oligodendrogenesis. Double knockouts show an expansion of progenitor regions in the embryonic ventral telencephalon resulting in abnormal morphology of the medial ganglionic eminence. Also, *Tcf3/12* cKOs exhibit a reduction of oligodendrocyte progenitor cells (OPCs) in mid and late embryonic stages. Interestingly, OPC numbers recover at postnatal stage, but a decrease in mature OLs remains at 1 and 2 months of age. Our preliminary data indicates that cortical interneurons from the Olig2+ progenitor lineage are less affected by the loss of *Tcf3/12* than OLs. Combined, our results suggest that *Tcf3* and *Tcf12* play a key role in ventral progenitors of the embryonic telencephalon and in multiple stages of the oligodendrocyte lineage.

Title: Changes in internodal length during development.

Authors: *A. BEAUDRY-RICHARD[1,2], N. JABASSINI[1], C. CORDANO[1], R. KOTHARY[2], J. R. CHAN[1], A. J. GREEN[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The pattern of myelin plays a crucial role in determining the speed of conduction of electrical signals in the nervous system. The principal determinants of internodal length during

development remain to be elucidated. Consequently, we don't yet understand the dynamic responsiveness of internodes and their capacity to tune their length. This project will characterize primary myelination dynamics and assess how internodal length is tuned over time. The mouse model of stochastically sparse labeled oligodendrocytes PLP-CreER^{T};STARS allows for precise quantification of internodal length. We use this model to study oligodendroglial myelination in the corpus callosum and the optic nerve. Preliminary results from these experiments reveal that each oligodendrocyte has a wide variety of internodal lengths during early development (postnatal day [P]14): internodes (reported as median [min-max]) are 33 μm long [12 to 89 μm] in corpus callosum of mice (N=3). We observed that early in development most internodes measured between 20 and 40 μm, and that the distribution of internodal length is skewed to shorter internodes (Skewness: 1.22). In the optic nerve, internodes measured at P18 were 77 μm long [51 to 144 μm], while at 7 months old (mo) internodes measured 120 μm long [50 to 192 μm]. We noted a shift in the distribution of internodal length between early (P18) and late (7mo) development: most internodes in the optic nerve at P18 measure between 60-80 μm and the general distribution was skewed to shorter internodes (Skewness = 0.74). However, internodes at 7mo mostly measured 100-120 μm and the distribution was Gaussian (Skewness = 0.07). In addition, we utilize the NG2-CreER^{T};Tau^{mgfp} model to characterize newly formed internodes during early, middle, and late development to learn how myelin wraps axons under normal conditions. Further experiments to study the impact of extrinsic cues on internodal length are ongoing. These approaches will shed light on how internodal length patterning is structured for optimal neuronal function. Not only do we establish that myelination during development is a dynamic process, but we also provide a model for internodal length determination.

Title: Ultrastructural analysis and 3D cellular reconstruction of developing astrocytes in the medial nucleus of the trapezoid body from volume electron microscopy

Authors: *E. AMICK, D. HELLER, V. MOSES, M. ATTALLA, L. DE VRIES, E. FRAHM, A. LYNN, A. GABBARD, K. CSEH, G. SPIROU;
Med. Engin., Univ. of South Florida, Tampa, FL

Abstract: Mature astrocytes display myriad morphological features, including blood vessel contacting endfeet, finger-like projections at tripartite synapses, and vellus processes ensheathing neuronal cell bodies, and diverse physiological characteristics. While the relationship between morphological diversity within cell types and functionality has been studied in multiple brain regions, the exact role of this heterogeneity remains elusive. The medial nucleus of the trapezoid body (MNTB) represents an excellent neurodevelopmental model due to the rapid maturation of a highly homogenous neuronal population that is monoinnervated by the largest terminal in the mammalian brain, the calyx of Held (CH). The CH terminal also provides a system for studying astrocytic regulation of synaptogenesis. Here, we utilized a developmental series of serial block-face scanning electron microscopy volumes to visualize astrocytic morphology at an ultrastructural level during CH development. In addition to the characteristic features above, we observed several novel morphological features, including large mitochondrial widths, prevalent stacks of endoplasmic reticulum, and axonal ensheathment. A comparison of all cell types identified these unique features as being exclusive to astrocytes across developmental ages, providing additional morphological characteristics for cell type identification. Along with these ultrastructural observations, we completed the first full astrocyte reconstructions at postnatal day (P)2, P4 and P6 to fully observe and analyze time-dependent morphological variations. Initial comparisons reveal a preservation of characteristic features across developmental ages, although some refinement is observed in the older astrocytes. A notable difference is the increased volume and degree of ramification of the P6 cell relative to younger ages. Endfeet were observed to be formed by all three reconstructed cells. Axonal wrapping was not observed at P2, while the P6 astrocyte formed more wraps than the P4. All three cells were observed to form vellus processes on MNTB neuronal cell bodies, with the P6 astrocyte contacting the largest number of cells. However, the dynamic morphology of astrocytes during CH maturation needs to undergo further analysis and quantification to elucidate their developmental roles. This study highlights the complex morphology of astrocytes and their diverse heterogeneity by identifying novel ultrastructure morphological features. Furthermore, our analysis of 3D cellular structures can be implemented for future cell-type classifications and computational models for astrocytic biophysical properties.

Title: Actin regulation impacting myelination in the central nervous system.

Authors: *K. DAHL[1], W. B. MACKLIN[2];
[1]Univ. of Colorado, Aurora, CO; [2]Dept Cell & Dev Biol., Univ. Colorado Med. Sch., Aurora, CO

Abstract: In the central nervous system (CNS), myelin is a specialized membrane elaborated by oligodendroglia, which facilitates rapid conduction of action potentials. Myelination is a critical element of normal vertebrate neurotransmission and CNS myelin pathophysiologies, such as multiple sclerosis or leukodystrophies, are associated with profound neurological disfunction. Therefore, it is essential to understand the molecular mechanisms that drive myelin formation. During myelination, oligodendrocytes undergo dramatic expansion and modification of cell processes and membranes. These complex morphological transitions are driven by various signaling pathways, including mTOR, which enhance filamentous actin (F-actin) polymerization during early remodeling of membranes committed to myelin sheath formation. However, the extent to which mTOR regulates actin dynamics and the downstream pathways recruited during this process have not been fully determined. Current studies focus on signaling from the rapamycin-insensitive mTOR complex 2 (mTORC2, defined by the subunit RICTOR) through the GTPase Rac1 to regulate actin dynamics and myelination. Rac1 activation requires the interaction of guanine nucleotide exchange factors (GEFs), at least one of which, TIAM1, mediates Rac1 activation via mTORC2 signaling. Branched F-actin, polymerized through Rac1, is necessary for early process extension in cultured oligodendrocytes. Here, we examine how mTORC2 impacts actin dynamics in oligodendrocytes both in vivo and in vitro. Driving loss of mTORC2 in oligodendrocyte progenitor cells (OPCs) using PDGFRa-Cre;RICTOR$^{fl/fl}$ mice altered myelination and reduced the complexity of premyelinating oligodendrocytes during early development. In vitro, pharmacological inhibition of mTOR decreased both F-actin and Rac1 activity. Adenovirus-mediated genetic ablation of mTORC2 impeded progression of OPC differentiation past the early A2B5 expressing stage, while Sholl analysis indicated reduced membrane complexity in these cells. In addition, OPCs overexpressing shRNA to knockdown TIAM1 reduced F-actin and process extension. These data demonstrate that Rac1-mediated mTORC2 signaling is essential for regulating actin dynamics during oligodendrocyte differentiation.

Title: Cortical layer distribution of SOX9+ astrocytes from V-SVZ neural/stem progenitor cells depends on time of birth

Authors: *I. KORTEBI[1,2], T. SHARMA[2], D. LOZANO-CASASBUENAS[2], A. OLFAT[2], E. DANIELE[1,2], M. FAIZ[1,2];
[1]Inst. of Med. Sci., [2]Div. of Anatomy, Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada

Abstract: Cortical astrocytes are highly heterogeneous cells with distinct gene expression profiles, phenotypes, and functions. They are born from neural stem/progenitor cells (NSPCs) during embryonic development starting at E15 and undergo a period of rapid expansion in the first postnatal week (P4-P7). Whether time of astrocyte birth from NSPCs determines their position within the murine cerebral cortex is not known. To determine whether time of birth influences astrocyte distribution in the upper (UL) vs. lower (LL) cortical layers, we permanently labelled ventricular-subventricular zone (V-SVZ) NSPCs and their progeny via *in utero* electroporation with PiggyBac (PB)-CAG-EGFP at E13, E15, 16, and 17 and sacrificed animals at P21. Immunohistochemistry (IHC) for the astrocyte lineage marker SOX9 was performed and EGFP+SOX9+ astrocytes were quantified and compared between UL and LL cortical layers within each timepoint. PB-based labelling of EGFP+SOX9+ astrocytes showed that E15- and E16-born astrocytes were primarily found in the UL at P21. As an alternative birth dating method, 5-ethynyl-2'deoxyuridine (EdU) was administered to pregnant mice at E13 and E16 and tissue was collected at P3 prior to astrocyte expansion. EdU labelling showed that SOX9+EdU+ astrocytes born at E13 were primarily found in the LL at P3, while those born at E16 were primarily found in the UL at P3. Altogether, these results suggest that the distribution of SOX9+ cortical astrocytes is influenced by time of birth from V-SVZ NSPCs.

Title: Functional effects of astrocyte-derived exosomes on neurite outgrowth

Authors: *S. KAJA[1], H. N. HARIANI[2], A. K. GHOSH[3], G. KALESNYKAS[5], W. K. JONES[4]; [1]Ophthalmology and Mol. Pharmacol. & Neurosci., [2]Grad. Program in Neurosci., [3]Grad. Program in Biochem. and Mol. Biol., [4]Mol. Pharmacol. & Neurosci., Loyola Univ. Chicago, Maywood, IL; [5]Experimentica Ltd., Vilnius, Lithuania

Abstract: Exfoliation glaucoma is the most common identifiable secondary form of open-angle glaucoma and associated with deposition of extracellular fibrillar material in ocular tissues. Genetic polymorphisms in lysyl oxidase-like 1 (Loxl1) are the most common cause of exfoliation glaucoma. The objective of this study was to determine the functional effects of extracellular vesicles (exosomes) derived from Loxl1-deficient primary optic nerve head astrocytes (ONHAs) on neuronal differentiation and viability. We generated an ONHA culture with ~50% Loxl1 knockdown by transducing ONHAs with lentivirus harboring Loxl1-targeting shRNA. Exosomes from primary cultures of rat ONHAs (naïve, scramble- and Loxl1 shRNA-transduced) were prepared by ultracentrifugation. Exosomes were characterized by nanoparticle tracking analysis and immunoblotting. Uptake of exosomes into rat E18 primary cortical neurons was assessed by quantitative microscopy. The functional effects of exosomes on primary neurons *in vitro* were determined by quantification of cell viability and neurite outgrowth after addition of exosomes. ONHA-derived exosomes expressed the prototypical markers, Alix and CD63, but were devoid of CD81. Exosomes derived from naïve as well as scramble- and Loxl1 shRNA-transduced ONHAs were similar in size (119.8 ± 4.3, 121.9 ± 2.8 and 121.1 ± 2.5 nm, respectively, n = 3, $P = 0.89$). Uptake of exosomes into primary neurons was time-dependent, peaking at 4h after addition (n = 3, $P < 0.05$). Viability of rat primary E18 cortical neuronal cultures did not differ in the presence of exosomes. However, naïve and scramble-transduced ONHA exosomes increased neurite outgrowth of primary cortical neurons by 20.1 ± 3.3% and 18.7 ± 2.0%, respectively (n=5, $P < 0.05$ compared with media alone). In contrast, exosomes from Loxl1 shRNA-transduced ONHAs prevented any increase in neurite outgrowth (2.2 ± 4.0% change; n = 5, $P = 0.98$).These data suggest ONHA-derived exosomes can exert functional effects on primary neurons *in vitro*. Altered exosome-mediated neuron-glia signaling in exfoliation glaucoma characterized by a chronic reduction of LOXL1 expression may contribute to the ocular manifestations of the disease.

Title: Genetic approach to study the contribution of Sonic Hedgehog in the CNS physiological myelination and the remyelination process after damage in the adult

Authors: S. NOCERA[1], M. A. MARCHENA[2], Y. LAÓ[3], L. SOBRINO[3], E. BURGOS[4], Ó. GÓMEZ-TORRES[4], R. LUJÁN[4], ***F. DE CASTRO**[5];

Abstract: Sonic Hedgehog (Shh) is the best-studied ligand of the Hedgehog pathway. Shh regulates vertebrate organogenesis and it is one of the main gradient-forming morphogens organizing the CNS. Shh gradients continues to act in the adult CNS modulating specification and self-renewal of neural stem cells, and is upregulated after acute brain injury. Recently, it has been shown that cell progenitors in the postnatal forebrain V-SVZ require Shh signaling to generate the oligodendrocytes of the corpus callosum. Oligodendrocytes are the glial cells whose myelin sheaths envolve myelinated axons axons, a critical step in development and the normal functioning of the CNS. These myelin-forming cells derive from oligodendrocyte precursor cells (OPCs) during pre- and postnatal CNS development, and a relevant population of OPCs physiologically remains during adulthood. These adult OPCs support myelin maintenance and physiological plasticity, as well as after demyelinating damage (Multiple Sclerosis -MS-, others)

they react in a restorative assay. Shh has been shown over-expressed in MS lesions, potentially regulating OPC responses driving to remyelination. However, the direct effect of Shh pathway on OPCs during postnatal development and in pathological conditions is still an open question, with substantial impacto n the role of Shh in MS.In our current work we show that the up or down-regulation of Shh signaling pathway affects OPC differentiation into myelin-forming oligodendrocytes both postnatally and in the adult, as well as modulate remyelination after damage. Furthermore, implanting OPCs in CNS areas that do not present myelin in physiological conditions (the retina), we show that the activation or the inhibition of Shh signaling cascade depends on the molecular environment, which is dynamic depending on the stage of development.

Title: Tgfbeta1-gpnmb signaling inhibits oligodendrogenesis from adult neural stem cells following demyelination

Authors: *D. RADECKI, J. SAMANTA;
Univ. of Wisconsin, Madison, WI

Abstract: Demyelinating diseases, such as multiple sclerosis (MS), are debilitating diseases where the underlying degenerative and potential regenerative mechanisms are incompletely understood. Since regeneration of oligodendrocytes (OLs) and myelin can prevent neurodegeneration, understanding the molecular mechanisms of remyelination is essential to design therapeutic strategies for repair of demyelinating lesions. Adult neural stem cells (aNSCs) lining the lateral ventricles in the mammalian brain, including humans and mice, have the potential to regenerate myelin. In the healthy brain, a subset of these aNSCs, expressing the transcription factor Gli1, migrate to the olfactory bulb and differentiate into interneurons and astrocytes, but do not generate OLs. Following demyelination, these aNSCs can be recruited to lesions where they can differentiate into myelinating OLs. However, the pathways regulating aNSC recruitment, and their ability to generate OLs in adults is incompletely understood. Furthermore, remyelination is enhanced when Gli1 is inhibited in these aNSCs. By analyzing the

transcriptome of these cells following demyelination, we identified GlycoProtein Non-metastatic Melanoma B (Gpnmb) as the most significantly downregulated gene in aNSCs lacking Gli1 expression, suggesting its role as a negative regulator of remyelination. Indeed, global loss of Gpnmb in Gpnmb-LacZ knock-in mice, resulted in enhanced generation of OLs from Gli1 aNSCs following demyelination. Loss of Gpnmb also downregulated the expression of TGFβR2, a TGFβ1 receptor subunit, which suggested that Gpnmb acts downstream or in tandem with TGFβ1 which is highly expressed in demyelinating lesions. Remarkably, *in vitro* treatment of aNSCs by TGFβ1 lead to upregulation of Gpnmb. Overexpressing Gpnmb in aNSCs further lead to upregulation of TGFβR2 along with inhibition of mature OL generation *in vitro*, suggesting a positive feedback regulation of the pathway leading to amplification of TGFβ1 signaling in aNSCs following demyelination. Consistently, genetic loss of TGFβR2 specifically in Gli1 aNSCs, resulted in enhanced recruitment and generation of mature OLs from these cells in the demyelinating lesion. Thus, TGFβ1 released from demyelinating lesions, induces Gpnmb expression, which further upregulates TGFβR2 to amplify the pathway in Gli1 aNSCs, thereby inhibiting their recruitment and differentiation into mature OLs.

Title: Generation of unique oligodendrocyte lineage cells following direct lineage reprogramming of reactive astrocytes

Authors: *J. BAJOHR, A. OLFAT, K. LEE, H. TAHA, D. LOZANO CASASBUENAS, M. FAIZ;
Univ. of Toronto, Toronto, ON, Canada

Abstract: Direct lineage reprogramming is a novel strategy which converts one cell type to another without the need for a pluripotent intermediate. Oligodendrocyte (OL) loss is characteristic of many neurological conditions, and thus astrocyte to OL reprogramming is of interest for central nervous system repair. Given the differential loss of OLs and their progenitors following disease, it is important to be able to generate OL lineage cells at different stages of development. Here we show that astrocytes can be converted to various cells of the OL lineage

in vitro when transduced with different transcription factors (TFs) involved in OL fate determination. Using GFAP driven lentiviruses containing TFs of interest, postnatal (P1-P5) cortical astrocytes were transduced and assessed for markers of the OL lineage at varying time points. Unexpectedly, our data showed that ectopic expression of a TF involved later in OL development resulted in the generation of O4+ newly forming OLs (nfOLs) relative to controls 14 days post transduction (DPT), while ectopic expression of an early OL fate specification TF did not. Although this early OL fate specification TF led to the increased production of PDGFRA+ oligodendrocyte progenitor cells (OPCs) by 14 DPT, longer culture (22 DPT) did not lead to an increase in O4+ nfOLs for this TF. Ectopic expression of a TF important for OL myelination showed a trend towards increased generation of MBP+ myelinating OLs. This lends support to the idea that different TFs can be used to produce different OL cell types. Live cell imaging of the reprogramming process confirmed that iOPCs and iOLs originate from S100β expressing astrocytes. Altogether, these findings demonstrate reprogramming of astrocytes to cells of the OL lineage, and that this technology can be tailored to generate cells at different stages of maturity. These studies lay the groundwork for novel, reprogramming-based strategies for diseases involving OL lineage cell loss.

Abstract: DiGeorge/22q11 Deletion Syndrome (22q11DS) is a complex disorder characterized by cardiovascular and craniofacial abnormalities, intellectual disability, schizophrenia, autistic

spectrum, or attention-deficit/hyperactivity, among other pathologies. 22q11DS is caused by a microdeletion of 30-50 genes of chromosome 22, while clinical manifestations are linked to early perinatal developmental feeding/swallowing disorders (dysphagia) whose origins remain poorly understood. Previously, we have shown that the LgDel mouse model of 22q11.2 DS mimics the human phenotypic spectrum, including perinatal dysphagia, and exhibits changes in neuronal excitability in the hypoglossal nucleus (nXII) motor neurons, that controls the tongue movement and play a key role in the swallowing process. Therefore, we asked whether nXII circuits abnormalities are present and associated with LgDel feeding/swallowing difficulties. We analyze whether alteration in neuronal excitability is induced by changes in neurotransmitters content or distribution in the nXII. We used a ChAT:GFP reporter to identify nXII motor neurons in young and adult animals. Confocal 3D reconstructions of motor neurons demonstrate dendritic and axonal abnormalities, including degenerating dendrites. Also, backscatter scanning electron microscopy allowed us to analyze nXII location, neuronal identity, and ultrastructural characteristics in motoneurons affected by the genetic lesion. nXII motoneurons of one-week-old LgDel showed dilated mitochondrial cristae, paler mitochondrial matrix, and swollen Golgi and endoplasmic reticulum compared to age-matched wild type. At later ages, we found that LgDel nXII motor neurons and interneurons displayed cytoskeletal sparse, organelle depleted, paler cytoplasm, as well as reduced synaptic frequency. Also, we found hypertrophy of perineuronal, perisomatic, perivascular, and perisynaptic astrocytic processes, indicating glial changes in the modulation of the LgDel synaptic neurotransmission. To explore alterations in the inhibitory/excitatory afferents in the LgDel group, we classified/quantified the number of presynaptic terminals contacting the soma of nXII motor neurons at P7 using 2D-SEM tile-acquisitions. In addition, we quantified and compared the GABA content in presynaptic terminals of nXII during development, finding a significant decrease in the GABA presynaptic content in nXII of LgDel group, supporting the idea of imbalance neurotransmission levels that could directly affect the functionality of this nucleus in the feeding and swallowing circuits during development.

Title: Partial penetrance phenotype in the 16p11.2 deletion syndrome mouse model

Authors: *J. TARANDA[1,2], J. VELINSKOVA[3], S. MUZUMDAR[1], K. PRADHAN[4], K. UMADEVI VENKATARAJU[1], R. PALANISWAMY[1], J. SUN[1], S. TURCAN[2], J. GILLIS[1], L. VELISEK[3], P. OSTEN[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Natl. Ctr. for Tumor Dis., Heidelberg, Germany; [3]New York Med. Col., Valhalla, NY; [4]Albert Einstein Col. of Med., New York, NY

Abstract: 16p11.2 deletion is a recurrent copy number variation of 600 kb chromosomal region that includes 28 genes and 1/200 in patients diagnosed with autism spectrum disorder (ASD). Here, we describe several new phenotypes with clinical relevance in the 16p11.2 deletion (df/+) mouse model. First, we show that in response to a convulsant drug pentylenetetrazol (PTZ), some, but not all, df/+ mice are more prone to seizures at lower doses of the drug than wild type littermates. Second, we further probe this phenotype in the df/+ mouse model using electrocorticography (ECoG) day/night recording, which revealed 1) changes in the awake and non-REM sleep time with significant alterations in low-frequency oscillations, 2) abnormal spontaneous cortical activity, and 3) increased susceptibility of approximately 50% df/+ mice to PTZ. Third, we provide evidence for higher excitability in thalamocortical pathways in about 50% of df/+ mice injected with PTZ, using our method of mapping whole-brain activation by serial two-photon (STP) tomography in transgenic c-fos-GFP reporter mice. Fourth, employing our STPT images analysis pipeline, we discover that 16p11.2 animals with more PTZ susceptibility present a significant reduction in some areas of the cortex, for example, the somatosensory sensory or motor cortex. Fifth, we ask whether the increased PTZ susceptibility in some df/+ mice represents a partially penetrant phenotype and, if so, whether high-susceptibility (HS) df/+ mice show different behaviors from their siblings low-susceptibility (LS) df/+ mice. This experiment, which comprised monitoring of home-cage behaviors (three 24-hour sessions over one week), followed by 3 PTZ injections (once a week, repeated three times), demonstrated that the df/+ mice indeed fall into two distinct HS and LS PTZ-dependent phenotypes and the HS df/+ show selective disruptions in sleep and increased grooming behavior. Finally, we analyze the whole-transcriptome RNA sequence from bulk samples from the cortex of P2 animals and the somatosensory cortex of adult male animals. Additionally, we included animals that presented HS and LS seizure phenotype and their wild-type littermates after to performed biopsies from the same brain area employed in the adult without any manipulation. Overall, our results reveal a seizure-like phenotype of partial penetrance that can be linked to sleep deficits and repetitive behaviors in isogenic 16p11.2 df/+ mice. The 16p11.2 df/+ mouse model thus recapitulates several important clinical features of autism, providing us with a unique opportunity to study the underlying brain circuit changes and test novel therapeutic approaches.

Title: Altered behaviour, metabolism and neural activity in a mouse model of intellectual disability with a mutation in PDZD8 gene

Authors: *A. PANTIRU, S. CLAPCOTE, J. JOHNSTON;
Sch. of Biomed. Sci., Univ. of Leeds, Leeds, United Kingdom

Abstract: Intellectual disability often results from neurodevelopmental disorders that begin in childhood and are characterised by impaired cognitive functioning and an intelligence quotient below 70. Although intellectual disability is caused by both environmental and genetic causes, severe forms are often associated with defects in single genes. Three siblings from a consanguineous family were diagnosed with intellectual disability, developmental delay and autistic features. This phenotype cosegregated with a homozygous frameshift mutation in the PDZD8 (PDZ domain containing protein 8) gene. PDZD8 is an ER-mitochondria tethering protein which regulates calcium dynamics in mammalian neurons and was not previously associated with human disease. The aim of this project is to characterise a mouse model with a frameshift mutation in PDZD8. PDZD8 disruption in mice leads to intellectual disability, altered spatial memory and hyperactivity compared to WT controls. Molecular characterization of PDZD8 mutation further displays changes in gene expression, with gene related to mitochondria, cellular stress, neurogenesis and brain growth increased. In addition, preliminary in vivo imaging displayed changed in spontaneous cortical activity in PDZD8 mice containing a calcium indicator GCaMP6 compared to WT. Currently, changes in neuronal dynamics in PDZD8 mice are further investigated. Overall, PDZD8 disruption in mice was liked to behavioural, molecular and neuronal activity changes.

Title: C. elegans as a model for gain and loss of function in GRIN1 and GRIN2A-D variants

Authors: *S. OKAFOR[1], P. J. ROY[2], A. J. RAMSEY[1];
[1]Pharmacol. and Toxicology, [2]Mol. Genet., Univ. of Toronto St. George Campus, Toronto, ON, Canada

Abstract: GRIN disorder is caused by rare mutations within one of the seven GRIN genes that code for N-methyl-D-aspartate receptor (NMDAR) subunits. Pathogenic variants have been identified across the GRIN sequence and their functional impact can be either gain- or loss-of-function. We are developing mutant *c. elegans* as a model system to determine the impact of pathogenic variants on NMDA receptor function. The *c. elegans* genes *nmr-1* and *nmr-2* are orthologous to human GRIN1 and GRIN2 genes. *nmr-1* and *-2* form heterodimeric complexes that function like human NMDARs and are co-expressed on motor interneurons: AVE, AVA, PVC, AVD, and RIM. To characterize gain (GoF) and loss of function (LoF) in variants of GRIN1 and GRIN2A disorder we will co-inject human GRIN1 and GRIN2A genes into wildtype nematodes and into *nmr-1;nmr-2* deletion nematodes then develop mutants carrying documented patient variants. Next we will characterize locomotory phenotypes with our custom-built worm tracking system. We hypothesize that our overexpression model and our ectopic expression model will experience abnormal levels of reversals, forward movement, foraging behavior, omega turns, and locomotory speed. GoF variants should experience an increase in the aforementioned locomotory behaviors while LoF variants should experience a decrease. In addition we expect that ectopically expressing GRIN1 and GRIN2A will result in partial rescue of *nmr-1;nmr-2* deletion locomotor phenotypes. We will then use our data and methods to screen for FDA approved drugs that will mitigate or rescue the effects of GoF or LoF phenotypes.

Title: Infantile spasms-linked Nedd4-2 mediates hippocampal plasticity and learning via cofilin signaling

Authors: *K. LEE[1], J. ZHU[1], C. A. CURIA[2], C. A. CHRISTIAN-HINMAN[1,2,3], J. S. RHODES[2,3,4], N.-P. TSAI[1,2,3];

Abstract: Individuals affected by infantile spasms (IS), such as those carrying mutations in an IS linked gene, neural precursor cell expressed developmentally downregulated gene 4-like (Nedd4-2), exhibit developmental delays and learning disabilities, but the underlying mechanism is unknown. Using conditional Nedd4-2 knockout mice, we uncovered that Nedd4-2 functions to maintain the excitatory synapses in hippocampal neurons and allows for late-phase long-term synaptic potentiation (L-LTP) at Schaffer-collateral synapses in the hippocampus. We also found that Nedd4-2 is required for multiple forms of hippocampus-dependent learning and memory. Mechanistically, we showed that a loss of Nedd4-2 leads to a decrease in actin polymerization caused by reduced phosphorylation of the actin-depolymerizing protein cofilin. Using a cell permeable peptide to promote phosphorylation of endogenous cofilin in Nedd4-2 knockout neurons, we could restore the number of hippocampal excitatory synapses and hippocampal L-LTP and partially restore hippocampus-dependent learning in mice. Together, our results reveal a novel mechanism underlying IS-associated learning disabilities and may provide information for future therapeutic strategies for IS.

Title: Developmental lead (Pb^{2+})-exposure causes altered brain excitability in the adult rat: in-vivo pilocarpine induced seizure pathophysiology

Authors: G. CRUZ[1], M. VASQUEZ[2], E. CABAÑAS[1], J. JOSEPH[1], M. MIAN[1], S. K. V. MADHIRA[1], L. S. NEUWIRTH[3];
[1]Biol. Sci., [2]Chem. & Physics, [3]Psychology & SUNY Neurosci. Res. Inst., SUNY Old Westbury, Old Westbury, NY

Abstract: Lead (Pb2+) is neurotoxicant, that causes early neurodevelopmental pathologies in the offspring of Pb2+-exposed dams. Studies show that maternal Pb2+-exposure disrupts the GABA-shift contributing to altered brain excitability and potentially epilepsy. Unlike high-level Pb2+-exposure that produces encephalopathy and seizure, low-level Pb2+exposure does not produce such overt symptoms. However, subtle neurotoxic influences of Pb2+ on altering the CNS excitation:inhibition balance can cause a range of neurodevelopmental disorders at subthreshold seizure levels. Thus, in order to assess how Pb2+-exposure might cause neurodevelopmental aberrations in brain excitability, we exposed Long Evans Hooded Rats to in-vivo pilocarpine-induced (380 mg/kg) seizures. Control rats (0 ppm) were compared against Perinatal Pb2+-exposed rats (150 ppm & 1,000 ppm) to determine if Pb2+-exposure dose-dependently exacerbated the developmental neuropathological conditions. Rats were tested 1-2 months following the cessation of Pb2+-exposure at PND 22. Rats were anesthetized and in-vivo recording electrodes were stereotaxically implanted into the hippocampal CA1 region of the hippocampus and recorded for 1 hr post-pilocarpine seizure induction. The seizure data were subjected to a Fourier Transform using a Power Spectrum Density analysis to convert all raw brain seizure activity into isolated brain waves (i.e., alpha, beta, delta, gamma, theta rhythms) in addition to slow and fast ripples to assess pathophysiological states that persisted into adulthood from the early neurodevelopmental Pb2+-exposures. The results show that pilocarpine-induced seizures in a sex-dependent and Pb2+-dependent manner producing aberrant brain excitability. The findings from this preliminary study suggest that Pb2+-exposure may cause sex-dependent vulnerabilities as a function of dose, and the time-period of development that emanate from a disrupted GABA-shift in early neurodevelopment. These findings are consistent with the subtleties of Pb2+-exposure causing neurodevelopmental pathologies of prefrontal cortical damage with concurrent learning and memory hippocampal deficits as a model for human fronto-executive dysfunction and intellectual disabilities; albeit, emerging from aberrant neurodevelopmental programming of GABAergic excitation with persistent elevations of brain activity across the lifespan.

Title: Investigating gene-environment interactions of developmental methylmercury exposure in zebrafish

Authors: *A. LUTZKE, C. DICKEY, E. JOHNSON, B. S. CARTER;
Univ. of Wisconsin Eau Claire, Eau Claire, WI

Abstract: Methylmercury (MeHg) is a common environmental contaminant, and prenatal or early environmental exposure to MeHg is known to cause developmental abnormalities. MeHg is cleared from the body by oxidative stress metabolism pathways involving glutathione (GSH). The amount of time MeHg remains in the body varies greatly across individuals, and this variation may be due in part to genetic polymorphisms in genes involved in MeHg metabolism. Certain alleles of GSH-related genes are correlated with elevated blood MeHg levels in adult humans; how these alleles affect MeHg metabolism during development is not well known. Our objective is to produce and validate mutant zebrafish lines with loss-of-function mutations in GSH-related genes (*gstp1, gstp2, gclm*) using CRISPR-Cas9 reagents and high-resolution melt analysis genotyping (HRMA). CRISPR targeting and genotyping primers were designed using CHOPCHOP web tools. Embryos were microinjected at 1-cell stage with Cas9 protein complexed with specific guide RNA per gene target. HRMA primers were confirmed using synthetic DNA templates matching the targeted gDNA sequence. Methods were implemented and confirmed using reagents targeting tyrosinase (*tyr,* pigment gene). HRMA was able to distinguish between PCR products from synthetic DNA templates differing by 10 base pairs for all genes tested, and it was able to distinguish mutation in *tyr* mutant fish compared to vehicle-injected fish. These results enable future experiments defining genetic influence on developmental toxicology of methylmercury.

Title: Anxiety-related behaviors are impaired in adult mice exposed to perinatal cerebellar injuries

Authors: *E. GUARNIERI, M. MENGUS, R. IMANE, S. TREMBLAY;
Res. center of the Sainte-Justine Univ. Hosp., Montréal, QC, Canada

Abstract: Developmental cerebellar cognitive affective syndrome affects growing preterm infants diagnosed with perinatal cerebellar injuries during their neonatal intensive care unit stay. To better characterize motor, social and behavioral long-term outcomes, and their cellular mechanisms, we experimentally induced right-sided cerebellar hemorrhages (CBH) and/or early inflammation state (EIS) in 2 days-old transgenic mice (B6.129P2(Cg)-C*x3Cr1*$^{\text{CreERT2-EYFP/iDTR}}$) with or without transient right-sided cerebellar microglial cell depletion. Sensorimotor and behavioral tests were blindly performed at P4-P14 (Grasping reflex acquisition) and at P60-P85 (Marbles burying, Open field, Y maze, Elevated Plus Maze, Social recognition test, Morris water maze, Rotarod and Footprint analysis). Our preliminary cohort results suggested that in presence of microglial cells, male mice exposed to CBH+EIS spent significantly (*P=0.01*) less time in the periphery area of the Open field (78.2 ± 3.5 %, *n*=8) compared to control males (92.9 ± 1.4 %, *n*=7). They also tended to spend less time in the closed arms of the Elevated Plus maze (74.6 ± 4.7 %, *n*=8) and increase their locomotor activity (5559 ± 314 cm, *n*=8) while performing these tests compared to control males (77.3 ± 1.8 %; 4020 ± 221 cm, *n*=7). In male mice, microglial cell depletion prior to insult seems to attenuate these anxious behaviors suggesting a deleterious role of microglia on brain development. Interestingly, in absence of microglial cells, female mice exposed to CBH+EIS tended to have better short-term memory on the Morris Water Maze test (7.3 ± 1.9 sec, n=3) compared to non-depleted females (22.2 ± 6.0 sec, *n*=5) also suggesting a deleterious impact of microglia on cognitive abilities acquisition. These results revealed long-term impairments induced by perinatal cerebellar injuries with sex differences and impact of microglial cell activation on brain development. Increasing number of tested animals is required to confirm these preliminary results.

Ctr., Washington, DC; [6]Pediatrics, Children's Natl., Washington, DC; [7]George Washington Univ. Sch. of Med. and Hlth. Sci., Washington, DC

Abstract: Background: Preterm birth is often associated with maternal immune activation (MIA), and premature infants are also exposed to prolonged periods of hypoxia (Hx) and inflammation. Preclinical studies of perinatal hypoxia in mice have identified developmental alterations in the cerebellum; however, the cellular and molecular mechanisms underlying the effects of combined MIA and hypoxia on cerebellar development in are unknown. **Hypothesis**: We hypothesize that MIA and chronic hypoxia results in cerebellar injury and disruption of Purkinje cells (PCs) circuitry, leading to adaptive learning deficits. **Methods**: We utilized the "double-hit" model of prematurity (MIA+Hx). We injected lipopolysaccharide (LPS) to the dams during mid- to late gestation, embryonic days 15 and 16 (E15, E16). Then we exposed the pups to sub-lethal chronic Hx from postnatal day 3 to 11 (P3-P11). We included 4 groups: Double hit (DH), saline-Hx, MIA-normoxia, saline-normoxia. We included 6-8 mice/group for morphological and behavioral analysis and 3 mice/group for transcriptomic analysis. We performed morphological assessment and transcriptomic analysis of the cerebellar cortex at two timepoints (P15 and P35). We also tested the DH mice at P35 using the Erasmus Ladder, a fully automated system for real-time monitoring of cerebellar-mediated motor learning and behavior. **Results**: The cerebellum of the DH mouse model revealed alterations in the external and internal granule cell layer and phenotypically immature PC with poor dendritic arborization, as compared to controls. Interestingly, although there were 1,529 differentially expressed genes (DEGs) between DH and controls (1188 up-regulated, 341 down-regulated), there were only 19 DEGs between Controls and Hx (9 up-regulated and 10 down-regulated) and only 13 DEGs (9 up-regulated and 4 down-regulated) between the DH and MIA-only group, indicated that MIA is a significant contributor to cerebellar injury and acts synergistically with Hx (second hit) on the cerebellum. In addition, a cerebellum-specific behavioral assessment (Erasmus ladder) in the DH mice showed an increased percentage of missteps compared to the controls. In addition, associative cerebellar learning, pairing an obstacle and a tone during the challenge phase, revealed a significant cerebellar motor learning deficit in the DH mice. **Conclusions**: In "double-hit" mice, a combination of prenatal maternal immune activation and postnatal chronic Hx (the two main insults in premature neonates), induced specific patterns of cerebellar injury, similar to premature humans, and compromised adaptive cerebellar learning, a hallmark of autism spectrum disorder.

Title: α5 $GABA_A$ receptor negative allosteric modulation - effects on inhibitory and excitatory hippocampal neurotransmission

Authors: *J. L. NUWER[1], M. L. BRADY[1], N. V. POVYSHEVA[2], A. COYNE[1], T. C. JACOB[1];
[1]Dept. of Pharmacol. and Chem. Biol., Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [2]Dept. of Neurosci. and Ctr. for Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In the central nervous system, GABA type A receptors ($GABA_A$Rs) generate fast inhibitory signals to dampen and control neuronal activity. $GABA_A$Rs are heteropentameric ion channels assembled from a pool of 19 subunit genes (α1-6, β1-3, γ1-3, δ, π, ε, θ, and ρ1-3), each with distinct spatial, temporal, and subcellular expression patterns. The specific subunit composition and arrangement confers distinct functional and pharmacological properties. α5 subunit-containing $GABA_A$Rs are enriched in the hippocampus and play critical roles in development, synaptic plasticity, cognition, and memory. Negative allosteric modulators (NAMs) that target α5 $GABA_A$Rs enhance cognition and have shown promise in preclinical studies to mitigate cognitive impairment in Down syndrome, schizophrenia, and post-anesthesia. Despite *in vivo* efficacy in both rodents and humans, no study has examined the effects of sustained α5 NAM treatment on inhibitory and excitatory synapse plasticity to identify mechanisms of action. Here we used L-655,708, an imidazobenzodiazepine that acts as a highly selective but weak α5 NAM, in conjunction with microscopy, biochemical, and electrophysiological techniques to better understand the functional effects of reducing α5 $GABA_A$R signaling in both developing and mature neurons. We show that 2-day pharmacological reduction of α5 $GABA_A$R signaling in immature neurons delays dendritic spine maturation and the NMDA receptor (NMDAR) GluN2B/GluN2A developmental shift, while 2-day treatment in mature neurons enhances surface synaptic GluN2A and reduces GluN2B. Despite these changes, total levels of key excitatory synapse proteins were largely unchanged, and mEPSCs were unaltered. Additionally, 2-day α5 NAM treatment does not alter the total surface levels or distribution of α5 $GABA_A$Rs, reduce the gephyrin inhibitory synaptic scaffold, or impair phasic or tonic inhibition. Furthermore, mature neurons remained sensitive to α5 NAM-mediated inhibition of the $GABA_A$R tonic current after 2-day α5 NAM treatment.

Together, these results provide initial mechanistic insight into α5 $GABA_AR$ regulation of dendritic spine and circuit maturation via an NMDAR-dependent mechanism. Importantly, α5 NAMs may have sustained efficacy with reduced tolerance liability than non-specific $GABA_AR$-targeting drugs, such as benzodiazepines. We are currently investigating the effects of long-term α5 NAM treatment and the regulatory mechanisms governing α5 $GABA_ARs$ and α5 NAM-induced plasticity. The results of these studies will be invaluable in determining therapeutic application of α5 $GABA_AR$-preferring drugs.

Title: Influence of GABA-A Receptor Intracellular Domain on Channel Activation and Desensitization

Authors: *A. TUNG[1], L. BLECKER[2], C. M. CZAJKOWSKI[2];
[1]Univ. of Wisconsin, Madison, Madison, WI; [2]Dept Neurosci., Univ. Wisconsin-Madison, Madison, WI

Abstract: Rapid opening and closing of GABA-A receptor (GABAR) channels regulate signaling in the brain, but the mechanisms underlying the channel's open, closed, and desensitized transitions remain unclear. Recent GABAR cryo-EM structures provide details about its extracellular and transmembrane domains, but little information exists about its intracellular domain (ICD) and its role in regulating channel gating. Interestingly, the intracellular region of the GABAR α subunit following the C-terminal end of the M3 transmembrane helix is lysine rich. We hypothesize that mechanisms underlying GABAR gating transitions may involve charged interactions between these lysine residues and other regions of the GABAR ICD. Here, we individually mutated three lysines in this region to alanine (α1K327A, α1K328A, and α1K336A). The mutations' effects on GABA EC50 and macroscopic current desensitization were measured using two-electrode voltage clamping of oocytes expressing wild-type and mutant GABARs. α1K327A increased GABA EC50 6- fold (212.8 ± 49.9 μM, n = 6) compared to α1β2γ2 WT (35.98 ± 1.03 μM, n=9) and significantly reduced GABAR desensitization. The extent of current desensitization after 60 seconds in saturating GABA (10mM) was 30.16 ± 6.72% (n=9) versus WT (63.0 ± 15.0%, n=13). α1K328A decreased GABA EC50 2- fold (18.4 ± 6.09 μM, n=3) and also significantly reduced the extent of current desensitization at 60 sec (18.2 ± 3.65%, n=5) compared to WT. α1K336A decreased GABA

EC50 2-fold (17.1 ± 2.45 μM, n=2) and had little effect on the extent of desensitization at 60 sec (59.3 ± 4.50%, n=5) compared to WT. Based on a GABAR ICD homology model, a1N386 is predicted to interact with a1K327. We found that alanine substitution of α1N386 also increased GABA EC50 4- fold compared to WT and had no effect on the extent of GABAR desensitization at 60 sec (69.8 ± 6.24%, n=3). These data indicate structural perturbations of residues in the GABAR ICD can influence macroscopic GABAR current desensitization and suggest that charged residues in the ICD play a role in regulating GABAR gating transitions.

Title: Beta3 subunit phosphorylation determines the assembly of synaptic and extrasynaptic $gaba_ars$

Authors: *C. CHOI[1], J. L. SMALLEY[1], S. J. MOSS[1,2], P. A. DAVIES[1];
[1]Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [2]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Impaired inhibitory signaling via γ-aminobutyric acid type A receptors ($GABA_ARs$) underlies the pathophysiology of many neuropsychiatric disorders such as autism and epilepsy. Neuronal inhibition is regulated by two major $GABA_AR$ populations: α1-containing synaptic and α4-containing extrasynaptic subtypes that mediate phasic and tonic currents, respectively. Having distinct α subunits ensures proper receptor localization within the plasma membrane by controlling interactions with the inhibitory synapse scaffold, and is thus critical to the fidelity of GABAergic inhibition. While both subtypes are required for inhibitory transmission, the mechanism underlying the assembly of the two $GABA_AR$ subtypes remains unknown. The membrane trafficking of $GABA_ARs$ is subject to modulation by phosphorylation of the serine 408 and 409 residues (S408/9) within the β3 subunits, which are common components of the two $GABA_AR$ subtypes. Substituting serines with alanines (S408/9A) compromises GABAergic inhibition and leads to autism-like behaviors. However, the role of S408/9 phosphorylation in mediating $GABA_AR$ assembly has not been explored. To this end, we examined the subunit compositions and protein interactors of endogenous α1- and α4-containing $GABA_ARs$ in 8-12-week-old male and female C57Bl/6 and S408/9A animals using immunoprecipitation coupled

with quantitative mass spectrometry, western blots, and bioinformatics analyses. We also performed confocal microscopy on cultured neurons from C57Bl/6 and S408/9A pups. Lastly, to understand the mechanism involved in $GABA_AR$ assembly, we examined the expression patterns of $GABA_AR$ subunits across different cellular compartments. We found that, in C57Bl/6 animals, the α1 and α4 subunits form distinct populations of $GABA_ARs$ and interact with distinct sets of proteins. In addition, the two subtypes are associated with different levels of phosphorylated S408/9 and have different expression patterns across cellular compartments. In S408/9A animals, however, the α1 and α4 subunits co-assemble, resulting in the formation of α1α4-containing $GABA_ARs$ and mis-trafficking of α4 subunits into synapses via interactions with synapse-targeting proteins. These results suggest that the phospho-regulation of S408/9 plays a critical role in the assembly of α1-containing synaptic and α4-containing extrasynaptic $GABA_AR$ subtypes. Mutating S408/9 compromises $GABA_AR$ assembly and thus inhibition, by altering the proteome and localization of α4-containing $GABA_ARs$. Collectively, these results suggest that S408/9 may be a novel therapeutic target for disease conditions with impaired GABAergic inhibition.

Title: Diazepam-induced down-regulation of the $GABA_A$ receptor alpha 1 subunit expression mediated by a calcium signaling pathway

Authors: N. B. MEDINA, M. V. PIETKO, ***M. C. GRAVIELLE**;
Inst. de Investigaciones Farmacologicas, Univ. de Buenos Aires-CONICET, Buenos Aires, Argentina

Abstract: Benzodiazepines are widely prescribed drugs for the treatment of anxiety, sleep disorders, and epilepsy; however, their long-term use is limited by the development of tolerance. In previous studies we reported that prolonged exposure of rat cortical neurons to diazepam, a classic benzodiazepine, induced transcriptional repression of the $GABA_A$ receptor α1 subunit gene. This regulatory process was prevented in the presence of nifedipine, an inhibitor of L-type voltage-gated calcium channels. The aim of this work was to investigate the signaling cascade triggered by the persistent treatment with diazepam that leads to the regulation of $GABA_A$ receptor expression. Results from this study indicated that a 48 h treatment of rat cortical neurons

with diazepam (1 μM) produced an increase in the intracellular calcium concentration measured in a multi-well plate reader using the calcium-sensitive fluorescent dye Fura 2-AM and a high potassium concentration (60 mM KCl) as a stimulus. This increase was abolished in the presence of nifedipine, suggesting that diazepam exposure induced an increase in the calcium influx through L-type voltage-gated calcium channels. Quantitative real-time PCR and western blots experiments showed that the diazepam-induced down-regulation of the α1 subunit expression was blocked by picrotoxin, a $GABA_A$ receptor channel blocker, and H-89, a protein kinase A inhibitor. Taken together, our results suggest that sustained stimulation of $GABA_A$ receptors by benzodiazepines activates an intracellular signaling cascade that involves the stimulation of the calcium influx through L-type voltage-gated calcium channels which results in the activation of a protein kinase A cascade, finally leading to the transcriptional repression of α1 subunit gene. This regulatory mechanism depends on the activation of $GABA_A$ receptors. Elucidation of the signaling pathway activated by the sustained exposure to benzodiazepines will contribute to understand the molecular bases of tolerance.

Title: Allopregnanolone effects on inhibition in hippocampal parvalbumin interneurons

Authors: *X. LU, P. LAMBERT, A. BENZ, C. F. ZORUMSKI, S. J. MENNERICK; Psychiatry, Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Allopregnanolone (AlloP) is an endogenous neurosteroid that potentiates ionotropic GABAergic inhibition in the CNS. AlloP has a rapid antidepressant effect and recently been approved for treating postpartum depression in women. However, the antidepressant mechanism of AlloP is largely unknown but could involve selective action at $GABA_A$ receptors containing the δ subunit. Previously, we and others showed that AlloP potentiates both phasic and tonic inhibition in the dentate granule cells (DGCs), which express α4δ-containing receptors. Using pharmacoresistant receptor subunit knock-in mice, we in fact found little evidence for selectivity at δ subunit-containing receptors despite previous evidence. In contrast to DGCs, hippocampal fast-spiking parvalbumin (PV) interneurons express an unusual variant partnership of δ subunits with α1 subunits. Here we hypothesized that native α1δ receptors may provide a strong substrate

for AlloP, resulting in potentiation of tonic disinhibition to DGCs. Contrary to the hypothesis, electrophysiology from genetically tagged PV interneurons in hippocampal slices showed that 100 nM AlloP promoted phasic inhibition by increasing the sIPSC decay, but tonic inhibition was not detectably altered. Co-application of 100 nM AlloP with 5 µM GABA did result in tonic current augmentation. Furthermore, 100 nM AlloP decreased the membrane resistance and the number of action potentials of DGCs but not PV interneurons. Taken together, our results indicate that PV interneurons possess low sensitivity to AlloP, which makes it unlikely that PV tonic current is a substrate for AlloP-induced tonic disinhibition.

Title: Selective targeting of the etomidate site of α6-containing $GABA_A$receptors

Authors: *P. SCHOLZE[1], K. SENDOREK[1], M. ERNST[1], X. SIMEONE[2];
[1]Med. Univ. of Vienna, Wien, Austria; [2]Univ. of Vienna, Wien, Austria

Abstract: $GABA_A$ receptors containing the α6 subunit are highly expressed in cerebellar granule cells, and less abundantly in many other neuronal and peripheral tissues. Animal models of several neuropsychiatric conditions suggest that compounds selectively activating or positively modulating cerebellar α6-containing $GABA_A$ receptors can alleviate essential tremor and motor disturbances in Angelman and Down´s syndrome, as well as impaired prepulse inhibition in neuropsychiatric disorders. Moreover, they have been suggested to reduce migraine and trigeminal-related pain by acting on α6-containing $GABA_A$ receptors on trigeminal ganglia. Within the scope of this study, we aim to develop novel α6-selective ligands as therapeutic prospects in neuropsychiatric conditions involving central and peripheral α6-containing $GABA_A$ receptors. The α6 subunit features unique amino acids contributing to ligand pockets in the ECD near “loop” C as well as in the TM1 contributing to the binding sites for etomidate and loreclezole. Not only the already known influence on furosemide is exerted by this upper TM1 segment, but several other scaffolds including some loreclezole derivatives target the etomidate pocket with some degree of selectivity that is conferred by these two amino acids. The two

unique amino acids in TM1 were subjected to mutational analysis and their impact on various ligands thought to bind at or near the etomidate site was investigated using two electrode voltage clamp electrophysiology on GABA receptors expressed in *Xenopus laevis* oocytes. We show that both mutants influence modulatory potency and efficacy of several known α6-preferring compounds.

Title: Glutamine synthetase and its role in astrogliosis and neurotransmission.

Authors: *S. F. J. NG[1], S. J. MOSS[1,2,3];
[1]Dept. of Neurosci., AstraZeneca-Tufts Lab. for Basic and Translational Neuroscience, Tufts Univ. Sch. of Med., Boston, MA; [2]Dept. of Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [3]Dept. of Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Glutamine synthetase (GS) is an enzyme that plays a central role in the regulation of nitrogen metabolism, through catalyzing the ATP-dependent condensation of glutamine and ammonia to glutamine: Glutamate + ATP + NH_4^+ → Glutamine + ADP + phosphate. It is predominantly found in astrocytes in the brain and contributes to detoxifying NH_4 and limiting glutamate accumulation to prevent excitotoxicity. It is the only enzyme capable of synthesizing glutamine, which is the principal metabolic precursor for the inhibitory neurotransmitter γ-aminobutyric acid (GABA), indicating its importance in in maintaining neurotransmitter supply and supporting neuronal inhibition. The essential role GS plays in the brain is revealed by the rare congenital mutations in humans, contributing to brain malformations, resulting in neonatal death. Constitutive inactivation of GS in mouse brain causes deaths 1-3 days after birth. Consistent with its role in supporting GABAergic inhibition, deficits in GS expression are found in hippocampi from human patients with temporal lobe epilepsy (TLE). However, whether these deficits directly contribute to the pathophysiology of epilepsy remains elusive. To address this, we have used stereotaxic injection of *Cre* recombinase-expressing adeno-associated viruses to locally ablate GS expression within the hippocampus of adult GS-FLOXED (GS^{flox}) mice. The impact of this manipulation on glia and neuronal structure, inhibitory neurotransmission, and seizure sensitivity were examined. Our results suggests that locally ablating GS expression in

hippocampal subdomains is sufficient to induce reactive astrogliosis, a hallmark of TLE, suggesting that agents which augment GS activity may be a useful therapeutic strategy to limit epileptogenesis.

Title: Subthreshold synaptic inputs to space-specific neurons

Authors: *P. HARRAST[1], W. M. DEBELLO[1], D. FIORAVANTE[2];
[1]UC Davis, Davis, CA; [2]Ctr. For Neuroscience, Univ. of California Davis, Davis, CA

Abstract: Neuronal computations performed by space-specific neurons (SSNs) in the barn owl inferior colliculus are well-studied via extracellular recordings, but there is very little data regarding subthreshold synaptic events. We used whole-cell voltage-clamp recordings and concentric bipolar stimulation in 35-50d old animals to map the topography of synaptic inputs preserved in ex vivo slices, and begin to determine the rules of integration for pairs of input locations. Recordings were visually targeted to large somas in the external nucleus of the inferior colliculus (ICX). Retrospective imaging revealed that approximately half of the cells contained toric-like spines, signature features of Type I SSNs. To map input topography, the electrode with narrow field of excitation was placed in the adjacent input nucleus, the lateral shell of the inferior colliculus (ICCls), and brief current pulses were applied in ascending steps from ~10 - 1000 microamps. The threshold current intensity for evoking an EPSC was determined. EPSCs were shown to be glutamatergic by pharmacology and manipulation of holding potentials. The bipolar electrode was then moved to a new location and the stimuli repeated. In this horizontal plane of section, different locations represent different values of interaural time difference (ITD). As predicted, the largest EPSCs were elicited when the bipolar electrode was placed at an iso-ITD contour within ICCls, and the EPSC magnitudes decreased as the sites of stimulation were moved to locations representing more ipsi or more contra ITDs. To measure EPSC integration, a second bipolar electrode was deployed. Once two effective sites were found, stimuli were presented individually or synchronously. Preliminary results indicate that the EPSCs elicited by synchronous stimulation were often larger than predicted by the sum of individual stimulations (i.e. supralinear summation). This effect appeared to be limited to nearby stimulation sites. Finally, at some single stimulation sites we observed paired-pulse facilitation. In total, these

experiments demonstrate the feasibility of measuring the topography, summation rules and capacity for short-term plasticity of synaptic inputs to SSNs. In addition to probing integration across the ITD axis, future experiments will use orthogonal slices which expose the sound frequency axis and a different set of neuronal computations.

Title: Propofol anesthesia changes dynamic stability in cortex

Authors: *L. KOZACHKOV[1], A. EISEN[1], A. BASTOS[1,2], J. A. DONOGHUE[1], M. K. MAHNKE[1], S. L. BRINCAT[1], E. N. BROWN[1,3], E. K. MILLER[1];

Abstract: Understanding the mechanisms by which anesthetics induces loss of consciousness (LOC) is critical for making anesthesia care safer and for understanding consciousness. Recent work suggests an optimal range of “Dynamic Stability” is critical for normal cortical function[1]. Dynamic Stability is the ability of network activity to “stay in its lanes”: be dynamic yet consistent, performing the same computations regardless of initial state and in the face of being perturbed by other activity, noise, and distractions. Too much stability and networks cannot process and integrate new inputs; too little stability and network activity spirals off into “chaos”. We tested how propofol, a widely used anesthetic, affects Dynamic Stability. We used local field potentials (LFPs) from the prefrontal cortex in non-human primates (NHPs) anesthetized with propofol [2]. We applied techniques in machine learning [3] to produce a time series with statistical properties approximating those of the neural data. We then computed the spectrum of Lyapunov exponents – a quantification of the degree of (in)stability present in the system. Preliminary results indicates that after propofol-induced LOC, there is increased stability in cortical networks relative to the awake state. This excess stability may contribute to LOC in part by rendering cortical networks impervious to inputs thereby disrupting cortical communication.

Title: Subthreshold oscillations can propagate as a wave by volume conduction

Authors: *C.-C. CHIANG[1], D. M. DURAND[2];
[2]Dept Biomed. Eng, [1]Case Western Reserve Univ., Cleveland, OH

Abstract: Rhythmic oscillations at different frequency bands have been observed in several regions of the brain. Some of these oscillations are classified as subthreshold membrane potentials (STO) and can influence neural spikes' timing. We reproduced the oscillating activity at different frequency ranges (5-50 Hz) in the longitudinal hippocampal slice expressing optopatch proteins by optical stimulation with blue laser pulse trains. We found that the optogenetically-induced neural oscillations could propagate across the hippocampal slice and go through a complete transection of the tissue. The propagation speed of these neural oscillations is about ~0.1m/s and is independent of the oscillating frequency. The speed increases with increasing amplitudes of the wave. The electric fields generated by these waves are 0.5~0.9 mV/mm between somatic and dendritic regions and ~0.4 mV/mm along the cell layer. We also observed that these subthreshold oscillations could interfere with each other. Optical stimulation applied simultaneously at each end of the slice generated a larger oscillation in the middle of the tissue (constructive effect). Similarly, when two stimulation waveforms with 180° phase delay are generated, an oscillation with a smaller amplitude was measured in the middle of the slice (destructive effect). Finally, we conducted pharmacological experiments to characterize these oscillations and found that these induced oscillations are not affected by the NMDA blocker, APV, but the speed increases when the HCN channels are inhibited. These results indicate that hippocampal subthreshold oscillations can propagate by volume conduction and generate

interference patterns. The role of these subthreshold waves in neural function is unknown, but the results suggest that at low voltage amplitude, the lack of refractory period could allow a novel analog form of preprocessing of neural activity.

Title: Control of sympathetic preganglionic output strength by modulation of spike propogation in branching axons along paravertebral sympathetic chain ganglia

Authors: *M. HALDER[1], Y. LI[1], A. J. SOKOLOFF[2], M. SAWCHUK[1], S. HOCHMAN[3]; [2]Dept Physiol, [1]Emory Univ., Atlanta, GA; [3]Dept Physiol, Emory Univ. Sch. Med., Atlanta, GA

Abstract: Spinal sympathetic preganglionic neurons (**SPNs**) issue divergent axonal projections onto ganglionic neurons (**GNs**) across multiple paravertebral chain ganglia. SPN axons labelled from ventral roots (**VRs**) issue branching axons which travel rostro-caudally in the interganglionic nerve (**IGN**) to innervate GNs across many segments. Neurobiotin labeling of adult mouse SPN axons have begun to identify the complexity of SPN branching. For 165 SPN axons originating from T7 VR, projections were seen across at least 10 segmental ganglia (mean of 140 synapses/axon in T5-T7 ganglia alone). Here we explore whether spike propagation failures across ganglia represent a physiologically modifiable feature of divergence gain control. Adult mouse thoracic sympathetic chain ganglia were dissected to remain in continuity *in situ* with connections from VRs. Synaptic transmission was blocked with hexamethonium. SPN axons were recruited at 2X suprathreshold intensities in thoracic VRs. Population conduction across branching (in IGN) and unbranching (in splanchnic) axons were recorded with suction electrodes. Recordings at 22º over 2hrs showed individual SPN axons undergoing spontaneous conduction block. After scaling for temperature dependent changes in spike height and width, increasing temperature from 22º progressively reduced rectified-integral responses in both unbranching (35% at 28º; 46% at 36º; n=2) and branching SPNs (27% and 35.6%; n=2). At 31-36º, spontaneous conduction block was always seen across ≥ 3 intervening ganglia (n=6/6) but not ≤2 segments (n=0/2). To assess activation history of spike propagation, we compared evoked responses before and 2s after 10 pulses of 5 & 10 Hz stimulus trains and observed facilitation of

conduction across ≥ 3 ganglia following 10Hz (n=3/3) and 5Hz (n=4/7) stimulation. SPNs express α_5-$GABA_A$ receptors and may be constitutively active (10.1523/jneurosci.2951-08.2008). We used $GABA_A$ receptor pharmacology to explore actions on spike conduction. The $GABA_A$ antagonist bicuculline (10μM) significantly reduced rectified integral values of the population volley in branching (34%; $p < 0.05$; n=6) but not unbranching SPNs (29%; $p < 0.1$; n=2). L655,708 (20μM), a negative allosteric modulator for α_5-GABAARs also reduced conduction in branching SPNs (33% $p < 0.06$; n=4). In sum, we demonstrate that conduction block of spikes in SPN axonal projections is prevalent and modifiable in a distance-, temperature-, activity- and neuromodulation-dependent manner. Further studies on $GABA_A$ receptor pharmacology are planned to better understand their subunit composition and mechanisms of endogenous modulation.

Title: Fluctuation of inter-regional delays in the human cerebral cortico-cortical communication

Authors: *J.-Y. MOON[1], *K. MÜSCH[1], C. E. SCHROEDER[2], C. J. HONEY[1];
[1]Dept. of psychological and brain sciences, Johns Hopkins Univ., Baltimore, MD; [2]Nathan Kline Inst. - Translational Neurosci. Div., Columbia Univ. Col. of Physicians and Surgeons, Orangeburg, NY

Abstract: In electric signals such as field-potentials measured across regions of the human brain, parietal signals frequently phase-lead the signals in temporal and frontal cortex, while waves of activity propagate along parieto-temporal pathways. In order to better understand the functional properties of such large-scale pattern of signal flow, we asked: (i) are inter-regional delays stable or variable over time? (ii) do the patterns of signal propagation co-vary with endogenous cortical rhythms? (iii) do the patterns of signal flow vary with external stimulus properties? We recorded electrocorticographic signals from the lateral cortical surface of 10 human participants as they listened to a 7-minute auditory narrative. In sliding 2-second windows, we identified inter-regional delays by computing the cross-correlation of voltage signals between nearby electrode pairs. For each time window, and for each electrode-pairs, we identified the time delay of maximal inter-electrode correlation from raw voltage signals. *Variable Latencies*: We found that

the auditory pathway exhibited a gradient of delays, with posterior temporal regions leading anterior temporal regions on average. However, the latencies between stages of auditory processing were not stable and fluctuated over time. Two distinct electrophysiological states were evident: one characterized by longer inter-channel latencies (propagating state), and the other shorter latencies (synchronized state). We also observed that latency changes were not confined to local region but global patterns change between these two states. *Low-Frequency Power*: Latencies were longer during bursts of 6-16 Hz power (propagating state) and were shorter during bursts of broadband power (synchronized state), consistent with models in which low-frequency oscillations regulate corticocortical interactions. The inter-regional delays were mostly endogenous, as the correlation between responses under repeated stimulus was weak. *Computational Model*: We designed a computational model for the inter-regional flows using a Stuart-Landau coupled oscillator model. Employing a network topology derived from human neocortical anatomy, we reproduced the inter-regional correlation and delay pattern. Our model indicates that inter-regional latencies increase when the strength of inter-regional influence are increased. Altogether, the data and models suggest that the couplings between human cortical regions are not stable in their delays, and that instead they transition between synchronized (associated with higher broadband power) and propagating states (associated with higher lower-frequency 6-16 Hz power).

Abstract: Hippocampal CA1 pyramidal neurons and interneurons exhibit complex and highly variable firing dynamics that play a key role in modulating the dynamics of the network to which they belong. These patterns can be successfully described by morphologically and biophysically realistic conductance-based models [1], but they cannot be easily reproduced by point neuron models. This can be fundamental when dealing with very large-scale networks including multiple brain areas/regions, because of the current technical limitations of supercomputer systems. Building up on a previous work [2], we have implemented an enriched Extended generalized leaky integrate-and-fire (E-GLIF) model for hippocampal CA1 pyramidal neurons and interneurons including more flexible reset rules for the membrane potential and intrinsic currents at each spike event. The aim is to reproduce the rich set of electrophysiological behaviours of hippocampal CA1 neurons as a functions of the incoming current (injected or synaptic). The linear nature of the equations (in contrast with other implementations), and an ad-hoc nondimensionalization procedure, allowed us to sensibly reduce the number of parameters and compute more tractable analytic solutions. This approach gave us the ability to perform a rigorous analysis of the equilibria stability as well as the monotonicity properties of the membrane potential as a function of the model's parameters. Furthermore, it was possible to determine general constraints on the model parameters, which were optimized against experimental findings. Such constraints, linked to the type of firing, lead to different functions for the reset rules depending on the pattern considered. Differently from the linear G-LIF models proposed in a recent work, which require a special set of experimental protocols and features, the optimization process for our model is based on basic experimental data such as spike numbers and spike-times.
The models have been validated against electrophysiological data recorded from hippocampal neurons activated by external (constant) stimuli. However, the models can reproduce typical firing behaviour of hippocampal CA1 pyramidal neurons and interneurons also in the presence of synaptic inputs. Finally, these reset rules can contribute in creating infinite copies of neurons statistically indistinguishable within the experimental variability ranges, therefore increasing the ability to better reproduce the full range of realistic firing scenarios, to build realistic circuits. 1. Abstract: The coupling of a bottom-up modeling approach with simplified neuron models represents a valuable strategy to simulate large-scale brain networks dynamics and high-level behaviors. In the present work, a data-driven and computationally efficient point-neuron representation is at the basis of a full-scale spiking network model of activity propagation within a mouse CA1 region. The network building computational effort was greatly reduced by exploiting a recently developed boosting modelling framework for Python, the Brain Scaffold Builder module (BSB), which provides multiple placement and connectivity strategies enabling simulations of arbitrary experimental conditions. Excitatory and inhibitory neurons (10% excitatory-inhibitory ratio) were placed in the simulation volume according to the Blue Brain Cell Atlas. Neuron pairs specific connectivity was obtained by modeling the geometrical probability volumes associated to pre-synaptic axons and post-synaptic dendrites. The neuronal morphological features (axonal and dendritic arborization shape and extension) were taken from literature and from Neuromorpho.org and MouseLight databases. Similarly to the formalism adopted in DTI tractography, for the majority of cell types the axonal probability volume was modelled as an ellipsoid and it was parametrized as a covariance matrix (eigenvalues corresponded to the semiaxes lengths while eigenvectors corresponded to 3D orientations). Dendritic arborizations were parametrized either as conical volumes with different heights, radii and orientations or as a combination of ellipsoids. This parametric description of axonic and dendritic volumetric extent allowed to consider the experimentally observed preferential orientation of pyramidal cell axons along the direction of the minimum distance between CA3 and subiculum, thus implementing the strong directionality in Pyramidal-to-Pyramidal activity propagation along transversal hippocampal slices that has been observed experimentally. Cell pairs were connected through a short-term dependent plasticity synapse model showing facilitation and depression as in Ecker et al 2020. Single neuron electrophysiological properties were implemented following a new G-lif implementation of hippocampal pyramidal neurons and interneurons.The initial benchmarks and validations reported in this work, show that by exploiting the BSB modeling framework and NEST simulator it is possible to build, with a

relatively easy workflow, a full-scale data driven network with biological plausible features able to reproduce the essential functional activity of a large scale circuit.

Title: The Brain Scaffold Builder: a new neuroinformatic framework for realistic brain modelling, a cerebellar use case

Authors: R. DE SCHEPPER[1], A. GEMINIANI[1], S. MASOLI[1], M. RIZZA[1], A. ANTONIETTI[1], E. D'ANGELO[1,2], ***C. CASELLATO**[1];
[1]Dept. of Brain and Behavioral Sci., Univ. of Pavia, Pavia, Italy; [2]IRCCS Mondino Fndn., Pavia, Italy

Abstract: Data-driven modelling of the brain requires a neuroinformatic framework implementing a general strategy to accommodate experimental data at different scales. To this end, we have developed the Brain Scaffold Builder (BSB), a tool for structural and functional microcircuit modelling. The BSB provides an organized staged workflow, multiple strategies for cell placement and connectivity, a configuration system capable of including detailed neuronal and synaptic models and the support for multiple simulators with transparent parallel processing. It is provided as an open-source package, applicable for multi-scale modelling of different brain areas. The interfaces with several simulators (NEURON, NEST, Arbor) allow to investigate the same brain region at different levels of resolution, depending on the scientific question about structure-function relationship. BSB effectiveness was tested on the cerebellar network, which has a complex geometry and raises a broad set of modelling challenges. For the first time, an entire module of mouse cerebellar cortex was reconstructed using morphologically realistic conductance-based multi-compartmental neuron models of granule, Golgi, Purkinje, stellate and basket cells. Different connection rules, such as convergence-divergence, touch detection and

voxel intersection, were used to generate the connectome, unifying a collection of scattered experimental data into a coherent construct. Baseline and sensory-burst stimulation were used for functional validation against *in vivo* recordings, monitoring the impact of subcellular and cellular mechanisms on signal propagation and spatio-temporal processing in the cerebellum. The integration of structural and functional properties through the model provides a new "ground truth" about cerebellar circuit organization capable of predicting neural dynamics *in vivo*.

Title: The shape of spectral peaks of EEG alpha-rhythms: Gaussian or not?

Authors: *N. SCHAWORONKOW[1], A. S. BENDER[2], B. VOYTEK[1,2,3,4];
[1]Cognitive Sci., [2]Neurosciences Grad. Program, [3]Halıcıoğlu Data Sci. Inst., [4]Kavli Inst. for Brain and Mind, Univ. of California San Diego, La Jolla, CA

Abstract: The alpha-rhythm is the most prominent oscillation in the human brain, characterized in the spectral domain by a peak in the 8-13 Hz frequency range. This spectral peak has been modelled frequently using the Gaussian distribution (Donoghue, Haller et al., 2020; Chiang et al., 2011; Blankertz et al., 2010), using a central frequency and a bandwidth parameter. We examined the Gaussian assumption using a large developmental EEG dataset using resting data in eyes open and eyes closed conditions of approximately five minutes in length. Data was available for 1205 participants, with ages ranging from 5 to 21 years.
We first computed the EEG power spectrum using Welch's method. Then the 1/f-component of the spectrum was fitted and subtracted. Recordings with a minimum spectral peak height of 10 dB (1/f-corrected) in the alpha-range were selected, retaining only datasets with a very high signal-to-noise ratio. The spectral peak was modelled using different types of probability distributions, centered around the individual alpha-peak: Gaussian, Laplace, Gamma as well as a kernel density estimation procedure. We find that spectral alpha-peaks for high signal-to-noise ratio exhibit a shape that is not well captured by a single Gaussian, underestimating the peakedness of the distribution, resulting in a reduced height of the spectral peak when modelled

by a Gaussian. In several instances, the spectral peak exhibited a non-symmetric skew and was not uni-modal. We illustrate how spatial-spectral decomposition can be applied to recover uni-modal spectral peaks to reduce the effects of rhythms with different peak frequencies overlapping in space and time.
An improved characterization of the shape of oscillatory peaks is informative for different purposes. First, this will lead to improved spectral parametrization procedures using for instance more appropriate basis functions for the spectral peaks. Second, a better spectral peak characterization may be helpful in deriving functional models of the alpha-rhythm, for instance, for disambiguating between dampening and desynchronization models (Liley & Muthukamaraswamy, 2020). The spectrum is a summary measure of neural oscillations, and the temporal structure of the alpha-rhythm exhibits more complexity than is commonly appreciated. But as spectra are easily computable, it would be of interest to exploit information present in spectra to the fullest extent to the most degree, for instance regarding long-range temporal correlations or waveform shape. Understanding the mechanisms underlying oscillatory activity in the human brain and their link to perception and cognition is central to understanding how our brain works.

Title: Resting state metabolite concentrations in the anterior cingulate cortex and their influence in inter-subject variability in Laser-Evoked-Potentials

Authors: *O. ORTIZ[1], J. ARCHIBALD[1,2], J. K. KRAMER[1,3,4,5];
[1]Intl. Colaboration on Repair Discoveries (ICORD), Vancouver, BC, Canada; [2]Dept. of Exptl. Med., [3]Dept. of Anesthesiology, Pharmacol. and Therapeutics, Fac. of Med., Univ. of British Columbia, Vancouver, BC, Canada; [4]Djavad Mowafaghian Ctr. for Brain Hlth. (DMCH), Vancouver, BC, Canada; [5]Hughill Ctr., Vancouver, BC, Canada

Abstract: Inter-subject variability is a major limiting factor for the adoption of Laser evoked potentials (LEPs) in clinical settings for the diagnosis of pain and pain conditions such as neuropathy. LEPs show clear deflections at latencies compatible with the conduction velocity of A δ-fibers, and the largest deflection is a negative-positive N2/P2 waveform measured at the scalp vertex. The anterior cingulate cortex (ACC) has been identified as one of the main cortical

generators of this waveform, and recently, an increase of glutamate (Glu) and glutamate + glutamine (Glx) concentrations in this region have been reported during the onset of pain. Here, we performed a correlational study using proton magnetic resonance spectroscopy (^{1}H-MRS) and surface electroencephalography (sEEG) to determine if resting state concentrations of Glu and Glx in the ACC can account for some of the inter-subject variability in the amplitude and latency of the N2/P2 components across a common level of pain perception. Four different levels of laser stimulation were presented, and inter-subject pain perception was controlled by analyzing a subset of LEPs rated to feel the same (i.e. same rating in the numeric rating scale) across all subjects. ^{1}H-MRS data were collected in an 8 mL voxel using a 3T Philips scanner. Food intake was standardized before data collection and females were tested only during their follicular phase. Preliminary results (n=4, 1f, mean age = 22.7 ± 5.5) show a negative inter-subject trend between then N2 amplitude and resting state concentrations of Glu and Glx (Glu, R^2=-0.71, p =0.29; Glx, R^2=-0.80, p=0.20) when controlling for perceived stimulus intensity. Furthermore, P2 amplitude also demonstrated a smaller negative trend with resting state concentrations of Glu and Glx (Glu, R^2=-0.51, p =0.49; Glx, R^2=-0.53, p=0.47). The latency of the N2 component also showed a positive trend with increasing levels of Glu and Glx (Glu, R^2=0.66, p =0.34; Glx, R^2=0.76, p=0.24). This relationship will be further examined in a larger cohort of healthy participants and other sEEG outcomes related to pain such as gamma-band oscillations will also be examined with relation to resting state concentrations of Glu and Glx. Understanding how the underlying biochemical environment of cortical generators affects inter-subject amplitude and latency of LEPs can help their implementation in clinical settings.

Title: Brain asynchrony following infection with SARS-CoV-2: Physiologic evidence based on electroencephalography and machine learning.

Authors: H. VALSAMIS[1,2], S. ABDUL BAKI[1,2,3], J. LEUNG[4], G. CHARI[1,2], I.-Y. RASHEED[1,2], B. WONG[1,2], V. PUNIA[5], D. NAIR[5], A. KANIECKI[5], M. EDHI[4], ***C. SAAB**[4,6,7]; [1]SUNY Downstate Hlth. Sci. Univ., New York, NY; [2]Kings County Hosp. Ctr., New York, NY; [3]Biosignal group, New York, NY; [4]Biomed. Engin., [5]Neurol., Cleveland Clin., Cleveland, OH; [6]Engin., Brown Univ., Providence, RI; [7]Case Western Reserve Univ., Cleveland, OH

Abstract: The high prevalence of symptoms consistent with central nervous system pathology following SARS-CoV-2 infection is contrasted by a lack of clinical tools to objectively assess

these symptoms and a poor understanding of their pathophysiology. Prior research based on the visual interpretation of electroencephalography (EEG) in patients with COVID-19 (C19) failed to identify distinct EEG signatures that discriminate between pre-existing illnesses and novel C19 pathology in the brain. Here, we performed quantitative analysis of EEG using a fully-automated EEG processing pipeline in large cohorts of patients at Cleveland Clinic, Ohio and Kings County Hospital Center, New York (n=156). First, compared to hospitalized patients prior to C19 in the same clinical environment, resting state global EEG power (averaged from 15 channels) in patients with confirmed C19 diagnosis is decreased in the 4-8 Hz theta band (0.19 $\mu V^2/Hz$ in C19+ vs. 0.22 $\mu V^2/Hz$ in C19-, $p = 0.011$), and increased in the 31-50 Hz gamma band (0.016 $\mu V^2/Hz$ in C19+ vs. 0.011 $\mu V^2/Hz$ in C19-, $p = 0.0064$). Moreover, phase amplitude coupling (PAC) between the theta phase and the gamma amplitude was lower in C19+ patients. Second, C19+ patients were distinguished from C19- patients with 71% accuracy using a binary neural net algorithm trained on PAC and spectral power features. These results demonstrate significant effects of SARS-CoV-2 on brain dynamics, particularly cross-frequency synchrony between bands known to have distinct biophysical mechanisms. This may potentially explain altered cognitive states in C19 'long-haulers' with neurological sequelae. Machine learning results, relative to visual analysis of EEG, further provide unbiased evidence for the impact of SARS-CoV-2 on brain activity irrespective of confirmed medical diagnosis or symptomatology, suggesting that a similar approach could be developed in the future to predict the trajectory of C19 disease.

Title: Transient neural oscillations reveal new biomarkers for therapeutic transcranial magnetic stimulation for MDD and PTSD

Authors: *A. MORRIS[1], S. TEMEREANCA[2], A. ZANDVAKILI[1], D. D. SLIVA[2], A. TYRKA[3], B. GREENBERG[1], L. CARPENTER[3], N. PHILIP[1], S. R. JONES[2];

Abstract: Repetitive transcranial magnetic stimulation (TMS) is a therapy for major depressive disorder (MDD) and post-traumatic stress disorder (PTSD). TMS effectiveness varies across patients and optimal protocols are unknown. Electroencephalography (EEG) examines changes in brain dynamics associated with TMS (Zandvakili et al, 2019). Standard EEG analysis methods investigate oscillations in highly averaged data. Recent studies indicate that, in non-averaged signals, EEG oscillations often emerge as brief high power transients, coined "events" (Jones, 2016; Shin et al, 2017). We applied such methods to identify and analyze event features in an attempt to describe novel biomarkers of TMS and their relationship to clinical outcomes. We collected resting 8-channel EEG before and after therapeutic TMS applied to the left dorsolateral prefrontal cortex in 23 patients with comorbid MDD and PTSD. Using our open-source toolbox (https://github.com/jonescompneurolab/SpectralEvents) we tested if resting state oscillations can be quantified as events in non-averaged data using 2-second windows. We then assessed if event characteristics - including event number, power, duration, or frequency span - changed after TMS or correlated with symptom improvement. Averaged omnibus power spectral density in resting EEG data revealed distinct peaks in canonical frequency bands including delta/theta (1-6 Hz), alpha (7-14 Hz), and beta (15-29 Hz). Investigation of non-averaged signals showed that oscillations in each band emerged as transient high-power events before and after TMS. Across all subjects, the number of frontal delta/theta ($p = 0.023$) and alpha ($p = 0.023$) events and the duration of medial delta/theta ($p = 0.001$) events decreased after TMS. Pretreatment event characteristics correlated with subsequent clinical response. Frontal delta/theta event frequency span was negatively associated with MDD & PTSD improvement ($r^2 = 0.24, 0.22$); medial alpha event power and duration were positively associated with MDD improvement ($r^2 = 0.17, 0.19$) whereas medial alpha event rate and duration were positively associated with PTSD improvement ($r^2 = 0.18, 0.18$); and frontal beta duration was negatively associated with PTSD improvement ($r^2 = 0.18$). Novel methods to characterize spectral events in non-averaged signals successfully identified transient periods of high power activity in resting state EEG data and provided insight into changes in event features potentially predictive of TMS treatment response. With further effort, transient signatures in EEG oscillations may provide new biomarkers of response and a better mechanistic understanding of TMS.

Title: Clock time: a foreign measure to brain dynamics

Authors: *S. VAN BREE[1,2], M. MELCÓN[3], L. KOLIBIUS[1,2], C. KERRÉN[4], M. WIMBER[1,2], S. HANSLMAYR[1,2];

Abstract: Human thought is highly flexible and dynamic, achieved by evolving patterns of brain activity across groups of cells. Neuroscience aims to understand cognition in the brain by analysing these intricate patterns. Here, we argue that this goal is impeded by the time format of our data - clock time. The brain is a system with its own dynamics and regime of time, with no intrinsic concern for the human-invented second. A more appropriate time format is cycles of brain oscillations, which coordinate neural firing and are widely implicated in cognition. These brain dynamics do not obey clock time - they start out of tune with clock time and drift apart even further as oscillations unpredictably slow down, speed up, and undergo abrupt changes. Since oscillations clock cognition, their dynamics should critically inform our analysis. We describe brain time warping as a new method to transform data in accordance with brain dynamics, which sets the time axis to cycles of clocking oscillations (a native unit) rather than milliseconds (a foreign unit). We also introduce the Brain Time Toolbox, a software library that implements brain time warping for electrophysiology data and tests whether it reveals information patterns in line with how the brain uses them.

Title: Individual slow wave events give rise to macroscopic fMRI signatures and drive the strength of the BOLD signal in human resting-state EEG-fMRI recordings

Authors: *M. ILHAN-BAYRAKCI[1], Y. CABRAL-CALDERIN[2], T. O. BERGMANN[3,1], O. TÜSCHER[1,3], A. STROH[3,1];
[1]Leibniz Inst. for Resilience Res., Mainz, Germany; [2]Max Planck Inst. for Empirical Aesthetics, Frankfurt, Germany; [3]Johannes Gutenberg-University, Mainz, Germany

Abstract: The slow wave state is a general state of quiescence that is interrupted by sudden bursts of activity or so-called slow wave events (SWE). Importantly, it is considered as the default activity of the cerebral cortex. Recently, the relationship between slow wave events and functional MRI (fMRI) blood oxygen level–dependent (BOLD) signals has been assessed in a rodent model which revealed a cortex-wide BOLD activation pattern. However, it remains unclear which macroscopic signature corresponds to these specific neurophysiological events in the human brain. Therefore, we analyzed well characterized simultaneous EEG-fMRI data during human Non-REM sleep. SWE were identified in the EEG data adapting a toolbox specific to slow wave detection. The individually detected SWE were then used as predictors in event-related fMRI analyses to examine the relationship between task-free, resting-state fMRI signals and slow wave events. For all 10 subjects we identified significant changes in BOLD activity in association with slow wave events covering substantial parts of the cortical and subcortical gray

matter. In line with the findings of the animal studies, we show a direct relation of a characteristic, non-oscillatory neurophysiological event to specific BOLD activation patterns. Notably, we found a correlation between the number of SWE and the spatial extent of these specific BOLD activation patterns, and we show that the strength of the BOLD response strongly depends on the amplitude of the SWE. Our study puts forward both a novel pipeline for analyzing resting state EEG - fMRI data based on well-defined events to be used as a regressor, and, provides direct evidence for a relation between the strength of a neuronal signal and its representation in BOLD fMRI. This is particularly important with regard to subsequent studies in early stages of neuropsychiatric disorders. As recent findings suggest hampered SWE propagation in neuropsychiatric diseases, it is critical to resolve the brain's slow wave activity state network architecture, which holds the potential for establishing an early imaging biomarker and a novel target for early treatment for a variety of diseases long before disease onset.

Title: Sex-related Differences in Cortical EEG, Hippocampal LTD and De-depression Following Prolonged Exposure to Deep Coma Isoflurane Anesthesia

Authors: R. TADAVARTY, T. MARIAM, X. DONG, ***P. SOJA**;
Pharmaceut. Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Cortical EEG activity beyond the isoelectric EEG of deep coma induced by inhalational anesthetics is poorly understood. Specific patterns of activity emerge in the EEG, as the dose of anesthetic is increased. In animal studies, when ISO % is increased, EEG activity changes from large-amplitude slow wave to burst suppression pattern, followed by an isoelectric EEG. Beyond the isoelectric EEG, randomly occurring fast, large-amplitude spikes (FLAS) appear. Since the transfer of information between the cortical and hippocampal networks is bi-directional, it is possible for activity in either of these networks to induce reciprocal changes in the other (PLoS One 2013; 8(9):e75257). However, the functional consequences within the hippocampal networks during this state are not known. The present study examined the effects of prolonged exposure to deep ISO (5%) on long-term depression (LTD) and de-depression (DD) of the excitatory post-synaptic potential (fEPSP) in the CA1 region of the hippocampus. We also

examined if changes to LTD and DD are sex-specific. Adult male or female Sprague Dawley rats (~ 600 g) were anesthetized and cortical EEG were recorded using screw electrodes positioned in S1 bilaterally. ISO % was gradually increased to 5%, representing a state of deep coma. This anesthetic plane was then maintained for over 4 h during which FLAS waves were continuously monitored, and the brains were removed subsequently for *in-vitro* experiments. Hippocampal slices were prepared from either naïve or ISO-exposed rats using standard procedures. CA1 field EPSPs were evoked by stimulating the Schaffer collaterals. LTD was induced using a low-frequency stimulation (1 Hz, 1200 pulses). After following LTD for 30 min, LTD was reversed using DD stimuli (4 X 100 Hz, 10 s inter-stimulus interval). When animals were exposed to ISO 5% for ~ 4 h, there was a significant reduction in the LTD of fEPSPs in males. Indeed, the DD stimuli, elicited a significant potentiation of the fEPSP. In females, however, LTD was not affected and DD stimuli reversed LTD to pre-tetanic baseline levels. At 1, 2, 3, and 4 h of deep ISO coma, the average number of FLAS waves recorded in 30 min epochs measured 12, 41, 88, and 119 in male rats and only 9, 14, 19, and 27 in female rats, respectively. LTD, among its other role(s) serves to balance the overall excitability of neural networks. Sustained deep ISO (5%) would be expected to "flood" the entire brain and thereby depress all neural activity. The greater FLAS wave activity that occurs during deep ISO coma and the accompanying marked suppression of LTD reversal in the male brain may reflect a novel sex-related shift toward excitatory processes requiring further study.

Title: Fingerprint of essential tremor on motor adaptation

Authors: *F. BLONDIAUX[1,2], L. LEBRUN[2,3], B. J. HANSEEUW[2,3], F. CREVECOEUR[1,2]; [1]Inst. of Information and Communication Technologies, Electronics and Applied Mathematics, Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Inst. of Neurosci., Univ. Catholique de Louvain, Brussels, Belgium; [3]Dept. of Neurol., Cliniques Universitaires Saint-Luc, Brussels, Belgium

Abstract: Objectives : Essential Tremor (ET), is characterized by involuntary oscillations of the limbs, mainly during voluntary movements. Although its origin remains unclear, there is a consensus on a neurogenic cause originating from a dysfunction of the cerebello-thalamo-

cortical loop. Given that previous studies highlighted a role of cerebellum in motor adaptation of eye and arm movements to changes in the environment, we sought to investigate the ability of patients with ET to adapt their movements in two different paradigms: an upper-limb adaptation task and a saccadic adaptation task. We reasoned that a deficit of adaptation observed in this population would constitute functional evidence supporting the hypothesis that ET is linked to cerebellar impairment.
Methods: We enrolled 40 volunteers, 20 ET patients (58.57 +- 15.45 years) along with 20 aged-matched healthy volunteers (56.79 +- 12.44 years). A neurological assessment confirmed their inclusion in the study. The task of saccadic adaptation consisted in performing saccadic eye movements towards a visual target that was jumped at the onset of saccade, resulting in an endpoint error. The task of upper-limb control consisted in visually-guided reaching movements disturbed by an orthogonal velocity-dependent force fields.
Results: During the saccadic adaptation task, reduced and slower adaptation was observed for the ET group in comparison with controls' behaviour. For the upper limb adaptation task, a lower asymptote characterized the learning curve of ET patients but the learning rates were comparable. In both tasks, we were able to dissociate movement components linked to anticipation and to online execution. The purely anticipatory phase of the movement, when feedback related to the movement was not yet available, did not reveal any significant differences between groups.
Conclusion: Altogether, our results suggest that ET patients' reduced adaptation may originate from impairment in online monitoring of their movements within a trial. These results could therefore expose an inability to correctly combine internal and sensory feedback, which in combination with the effect of sensorimotor delays leads to the production of tremor. These results support the hypothesis of a cerebellar involvement in ET, and could pave the way to create new tests to develop a positive diagnostic strategy and complement current clinical evaluations.

Title: Ptprd phosphatase inhibitors and pams for rls, alzheimer's neurofibrillary pathology and reward from addictive substances

Authors: *G. UHL[1], I. HENDERSON[2], E. D. LEVIN[3], W. WANG[4], D. K. JOHNSON[5], T. PRISINZANO[6];
[1]Univ. of Maryland and VAMHCS, Baltimore, MD; [2]Biomed. Res. Inst. of New Mexico, Albuquerque, NM; [3]Duke Univ. Med. Ctr., Durham, NC; [4]Pharm., Univ. of Arizona, Tucson, AZ; [5]Pharm., Univ. of Kansas, Lawence, KS; [6]Univ. of Kentucky, LExington, KY

Abstract: The receptor type protein tyrosine phosphatase PTPRD is highly expressed by neurons and concentrated in their presynaptic terminals. PTPRD's activation by extracellular binding partners is thought to change activity of its intracellular phosphatase in altering tyrosine phosphorylation of a number of synaptic proteins that include the tau kinases GSK3 beta and GSK3 alpha. Human PTPRD genomic variants are associated with Restless leg syndrome, densities of neurofibrillary tangles in Alzheimer's disease (AD) postmortem brains, levels of PTPRD expression in postmortem human brains and a number of addiction-associated phenotypes. Mice with reduced PTPRD expression display addiction, RLS and AD-related phenotypes. These and other results suggest that reduced PTPRD function would reduce reward from addictive drugs and that increased PTPRD function would reduce accumulation of neurofibrillary pathology and RLS symptoms. We now report that selected flavanols, especially quercetin, act as substrate-selective positive allosteric modulators of the ability of PTPRD's phosphatase to dephosphorylate phosphotyrosine (pY) GSK3 alpha/beta and thus to downregulate activity of this tau hyperphosphorylator. In silico docking studies provide a novel candidate mechanism for this action. We report that NHB1109, a novel analog of our lead compound PTPRD phosphatase inhibitor 7-BIA, displays good potency and selectivity in vitro, reasonable oral bioavailability and therapeutic index and ability to reduce mouse cocaine-conditioned place preference and rat remifentanil self administration. These results each support PTPRD as a novel target for new therapeutics that inhibit or enhance its activities in ways that should benefit these three common human disorders. Comparisons between quercetin effects on PTPRD's abilities to dephosphorylate pYGSK3 phosphopeptide *vs* its effects on dephosphorylation of other PTPRD substrates supports the novel concept of substrate-specific positive allosteric modulation.

Title: Electroencephalographic endpoints as translational central pharmacodynamic biomarkers of the activity of PRAX-944, a novel T-type calcium channel blocker for the treatment of essential tremor

Authors: *L. SCOTT, C. B. PURYEAR, G. BELFORT, T. SNYDER, S. RAINES, Z. A. HUGHES, A. WEHR, M. HARD, B. RAVINA, M. WITTMANN;
Praxis Precision Medicines, Cambridge, MA

Abstract: Essential tremor (ET) is the most common movement disorder affecting approximately 7 million patients in the United States alone. Mounting evidence suggests that tremor is caused by increased neuronal burst firing and oscillations in cerebello-thalamo-cortical circuitry, which is thought to be driven by T-type Ca^{2+} channel activity. Furthermore, T-type Ca^{2+} channels regulate EEG power in the sigma band (σ-power, 11-15 Hz) during non-rapid eye movement (NREM) sleep. Therefore, we sought to use modulation of NREM σ-power as a translational biomarker for assessing whether we can achieve potentially therapeutic levels of central blockade of T-type Ca^{2+} channels in humans at doses that are well tolerated. We tested the effects of PRAX-944, a novel selective T-type Ca^{2+} channel blocker in clinical development for the treatment of ET, in the rat harmaline-induced tremor model. PRAX-944 dose-dependently reduced tremor by 50% and 72% with 1 mg/kg and 3 mg/kg doses, respectively. Both reductions were significantly different compared to vehicle ($n=15-45$, $p<0.05$). Effects in the rat spontaneous locomotor assay were assessed, and although doses of ≥10 mg/kg reduced total distance moved ($n=10-20$, $p<0.05$), activity was not reduced at doses ≤3 mg/kg. NREM σ-power was used as a mechanistic biomarker of T-type Ca^{2+} channel blockade in rat and human studies. PRAX-944 produced robust dose-dependent effects on NREM σ-power in rats across a similar dose range that decreased harmaline-induced tremor. Notably, 1 and 3 mg/kg doses of PRAX-944 reduced NREM σ-power by approximately 30 and 50% ($n=11$, $p<0.05$), respectively. Data from healthy participants, in a within-subject dose-escalation Phase 1 study, showed similar robust and dose-dependent reductions in NREM σ-power across a wide and well-tolerated dose range (5-120 mg) ($n=8-10$ per dose, $p<0.05$). Importantly, NREM σ-power was reduced by approximately 25-50% at doses of 20-80 mg, with no meaningful further reduction achieved above 80 mg. Additional exploratory analysis on awake EEG periods showed that gamma frequency power was also reduced in a dose-dependent manner. Administration of PRAX-944 in rats and humans produced consistent effects on NREM σ-power, which may represent a robust and translational biomarker of T-type Ca^{2+} channel blockade. Reduced NREM σ-power in rats was observed at doses that reduced harmaline-induced tremor. The comparable reduction in NREM σ-power in humans indicates that robust blockade of T-type Ca^{2+} channels was achieved at well-tolerated doses. These findings suggest that the doses of PRAX-944 tested here may hold promise for patients with ET.

Title: Effect of treatment with iron chelator NBMI on the expression of specific metabolic brain patterns in patients with multiple system atrophy and progressive supranuclear palsy: exploratory findings

Authors: *M. PEROVNIK[1,3], Ž. DRAKULIĆ[1], J. JAMŠEK[2], D. GEORGIEV[1,3], D. FLISAR[1,3], Z. PIRTOŠEK[1,3], M. TROŠT[1,2,3];

Abstract: Objective: To explore the effect of N1, N3-bis (2-mercaptoethyl sophthalamide (NBMI)) treatment on brain metabolism. **Background:** Multiple system atrophy (MSA) and progressive supranuclear palsy (PSP) are progressive, incurable atypical parkinsonian syndromes, characterized by accumulation of α-synuclein and tau protein, respectively. Abnormal protein aggregation can be triggered by elevated ferric iron concentrations and abnormal brain iron accumulation has been observed before. NBMI is a safe and efficacious membrane and blood brain barrier passing metal chelator and antioxidant that strongly binds toxic metals. **Methods:** This was a pilot exploratory, randomised, placebo-controlled, double blinded, cross-over, Phase 2a study to explore efficacy and safety of NBMI treatment in 20 MSA or PSP patients (EMERA006, EudraCT: 2018-000506-34). 2 MSA and 3 PSP patients were additionally scanned with FDG PET twice, at baseline and at last visit. We performed TPR network analysis to measure the expression of MSA-related pattern (MSARP) and PSPRP in all FDG PET scans (1). **Results:** Clinical and imaging data are presented in Table 1. One MSA patient progressed slower than normal compared to normal progression of MSARP and Unified MSA Rating Scale (UMSARS) historical data (1, 2). The other MSA patient progressed similarly compared to the reference data. One PSP patient improved based on decreased PSPRP expression score and reduction in PSP Rating Scale (PSPRS) score. One PSP patient progressed slower than normal compared to normal progression of PSPRP and PSPRS historical data (1, 3). One PSP patient progressed similarly compared to the reference data based on PSPRP expression, but did not progress based on PSPRS score. **Conclusion:** Treatment with NBMI may slow down the progression of neurodegenerative changes in MSA and PSP at least in some patients. Larger groups and longer follow-up are needed to further assess its efficacy on group level. **References:** 1. Perovnik M et al. *MDS 2021* [in press]; 2. Title: The effect of afferent feedback on tremor propagation: a modeling study

Authors: *I. SYNDERGAARD[1], D. B. FREE[2], S. K. CHARLES[3], D. FARINA[4];
[2]Mechanical Engin., [3]Mechanical Engin. and Neurosci., [1]Brigham Young Univ., Provo, UT;
[4]Bioengineering, Imperial Col. London, London, United Kingdom

Abstract: Tremor is the most common movement disorder, affecting over 10 million individuals in the United States alone. A new field of tremor research is *tremor propagation*, which refers to the way tremor spreads throughout the upper limb because of mechanical coupling and neural feedback. Understanding tremor propagation is important because it may allow us to determine which muscles are most responsible for tremor, and thus where to intervene to suppress tremor optimally. So far, we have investigated tremor propagation using only open-loop multiple-input multiple-output (MIMO) models [1, 2]. While these studies yielded many significant insights into the mechanisms of tremor propagation, they did not include known neural feedback mechanisms.We expanded on prior models by including the effects of Golgi tendon organs (modeled as pure homonymous force feedback) and muscle spindles (type Ia and type II signals, modeled together as homonymous and heteronymous proportional/derivative feedback) to create a closed-loop MIMO model of the upper limb. Feedback gains were gleaned from the literature and stability analyses. The subsystem transformation from neural input to muscle force was analyzed with and without force feedback to simulate the effect of Golgi tendon organs on tremor. The full model was then analyzed by averaging magnitude ratios at tremor frequencies under the following conditions: without feedback, with force feedback alone, with proportional/derivative feedback alone, and with both force feedback and proportional/derivative feedback.We found that force feedback significantly increased the system’s response at tremor frequencies, especially as neural round-trip travel time increased (i.e. for more distal muscles). Consequently, force feedback increased the system’s bandwidth, amplifying the effect of tremorogenic neural signals. Compounding the problem, force feedback decreased the system’s response at low frequencies (such as in holding a posture), requiring greater neural drive to complete a desired movement, which may increase the tremorogenic signal as well. In contrast, proportional/derivative feedback had little effect on the average magnitude ratio of the system.

However, since it included heteronymous feedback, proportional/derivative feedback did spread tremor between the degrees of freedom of the arm.According to our simulations, neural feedback has a significant influence on tremor and how it spreads throughout the limb. Therefore, neural feedback should be included in models of tremor propagation. Understanding tremor propagation may eventually allow us to determine where to intervene to optimally suppress tremor.

Title: Closing the loop on essential tremor in multiple subjects, using thalamic and cortical control signals

Authors: *B. PARKS, K. D. FOOTE, A. GUNDUZ;
Univ. of Florida, Gainesville, FL

Abstract: Essential tremor (ET) is a neurological disorder that is predominantly characterized by action tremor, is sometimes accompanied by rest tremor, and is one of the most common neurological disorders. Deep brain stimulation (DBS) of the ventral intermediate nucleus (Vim) region of the thalamus in an open loop setting is a common therapeutic strategy for tremor control. If tremor is not present during rest, continuous stimulation may lead to extraneous stimulation, potentially inducing side effects such as speech impairment, and may prematurely deplete the battery. Closed-loop DBS (CL-DBS) is a method of recording neurophysiology and triggering stimulation on only during specific epochs. As part of standard clinical care, a depth lead is placed within the Vim region; for the purposes of our study a cortical strip is placed over the primary motor cortex, specifically targeted at the hand knob region. Using an investigational bidirectional neurostimulator (Summit RC+S, Medtronic PLC), we recorded movement-related changes in spectral content from the cortical strip and the depth lead to implement cortical-based closed-loop (CL_C), and depth-based closed-loop (CL_D), respectively. To determine feasibility of both CL-DBS paradigms, movement tasks (goal-directed motions of the upper limbs), and holding tasks (maintaining position against gravity) are tested. The frequency band was independently chosen for each lead using a Fisher discriminant analysis, and was typically within the alpha/beta bands (8-30 Hz). The RC+S is equipped with a linear discriminant analysis, and utilizes the frequency band previously defined to check against a threshold for epoch determination. Here we show data collected from two patients, who both show consistent

performances using real-time power bands to drive closed-loop paradigms from either the cortex or the depth lead. Almost all trials, including both movement and holding tasks, performed above chance with $p < 0.05$ when using either the cortical or the depth lead to control stimulation. Clinical efficacy is simultaneously maintained, as determined by a tremor rating scale (TRS) score. All stimulation trials showed a lower score (less tremor) compared to a preoperative baseline score, and all closed-loop trials (CL_C and CL_D) were substantially equivalent to open-loop DBS. As proof of concept in two separate subjects, we have shown that there is potential to use the depth lead alone for recording neurological signals and subsequently triggering stimulation on/off. Translating these results to a broader population may decrease number of battery placement surgeries while maintaining clinical benefit.

Title: Bi-hemispheric transcranial direct current stimulation promotes neuroplasticity and anticipates motor recovery in a mouse model of ischemic stroke

Authors: M. BOLLA[1], S. A. BARBATI[1], V. LONGO[1], A. RE[1], F. PACIELLO[1], M. RINAUDO[1], F. VECCHIO[2], P. M. ROSSINI[2], C. GRASSI[3], *M. V. PODDA[3];

Abstract: Introduction: Several studies have revealed that early treatment of ischemic stroke ameliorates stroke-related excess mortality and morbidity. However, stroke still represents one of the most common causes of death and long-term disability, so strategies promoting post-stroke functional recovery are necessary. For this purpose, we investigated the effect of bi-hemispheric transcranial direct current stimulation (tDCS, with the anode over the lesioned motor cortex and the cathode over the contralateral side) to promote motor function recovery and its mechanisms in a mouse model of motor cortex focal ischemia. **Methods:** Mice were subjected to Rose-Bengal photothrombosis in the forelimb area of the motor cortex. Seventy-two hours after stroke, mice underwent tDCS treatment (one session a day for 3 consecutive days). In order to evaluate motor function, grid-walking, single pellet reaching, and grip strength tests were performed. Local field potential recordings were used to assess brain connectivity. Western immunoblotting,

ELISA, qRT-PCR and Golgi-Cox staining were carried out to shed light on tDCS-promoted stroke recovery mechanisms. **Results:** Results showed an important role of tDCS to improve and anticipate motor recovery at the early subacute stage. In particular, tDCS was able to induce brain-derived neurotrophic factor (BDNF) expression and BDNF-dependent pathways, as well as to enhance structural plasticity and functional connectivity in motor and somatosensory cortices. The tDCS-promoted rescue was paralleled by enhanced plasma BDNF level, suggesting its potential role as circulating prognostic biomarker. Notably, in mice treated with BDNF TrKB receptor inhibitor (ANA-12) we did not observe the beneficial effects of tDCS on motor recovery and connectivity and the tDCS-induced increase of spine density, pERK, pCaMKII, pMEF and PSD-95. **Conclusions:** Our study points out that tDCS subacute treatment speeds up motor recovery after stroke. Here, enhanced BDNF expression following tDCS application appears fundamental to support the beneficial effects of tDCS. Therapies commonly adopted in stroke are based on physical rehabilitation, which is often delayed to a later stage when plastic responses are progressively lower. In this context, tDCS might be relevant to speed up and ameliorate post-stroke deficits in support of standard treatments.

Title: Role of astrocytic G6PD in oxidative stress and neuronal protection after ischemia

Authors: *Z. ZHANG, N. ZHANG, S. DING;
Univ. of Missouri-Columbia, COLUMBIA, MO

Abstract: Astrocytes are the predominant glia cell type in the central nervous system. Astrocytes are activated and experience notable changes in morphology, cell proliferation and gene expression after focal ischemic stroke (FIS). A growing body of evidence suggest that these reactive astrocytes play an important role in neuronal and brain protection after FIS. We found that glucose-6-phosphate dehydrogenase (G6PD), the rate limiting enzyme in pentose phosphate pathway (PPP), is highly unregulated in reactive astrocytes. PPP is a parallel pathway to glycolysis for glucose catabolism. In addition to providing essential metabolites for cell proliferation, PPP is vital for the production of NADPH which is essential for the production of reduced glutathione (GSH), the primary antioxidant for combating oxidative stress in disease condition. To study the effect of G6PD on metabolic reprogramming and oxidative stress after

ischemic stress, we overexpress G6PD in primary astrocytes through DNA transfection. We found G6PD overexpression significantly reduced extracellular acidification rate, an indirect measurement of glycolysis while did not affect oxygen consumption rate (OCR). Overexpression of G6PD increased the production of NADPH, but reduced NAD^+. Moreover, G6PD overexpression increased GSH with concurrent decrease in reactive oxygen species (ROS). Our results suggest G6PG overexpression causes metabolic shift from glycolysis to PPP without affecting mitochondrial function, and increases anti-oxidant capacity. Finally, G6PD overexpression can promote cell survival after oxygen-glucose deprivation (OGD) of astrocytes. Our results also show that the upregulated production of GSH dramatically decreases ROS production. In summary, our research suggests that reactive astrocytes can play an important role in neuronal and brain protection and recovery after ischemic stroke through reducing oxidative stress via increasing G6PD expression and promoting PPP might be a potential therapeutic approach for stroke.

Title: Elevated plasma neurofilament light chain levels predict improvement in the late phase after stroke

Authors: *M. PEKNA[1], A. STOKOWSKA[1], L. BUNKETORP KÄLL[1], C. BLOMSTRAND[1], J. SIMRÉN[1], M. NILSSON[2], H. ZETTERBERG[1], K. BLENNOW[1], M. PEKNY[1];
[1]Univ. of Gothenburg, Gothenburg, Sweden; [2]Univ. of Newcastle, Newcastle, Australia

Abstract: Background: Although functional recovery is most pronounced in the first 6 months after stroke, improvement is possible also in the late phase. We explored the value of plasma neurofilament light chain (NfL), a biomarker of axonal injury and secondary neurodegeneration, for the prediction of functional improvement in late phase after stroke.**Methods:** We measured baseline plasma NfL levels in 115 participants of a trial on the efficacy of multimodal rehabilitation in late phase after stroke. We determined the association between NfL levels, impairment in balance, gait and cognitive domains, and improvement 3 and 9 months later.**Results:** Plasma NfL levels were associated with the degree of impairment in all three domains. Individuals with meaningful improvement in balance and gait capacity had higher

plasma NfL levels compared with non-improvers (*P*=0.001 and *P*=0.018, respectively). Higher NfL levels were associated with improvement in balance (OR 2.34, CI: 1.35-4.27, *P*=0.004) and gait (OR 2.27, CI: 1.25-4.32, *P*=0.009). Elevated plasma NfL levels showed a positive predictive value for cognitive improvement, and this effect was specific for the intervention targeting the cognitive domain. The association of NfL levels with cognitive improvement withstood correction for baseline impairment, age and total years of schooling (OR 7.54, CI: 1.52-45.66, *P*=0.018).**Conclusions:** In addition to its established role as a biomarker in the acute phase, elevated circulating NfL levels may predict functional improvement in late phase after stroke. Our results should prompt further studies into the use of plasma NfL as a biomarker in late phase after stroke.

Title: Circuit specific plasticity changes after post-stroke optogenetic stimulation

Authors: *T. CHIANG[1], S. VAHDAT[4], A. V. PENDHARKAR[1], S. HARVEY[2], H. UCHINO[2], Z. CAO[1], A. KIM[1], M. CHOY[2], H. CHEN[1], H. J. LEE[2], M. Y. CHENG[1], J. H. LEE[3], G. K. STEINBERG[1];
[1]Neurosurg., [3]Neurol. & Neurolog. Sciences, Bioengineering, Neurosurg., [2]Stanford Univ., Stanford, CA; [4]Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Background: Functional recovery after stroke is attributed to rewiring of neural connections. We have demonstrated that optogenetic stimulations in the ipsilesional primary motor cortex (iM1) can promote functional recovery. Recently our brain imaging data indicate that iM1 stimulated mice can restore activation of the ipsilesional cortico-thalamic tract. To address whether iM1 stimulation enhanced post-stroke plasticity in the cortico-thalamic tract, we investigate the expression of plasticity markers in the ipsilesional thalamus (iTH). We also selectively stimulate the cortico-thalamic circuit and examine its effects on plasticity changes

and functional outcome. Methods: For iM1 stimulation, mice were injected with AAV1-CaMKIIa-hChR2 virus and implanted with optical fiber in iM1 (C57BL6 male mice, 6-7 weeks old). To selectively stimulate the cortico-thalamic circuit, mice were injected with AAV1-CaMKIIa-hChR2 virus in iM1 and an optical fiber was implanted in the ipsilesional thalamus (iTH). Six weeks were allowed for virus expression and mice underwent transient middle cerebral artery occlusion (tMCAo, 30min). Mice received optogenetic stimulations from PD5-14. Functional recovery was evaluated by rotating beam test at pre-stroke and post-stroke days (PD) 4, 7 and 14. Brain sections were immunostained with plasticity marker synaptophysin and imaged for co-localization of synaptophysin and ChR2. Western blot analysis of plasticity markers was performed for thalamic tissue. Results: Rotating beam test show significant functional improvement in iM1-stimulated mice (Stim group) when compared to non-stimulated mice (NoStim group). iM1-stimulated mice showed higher expression of axonal growth marker GAP43 in iTH. Immunostaining and co-localization analyses with pre-synaptic marker Synaptophysin indicate that iM1-stimulated mice exhibited higher co-localization of $ChR2^{+}$/$Synaptophysin^{+}$ terminals in thalamus. Furthermore, histology showed robust ChR2 is expression in the iM1-iTH motor cortico-thalamic circuit, and selective stimulation of this cortico-thalamic circuit is sufficient to improve recovery, Conclusion: Our results show that cortico-thalamic circuit is a key circuit involved in post-stroke recovery. Ongoing studies include investigating plasticity changes in the iTH as well as transcriptome profiling of the cortico-thalamic circuit.

Title: Analysis of miRNA patterns in peri-ischemia and secondary degenerating tissue after focal experimental stroke: beneficial impact by enriched environment

Authors: *J. ROMER[1], A. LADWIG[1], V. ZIMMERMANN[1], S. BLASCHKE[1], M. A. RÜGER[1], M. BERGAMI[2], G. R. FINK[1], M. SCHROETER[1];
[1]Dept. of Neurol., [2]CECAD, Univ. Hosp. of Cologne, Cologne, Germany

Abstract: Modifiable risk factors such as diet and physical inactivity have a large impact on the outcome of stroke. Specifically, hyperglycemia in stroke has been shown to lead to higher morbidity and mortality. Blood brain barrier disruptions and increased inflammation amongst others were postulated as possible contributing factors. On the contrary, exercise is known to have positive effects on the brain such as reduction of inflammation, increased synaptic plasticity and neuronal arborization. This study asks for the influence of miRNA signals on the functional modification of the behavioral outcome after focal cerebral ischemia in the cortical motor area. Male mice were housed in enriched environment (EE) or control conditions (CC) with a high fat (HFD) or normal chow diet (NCD). After 6 weeks mice were subjected to focal photothrombotic stroke (PT). At day 16 post PT, mice were sacrificed, RNA was extracted from the infarct tissue and ipsilateral subcortical tissue (thalamus; as secondary degenerating area) and their respective contralateral counterparts. Anti (miR-9, -22, -124, -181c)- and pro-inflammatory (miR-147, -155, -210) micro RNAs and downstream mRNAs (NF-kB, STAT3, GFAP, Iba1, Arg1 and iNOS) were analyzed by qPCR. Protein expression for Arg1 and iNOS were further examined by Western Blot. In the infarct tissue we found a diet dependent correlation between miRs, specifically miR-155 was found reduced in NCD compared to HFD. Subcortically, most miRs showed a positive correlation in CC, while in EE, miRs appeared to be more differentially regulated. We also found a negative correlation between functional recovery and miR expression in the infarct area in the CC groups, but no correlation in the EE groups. Further, NF-kB and STAT3 expression was found highest in the EE HFD group in all areas, correlating inversely with subcortical miR expression. Environmental and dietary changes differentially influence miRNA expression patterns in stroke tissue and distant secondary degenerating areas. In CC, inflammatory and non-inflammatory miRNAs and mRNAs reacted together while in EE those were found independent of each other suggesting an inhibition of inflammatory cascades. Changing miRNA patterns may pose a mechanism by which EE acts beneficially after stroke.

Title: Both functional and structural effects of an enriched environment (EE) and nutrition on the outcome after experimental stroke in mice

Authors: *M. SCHROETER[1], A. LADWIG[1], V. ZIMERMANN[1], J. ROMER[1], S. BLASCHKE[1], H. BACKES[2], A.-L. CREMER[2], M. ASWENDT[1], D. WIEDERMANN[2], S. VLACHAKIS[1], M. A. RUEGER[1], M. BERGAMI[1], G. R. FINK[1];
[1]Univ. of Cologne, Cologne, Germany; [2]Max-Planck Inst. for Metabolism Res., Cologne, Germany

Abstract: Background: Stroke is the second most common cause of death worldwide and the most common cause for disability in adulthood in Germany. Comorbidities like diabetes and obesity have been shown to worsen the outcome, while physical therapy and an active lifestyle can ameliorate it. Aims: We examined the functional and structural effects of an enriched environment (EE) and nutrition on the mice outcome after experimental stroke. Methods: Male mice were housed in EE or control conditions (CC) with a high fat (HFD) or normal chow diet (NCD). At week 6, mice were subjected to focal photothrombotic stroke (PT). T2-weighed MRI imaging at day 2 after stroke measured infarct size. A neuroscore, a grid walk test, and an open-field test were performed for functional neurological assessment. PET imaging was performed before the stroke and at days 1 and 14 post-stroke. A week before and after PT, the mice underwent glucose and insulin tolerance tests. Immunohistochemistry (IHC) assessed neuronal damage, infarct volume, neovascularisation, glial scar formation, and microglial activation and polarization. Atlas-based brain mapping was used to identify specific brain regions of interest for analysis and correlation with PET and MRI data. Results: While mice in EE did not show any significant weight gain under HFD, they exhibited an impaired glucose tolerance compared to the group in CC. Immediately after stroke and during recovery, the EE NCD group showed better scores on the functional tests, although there was no significant difference between infarct size on MRI or FDG uptake in PET at day 2. On day 14, however, the EE group showed improved FDG uptake. IHC revealed an increased Arg1/iNOS ratio in the infarct, a denser infarct scar, and reduced astrogliosis in non-infarct brain tissue. Specifically, the EE NCD group revealed an inverse correlation of Iba1 and GFAP+ cells in most brain regions. Conclusion: EE improves functional outcomes after stroke. Immediate effects are possibly due to whole-brain network effects between neuronal and glial cells due to exercise in EE, while long-term effects might be caused by a better containment and improved pro-/anti-inflammatory balance within and around the infarct tissue.

Title: Testing the effects of common medications on VNS-mediated plasticity

Authors: *T. DANAPHONGSE, R. MORRISON, S. ABE, K. ADCOCK, V. EZHIL, A. SOMANEY, M. KILGARD, S. HAYS;
Univ. of Texas, Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) paired with rehabilitative training enhances recovery of function in a range of neurological injuries such as stroke, post-traumatic stress disorder, and spinal cord injury. Previous studies suggest that VNS-dependent recovery of motor function is supported by synaptic plasticity within central networks via activation of cholinergic, noradrenergic, and serotonergic systems. Patients undergoing VNS-paired rehabilitation are commonly prescribed medications that influence these neuromodulatory systems for issues directly stemming from their specific neurological injuries, related comorbidities, or other unrelated conditions. Based on their mechanisms of action, it is possible that these medications may impact treatment in patients undergoing VNS therapy. Alternatively, the common clinical doses of these medications may not reach a level to substantially impair VNS-dependent effects on the central nervous system. Because these medications are often critical to maintaining quality of life for those who take them, a clear understanding of how clinically-relevant doses of these drugs is critical to the clinical implementation of VNS-based therapies. In this study, we tested the effects of commonly prescribed medications at clinically relevant doses on VNS-mediated plasticity. We trained rats to perform a motor task paired with VNS and daily injections of either oxybutynin, prazosin, duloxetine, or saline, and measured subsequent reorganization of the motor cortex, a robust marker for neural plasticity that underlies many VNS-dependent benefits.

A focal cortical lesion such as a stroke results in brain network changes in distant areas. Described as crossed cerebellar diaschisis the change of cerebellar (functional) activity is connected to recovery from stroke. Factors that can influence recovery are diet and exercise. Specifically, hyperglycemia and immobility are known risk factors for a poor outcome both in human and under experimental stroke conditions. In the present study we aimed to identify specific transcriptomic patterns in cerebellar tissue after experimental stroke in mice under different diet and environmental influences, to assess genomics in good versus poor recoverees after stroke in a paradigmatic way. Male mice were housed in enriched environment (EE) or under control conditions (CC) with a high fat (HFD) or normal chow diet (NCD). After 6 weeks mice underwent cortical photothrombotic stroke (PT). Functional tests assessed neurological deficits. 16 days post-infarct mice were sacrificed and RNA from cerebellar tissue was extracted. The transcriptome was sequenced and underwent bioinformatics analysis.We found most differentially expressed genes to be grouped into either inflammatory, cellular stress/ apoptosis, metabolic, neuroprotective, and in blood-brain-barrier associated pathways. In particular, EE ameliorated gene expression for neurotransmission and oxidative phosphorylation and decreased inflammatory genes, while the diet influenced mostly inflammation- and blood brain barrier associated genes. In conclusion, the combination of a healthy diet and physical exercise resulted in the most favorable outcome after stroke possibly due to gene expression modification in synaptic, neuroprotective, metabolic and anti-inflammatory pathways. This exploratory study thereby reveals molecular targets for improving the outcome after stroke.

Abstract: This study aimed to cluster multifaceted functional recovery patterns of first-ever stroke patients using the unsupervised learning algorithm of artificial intelligence (AI) and to examine the validity of clusters by generating the prediction model using the boosting algorithm. This study was an interim analysis of the Korean Stroke Cohort for Functioning and Rehabilitation (KOSCO) dataset, which is a prospective multicenter cohort. Multifaceted functional assessments were performed five or six times repeatedly from seven days to 24 months of stroke onset. Out of 7,858 patients enrolled, 4,389 ischemic stroke (IS) and 1,146 hemorrhagic stroke (HS) patients who completed the functional assessment at 24 months after onset were included in this analysis. In k-means clustering analysis, multifaceted functional assessment scores, demographic features, and clinical information were used as input variables. The optimal cluster k number was determined by finding the highest k with at least a silhouette score of 0.2. IS patients were clustered into 11 groups while HS patients were clustered into 13 groups. Using 70% of the dataset, the prediction model for clustering was generated using the boosting algorithm. The validity of the prediction model was examined using the rest 30% of the dataset. All statistical analysis was implemented using the R (version 4.0.3). In both IS and HS, each cluster showed distinct clinical characteristics and functional recovery pattern which included the overall high function group, the overall low function group, the gradual improvement group, the late declining group, etc. Each cluster also showed different mean age and initial stroke severity measured by NIHSS scores. In validation of prediction model using

boosting algorithm, both IS and HS clusters showed high prediction accuracy (IS, 0.805; HS, 0.881). In our knowledge, this is the first study performing successful clustering of long-term functional recovery pattern in ischemic and hemorrhagic stroke patients using AI. Early identification and accurate prediction of long-term functional outcome will be useful for developing customized treatment of these patients.

Title: Dorsal skull meningeal lymphatic vessels drain blood-solutes after intracerebral hemorrhage

Authors: *A. VIRENQUE[1], R. BALIN[1], S. ANTILA[2], K. ALITALO[2], F. M. NOE[1];
[1]Neurosci. Center, Helsinki Inst. of Life Science, Univ. of Helsinki, Helsinki, Finland; [2]Wihuri Res. Inst. and Translational Cancer Med. Program, Univ. of Helsinki, Helsinki, Finland

Abstract: Early intracranial hematoma drainage is crucial for the treatment of intracerebral hemorrhage (ICH). Currently, there are no available non-invasive strategies, which have been clinically approved as an aid in ICH resolution. The identification of novel therapeutic targets is therefore essential to develop safe and effective therapeutic strategies. Here we investigated the possible function of the meningeal lymphatic vessels (mLVs) in ICH resolution. To better identify the role of the mLVs we used two preclinical mouse models of ICH, mimicking focal cortical ischemic hemorrhage and subcortical extended hemorrhage, and characterized the dynamics of blood drainage through the dorsal mLVs. We also analyzed the effect of mLV drainage on the functional recovery after subcortical ICH, in mice presenting an acquired mLV deficit. After ICH induction in adult male and female mice, we observed a specific flow of blood-derived components within the mLVs, suggesting that the meningeal lymphatics can play a role in facilitating the hemorrhage drainage (no sex-related differences were observed). We also found that local formation of new mLVs is directly correlated with ICH-related neuroinflammation levels. Mice presenting acquired mLV dysfunction showed a delayed

recovery after ICH and a drop of functional connectivity in the areas affected by the intracranial hematoma. These findings suggest that meningeal lymphatics are involved in the resolution of ICH and could provide a valuable therapeutic target.

Title: A Novel WW Domain-dependent Interaction between Magi-2 and GluA1 Underlies a Potential Role in Synaptic Transmission in the Spinal Cord Dorsal Horn Following Inflammation

Authors: *G. SHEEHAN[1], J. KRISHNAN[1], P. AHUJA[1], A. BHATTACHARJEE[2]; [1]SUNY at Buffalo, Buffalo, NY; [2]Univ. at Buffalo - The State Univ. of New York, Buffalo, NY

Abstract: Membrane-Associated Guanylate Kinase, WW and PDZ Domain Containing 2 (Magi-2, S-SCAM) is a synaptic scaffolding molecule containing 2 WW and 6 PDZ domains that has been shown to regulate glutamatergic synaptic transmission. Here we show for the first time a novel WW-domain dependent interaction with the AMPA receptor subunit GluA1. This interaction leads to protection from protein degradation promoted by cotransfection with the E3-ubiquitin ligase Nedd4L. Mutation of a previously unidentified WW-domain within the GluA1 C-terminus blocked this Nedd4L-depedent degradation and enhanced GluA1 protein expression in the presence of Nedd4L. In addition to the protective effect, simultaneous transient transfection of GluA1 and Magi-2 led to increased surface expression of GluA1 as measured by membrane biotinylation. This increase was recapitulated by a two-fold increase in glutamate-induced peak GluA1 current densities in transiently transfected HEK-293T cells. Owing to the importance of calcium-permeable GluA1 homomers and their enhanced contribution to EPSCs in the dorsal horn (DH) of the spinal cord following various insults to peripheral sensory afferents we sought to explore a physiological role for the interaction of Magi-2 and GluA1 in the spinal cord. Lumbar DH tissue was collected from WT C57BL/6J mice and co-immunoprecipitation of GluA1 was confirmed via Magi-2 pulldown. Confocal immunofluorescence further illustrated colocalization of GluA1 and Magi-2 along dendrites in the superficial DH. Overall, Magi-2 was shown to have somewhat restricted expression in Lamina 1 and 2o, as well as in deeper lamina 4/5 with a higher degree of colocalization with TacR1 expressing neurons in Lamina 1 and 2

compared to PKCy expressing neurons in lamina 2i and 3. To probe for a role for Magi-2 in pain behaviors, lumbar SC tissue was taken following peripheral administration of CFA. An increase in the Magi-2 alpha isoform was seen in the ipsilateral DH. Further experiments will explore the behavioral and *ex vivo* electrophysiological effect of spinal cord DH Magi-2 knockdown in basal and inflammatory pain conditions.

Title: Magi-1 deficiency decreases thermal sensitivity and increases hindpaw weight bearing in a nerve entrapment mouse model of neuropathic pain

Authors: *M. MARTIN[1], A. BHATTACHARJEE[2];
[1]State Univ. of New York, Buffalo, Buffalo, NY; [2]Univ. at Buffalo - The State Univ. of New York, Buffalo, NY

Abstract: Neuropathic chronic pain is a leading cause of disability that can be caused by nerve entrapment, nerve injury, diabetes, viral infection, and chemotherapy. Current treatments either lack efficacy or have adverse side effects including abuse liability. Application of local anesthetics, which blocks all sodium channels, is currently considered as a first line treatment strategy for neuropathic pain. Instead of blocking sodium channels, an alternative method to treating neuropathic pain could be to disrupt their trafficking. Recent studies have indicated that WW domain-containing ubiquitin ligases are downregulated during nerve injury causing an increase in membrane targeting of sodium channels. The scaffold proteins responsible for sodium channel targeting and membrane stabilization in DRG neurons have not been fully characterized but our recently published studies identified the WW domain containing scaffold protein called Magi1, as a potential candidate (PMID: 30860870). Using an *in vivo* sciatic nerve knockdown approach strategy, we tested the consequences of Magi1 knockdown after established neuropathic pain. We used the sciatic nerve cuff model, which models nerve entrapment injury, in male and female mice. The Hargreaves thermal assay and dynamic weight bearing assay was used to confirm unilateral neuropathic pain, and was then followed by Magi1 *in vivo* knockdown. Magi1 knockdown was confirmed by Western analyses. We found an

increase in the thermal withdrawal latency during Magi1 knock-down in neuropathic mice compared to the shRNA treated mice. We also saw an increase of the percent weight borne on the ipsilateral paw in the Magi-1 knock-down mice using dynamic weight-bearing measurements compared to scrambled shRNA treated mice. Future studies will examine the consequences of Magi-1 knockdown on the electrophysiological properties of DRG neurons. Our studies reveal Magi-1 as a potential analgesic target for analgesia for nerve entrapment-induced neuropathic pain.

Title: Dynamic Weight Bearing More Closely Resembles the Thermal Hyperalgesia Phenotype, rather than Mechanical Allodynia during Sciatic Nerve Cuff-induced Neuropathic Pain

Authors: G. SHEEHAN, M. K. MARTIN, ***A. BHATTACHARJEE**;
SUNY-Buffalo, Buffalo, NY

Abstract: Chronic constriction injury (CCI) of the sciatic nerve is a widely used model of neuropathic pain in rodents and two common behavioral phenotypes observed following CCI are thermal hyperalgesia and mechanical allodynia, as measured by the Hargreaves and Von Frey tests respectively. In this study, we used the sciatic nerve cuff variant of CCI in mice, which models nerve entrapment neuropathic pain in humans. Typically, thermal hyperalgesia recovers within 28-30 days following nerve cuff, while mechanical allodynia persists for at least 60 days (PMID: 18006342). Reflexive mechanical allodynia during CCI and indeed other neuropathic pain models, have been extensively used to model “chronic pain” where circuitry changes that occur in the lumbar spinal cord can be studied. Here we propose that in contrast to these evoked measures of nociceptive hypersensitivity, Dynamic Weight Bearing, where an unrestrained animal is allowed to freely roam, provides a more clinically relevant behavioral measure of ongoing pain in mice. We found that the effect of sciatic nerve cuff on the ratio of weight bearing by the injured relative to uninjured hindlimbs more closely resembles that of thermal hyperalgesia, following the trend toward recovery by about 28-30 days. Thus, we posit that non-myelinated, peptidergic C-Fibers innervating lamina I are the primary source of ongoing pain in mice following sciatic nerve cuff creating an anticipatory pain state that underlies the

recoverable weight bearing phenotype. We therefore propose that thermal hyperalgesia, rather than mechanical allodynia in the nerve cuff/CCI model is a more relevant behavioral measure when considering pharmacological interventions for persistent ongoing neuropathic pain.

Abstract: TRPM8 antagonists derived from its cognate ligand, (−)-menthol, are underrepresented. We determine the absolute stereochemistry of a well-known TRPM8 antagonist, (−)-menthyl 1, using VCD and 2D NMR. We explore 1 for its antagonist effects of the human TRPM8 (hTRPM8) orthologue to uncover species-dependent inhibition versus rat channels. (−)-Menthyl 1 inhibits menthol- and icilin-evoked Ca^{2+} responses at hTRPM8 with IC_{50} values of 805 ± 200 nM and 1.8 ± 0.6 μM, respectively, while more potently inhibiting agonist responses at the rat orthologue (rTRPM8 IC_{50} (menthol) = 117 ± 18 nM, IC_{50} (icilin) = 521 ± 20 nM). Whole-cell patch-clamp recordings of hTRPM8 confirm the 1 inhibition of menthol-stimulated currents, with an IC_{50} of 700 ± 200 nM. We demonstrate that 1 possesses ≥400-fold selectivity for hTRPM8 versus hTRPA1/hTRPV1. (−)-menthyl 1 can be used as a novel chemical tool to study hTRPM8 pharmacology and differences in species commonly used in drug discovery.

Title: IL-23/IL-17A/TRPV1 axis produces mechanical pain via macrophage-sensory neuron crosstalk in female mice

Authors: *X. LUO[1], O. CHEN[1], Z. WANG[1], S. BANG[1], J. JI[1], S. LEE[3], Y. HUH[1], K. FURUTANI[1], Q. HE[1], X. TAO[1], M.-C. KO[4], A. BORTSOV[1], C. DONNELLY[1], Y. CHEN[2], A. NACKLEY[1], B. TEMUGIN[3], R.-R. JI[1];

[1]Anesthesiol., [2]Neurol., Duke Univ., Durham, NC; [3]Univ. of Cincinnati, Cincinnati, OH; [4]Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: Sex dimorphism in chronic pain is a well-recognized clinical phenomenon, as females are more likely to suffer from chronic pain conditions. However, female-specific pain signaling is not well studied. Recently, we find that macrophages may use distinct pathways to modulate pain, and macrophage toll-like receptor 9 drives chronic pain only in males. In this study, we first investigate a female-dominant pathway which drives the crosstalk between macrophages and sensory neuron in chronic pain. Intraplantar (i.pl.) administration of interleukin 23 (IL-23) produces mechanical allodynia and conditioned place aversion in female but not male naïve mice. In the mouse model of chemotherapy-induced peripheral neuropathy (CIPN), *Il23* or *Il23r* deficiency or IL-23R antagonist P2305 exhibits anti-nociceptive effects only in female mice, indicating a female-specific role of IL-23/IL-23R axis in pain signaling. Notably, Estrogen deficiency after ovariectomy abrogates IL-23-induced pain and analgesic effects of P2305 against CIPN in females, and estrogen treatment enables IL-23-induced pain in males, implicating a regulative role of estrogen signaling. Female mice exhibit greater IL-23^{+} macrophage subset in DRG than males in CIPN *in vivo*, suggesting macrophages as the source of IL-23. Even IL-23 requires TRPV1^{+} C-fiber nociceptors to induce pain, IL-23 doesn't activate DRG sensory neuron directly. Macrophage ablation by clodronate abolishes IL-23-indued pain in females, whereas T cell deficiency by *Rag1*$^{-/-}$ or nude fails to do so, indicating an involvement of macrophage IL-23R signaling. Of note, IL-23 promotes macrophage release of IL-17A in females. Further, IL-17A induces mechanical allodynia, evokes calcium influx and potentiates action potential firing in DRG sensory neurons in a female-dominant manner, suggesting IL-17A as downstream effector of macrophage IL-23 signaling. Moreover, TRPV1 is also required for IL-23- and IL-17A-induced pain in females, and TRPV1 agonist capsaicin produces female-dominant mechanical allodynia in naïve mice. *In situ* hybridization evidence indicates female and male mice exhibit comparable *Il17ra*$^{+}$/*Trpv1*$^{+}$/*Erα*$^{+}$ DRG neurons, which provides neuronal components in IL-23/IL-17A/TRPV1 axis. Depletion of *Erα* in TRPV1^{+} C-fiber nociceptors reduces IL-23, IL-17A and capsaicin-induced pain in females, suggesting contributive role of neuronal estrogen signaling in this pain axis. In summary, this study demonstrates that the IL-23/IL-17A/TRPV1 axis regulates female-specific mechanical pain via neuro-immune interactions and suggests this axis as a novel target of precision therapy for women chronic pain patients.

Title: Phenotypic and functional characterization of CD4+ T cells in dorsal root ganglion of naïve and paclitaxel-treated male and female mice

Authors: *D. J. GOODE, N. E. MECUM;
Univ. of New England, Biddeford, ME

Abstract: Chemotherapeutic agents are often a life-saving cancer treatment, but the development of chemotherapy induced peripheral neuropathy (CIPN) is a major dose-limiting toxicity resulting in intractable pain that restricts the cancer survival rate. Recent reports demonstrate that mice lacking T cells have prolonged mechanical hypersensitivity after treatment with paclitaxel (PTX). The cytokines IL-10 and IL-4 have also been shown to be protective against CIPN, yet the sources of these cytokines in the dorsal root ganglion (DRG) after injury are unknown. The major IL-10 and IL-4 secreting immune cell is the CD4+ T cell; however, identification of CD4+ T cells in naïve and injured dorsal root ganglion (DRG) is still in its infancy. Here, we characterized the phenotype and functional properties of CD4+ T cells in acutely dissociated DRGs of naïve and PTX-treated female and male C57BL6/J mice using multi-color flow cytometry. Naïve females had a greater percentage of CD4+ T cells in the DRG compared to naïve male mice. The CD4+ T cells present in naïve male and female DRG had an effector/memory phenotype (CD44+) and were predominantly anti-inflammatory. However, the anti-inflammatory CD4+ T cell subpopulations were different in males and females. Females had a higher frequency of suppressive Foxp3+ T regulatory cells (Tregs) and IL-4 producing CD4+ T cells whereas males had a higher frequency of latency activated peptide+ (LAP; the pro-peptide of transforming growth factor-β) CD4+ T cells, another suppressive CD4+ T cell population. PTX increased anti-inflammatory Foxp3 Tregs and IL-4 producing CD4+ T cells in the DRG during the resolution of CIPN in both male and female mice; however, the frequencies were much higher in female DRG. IL-10 producing CD4+ T cells were also significantly greater in females than in males after PTX administration. Interestingly, PTX only increased pro-inflammatory IL-17A+ CD4+ T cells in the DRG of male mice, not female. The PTX-induced increase in CD4+ T cell populations in mouse DRG were transient as the frequencies returned to baseline levels when the mice were no longer mechanically hypersensitive. Our results demonstrate that PTX changes the phenotype and functional properties of CD4+ T cells in the DRG of male and female mice, indicating a potential target for treatment of CIPN.

Title: Cannabichromene Effectively Reduces Cisplatin-Induced Neuropathic Pain

Authors: *M. A. DE LEON[1], V. RAJE[1], W. GUL[2,4], M. A. ELSOHLY[2,4], N. M. ASHPOLE[3], H. M. HARRIS[2];
[1]Biomolecular Sci., [2]Univ. of Mississippi, Oxford, MS; [3]BioMolecular Sci., Univ. of Mississippi, University, MS; [4]ElSohly Labs. Inc., Oxford, MS

Abstract: Cisplatin is a commonly used chemotherapy that has a dose limiting effect whereby 30-70% of patients develop peripheral neuropathy. Cisplatin induced neuropathy (CIN) presents in a stocking and glove pattern with patients reporting symptoms of allodynia. While current therapeutics show little success in treating CIN, recent studies suggest cannabis-based therapeutics as a potential treatment of CIN neuroinflammation and pain. While multiple studies have explored the effects of delta-9-tetrahydrocannabinol and synthetic cannabinoids against CIN, cannabinoids devoid of psychoactive effects would likely be a stronger candidate for drug development. Cananbichromene (CBC), a non-psychoactive cannabinoid, has shown to have antinociceptive properties across acute pain models of thermal and inflammatory pain. It is unknown if CBC can attenuate chronic allodynic pain. This study evaluated the effects of CBC against CIN induced allodynia. Our lab assessed whether CBC was able to 1) attenuate CIN (Experiment 1) and 2) prevent the development of CIN (Experiment 2). Mice in Experiment 1 received six cisplatin administrations on alternating days over 12 days with Ringers solution on non-cisplatin days. An electronic Von Frey (eVF) was used to measure withdrawal thresholds at baseline and following the 6th cisplatin administration. Two days following the last cisplatin injection, mice received either vehicle, oxycodone, or CBC (10, 25, or 50 mg/kg) then measured on the eVF 30 min later. Mice in Experiment 2 received CBC throughout the CIN induction protocol and tested on the eVF following the sixth cisplatin administration. In Experiment 1, mice receiving cisplatin showed a decrease in withdrawal thresholds, indicative of allodynia. On drug test day, vehicle treated mice continued to display low withdrawal thresholds while oxycodone increased withdrawal thresholds, indicative of analgesia. CBC produced a dose response whereas mice receiving 25 and 50 mg/kg showed increased withdrawal thresholds comparable to oxycodone. In Experiment 2, co-administration of 25 mg/kg CBC during the cisplatin regimen, significantly reduced tactile allodynia, even with a 2-day CBC wash-out period. These data suggest CBC's ability to not only attenuate the effects of cisplatin-induced neuropathic pain, but it also prevents or delay the onset of CIN. Further studies regarding the effects of CBC on the underlying pathophysiological response to CIN are ongoing. Together,

these data suggest CBC may have utility as a potential therapy for preventing or alleviating neuropathic pain.

Title: Oxidative DNA damage and cisplatin neurotoxicity is exacerbated by reducing the expression of 8-oxyguanosine glycosylase and AP endonuclease 1 in sensory neurons

Authors: *A. BEHROUZI[1], H. XIA[1], E. L. THOMPSON[1], M. R. KELLEY[2], J. C. FEHRENBACHER[1];

Abstract: Chemotherapy-induced peripheral neuropathy is a debilitating and dose-limiting adverse effect of anticancer treatment affecting cancer patients and survivors. Cisplatin, a common chemotherapeutic, is one of the most toxic chemotherapeutics and causes numbness, hypersensitivity to cold, and burning pain. Cisplatin generates DNA adducts and oxidative stress, the latter of which can result in oxidative DNA damage. The base excision repair (BER) pathway is the primary way sensory neurons repair cisplatin-induced oxidative lesions, such as 8-oxyguanosine (8-oxoG); however, the role of the different BER enzymes has not been assessed in sensory neurons. Understanding how oxidative DNA damage alters neuronal function is critical to understanding the mechanisms for cisplatin-induced neurotoxicity. Here, we utilized an in vitro model of cultured sensory neurons and siRNA technology to decrease the expression of the first two enzymes of the BER pathway, 8-oxoG glycosylase (OGG1) and AP endonuclease 1 (APE1) and measured sensory neuronal function and morphology. The content and stimulated release of the neuropeptide, calcitonin gene-related peptide (CGRP), was assessed as a surrogate for neuronal function in combination with immunohistochemical identification of cisplatin-induced DNA adducts and 8-oxoG. We found that knockdown of either BER enzyme alone did not affect CGRP release in the absence of cisplatin treatment, but increased the sensitizing effects of cisplatin on CGRP release. Surprisingly, combination knockdown had an additive effect in the presence of cisplatin, even though the enzymes are thought to participate in a linear

pathway. Decreasing OGG1 had a dramatic effect on neuronal morphology even in the absence of cisplatin, suggesting a novel role for the BER enzyme in regulating neurite homeostasis. Collectively, these data suggest that OGG1 and APE1 are neuroprotective in the presence of oxidative stress, such as that induced by cisplatin. Further research will examine how each of these BER enzymes contributes to neuronal homeostasis in conditions of high oxidative stress.

Title: The Role of Interleukin 23 receptor down modulator Tyrosine kinase 2, in Vincristine-induced Peripheral Neuropathy.

Authors: *Y. CHOI[1], H. LEE[1,2], S. JUNG[1];
[1]Physiol., Hanyang Univ., Seoul, Korea, Republic of; [2]Dept. of Molecular, Cell. and Developmental Biol., Univ. of Michigan, Michigan, MI

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a common adverse effect, manifested by numbness, ticking and allodynia in 30-40% of cancer patients who have taken anticancer drugs chronically. Vincristine is a chemotherapeutic agent with activity against several of the most common cancers, including those of acute lymphocytic leukemia, acute myeloid leukemia, Hodgkin's disease, neuroblastoma and small cell lung cancer. Vincristine exerts its anti-tumor effects by binding to tubulin protein, stopping the cell from separating its chromosomes during metaphase; the cell then undergoes apoptosis. Although vincristine-induced CIPN is the most commonly reported neurotoxic and dose-limiting side effect, its mechanism remains to be fully defined. It is well understood that CIPN increases immune chemokines due to chemotherapy, and as a result, it induces inflammation and triggers pain hypersensitivity in Dorsal root ganglion (DRG). Here, we have shown that IL-23 pathway in DRG acts as an important role in vincristine-induced CIPN model. IL-23 has increased in vincristine-induced CIPN model, and when IL-23 receptor pathway was blocked, IL-23 has decreased. Especially when p19 and p40, the IL-23 subunit was neutralized using antibody, pain level has decreased only when p19 was inhibited. Moreover, when ruxolitinib, the inhibitor of JAK2, which is the IL-23 receptor down-modulation was treated, there was no significant change in the pain level. As a result, our data shows that IL-23 pathway is highly related to pain hypersensitivity in

vincristine-induced CIPN, and among the IL-23 receptors from the pathway, down-signal of IL-23R and TYk2 acts as an important role in vincristine-induced CIPN.

Title: Chemokine receptor CXCR2 and its role in the pathway of CIPN in Dorsal Root Ganglion

Authors: *H. CHO, Y. CHOI, Y. HAN, S. JUNG;
Hanyang Univ., Seongdong-gu, Korea, Republic of

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a major drawback in the use of chemotherapeutic agents for patients with cancer. Even though diverse studies on this issue have identified a broad scale of molecules that might be related to CIPN, there has not yet been any differentiation of pathways to different chemotherapeutic agents. Since vincristine and oxaliplatin are some of the widely used chemotherapeutic agents, identifying the different pathways of these drugs and suggesting their possible treatment is crucial.
Mechanical allodynia results showed that when reparixin, the CXCR1/2 (C-X-C chemokine receptor type 1/2) blocker was treated with vincristine and oxaliplatin, only oxaliplatin-induced CIPN showed improvements. Furthermore, when imatinib, the abl-bcr inhibitor which is a critical pathway in the interleukin 23 signaling pathway was treated with, improvements were only observed in vincristine-induced CIPN. Real-time Polymerase Chain Reaction data showed that CXCR2 was increased in oxaliplatin-treated mice, but not in vincristine-treated mice, which further suggests the different pathways in vincristine and oxaliplatin.
Therefore, even though the physiological result of different chemotherapeutic agents is CIPN, since the pathway of causing CIPN between vincristine and oxaliplatin differs, it is important to pick the adequate treatment for each specific chemotherapeutic agent.

Title: Examination of neuronal arborization in the lumbar dorsal root entry zone as a potential mechanism of burn pain chronification

Authors: M. P. HUNTER, D. J. CANTU, T. P. OLAOLUWA, D. L. AVERITT, *D. L. HYNDS;
Texas Woman's Univ., Denton, TX

Abstract: Burn victims experience severe pain that can become chronic and present as enhanced sensitivity to noxious (hyperalgesia) and non-noxious (allodynia) stimuli. Chronic burn pain development may involve neural plasticity, including reorganization of the central neural processes of the sensory neurons entering the spinal cord. We previously developed and characterized a rat model of full thickness thermal injury that displays persistent pain behaviors for up to 4 weeks post-injury. Thermal injury enhances the release of proinflammatory and pronociceptive (pro-pain) peptides in the spinal dorsal horn, but it is not known if sensory neuron afferent reorganization occurs and contributes to burn pain. We hypothesize that a full thickness thermal injury increases axonal sensory process arborization and synapsing in the rat spinal dorsal horn developing persistent burn pain behaviors. Adult female Sprague-Dawley rats (n=6/group; 200-300 g) received a sham injury (room temp. soldering iron tip) or a full thickness thermal injury to the plantar surface of the right hind paw (1% total body surface area) by applying a soldering iron tip at 100°C for 30 seconds. Thermal hyperalgesia and mechanical allodynia were tested at 24, 48 and 72 hours and once/week for 2 weeks. Rats were perfused with 4% paraformaldehyde and the lumbar spinal cords dorsal root ganglia (DRG) at L2-L6 were extracted. Immunohistochemistry and western blotting identified changes in markers of pain signaling, including the proinflammatory peptides calcitonin gene-related peptide (CGRP) and substance P, and the nociceptive transient receptor potential vanilloid 1 (TRPV1) ion channel. Sprouting axons were identified by nerve growth factor (NGF), beta III tubulin, and growth associated protein 43 (GAP43) labeling. Significant thermal hyperalgesia and mechanical allodynia developed at 24 hours and were maintained through 2 weeks post-injury. CGRP and substance P labeling increased in the lumbar dorsal horns and DRG and afferents displayed an increase in TRPV1 immunoreactivity in thermal-injured rats. Burn injured rats had increased beta III tubulin labeling in ipsilateral dorsal horns in processes that were also immunoreactive for CGRP. Together, these data indicate that thermal injury increases arborization of nociceptive sensory afferents in the lumbar dorsal horn. Our current studies are focused on further characterization of the sensory neuron populations and signaling pathways altered in the lumbar spinal cord that may contribute to burn pain chronification. Arborization may represent an alternative target to manage chronic pain development in burn patients.

Abstract: Chronic pain is a highly prevalent and debilitating condition which imposes an enormous burden on health care systems and society. Given its complexity, the underlying mechanisms and causes are still not fully understood. Indeed, pain is not the mere result of noxious stimuli traveling to the brain. Emotional, cognitive and behavioral components are closely interconnected with the noxious sensory experience. For this reason, it is extremely complicated to obtain an objective and reliable measure of the pain level perceived by patients. Today, the clinical standard are self-report scales. Unfortunately, they lack reliability and are biased due to their subjective nature. Advanced machine learning algorithms can be a solution, by predicting the pain experience from patterns in data obtained from patients. However, the majority of studies applying this strategy do not consider the emotional and cognitive state of the subjects, inevitably leading to the denial of this major component in the pain experience.The aim of work is to obtain a reliable and objective measurement of pain through machine learning algorithms applied on multidimensional objective and subjective data recorded in healthy and chronic pain patients. Subjects underwent experimentally induced pain through contact heat evoked potential (CHEP) and pinprick evoked potential (PEP) experiments. During the sessions, subjective (i.e., questionnaires on demographics, psychological health and coping with pain), objective (i.e., electroencephalography, skin conductance), semi-subjective (i.e., temporal summation, conditioned pain modulation, quantitative sensory testing) data has been collected. After a pre-processing step, different features have been extracted from the physiological signals. Machine Learning models were then applied to both subjective and objective features with two goals: i) classify the perceived pain level and ii) understand the contribution of each feature to

the prediction. Preliminary results confirm our hypothesis, by showing the contribution of both subjective and physiological factors to the prediction of pain level.Our framework holds promises to improve pain models. A new objective pain scale could satisfy the current search for a more precise measurement and biomarkers of chronic pain. A better understanding of the nature of the pain causes will help regulating the correct dosage of analgesics, and be a useful tool in fighting the increased opioid use. Furthermore, it would pave the way to personalized therapies accounting for inter-individual differences in pain perception, allowing for personalized control of therapies.

Hosp., Turku, Finland; [13]Stanford Univ. Med. Sch., Palo Alto, CA

Abstract: Ankle sprain is common in the adolescent population, about 40% of whom may experience chronic pain following the injury. While the pain is primarily caused by damage to the peripheral nerves of the lower limbs, it is unclear how the same damage affects the central nervous system (CNS). Here, we systematically studied how neuropathic pain affects the CNS

and whether there are associations between CNS properties and participant's self-reported pain as measured with the painDETECT questionnaire (PDQ). To this end, we recruited patients with clinically confirmed neuropathic pain resulting from unilateral ankle sprain. We investigated the evolution of the white matter microstructure and the resting-state functional connectivity (rs-fc) of the somatosensory-motor systems. Participants were scanned twice (30 controls, 61 patients: 32 right + 29 left injury; time 1: 0-6 months, time 2: >6 months after injury) to obtain DWI and fMRI data (32-ch head coil, 3T Siemens Magnetom Trio). At time 1, compared to controls, right injury patients had lower fractional anisotropy (FA) in some segments of the left corticospinal tract (CST) only, while left injury patients had normal FA in the bilateral CST. Right injury patients had higher rs-fc of the left caudate to both the left pre- and post-central gyri, while left injury patients had lower rs-fc between the left thalamus and pre-central gyrus. At time 2, both the CST and rs-fc effects were no longer apparent in right injury patients, but there was higher axial diffusivity than controls, in the segment of the corpus callosum connecting the bilateral primary motor cortices. Also at time 2, left injury patients had lower FA than controls in some segments of the left CST only, and showed no rs-fc effects. Even though there was clinically confirmed neuropathic pain in patients, we found no associations between PDQ and the CNS properties that were different between groups. Consistent with the decussation of the limb's nerve projections to the contralateral hemisphere, we found that in right ankle injury patients only, there is an early but transient divergence from normative data in both white matter and rs-fc in the left hemisphere. However, there may be long-lasting changes to the structural connectivity of the bilateral motor cortices. On the other hand, in left ankle injury patients, there appears to be nascent structural changes in the ipsilateral (right) CST, long after sustaining the initial peripheral nerve damage. Our results demonstrate differential CNS changes concerning primarily the motor cortex after peripheral nerve injury, possibly suggesting differences in adaptive mechanisms in case of injury to either ankle.

Title: MIF antagonist ISO-1 prevents hypersensitivity and modulation of nociceptive synaptic transmission in a model of peripheral neuropathy

Authors: *M. PONTEARSO, P. ADAMEK, J. SLEPICKA, D. SPICAROVA, J. PALECEK; Lab. of Pain Res., Inst. of Physiology, Czech Acad. of Sci., Prague, Czech Republic

Abstract: There is an urgent need for new treatment options of chronic pain. Genetic deletion of macrophage migration inhibitory factor (MIF) prevents the development of hypersensitivity induced by peripheral nerve injury or inflammation. This proinflammatory cytokine MIF exerts its biologic functions mainly through binding to the putative membrane receptor, CD74. MIF tautomerase inhibitor (S,R)-3(4-hydroxyphenyl)- 4,5-dihydro-5-isoxazole acetic acid methyl ester (ISO-1) binds the MIF active site and blocks the MIF-CD74 binding. We have investigated the effect of ISO-1 treatment (20mg/kg i.p.) on mechanical hypersensitivity and excitatory and inhibitory synaptic transmission in the spinal cord dorsal horn in a model of neuropathic pain induced by chronic constriction injury (CCI) of sciatic nerve. Electronic Von Frey tests to assess mechanical hyperalgesia and specific optogenetic stimulation of inhibitory neurons combined with patch-clamp recording from neurons in acute mouse spinal cord slice were used. Spontaneous excitatory postsynaptic currents (sEPSCs) and light-evoked inhibitory postsynaptic currents (le-IPSCs) from superficial dorsal horn neurons were recorded. Electrophysiological experiments were performed in adult male transgenic mice VGAT-ChR2-eYFP line 8, that express an optimized channelrhodopsin specifically in GABAergic and glycinergic neurons. CCI in our experiments induced mechanical hyperalgesia, significantly increased the sEPSC frequency and decreased the amplitude of light-evoked IPSCs in excitatory dorsal horn neurons. These pathological effects of the CCI were largely diminished by the ISO-1 treatment. Our results suggest that blocking the MIF by ISO-1 inhibitor prevents the development of hypersensitivity after nerve injury. One of the underlying mechanisms of the ISO-1 treatment could be reduction of pathological macrophage modulation of excitatory and inhibitory synaptic transmission in the spinal cord dorsal horn.

Title: Spinal cord circuit dysfunction underlying over-reactivity to touch in neuropathic pain

Authors: *G. RANKIN, A. CHIRILA, S. CHOI, A. J. EMANUEL, S.-Y. TSENG, J. DRUGOWITSCH, C. D. HARVEY, D. D. GINTY;
Dept. of Neurobio., Harvard Med. Sch., Boston, MA

Abstract: In cases of nerve injury and ensuing neuropathic pain, normally innocuous tactile stimuli are often perceived as painful. This manifestation of neuropathic pain, known as mechanical allodynia, is often therapy-resistant and the responsible mechanisms for over-reactivity to tactile stimuli remain unclear. Fundamental work studying mechanical allodynia has proposed sites of dysfunction in both peripheral sensory neurons as well as within spinal cord circuits, however, how changes in either of these alters processing of somatosensory information in the intact animal is unknown. To this end, we are using large scale in vivo recordings and the SNI model of neuropathic pain to investigate how individual tuning properties and population dynamics of spinal cord interneurons and projection neurons, in both superficial and deep laminae of the dorsal horn, change in the allodynic state. Surprisingly, despite robust behavioral over-reactivity to mechanical stimuli in SNI mice, we do not observe an overall increase in sensitivity or reactivity of spinal cord interneurons. However, we do observe a decrease in sustained firing during 500ms step indentations of the skin and this change appears most prominent in spinal inhibitory interneurons, including the PV^+ inhibitory interneurons previously implicated in mechanical allodynia. Interestingly, we also observe a decrease in the synchrony of evoked firing in SNI mice across individual spinal cord interneurons and this deficit is recapitulated by specifically silencing the PV^+ interneurons. These findings suggest that decreased correlated activity across the dorsal horn may be a general feature of the neuropathic pain state and point to a circuit level dysfunction brought about by alterations in PV^+ interneurons. To ask whether changes in synchronous firing across neurons of the dorsal horn are uniquely caused by aberrant PV^+ interneurons or by disruption of feedback or feedforward inhibitory circuits in general, we are currently silencing other components of dorsal horn inhibitory pathways and monitoring evoked synchrony. These results will determine the contributions of dorsal horn inhibitory circuit motifs to alterations of spinal cord population dynamics associated with mechanical allodynia in chronic neuropathic pain states. This work is supported by NSF DGE1745303, NIH BRAIN Grant R01AT011447, and the Howard Hughes Medical Institute.

Title: Astrocyte reaction in the lateral habenula contributes differently to spontaneous and evoked pain in paclitaxel induced peripheral neuropathy

Authors: *X. GUO;
Univ. of Illinois at Chicago, Chicago, IL

Abstract: The detrimental painful peripheral neuropathy induced by paclitaxel treatment (PIPN) significantly impacts the chemotherapy and the quality of life for cancer patients and may lead to the cessation of the chemotherapy and poor clinical outcomes. There is a knowledge gap in our understanding of the mechanisms underlying PIPN. The importance of glia pathophysiology, especially in terms of spinal reactive astrocytes, to the etiology of chronic pain has been investigated in multiple chronic pain models in recent several years; however, less is understood regarding their regulation at the supraspinal level. As an anti-reward center which is responsible for coding aversive emotional signals, the lateral habenula (LHb) has been extensively studied in stress related conditions such as depression and pain. However, whether reactive astrocytes in the LHb are responsible for pain signaling and how this process is regulated are not yet understood. In the current study, we investigated the astrocyte reaction in the LHb, evoked hypersensitivity (mechanical and heat hyperalgesia), ongoing spontaneous pain behaviors and comorbid anxiety-like behaviors in a mouse model of chronic PIPN. We demonstrated the presence of astrocyte reaction in the LHb, as indicated by the enhanced immunoreactivity of GFAP after 35 days in PIPN. The astrocyte reaction was diminished by the treatment with L-α-aminoadipic acid (L-α-AA), an astrocyte inhibitor. L-α-AA selectively attenuated the ongoing spontaneous pain and anxiety-like behaviors but did not alter the evoked hyperalgesia in PIPN, supporting the hypothesis that the reactive astrocytes have distinct contributions to the sensory and affective components of pain in PIPN.

Title: Spinal Neuropeptide Y1 Receptor-expressing Interneurons Represent a Pharmacotherapeutic Target for the Treatment of Neuropathic Pain

Authors: *T. S. NELSON[1,2,3,4], D. F. S. SANTOS[1,2,3], C. M. AROKIARAJ[5,2,3], E. NGUYEN[5,2,3], S. E. ROSS[5,2,3], R. P. SEAL[5,2,3], B. K. TAYLOR[1,2,3];
[1]Dept. of Anesthesiol. and Perioperative Med., [2]Ctr. for Neurosci., [3]Pittsburgh Ctr. for Pain Res., [4]Ctr. for the Neural Basis of Cognition, [5]Dept. of Neurobio., Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Neuropeptide Y (NPY) in the spinal cord dorsal horn exhibits long-lasting inhibitory control of nociceptive transmission after peripheral nerve injury (PNI). Dorsal horn neurons that express the neuropeptide Y1 receptor (Y1-INs), an inhibitory G protein-coupled receptor, are well positioned in the nervous system to mediate the anti-nociceptive actions of NPY. The aims of this study were to test if Y1-INs are both *necessary* and *sufficient* for the manifestation of PNI-induced mechanical and cold hypersensitivities via *in vivo* chemogenetic, optogenetic, and pharmacological approaches. Further we characterized dorsal horn Y1-INs via fluorescence *in situ* hybridization (FISH) and looked for conservation of gene expression in higher order species. Chemogenetic inhibition of Y1-INs with clozapine N-oxide did not alter baseline mechanical or cold sensitivity; however, following PNI, chemogenetic inhibition abolished mechanical and cold hypersensitivities ($p<0.05$, n=7 mice/group). We conclude that spinal cord dorsal horn Y1-INs are *necessary* for the full manifestation of neuropathic pain. Next, we found that chemogenetic activation of Y1-INs was *sufficient* to induce multiple signs of pain including spontaneous nocifensive behaviors (lifting of hindpaw, licking, guarding, biting) ($p<0.05$, n=3-5 mice/group) as well as heat, cold, and mechanical hypersensitivities ($p<0.05$, n=7-8 mice/group), and conditioned place aversion ($p<0.05$, n=7-8 mice/group). Similarly, *in vivo* optogenetic activation of spinal Y1-INs produced a frequency-dependent decrease in both mechanical and cold withdrawal thresholds ($p<0.05$, n=8 mice/group). Together, these results suggest that Y1-INs are a potential therapeutic target for neuropathic pain. To test this, we conducted PNI and then targeted Y1-INs with the Y1 receptor agonist, Leu^{31} Pro^{34}. We found that Leu^{31} Pro^{34} (0.1-10µg/5µL, i.t.) dose-dependently reduced mechanical and cold hypersensitivity ($p<0.05$, n=8-11); both were blocked by coadministration of the selective Y1 receptor antagonist, BIBO 3304 (10µg/5µL, i.t.). Additionally, FISH in mouse lumbar dorsal horn tissue revealed that Y1-INs segregate into three distinct populations that are demarcated by expression of *Grp* (60.61 ± 3.78%), *Cck* (16.60 ± 0.63%), or *Npff* (24.55 ± 1.75%). We found that these Y1-IN subpopulations are conserved in the porcine, macaque, and human spinal cord dorsal horn, altogether suggesting them to be promising pharmacotherapeutic targets for neuropathic pain.

Title: C5a signaling in spinal mechanisms of chronic pain

Authors: K. AGASHKOV[1], A. L. KEYES[3], S. ROMANENKO[1], O. HALAIDYCH[2], Y. ANDRIANOV[1], N. VOITENKO[1,4], Y. M. USACHEV[3], *P. BELAN[2,4];

[3]Pharmacol., Univ. of Iowa, Iowa City, IA; [4]Kyiv Academic Univ., Kyiv, Ukraine

Abstract: The complement system is a principal component of innate immunity that is rapidly recruited through a cascade of enzymatic reactions to contribute to host defenses via diverse mechanisms. In spite of growing evidence implicating the complement system in various chronic pain states, the underlying mechanisms are not well understood. Recent studies suggest that neuropathic pain is associated with a robust upregulation of complement effectors in the spinal cord, which ultimately leads to production of a highly active complement product, C5a. Here we have elucidated C5a-dependent spinal mechanisms that contribute to the development of neuropathic pain induced in mice by spared nerve injury (SNI). First, we examined the effect of a potent and selective antagonist of the C5a receptor (C5aR1), PMX205 and found that its single i.t. administration produced a strong immediate analgesic effect. This analgesic effect strongly suggests that C5a/C5aR1 signaling plays an important role in the development and maintenance of neuropathic pain following SNI. Next, we generated a mouse expressing a fluorescent reporter of Ca^{2+} concentration, GCaMP5G-TdTomato, in microglia. Intact spinal cord was dissected from these mice, and used for testing the effect of complement C5a on microglia responses by multiphoton Ca^{2+} imaging. We found that C5a produced rapid transient increases of cytosolic Ca^{2+} concentration in spinal cord microglia that probably resulting in the release of mediators affecting neuronal activity. Therefore, we examined whether application of C5a mimics the effect of SNI producing an increased activity in projection or unidentified superficial dorsal horn neurons within the intact spinal cord. We have found that the number of action potentials evoked by the saturating dorsal root stimulation in about half of both neuronal populations was significantly increased after the C5a treatment. We have also observed an initiation of burst firing in some neurons and an increase in a frequency of spontaneous firing in a subpopulation of cells. Overall, these findings are consistent with the hypothesis that C5a/C5aR1 signaling and spinal cord microglia, as a primary target of C5a action, play an important role in the development and maintenance of neuropathic pain following SNI.

Title: Targeted manipulation of PFC 5HT2A receptors and KV7 channels attenuates chronic neuropathic pain in rats

Authors: *V. S. VIZCARRA[1], K. R. BARBER[4], G. FRANCA-SOLOMON[1], A. SMITH-FLINT[1], A. LIPINSKI[1], L. MAJUTA[1], P. R. LANGLAIS[1], T. M. LARGENT-MILNES[1], T. W. VANDERAH[2], A. C. RIEGEL[3];
[1]Pharmacol., [2]Phamarcology, [3]Pharmacology, Neuroscience, Optical Sci., Univ. of Arizona, Tucson, AZ; [4]Pharmacol., Unviersity of Arizona, Tucson, AZ

Abstract: Despite extensive research, chronic pain remains a disabling disease with limited therapeutic options. Whereas much is understood about pain transmission in the periphery, less is known about pain integration in the cortex. Preclinical studies associate increased pain perception with modifications in the structure and function of the prefrontal cortex (PFC). Unpublished studies from our laboratory indicate hyperexcitability in certain PFC neurons following neuropathic spared nerve injury (SNI). Other recent publications reported thatPFC pyramidal neurons innervating the pontine region of the brainstem are important for the descending regulation of pain and express both excitatory Gq-coupled 5HT2A receptors (5HT2AR) and its effector system, the inhibitory Kv7 ion channel. Although both 5HT2AR blockade or Kv7 channel activation is reported to produce antinociceptive effects in the periphery, this has not been demonstrated for cortical systems in a chronic pain model. To evaluate this possibility, we tested the *hypothesis* that local blockade of 5HT2AR or stabilization of Kv7 ion channels in the PFC would attenuate the mechanical allodynia associated with SNI. Adult male Sprague Dawley rats (P52) underwent surgery to receive either a unilateral SNI (n=18) or surgical controls (Sham; n=17). At 18-19d post-surgery, sham and SNI rats with confirmed allodynia received bilateral cannula targeting the prelimbic (A32V) region. At 21-32d, rats received counterbalanced (Latin square) bilateral infusion (0.5 uL) of vehicle (0.01 M phosphate buffer saline and 0.1 M HCL, pH adjusted to 5.8 using 0.1M NaOH), the 5HT2A antagonist M100907 (0.1 ug), the FDA approved Kv7 channel stabilizer retigabine (0.1 ug), or combined infusion of M100907 and retigabine. Relative to baseline measurements collected 15 min prior to testing, M100907, retigabine, or the combination robustly attenuated allodynia in

SNI rats at 3, 10 and 15 min after infusion. The resulting hypersensitivity thresholds in SNI rats measured using the up-down method resembled those in sham animals. By contrast, Sham-rats receiving similar drug injections showed no change in withdrawal thresholds. Baseline measurements in the SNI/Sham groups did not vary across testing days. Ongoing studies are evaluating the parallel changes in PFC mRNA and protein levels of 5HT2A and Kv7 channels using RNAscope, immunohistochemistry and proteomics. Taken together these results support a growing body of preclinical literature indicating that chronic neuropathic pain alters PFC function, warranting further investigation of the central PFC actions of 5HT2A antagonists and KV7 channel stabilizers in neuropathic pain.

Title: Functions of Tacr1- and Gpr83-expressing spinoparabrachial neurons and their neuropeptide signaling in acute and neuropathic pain

Authors: *S. CHOI[1], J. TURECEK[1], A. R. MAGEE[1], D. A. YARMOLINSKY[2], C. J. WOOLF[2], D. D. GINTY[1];

Abstract: Pain is initiated by the activation of nociceptors that innervate the skin and internal organs. Nociceptive signals are propagated into the spinal cord and then transmitted to the brain by spinal cord projection neurons (PNs). These spinal PNs are attractive therapeutic targets for pain treatment because nociceptive signals emanating from the periphery are channeled through these spinal cord output neurons *en route* to the brain to produce pain sensations. Spinoparabrachial (SPB) neurons, a major population of spinal PNs that innervate the lateral parabrachial nucleus of the pons, represent an ideal neuronal population for developing new approaches to treat pain because they convey touch and pain information to higher brain centers that control the affective aspects (i.e., emotional “feelings”) of touch and pain. Previously, we showed that *Tacr1*$^+$ and *Gpr83*$^+$ SPB neurons form two largely-nonoverlapping subdivisions of the SPB pathway that cooperate to convey tactile, thermal and noxious signals from the spinal cord to the brain. To further define the contribution of each SPB subdivision to pain sensation and associated behavioral responses to noxious stimuli, we have begun to examine the effects of acute silencing of *Tacr1*$^+$ and *Gpr83*$^+$ SPB neurons, individually or simultaneously, on nocifensive behaviors using a newly generated dual recombinase-dependent SYP1-miniSOG mouse line that enables selective, light-dependent silencing of synaptic transmission. In addition, to determine if neuropeptide signaling mediated by either TACR1, GPR83 or both in the spinal cord is required for pain transmission, we also have begun to examine acute and neuropathic pain behaviors following spinal cord-specific deletions of the *Tacr1* and *Gpr83* genes using mouse lines that harbor conditional alleles of *Tacr1* and *Gpr83* in conjunction with spinal cord specific Cre lines. Collectively, these behavioral analyses will provide insights into the functions of *Tacr1*$^+$ and *Gpr83*$^+$ SPB neurons and neuropeptide signaling mediated by the TACR1 and GPR83 GPCRs in acute and neuropathic pain and may reveal novel therapeutic targets for treating pain.

Title: Visual modulation of spectrotemporal receptive fields in mouse auditory cortex

Authors: *J. BIGELOW[1], R. J. MORRILL[1], T. R. OLSEN[1], S. N. BAZARINI[1], A. R. HASENSTAUB[2];

Abstract: Recent studies have established significant anatomical and functional connections between visual areas and primary auditory cortex (A1), which may be important for perceptual processes such as communication and spatial perception. However, much remains unknown about the microcircuit structure of these interactions, including how visual context may affect different cell types across cortical layers, each with diverse responses to sound. The present study examined activity in putative excitatory and inhibitory neurons across cortical layers of A1 in awake male and female mice during auditory, visual, and audiovisual stimulation. We observed a subpopulation of A1 neurons responsive to visual stimuli alone, which were overwhelmingly found in the deep cortical layers and included both excitatory and inhibitory cells. Other neurons for which responses to sound were modulated by visual context were similarly excitatory or inhibitory but were less concentrated within the deepest cortical layers. Important distinctions in visual context sensitivity were observed among different spike rate and timing responses to sound. Spike rate responses were themselves heterogeneous, with stronger responses evoked by sound alone at stimulus onset, but greater sensitivity to visual context by sustained firing activity following transient onset responses. Minimal overlap was observed between units with visual-modulated firing rate responses and spectrotemporal receptive fields (STRFs) which are sensitive to both spike rate and timing changes. Together, our results suggest visual information carried by infragranular inputs influences sound encoding across cortical layers in A1, and that these influences independently impact qualitatively distinct responses to sound.

Title: Audiovisual task switching rapidly modulates stimulus encoding and activity levels in mouse auditory cortex

Authors: *R. J. MORRILL, J. DEKLOE, J. BIGELOW, A. R. HASENSTAUB;
Otolaryngology / Ctr. for Integrative Neurosci., UC San Francisco, San Francisco, CA

Abstract: During everyday behavior, the sensory systems are in constant competition with each other for attentional resources. The brain must allocate attention to the sensory stream with the most behaviorally meaningful signals. How does modality-specific attention transform cortical sensory representations? To address this question, we created an auditory/visual rule-switching task for mice and made translaminar recordings in the auditory cortex during task performance. We show that attending to sound while ignoring visual stimuli modulates single-unit responses primarily through a reduction of stimulus-evoked and pre-stimulus activity in deep cortical cell populations. We then use a PSTH-based pattern classifier to show that the general reduction in activity does not impair decoding but instead increases mutual information encoding efficiency. Analysis of spectrotemporal receptive field nonlinearities shows that attending to sound switches auditory cortical encoding to a mode in which physical aspects of sound are more prominently represented. Finally, we show that task errors are predicted by activity levels in the same population of neurons that is modulated by modality-specific attention, suggesting that these neural effects are behaviorally meaningful correlates of task performance. Taken together, this work shows that attending to sound over vision quiets ongoing activity in the auditory cortex, shifting information transfer toward sound representation. Consistent with our previous research [Morrill & Hasenstaub J. Neurosci. 2018], this suggests that the deepest cortical layers serve as a hub for integrating extramodal contextual information.

Title: Topographical distribution of spectrotemporal receptive field properties in bat primary auditory cortex

Authors: *K. BAKSHI[1], S. MACIAS[2], T. W. TROYER[3], M. SMOTHERMAN[1];
[1]Inst. for Neuroscience; Biol., [2]Biol., Texas A&M Univ., College Station, TX; [3]Biol., Univ. Texas San Antonio, San Antonio, TX

Abstract: Spectrotemporal modulations are a prominent feature of natural sounds including animal vocalizations and human speech. The neural networks of the mammalian primary auditory cortex (A1) that encode and categorize communication sounds remain incompletely understood in part because of the heterogeneous distribution of interacting neuronal subtypes and microcircuits serving different functions throughout A1. To get around this problem, we investigated the topographical distribution of tuning properties throughout A1 in an auditory substrate homogenously specialized to process one specific acoustic feature, the downward frequency modulated (FM) sweep utilized in bat echolocation. While the majority of A1 neurons in bat auditory cortex are preferentially tuned to downward FM sweeps, the entire cortex is required to capture and categorize patterns of spectral details embedded within each biosonar echo. Here, we used linear, dual shank 32-channel translaminar microelectrode arrays to extract frequency response areas (FRAs) and spectrotemporal receptive fields (STRFs) from the A1 of adult male and female Mexican free-tailed bats (*Tadarida brasiliensis*) in response to broadband dynamic moving ripple (DMR) stimuli. We extracted a total of 170 STRFs across the A1 from spike-sorted single units (60) and multiunit activity (110) with most of our sampled STRFs at cortical depths corresponding to input layer 4. STRF best frequencies ranged between 10-55 kHz. We quantified the spectral and temporal modulation transfer functions (sMTF and tMTF, respectively) to determine neural tuning preferences in the spectral and temporal dimensions. The goal of this project is to compare STRF properties across cortical layers and throughout the tonotopic axis of A1 to reveal spatial patterns in the neuronal response properties that may in turn shed light on the functional organization of A1 neural networks processing downward FM sweeps. We found evidence of neuronal sub-categories that were classified as having simple or complex (multi-peaked) STRFs. For simple STRFs, sMTFs and tMTFs were evaluated as a function of best frequency and spatial location and revealed tonotopic trends similar to those reported for non-specialized animals.

Title: Sequential organization of critical periods in the mouse auditory system

Authors: *P. VALERIO, M. NAKAMURA, S. BHUMIKA, M. SOLYGA, T. R. BARKAT; Univ. of Basel, Basel, Switzerland

Abstract: Neuronal circuits are shaped by experience during time windows of increased plasticity in postnatal development. In the mouse auditory system, the critical period for simple sounds - pure frequency tones - is well defined from postnatal days 12 to 15 (Barkat et al., 2011). However, the critical period for frequency modulated sweeps (FMS), a more complex sound than pure tone, occurs weeks later, from postnatal days 31 to 38 (Bhumika et al., 2020). Whether such critical periods are timed by a temporally precise developmental program or sequentially organized, where the closing of one critical period triggers the opening of the next, was not yet known. Our work aimed to unravel the underlying neuronal mechanisms of critical periods in the auditory system, as well as their dependency on each other. We performed in vivo electrophysiological recordings and immunohistochemistry in the mouse primary auditory cortex in combination with molecular and sensory manipulators to elucidate the biological constraints on critical period timing. We demonstrated that passive exposure to FMS from postnatal days 31 to 38 leads to long-term changes in the temporal representation of sweep directions. Immunohistochemical analysis showed a decrease in parvalbumin (PV) expression in cortical layer 4 during this critical period, which was paralleled with a transient increase in responses to FMS. Despite the downregulation in layer 4 PV expression, the PV cell number was not altered. Continuous white noise exposure prevented PV expression decrease and delayed the FMS critical period onset, suggesting a reduction in inhibition as a mechanism for this plasticity. Passive sound exposure further revealed that the cortical representation of the two sound features - pure tone and FMS - are not influencing each other. Enhancing gamma-aminobutyric acid (GABA) function before the critical period for pure tones accelerated it without changing the critical period for FMS (Nakamura et al., 2020). Delaying the critical period for pure tones did also not affect FMS critical period. Together, these results demonstrate that, although sequentially organized, critical periods can be temporally shifted without affecting each other and are therefore timed by a precise developmental program. This work reveals an unexpected picture of the independence of sound features and their related developmental plasticity in the auditory cortex. Understanding the dependencies, the cortical presentations of sensory features, and their related developmental plasticity adds fundamental knowledge about how our central sensory system is built, organized, and functioning.

Title: Neuronal population dynamics upon complex sound stimulation in the auditory cortex in an auditory processing-impaired mouse model

Authors: *S. L. WADLE[1], T. T. X. SCHMITT[1], J. ENGEL[2], S. KURT[2], J. J. HIRTZ[1]; [1]Physiol. of Neuronal Networks, Biol., TU Kaiserslautern, Kaiserslautern, Germany; [2]Biophysics & CIPMM, Saarland Univ., Homburg, Germany

Abstract: The extraction of specific features from a complex acoustic environment is essential for orientation, social interaction, and surviving in everyday life. To successfully accomplish this task, it is necessary that every station in the pathway involved functions properly. The α2δ3 auxiliary subunit of voltage-gated calcium channels (VGCCs) is expressed in spiral ganglion and principal neurons of the auditory pathway. Its loss leads to reduced VGCCs and structurally and functionally impaired endbulb of Held synapses of the auditory nerve despite normal hearing thresholds. These changes are accompanied by deficits on the behavioral level. Albeit being able to distinguish simple pure tones (PTs) from each other, α2δ3-KO mice fail to discriminate between amplitude modulated (AM) tones (Pirone et al. (2014) α2δ3 Is Essential for Normal Structure and Function of Auditory Nerve Synapses and Is a Novel Candidate for Auditory Processing Disorders. J Neurosci 34(2):434-445). We wanted to investigate how these changes in early stations of the auditory pathway affect neuronal networks in the auditory cortex (ACx). Therefore, we injected AAV-hSyn1-jGCaMP7f into the ACx of α2δ3-KO mice and littermate controls. After 13 days we performed two-photon calcium imaging of neurons in Layer 2/3 of the ACx in awake animals while presenting different sets of acoustic stimuli in a passive listening task in daily sessions over a time course of 2 weeks. Stimuli consisted of PTs, AM tones, single animal vocalizations and a complex acoustic environment, containing several animal vocalizations.

Correlation-based clustering of neuronal activity during single animal vocalizations revealed no difference between genotypes regarding the number of clusters formed, as well as the number of neurons per cluster. Interestingly, physical distances between cells in clusters in KO animals are larger compared to controls, indicating integration from a larger area, pointing to a less structured organization. In addition, activity in clusters in KO animals is less correlated than in controls, possibly indicating impairments in spectro-temporal processing. Overall, these results indicate altered processing of complex acoustic stimuli in the ACx of α2δ3-KO mice. Whether these differences are gradually increasing or decreasing with complexity of the stimulus, as well as if subfield-specific alterations are present, is currently under investigation.

Title: Differential temporal modulation tuning in auditory responses between inhibitory and excitatory neurons in ferret auditory cortex.

Authors: *M. LOPEZ ESPEJO[1], S. V. DAVID[2];
[2]OHRC, [1]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Research in the mouse auditory cortex has shown differences in sound tuning properties between excitatory and inhibitory neurons. This differential inhibitory tuning is thought to sharpen spectral and temporal tuning and to contribute to gain control in excitatory pyramidal neurons. However, the generality of differential inhibitory and excitatory tuning across species remains unexplored, particularly in the case of non-rodent species. To explore this issue we used the inhibitory interneuron-specific promoter mDlx to drive cell-type specific expression of channelrhodopsin (ChR2) in the auditory cortex of ferrets. We confirmed expression of ChR2 and colocalization with GABAergic neurons histologically. We then recorded the sound evoked activity of neuronal ensembles using a silicon multielectrode array with an integrated optic fiber. During recordings, we identified putative inhibitory interneurons by short-latency responses to a brief blue-laser stimulus. We characterized differences between ChR2+ and ChR2- neurons in spectrotemporal receptive fields (STRFs) and temporal integration properties. Preliminary results suggest that tuning differs between cell types mostly in temporal properties. Inhibitory, ChR2+ neurons respond with greater latency and duration than ChR2-. Frequency tuning, unlike in mice, showed no significant difference, but this result must be confirmed with a larger sample.

Title: Overcoming deficits in the C57BL/6 mouse auditory spatial topography reveals that high-frequency hearing is required for frontal sound localization in the superior colliculus

Authors: *Y. SI[1], S. ITO[2], A. M. LITKE[2], D. FELDHEIM[1];
[1]MCD Biol., [2]Santa Cruz Inst. Particle Physics, UC Santa Cruz, Santa Cruz, CA

Abstract: The ability to locate the source of a sound in a complex environment and determine its saliency is critical for survival. A topographic map of auditory space has been found in the superior colliculus (SC) of a range of species, including CBA/CaJ mice, in which high-frequency monaural spectral cues and interaural level differences are used to generate spatial receptive fields (RFs) along the azimuth. Unfortunately, C57BL/6 mice, a strain widely used for transgenic manipulation, display an age-dependent hearing loss due to an inbred mutation in the *CDH23* gene that affects cochlear hair-cell tip link stability. To overcome this problem, auditory researchers have been using young (around 3-month) C57BL/6 mice in their studies, an age that has shown to have normal hearing thresholds, despite the fact that important details of the phenotypes of the age-dependent hearing loss, such as spectral responses and spatial localization, have not been well characterized. Here, using blind analysis and large-scale in vivo physiological recordings of SC neurons in response to auditory stimuli, we show that 2-4-month C57BL/6 mice (n = 15, 3869 SC neurons recorded) of both sexes lack neurons with frontal auditory RFs and therefore do not have a topographic representation of auditory space in the SC. Analysis of the spectrotemporal receptive fields (STRFs) of the SC auditory neurons shows that C57BL/6 mouse SC neurons lack the ability to detect the high-frequency (>40kHz) spectral cues that are needed to compute frontal RFs. We also show that either crossing C57BL/6 with CBA/CaJ (n = 6, 1266 SC neurons recorded) or introducing one copy of the wildtype *CDH23* gene to the C57BL/6 mice (n = 7, 1348 SC neurons recorded) rescues both the high-frequency hearing deficit and the auditory map of space. Together, these findings 1) show that the computation of frontal RFs in the SC is correlated with the ability of SC neurons to respond to high-frequency sound, 2) should alert auditory researchers that C57BL/6 mice have significant high-frequency hearing deficits and consequently impaired auditory spatial topographic mapping in the SC even around 3 months of age, and 3) show that F1 progeny of C57BL/6 × CBA/CaJ mice or the introduction of the wild type *CDH23* gene in C57BL/6 mice restores the azimuthal auditory topographic map in the mouse SC.

Title: Quantification of spatial variability in auditory cortical areas affecting stereotaxic targeting

Authors: *D. NARAYANAN, H. TSUKANO, A. M. KLINE, K. ONODERA, H. K. KATO; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: A major goal of neuroscience is to understand the specific functions of individual brain regions. Stereotaxic coordinates based on brain atlases are widely used for targeting individual regions for experiments such as viral injections, imaging, and electrophysiology. However, in the mouse neocortex, due to the lack of cytoarchitecturally defined landmarks that delineate borders between functional areas, it remains unclear how variability across individual animals affects the precision of stereotaxic targeting. Moreover, in the auditory system, it is becoming evident that the coarse delineation of auditory cortices in the mouse atlas as “A1, AuD, and AuV” is insufficient to describe the true complexity of their functional organization. Therefore, to build a more solid understanding of the cortical area-specific functions, it is necessary to reevaluate the accuracy of area boundaries in brain atlases. Here, to evaluate the spatial variability of functionally identified auditory cortical areas across individual animals, we analyzed intrinsic imaging signal data from over two hundred mice. We quantified variabilities in both (1) inter-areal relative locations and (2) absolute stereotaxic areal locations, and examined the influences of various factors, including genotype, age, and sex. Using these two metrics, we will estimate the likelihood of failure in the stereotaxic targeting of auditory areas. Finally, we will compare the stereotaxic coordinates of “AuV” in the atlas with our targeted marking of the functionally identified secondary auditory cortex (A2) to directly quantify the deviations. Our preliminary data suggest that stereotaxic targeting is prone to inaccuracy due to the marked spatial variability across individuals, indicating the necessity of targeting based on functional mapping. Together, we hope our work sets a new standard and helps the field move forward in dissecting cortical circuits to identify the unique roles of individual auditory cortical areas.

Title: Inhibitory gating of coincidence-dependent sensory binding in secondary auditory cortex

Authors: *A. M. KLINE, D. APONTE, H. TSUKANO, A. GIOVANNUCCI, H. K. KATO; Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Integration of multi-frequency sounds into a unified perceptual object is critical for recognizing syllables in speech. This “feature binding” relies on the precise synchrony of each component’s onset timing, but little is known regarding its neural correlates. We find that multi-frequency sounds prevalent in vocalizations, specifically harmonics, preferentially activate the mouse secondary auditory cortex (A2), whose response deteriorates with shifts in component onset timings. The temporal window for harmonics integration in A2 was broadened by inactivation of somatostatin-expressing interneurons (SOM cells), but not parvalbumin-expressing interneurons (PV cells). Importantly, A2 has functionally connected subnetworks of neurons preferentially encoding harmonic over inharmonic sounds. These subnetworks are stable across days and exist prior to experimental harmonics exposure, suggesting their formation during development. Furthermore, A2 inactivation impairs performance in a discrimination task for coincident harmonics. Together, we propose A2 as a locus for multi-frequency integration, which may form the circuit basis for vocal processing.

Title: Regulation of sensory processing in the primary auditory cortex by recurrent inputs from deep cortical layers

Authors: *K. ONODERA, H. K. KATO;
Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Information flow in the sensory cortex has been described as a predominantly feedforward sequence with deep layers as the output structure. Although recurrent excitatory projections from layer 5 (L5) to superficial L2/3 have been identified by anatomical and physiological studies, their functional impact on sensory processing remains unclear. Here, we use layer-selective optogenetic manipulations in the primary auditory cortex to demonstrate that feedback inputs from L5 suppress the activity of superficial layers, contrary to the prediction from their excitatory connectivity. This suppressive effect is predominantly mediated by translaminar circuitry through intratelencephalic (IT) neurons, with an additional contribution of subcortical projections by pyramidal tract (PT) neurons. Furthermore, L5 activation sharpened tone-evoked responses of superficial layers in both frequency and time domains, indicating its impact on cortical spectro-temporal integration. Together, our findings challenge the classical view of feedforward cortical circuitry and reveal a major contribution of inhibitory recurrence in shaping sensory representations.

Title: Neuronal population representations within and across cortical areas during perceptual decision making

Authors: *A. I. JASPER[1], C. K. MACHENS[4], B. M. YU[5,6], A. KOHN[1,2,3];

Dept., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Performing a perceptual task requires encoding sensory and decision signals in neuronal population responses and relaying these population signals between relevant brain areas. Numerous studies have investigated how sensory and decisions signals are encoded by single neurons. However, how the population representation of sensory and choice information relate to each other is poorly understood, and how these signals are relayed across brain areas on a trial-by-trial basis is nearly unexplored. To address these questions, we measured neuronal population activity simultaneously in early (primary visual cortex, V1) and midlevel (V4) visual cortex, while a macaque monkey performed a match-to-sample task. We implanted microelectrode arrays to sample ~50-100 neurons in each area, with retinotopically aligned receptive fields. We first compared the representation of stimulus and choice signals by asking how much information about each variable was available along the decoding axis of the other. We found that the representation of stimulus and decision signals were misaligned within both V1 and V4 populations: the decoding axis for one variable captured little of the available information about the other. These results appear inconsistent with proposals that decision signals reflect fluctuations in sensory neurons which drive decisions and proposals that decision signals reflect top-down beliefs about stimulus identity. Both proposals should result in aligned representations. We then used a dimensionality reduction approach—canonical correlation analysis—to understand how sensory and decision signals were relayed between areas. Consistent with previous work, we found that V1 and V4 population activity were related through a low-dimensional mapping-a communication subspace. Sensory information was robust in the communication subspace, in both areas. However, decision signals showed a marked asymmetry: nearly all decision-related activity in V1 was evident in the communication subspace, whereas in V4 much of the decision information was not. These results suggest a selective transmission of decision-related activity between visual areas. Together our findings suggest that decision signals in sensory cortex may have a different purpose than considered to date.

Title: Interdigitating modules for visual processing during locomotion and rest in mouse V1

Authors: *A. M. S. MEIER, A. BURKHALTER;
Neurosci., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Sensory responses are not rigid representations of stimuli, but instead are modulated by behavioral context. A prominent example of this occurs in mouse primary visual cortex (V1), in which locomotion increases the gain of visual responses in excitatory neurons. This elevated responsiveness has been shown to increase the fidelity of stimulus representations across the neuronal population, enhance plasticity, improve visual object detection, and facilitate recovery of visual function after cortical damage. Multiple mechanisms driving this modulation have been described, including release of inhibition from somatostatin (SST) neurons and activation of long-range inputs from the midbrain locomotor region. The wide variability of locomotion modulation among V1 neurons raises the question of whether modulation is randomly distributed among cells, or is present in a discreet population distinguished by connectivity, location, or response tuning. Previously we showed that Layer 1 (L1) contains interdigitating modules with high or low expression of muscarinic acetylcholine receptor 2 (M2+ patches and M2- interpatches) [Ji et al. 2015]. L2/3 cells aligned with M2- interpatches are tuned for features of moving objects, including temporal frequency and motion coherence, suggesting that they may play a specialized role in processing the dynamic visual stimuli encountered during locomotion. In this study, using calcium imaging in locomoting mice, we found periodic clusters of neurons in L2/3 with high locomotion modulation which are aligned with M2- interpatches. Additionally, M2- interpatch-aligned cell pairs showed an increase in correlated trial-to-trial variability (noise correlations) at long distances across V1, suggesting a role in integrating stimuli across the visual field, possibly for detecting optic flow or large moving objects. Using viral tract tracing and immunostaining, we found that two network architectures may account for this population-specific locomotion modulation: increased expression of SST projections in M2- interpatches and preferential targeting by secondary motor cortex inputs to M2- interpatches. Finally, we elucidate a possible role of M2- interpatch cells in visual guidance of behavior by showing that somas and dendrites aligned with M2- interpatches project to primary motor cortex. These findings reveal a specialized role for M2- interpatch cells in integrating and exploiting stimuli from a wide visual field during locomotion.

Title: The lateral geniculate nucleus as a potential target for prosthetic stimulation in freely moving tree shrew

Authors: *J. WANG, H. AZIMI, M. KAESER, M. HARVEY, G. RAINER;
Dept. of Med., Univ. of Fribourg, Fribourg, Switzerland

Abstract: The visual thalamic lateral geniculate nucleus (LGN) is a potentially attractive target for visual prosthetics due to its laminar and retinotopic organization. Here we are interested in studying how visual stimulation and electrical or optogenetic activation of the LGN impact visually based behavior and neural circuit responses in the visual pathway. We chose the northern tree shrew *T. belangeri*, a diurnal mammal with a highly developed visual apparatus. In behavioral studies, we used an opaque globe containing a nose-poke at its center to deliver visual stimuli in an approximately retinotopic fashion using a projector in freely moving animals. Tree shrews readily learned to nose poke in these conditions for a juice reward in absence of food or water restriction, and performed up to 1250 trials per day. In a discrimination paradigm, animals had to discriminate 20 Hz target full field visual flicker from distractor flicker (e.g. 1Hz or 40Hz). We studied acquisition of various flicker discriminations, as well as capacity of tree shrews to generalize to previously untrained flicker frequencies. In a detection paradigm, tree shrews had to enter a nose-poke, and remain there until a visual stimulus, in this case a cloud of moving dots resembling a phosphene, was presented at a particular visual field location. Preliminary data suggests that tree shrews can quickly acquire this detection task, achieving good behavioral performance for stimuli of 2° diameter in size.We have validated expression AAV2-CaMKIIα-ChR2 constructs in tree shrew LGN, and observed robust axonal expression in layer 4 of primary visual cortex, the major thalamocortical LGN projection target. In anesthetized experiment functional validation, we have also demonstrated robust LFP and spiking activity entrainment within the LGN to blue light pulses delivered at various rates between 5 and 80 Hz. We have also performed functional validation for LGN electrical microsimulation, where we could demonstrate activity entrainment to stimulation pulses in LGN as well as V1. Our findings suggest that the tree shrew could be a useful animal model system to systematically study how electrical or optogenetic interventions in the LGN impact activations across the visual pathways.

Title: Relativistic-like spatiotemporal distortions occur in young children at the time of saccades

Authors: *N. DOMENICI[1,2], A. TONELLI[1], M. GORI[1];
[1]Inst. Italiano di Tecnologia, Genova, Italy; [2]Dibris, Univ. degli Studi di Genova, Genova, Italy

Abstract: Adults perform more than 10,000 saccades per hour during wake, although most of them are unintentional. Interestingly, saccades produce big changes in visual perception, such as spatial mis-localization and temporal compression. Visual distortions within the peri-saccadic timeframe offered a powerful insight regarding how the human brain encodes space and time information. These effects have been explained considering receptive fields' predictive anticipatory remapping of neurons in both visual and parietal cortices. Even if incredibly fast, these remapping mechanisms are not instantaneous as they are constrained within the biophysical limit of neural communication. Nonetheless, it is reasonable to assume that the speed of remapping must be close to its limit, as predictive remapping must offset saccadic displacement. Because of this, spatial and temporal distortions observed during saccadic movement have been considered relativistic-like. In the current work, we investigated whether peri-saccadic spatiotemporal modulations also occur in children, whose maps in the brain might update at a different pace. To evaluate this possibility, we compared peri-saccadic spatial and temporal distortions between children (7-14 years old) and adults. Spatial modulations were evaluated asking participants to reproduce the position of a bar briefly presented before, during, or after the saccadic movement. Temporal distortions were instead evaluated asking participants to compare a post-saccadic fixed interval with a peri-saccadic interval, whose duration changes across trials. Regardless of their age, all the participants experienced the same level of spatiotemporal distortions, suggesting that the speed of remapping does not change between children and adults. In the end, our findings support the hypothesis that relativistic-like spatiotemporal compressions are an inherent feature of predictive remapping, and that such neural mechanisms have already reached functional maturity at 7 years of age.

Title: Brain state effects on responses of early visual cortex neurons: A system identification approach.

Authors: *J. J. SOORIYAARACHCHI[1], C. ZHAN[2], C. L. BAKER[3];
[1]Physiol., McGill Univ., Montreal, QC, Canada; [2]Biomed. Engin., Southern Med. Univ., Guangzhou, China; [3]Ophthalmology, McGill Vision Res. Unit, Montreal, QC, Canada

Abstract: A visual cortex neuron's response depends not only on the characteristics of a visual stimulus in relation to its receptive field (RF), but also "brain state" fluctuations which cause substantial trial-to-trial variability. Brain state effects on sensory coding are poorly understood, potentially compromising RF estimation. Here we analyzed the interaction between a neuron's spiking response and brain state inferred from local field potentials (LFPs) to obtain better quantitative estimates of neuronal RFs. We used extracellular recordings from the primary visual cortex of anesthetized, paralyzed cats recorded with 32-channel NeuroNexus probes (polytrodes and linear arrays) which responded to rapid sequences of natural images (Talebi and Baker, 2012). Low-pass filtering (< 100Hz) was employed to extract LFPs from the raw recorded signals, and single units were isolated using SpikeSorter software (Swindale & Spacek, 2015). Phase amplitude coupling (PAC) provided an indication of the relationship between spiking responses and different frequency bands of the LFP signal. We then employed a system identification approach using machine learning, with a model architecture incorporating an LFP-driven filtering pathway in parallel with a stimulus-driven RF pathway, followed by a simple output nonlinearity. The model parameters were estimated with an iterative regression algorithm with L2 regularization, using TensorFlow and Keras on a training dataset, along with a validation dataset for regularization. The variance accounted for (VAF) was used to evaluate the model's predictive performance on a hold-back test dataset. Results from the PAC analysis showed that the spiking responses of neurons are strongly linked to various frequency band oscillations as well as the envelope of high frequency gamma oscillations (30-100 Hz) of the LFP signals. The system identification revealed the relevance of similar LFP frequency bands. However, different neurons recorded simultaneously showed significant relationships with different frequency ranges of the LFP (e.g. delta, beta), and varying degrees of contribution from the gamma envelope. Incorporating brain state effects provided significant improvements in VAF measures of predictive performance, in spite of the additional model parameters. These findings highlight the importance of incorporating the trial-to-trial variability due to brain state variations in studies of sensory coding at the single neuron level and indicate that the nature of brain state variations may vary substantially across different neurons.

Title: Does running modulate visual responses in primate V1?

Authors: *J. LISKA[1], J. L. YATES[2], J.-O. MUTHMANN[1], A. HUK[1];
[1]Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX; [2]Univ. of Rochester, Rochester, NY

Abstract: Although activity in mouse visual cortex is strongly modulated by running, it is unknown whether similar occurs in primate V1. In fact, attentional and other-top down modulations are notoriously small and difficult to elicit in single V1 neurons in monkeys. To test whether insights from rodents translate to primates, we measured activity in V1 of marmoset monkeys when they were running and stationary. Because marmosets are a largely arboreal species, we provided them an "infinite branch" on which they can comfortably remain stationary or freely locomote. We recorded single- and multi-unit activity in foveolar V1 using chronically-implanted 64-channel 3D "N-form" electrode arrays, while presenting sinusoidal gratings of varying orientation, spatial frequency, and direction. We measured gaze position and also mapped receptive fields using reverse correlation. Both marmosets naturally alternated between running and stationary periods running ~20% of the time. Running epochs were defined as periods of forward movement at a speed greater than 3 cm/s; mean running speed was 19 and 14 cm/s for the two monkeys, respectively. We have recorded 415 unique units in 24 sessions in one marmoset and 42 units from 1 session in a second marmoset. To test for the presence of running modulations, we resampled trial-balanced firing rates both before stimulus onset and during the presentation of drifting sine wave gratings. We measured direction tuning curves for each behavioral state (running vs. stationary) and compared the difference in tuning curve peaks to a surrogate "null" distribution of differences generated by resampling after artificially shuffling the behavioral state. We then evaluated the fraction of units with significant modulation. We observed no net or unified population-level effects during running; however, 5% of units increased baseline firing rate, 9% decreased baseline firing rate, 9% increased stimulus-evoked firing rate, and 9% decreased stimulus-evoked firing rate (false positive rate = 5%). While such effects are not comparable to the large modulations observed in rodents, recent work has shown running modulations to be highly cell-type specific in rodents, and we have only begun to categorize the small subset of cells that show possible statistically-significant running

modulations in our dataset. Further analysis of the properties of the modulated cells is required for more definitive conclusions about the existence and nature of locomotion effects in primate V1.

Title: Distinct "driving" versus "modulatory" influences of different visual corticothalamic pathways

Authors: *M. A. KIRCHGESSNER[1,2,3], A. D. FRANKLIN[1,4], E. M. CALLAWAY[1,2]; [1]Salk Inst., La Jolla, CA; [2]Neurosciences Grad. Program, Univ. of California San Diego, La Jolla, CA; [3]New York Univ. Sch. of Med., New York, NY; [4]Sainsbury Wellcome Ctr., London, United Kingdom

Abstract: Higher-order (HO) thalamic nuclei, such as the pulvinar in the visual system, interact extensively with the cerebral cortex in ways that are thought to be important for sensation and perception, attention, and many other important brain functions. However, a complete mechanistic understanding of these corticothalamic interactions - especially those involving the HO thalamus - is lacking. One notable organizational feature of corticothalamic connectivity that is shared across sensory and even non-sensory systems is that HO thalamic nuclei (including the pulvinar) are innervated by two distinct excitatory corticothalamic (CT) populations in layers 5 and 6. The functional significance of having these two different CT pathways to the HO thalamus is not known but has generated significant interest and speculation. One prevailing idea in the field is that layer 5 (L5) projections may be the primary “drivers” of functional response properties in their HO thalamic targets, whereas layer 6 (L6) projections act instead as “modulators”. However, whether distinct CT projections exert different functional influences (e.g., “driving” versus “modulatory”) on the HO thalamus *in vivo* has never been directly tested. To address this question, we utilized different transgenic mouse lines and viral approaches to selectively express inhibitory opsins in L6 and/or L5 CT neurons of the primary visual cortex (V1) and recorded single unit activity from V1 and the pulvinar (also known as LP) in awake mice. We additionally recorded from the first-order (FO) visual thalamic nucleus, the

dorsolateral geniculate nucleus (dLGN), which also receives L6CT "modulatory" input but is not innervated by L5. By optogenetically inactivating one or the other CT population in V1, we demonstrate that L5, but not L6, CT projections drive visual responses in the HO visual pulvinar, even while both pathways provide retinotopic, baseline excitation to their thalamic targets. Dual optogenetics experiments confirmed that individual pulvinar neurons are "driven" by V1 L5 but not by L6. We also explored the functional influence of the superior colliculus (SC) on a region of the pulvinar that receives both V1 and SC input. Individual pulvinar neurons could be driven by the SC, by V1 L5, or even by both, suggesting that different "driving" inputs can converge onto individual cells. Altogether, these results reveal how different cortical (and subcortical) projections play distinct roles in shaping activity and sensory response properties in the HO visual thalamus.

Title: Functional and anatomical characterization of parallel spatiotemporal frequency channels in the mouse retinogeniculocortical pathway.

Authors: *H. WANG, O. DEY, E. M. CALLAWAY, B. STAFFORD;
Salk Inst., La Jolla, CA

Abstract: Primate retinal ganglion cells (RGCs) form anatomically and functionally segregated parallel pathways that project to the primary visual thalamus (LGN) and form distinct output channels to different layers of primary visual cortex (V1) (Nassi 2009). Whether a similar organization exists in the mouse is not well understood. Evidence suggests that a pathway originating from direction-selective RGCs transmits direction information to layer 1 of V1 via the LGN "shell" (Cruz-Martín 2014). Whether other RGCs types, like those tuned to different spatial frequencies (SFs) and temporal frequencies (TFs), that project to the LGN "core" form parallel channels to layer 4 of V1 in mice is unknown. We used two-photon calcium imaging to characterize layer 4 neurons labeled by two transgenic mouse lines (Nr5a1-Cre and Scnn1a-Tg3-Cre) and found that they are tuned to different SFs, TFs, and speeds. Mice were injected with AAV-FLEX-GCaMP6s in V1 and visual responses to drifting sine wave gratings and coherent

dot motion stimuli were imaged to reveal preferred SF, TF, and speed. We found significant differences between Nr5a1 (n=121) and Scnn1a-Tg3 (n=231) neurons in preferred SF, TF, and speed tuning. Nr5a1 neurons preferred lower SFs (median = 0.02 cpd vs. 0.04 cpd, p = 4.8e-9), and higher TFs (median = 3.1 cps vs. 0.9 cps, p = 1.4e-29) than Scnn1a-Tg3 neurons. Among speed tuned neurons, Nr5a1 neurons preferred faster speeds than Scnn1a-Tg3 neurons (median = 128 deg/s vs. 21.1 deg/s, p = 7.5e-11). Next, we labeled RGCs that provide input (via LGN) to Nr5a1 or Scnn1a-Tg3 neurons using transsynaptic rabies virus tracing. We first injected Cre-dependent AAVs expressing optimized rabies glycoprotein (AAV-FLEX-oG) and TVA (AAV-FLEX-GFP-TVA) into V1 of Nr5a1-Cre and Scnn1a-Tg3-Cre mice, and a non-Cre dependent AAV expressing oG into LGN. 21 days later, G-deleted rabies virus (EnvA-RVdG-mCherry) was injected into V1. 7 days later, mice were perfused, and brains and retinas harvested. Retinas were stained for anti-RFP and anti-ChAT. RGC type was characterized based on the stratification pattern of their dendrites relative to the ChAT bands in confocal z-stacks. The results of this study are currently being analyzed; we expect differences in RGC dendrite stratification based on RGC types that respond to different SFs, TFs, or speeds.

Title: Morphological evidence for multiple distinct channels of corticogeniculate feedback originating in mid-level extrastriate visual areas of macaque monkeys and ferrets

Authors: *M. ADUSEI[1], A. J. MURPHY[1], J. M. HASSE[2], E. M. CALLAWAY[3], W. M. USREY[4], F. BRIGGS[1];
[1]Univ. of Rochester Neurosci. Grad. Program, Rochester, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Salk Inst., La Jolla, CA; [4]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: In the visual system, retinal information reaching the lateral geniculate nucleus (LGN) of the thalamus is mainly relayed to the primary visual cortex (V1). Geniculocortical projection neurons in the LGN include magnocellular, parvocellular, and koniocellular cells that convey distinct, stream-specific visual information. While the majority of geniculocortical neurons project to V1, there are also sparse geniculocortical projections to extrastriate visual cortical

areas that are thought to originate primarily from koniocellular cells. Importantly, feedforward geniculocortical projections to V1 are complemented by reciprocal, feedback corticogeniculate projections. In macaque monkeys and ferrets, multiple morphologically distinct corticogeniculate subtypes exist in V1, and also in V2. Here we investigated whether corticogeniculate neurons are present in extrastriate visual cortex and whether these neurons are morphologically homogeneous, i.e., aligned with primarily koniocellular geniculocortical inputs, or diverse. We identified and characterized the morphology of corticogeniculate neurons in three macaque extrastriate visual cortical areas: V4, MT, and MST, and their ferret homologs: area 21a, PMLS, and PLLS respectively. We discovered morphologically diverse corticogeniculate subtypes in all three extrastriate areas across the two species. Most extrastriate corticogeniculate neurons were morphologically similar to those previously identified in V1 and V2. Whether unique corticogeniculate subtypes send stream-specific information to the LGN is not known, but prior physiological evidence based on axon conduction latencies and visual responses properties suggests that distinct corticogeniculate subtypes align with the feedforward parallel processing streams. Together, our findings suggest that V1-independent reciprocal connectivity between the LGN and extrastriate visual cortex, in ferrets and macaques, involves multiple diverse corticogeniculate cell types possibly relaying functionally distinct visual signals.

Title: Motion/direction-sensitive thalamic neurons project extensively to the middle layers of primary visual cortex

Authors: *J. ZHUANG, Y. WANG, N. OUELLETTE, E. TURSCHAK, R. LARSEN, K. TAKASAKI, T. DAIGLE, B. TASIC, J. WATERS, H. ZENG, R. C. REID;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The motion/direction-sensitive and location-sensitive neurons are two major functional types in mouse visual thalamus that project to the primary visual cortex (V1). It has been proposed that the motion/direction-sensitive neurons mainly target the superficial layers in V1, in contrast to the location-sensitive neurons which mainly target the middle layers. Here, by

imaging calcium activities of motion/direction-sensitive and location-sensitive axons in V1, we find no evidence for these cell-type specific laminar biases at population level. Furthermore, using a novel approach to reconstruct single-axon structures with identified *in vivo* response types, we show that, at single-axon level, the motion/direction-sensitive axons have middle layer preferences and project more densely to the middle layers than the location-sensitive axons. Overall, our results demonstrate that Motion/direction-sensitive thalamic neurons project extensively to the middle layers of V1, challenging the current view of the thalamocortical organizations in the mouse visual system.

Abstract: Higher-order (HO) thalamic nuclei contribute to sensory processing via projections to primary and higher cortical areas, but it is unknown which of their cortical and sub-cortical inputs contribute to their distinct output pathways. We used sub-population specific viral strategies in mice to anatomically and physiologically dissect the inputs and outputs of the HO thalamic nuclei of the somatosensory and visual systems (POm and Pul respectively). Employing a complementary optogenetics and electrical stimulation strategy, we show that HO thalamic synapses in cortex have functionally divergent properties in primary (S1 and V1) vs. higher cortical areas (S2 and Higher Visual Areas or HVAs). HO thalamic projections onto excitatory targets in S1 and V1 were weakly modulatory while projections to S2 and HVAs were drivers of post-synaptic targets.
Then, using G-deleted rabies tracing verified by optogenetics to map inputs to HO thalamus, we

show that HO thalamocortical cells in POm projecting to S1 are driven by layer 5 of S1, S2, and M1, and that HO thalamocortical cells in Pul projecting to V1 are driven by layer 5 of V1 and HVAs. Therefore, in both sensory systems, layer 5 of primary and secondary sensory cortex drive trans-thalamic feedback modulation of primary sensory cortex through HO thalamus. These results highlight conserved organizational principles that may be shared by other HO thalamic circuitry, and they support the hypothesis that all direct cortico-cortical projections in the brain are paralleled by cortico-thalamo-cortical or trans-thalamic pathways, even in the feed-back direction. They also suggest that feedforward trans-thalamic pathways act as drivers well suited to information-bearing, while feed-back through HO thalamus is modulatory, as has been hypothesized for cortico-cortical projections.

Title: Center-surround spatial organization of corticogeniculate feedback

Authors: *A. N. SANCHEZ, H. J. ALITTO, W. M. USREY;
Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Neurons in the lateral geniculate nucleus (LGN) process and relay visual signals from the retina to primary visual cortex (V1). V1, in turn, gives rise to feedback pathways terminating in the LGN. Although much is known about the anatomical organization of corticogeniculate (CG) feedback, relatively less is known about its role during sensory processing. Because CG feedback can provide monosynaptic excitation and disynaptic inhibition to LGN neurons, the effects from CG feedback may be complex. We have previously shown that the filtering of retinal spike trains by the LGN depends upon both stimulus size and contrast. Specifically, the likelihood that a retinal spike is transmitted to the cortex is reduced by both large stimulus sizes (e.g., extraclassical suppression) and high stimulus contrasts (e.g., contrast gain control). Thus, current work is focused on understanding how CG feedback may contribute to these two processes in the LGN. To investigate the influence of CG feedback on visual processing in the LGN of awake primates, we infected V1 (n = 2 macaque monkeys) with either Jaws or DLX-channelrhodopsin and reversibly silenced CG neurons. To remove both the monosynaptic

excitation and disynaptic inhibition from V1 onto the LGN, we inactivated retinotopically defined regions of V1 while recording from individual parvocellular LGN neurons (median retinotopic displacement 1.5^{o}, 52 off-center cells, 25 on-center cells). Our results demonstrate that CG feedback has a functional center-surround organization that differentially modulates LGN classical and extraclassical mechanisms. Importantly, the polarity of the organization is dependent upon the presence of extraclassical suppression. When extraclassical suppression is present (a feature most common in off-center cells), CG feedback amplifies responses to stimuli that are restricted to the LGN neuron's classical receptive field and suppresses responses to stimuli that extend into the extraclassical surround. By contrast, the polarity of excitation and suppression from CG feedback is reversed when LGN neurons exhibit surround facilitation (a feature most common in on-center cells). In this case, CG feedback suppresses responses to stimuli restricted to the classical receptive field and facilitates responses to stimuli that extend into the extraclassical surround. Ongoing experiments are investigating how stimulus contrast influences this center-surround organization of cortical feedback. These results require revision to our current view of corticothalamic circuitry and have important implications for understanding the dynamics of thalamocortical interactions.

Title: Cortico-thalamic projections gate alpha rhythms in the pulvinar

Authors: *N. CORTES[1], L. IKAN[1], R. ABBAS FARISHTA[2], C. F. CASANOVA[1];
[2]Sch. of optometry, [1]Univ. De Montréal, Montreal, QC, Canada

Abstract: Two types of cortico-thalamic terminals reach the pulvinar nucleus of the thalamus, and their distribution varies according to the hierarchical location of the projecting cortical neurons. While type 2 terminals are more abundant at lower hierarchical levels, higher cortical areas mostly exhibit type 1 axons. Terminal types 1 and 2 evoke an excitatory postsynaptic potential (EPSP) that is facilitated (short-term facilitation, STF) or depressed (short-term depression, STD) over time, respectively. These observations yield fundamental questions about the role of these different terminal types along the cortical hierarchy. Our theoretical results support that the co-action of the two types of terminals produces different oscillatory rhythms in pulvinar neurons. More precisely, at a specific range of connectivity weights, terminals type 1

and 2 produces alpha-band oscillations. Interestingly, when the two types of terminals are empirically arranged as the projections of areas 17 and 21a into the pulvinar, the actions of these cortico-thalamic connections are antagonistic. When area 17 (21a) generates low-band oscillatory activity, cortical area 21a (17) shifts pulvinar responses to stable asynchronous spiking activity. To further investigate such oscillatory effects along the transthalamic pathway, we created a cortical feedforward network of two cortical areas with cortico-thalamic connections to a pulvinar-like network. This model simulated the interaction between cortical areas 17 and 21a with the pulvinar. Here, the transthalamic pathway allows the propagation of alpha waves from the pulvinar to area 21a. This oscillatory transfer is ceased when reciprocal connections from area 21a reach the pulvinar, so functionally closing the cortico-thalamic loop. The pulvinar shows a bi-stable spiking activity, oscillatory or irregular asynchronous spiking, whose responses are gated by the different activation of cortico-pulvinar projections from areas 17 and 21a. Preliminary experimental results are shown to reinforce such theoretical findings.

Title: Narrowband gamma oscillations propagate throughout the mouse thalamocortical visual system

Authors: *D. SHIN, J. DEL ROSARIO, K. PEELMAN, B. HAIDER;
Biomed. Engin., Georgia Tech. and Emory Univ., Atlanta, GA

Abstract: Rhythmic neural activity in the “gamma” range (30 – 80 Hz) is thought to play an important role in communication between brain areas. Recent studies in awake mice show that strong narrowband gamma oscillations (NBG; 50-70Hz) in mouse primary visual cortex (V1) arise from the lateral geniculate nucleus (LGN; Niell and Stryker, 2010; Saleem et al., 2017). The strength of NBG in V1 varies with visual stimuli, but also with behavioral state and task performance (Speed et al., 2019), suggesting NBG may contribute to perception. It remains unknown if NBG activity spreads to higher visual areas (HVAs), and whether its timing is conserved across LGN, V1, and HVAs. Answering these questions requires large-scale simultaneous neural recordings from LGN, V1, and HVAs, and a framework for detecting and

quantifying population and single-neuron level NBG activity.
Here we analyzed the Allen Institute's Visual Coding dataset of simultaneous multi-site Neuropixels recording across LGN, V1, and HVAs in awake mice (33 sessions). We analyzed population signals (local field potential, LFP), single neuron spiking, and pairwise neuronal interactions to assess the strength and timing of NBG activity throughout the mouse visual system. We established a framework of identifying neurons with significant NBG spiking activity (NBG cells) using both auto-correlogram (ACG) and cross-correlogram (CCG) analysis. We performed several control measures to ensure that the identification of NBG cells was unlikely to be artefactual
We found strong evidence for NBG activity simultaneously across LGN, V1, and HVAs. First, we observed significant NBG LFP power in all recorded HVAs. Second, we found significant NBG cells in these same recordings in all HVAs (57 cells, 15 sessions). Third, we found significant pairwise correlated spiking between NBG cells in LGN ,V1 and HVAs. Many pairs showed significant CCG peaks then troughs at short latencies (< 4.5ms), suggesting direct functional interactions (Senzai et al., 2019, Siegle et al., 2021). Remarkably, the likelihood of significant pairwise interactions between pairs of NBG cells in V1 (4.72%, n = 126 pairs), was significantly higher than among all other V1 cells (1.1%, n = 2974 pairs) during the same recordings ($p<1e-8$). These effects suggest that NBG activity propagates through a preferred subnetwork of neurons across LGN, V1, and HVAs. These findings identify a substrate for rapid NBG communication across multiple visual areas in awake mice.

Title: Pulvinar modulates cortical visual activityby increasing the gamma band contrast response.

Authors: *L. IKAN, N. CORTES, C. F. CASANOVA;
Ecole d'optométrie, Univ. de Montréal, Montreal, QC, Canada

Abstract: The pulvinar has a widespread connectivity with the visual cortex. A recent study from our group has described the impact of silencing the pulvinar on the contrast response function (CRF) of neurons in two distinct hierarchical cortical areas of the cat visual cortex, namely areas 17 and 21a (de Souza et al., 2019). To study whether oscillatory cortical signals depend upon the pulvinar activity, we studied the contrast response of the gamma- and alpha-band oscillatory responses in areas 17 and 21a during thalamic inactivation. Our data showed

that the pulvinar inactivation altered the response gain in both areas, but with more significant changes observed in area 21a. These findings were based on the linear change of the CRF position (driver effect) and the nonlinear variation in the CRF dynamic range (Rmax; modulatory effect). Extracellular responses to full-field gratings of varying contrast were recorded in both cortical areas in anesthetized cats using linear probes before, during and after the GABA inactivation of pulvinar. Local field potentials (LFPs) from low-pass filtering of raw recordings were analyzed with Wavelet to assess oscillatory gamma waves. During inactivation, gamma frequency increases as a function of increased visual contrast in area 21a. In area 17, there was no significant changes across cortical layers after pulvinar inactivation, whereas in area 21a, the inactivation yielded an increase in Rmax in most layers but mainly in layer IV as the coefficient of variation for Rmax increased by ~25% for layer IV in area 21a for gamma rhythms. These findings indicate that the pulvinar enhanced gamma-band synchronization in higher-order cortical areas, in agreement with the notion that it is involved in the attentional modulation of visual cortical neurons.

Title: Learning the Feedback Connections from V1 to LGN via Information Maximization

Authors: *R. EGHBALI[1,2], F. T. SOMMER[3], S. SHERMAN[4];
[1]Baker Computat. Hlth. Inst., Univ. of California, San Francisco, CA; [2]Berkeley Inst. for Data Sci., [3]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, CA; [4]Dept Neurobiol, Univ. Chicago, Chicago, IL

Abstract: The lateral geniculate nucleus (LGN) relay cells act as a gateway for transmitting visual information from retina to the primary visual cortex (V1). The activities of thalamic relay cells are modulated by feedback connections emanating from layer 6 of V1. This gives the cortex a degree of control over the flow of information from retina to V1. While the receptive field properties of these early parts of the visual system are relatively well understood, the function, computational role, and details of the feedback network from V1 to LGN are not. Previous

studies suggest that the feedforward Shannon information could be important for understanding the function of the feedback. Computational models of efficient coding were able to derive receptive field properties of retinal ganglion and V1 simple cells from optimizing Shannon information. Further, previous experimental results have suggested that the feedback increases the Shannon information.
Motivated by this earlier work, we try to understand the function of the feedback as optimizing the feedforward information to cortex. To model this, we set up an information maximization problem to learn a set of convolutional feedback kernels. These kernels determine the strength and sign of feedback from a V1 cell to all ON and OFF LGN relay cells in the receptive field and the surrounding ones in the parvocellular pathway. The feedback kernels resulting from our optimization have either a "Mexican hat" shape or its flipped version depending on the polarity match or mismatch. For example, the kernel suggests an excitatory feedback on an ON LGN cells from a V1 cell fed by ON LGN cells when the two receptive field locations largely overlap. Conversely, the feedback is inhibitory when the receptive fields are slightly offset. There is no feedback when the receptive fields are further offset. The feedback effect reverses when there is a mismatch in polarity. Although only driven by the maximization of Shannon information in V1, our model conforms --and thus can explain-- recent experimental results in the literature.

Title: Task-based reactivation makes visuomotor memories susceptible to interference

Authors: T. SURESH, A. KUMAR, ***P. K. MUTHA**;
Indian Inst. of Technol. Gandhinagar, Gandhinagar, India

Abstract: Learning and memory are essential functions of daily life. Memory consolidation theory states that memories are labile immediately after acquisition and become stable after consolidation, defined as resistance to interference. However, the reconsolidation theory posits that when a consolidated memory is reactivated, it becomes fragile and susceptible to interference and requires "reconsolidation" for long term storage. We aimed to study the effect of reactivation on the consolidation in motor memories. In our first experiment, we used a visuomotor adaptation task and a 3-day A-B-A study design, wherein following baseline practice, subjects learned a 30° counter-clockwise rotation A on day 1 followed by a competing

30° clockwise rotation B on day 2, and were retested on A on day 3. Subjects were divided into two groups, depending on whether the prior memory of A was briefly reactivated on day 2 just before B learning (A-AB-A) or not (A-B-A). Surprisingly, we found robust interference in both groups. Specifically, A learning on day 3 was not different from naïve A learning on day 1 in either group, suggesting that interference might be independent of task-based reactivation. We then wondered whether the effect of reactivation was being masked by anterograde effects of B learning on the learning of A on day 3. In a second experiment, we therefore introduced null rotation (N) trials prior to A learning on day 3 in two new groups with (A-AB-NA) and without (A-B-NA) reactivation. These null trials served to wash out anterograde effects of B learning. Remarkably, we now found interference only in the reactivation group. Without reactivation, the memory of A acquired on day 1 was protected and could be expressed as savings on day 3. Taken together, our findings suggest that task-based reactivation can make a memory labile and susceptible to interference from a competing memory. This view is aligned with previous studies that suggest that reactivation brings a consolidated memory from an inactive to an active state; in this active state, any new information can modify the original memory. These results hold implications for strategizing protocols aimed at improving motor memory retention in neurorehabilitation and sports.

Title: Presenting endpoint feedback at movement onset maximizes implicit sensorimotor learning

Authors: *T. WANG[1,2], G. AVRAHAM[1,2], J. S. TSAY[1,2], R. IVRY[1,2];
[1]Psychology, [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: A classic observation in sensorimotor adaptation is that learning is better with online feedback compared to endpoint feedback. There are a number of possible explanations for this difference: Online feedback is dynamic, continuous, and begins with movement onset whereas endpoint feedback involves the static presentation of feedback at the end of movement. Although these factors are typically confounded in comparisons of online and endpoint feedback, the relevance of timing is shown by the dramatic attenuation of learning that is observed when endpoint feedback is delayed, even by as little as 100 ms (Held et al. 1966; Kitazawa et al. 1995).

The cost of delaying feedback raises the complementary question, does advancing the timing of "endpoint" feedback improve learning?
To explore this problem, we used a visuomotor adaptation task in which participants reach to a visual target. To provide advanced feedback, we used the visual clamp method in which the feedback cursor is always presented at an invariant position, deviated from the target by a fixed angle (and thus independent of hand position). Despite instructions to ignore this task-irrelevant feedback, participants show implicit motor adaptation with all of the hallmarks of adaptation in response to standard feedback. An unexplored advantage of clamped feedback is that it allows us to manipulate the timing of the feedback, independent of the movement.
We first replicated the advantage of online feedback over endpoint feedback with a visual clamp, comparing when the clamp was visible throughout the reach with its radial position aligned to the hand position to a condition in which the clamp only appeared at radial position of the target. Asymptotic values of adaptation for the online and endpoint conditions were 20.5° and 14.0°, respectively. Strikingly, when the "endpoint" feedback was presented at movement onset, the asymptotic value was 20.9°, a value similar to that observed with online feedback. The duration of the advanced feedback did not impact adaptation. Learning functions were similar for advanced feedback that persisted throughout the movement or was limited to 20 ms. In subsequent experiments, we manipulated the timing of endpoint feedback, including presenting it up to a couple hundred milliseconds prior to movement initiation. We found that the range of feedback time that drives the maximal level of adaptation was narrow (±50 ms relative to movement onset). These results demonstrate that the primary advantage of online feedback is not related to the dynamic, continuous nature of the signal, but rather that the feedback signal for online feedback appears earlier than with standard endpoint feedback.

Title: Learning twice the same motor task to investigate the mechanisms of anterograde interference

Authors: *R. HAMEL[1], J.-F. LEPAGE[3], P.-M. BERNIER[2];
[2]Dept. de Kinanthropologie, [1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [3]Pediatrics, Sherbrooke Univ., Sherbrooke, QC, Canada

Abstract: Anterograde interference has been repeatedly attributed to a competition between differing task memories. However, recent development alternatively suggests that initial learning may trigger a refractory period that occludes neuroplasticity and impairs subsequent memory formation, consequently mediating interference independently of memory competition. Accordingly, this work tested the hypothesis that interference can emerge when participants adapt *twice to the same gradually introduced visual deviation*, that is when competition between memories is prevented. In a first experiment, the inter-session interval (ISI) between two identical adaptation sessions was manipulated to be 2 min (n = 20), 1 h (n = 20) or 24 h (n = 20). Retention, through immediate reach aftereffects, was evaluated after each session. Results revealed that retention of the second session was impaired as compared to the first one when the ISI was 2 min but not when it was 1 h or 24 h, indicating a time-dependent process. Results from a second experiment (n = 20) replicated those of the first one and revealed that adding a third adaptation session with a 2 min ISI further impaired retention, indicating a dose-dependent process. Results from a third experiment (n = 20) revealed that the retention impairments did not take place when a learning session was preceded by the simple execution of baseline reaches without concurrent adaptation, thus ruling out fatigue and confirming that retention is impaired specifically when preceded by a learning session. A fourth experiment (n = 24) behaviorally manipulated the putative overlap between adaptation-specific neural networks recruited by the two adaptation sessions. Results showed that anterograde interference emerged regardless of memory competition and along a gradient as a function of the adaptation sessions' similarity; adaptation under similar conditions generated more anterograde interference than adaptation under dissimilar conditions, indicating that putatively overlapping neural networks are required to generate interference. Altogether, the present results introduce the possibility that a time-, dose-, learning-, and network-dependent refractory period contribute to the emergence of anterograde interference.

Title: Spontaneous recovery in an untrained arm: insight into interlimb generalization of motor memories

Authors: *A. KUMAR[1], P. K. MUTHA[2];
[1]Mechanical Engin., [2]Biol. Engin., Indian Inst. of Technol., Gandhinagar, India

Abstract: Multi-rate models of motor adaptation predict spontaneous recovery, or transient expression of previously learned behavior, following an adaptation-extinction paradigm. This recovery has been attributed to a slow, implicit mechanism which operates in parallel with a fast, explicit process to drive learning and formation of a motor memory. We (Kumar et al., 2020) recently showed that the memory representation acquired via the slow process is effector-independent. We found that generalization of learning to an untrained arm, the signature of an effector-independent memory, was well-predicted by the level of the slow process reached during learning with the opposite arm. We therefore asked whether spontaneous recovery would be seen in an untrained arm, following an adaptation-extinction experience with the opposite arm. Two groups of right-handed subjects first adapted to a 30-degree counterclockwise visuomotor rotation (A, 200 trials) and were then exposed to a 30-degree clockwise rotation (B, 20 trials). Subjects then performed 80 "error clamp" trials with the opposite arm; on these trials, the visual error was clamped to zero. One group (LR) adapted to rotations A and B with their left arm and then performed the error clamp trials with their right arm. This order was reversed for the second group (RL). We first observed that adaptation to A and B was not different between the groups. However, spontaneous recovery was evident only in the LR group. That is, the right arm of the LR group was directed as if it was compensating for rotation A (learned previously by the left arm), even though this rotation was not present and error had been clamped to zero. Thus, learning seemed to generalize from the left arm to the right, and was expressed as spontaneous recovery. In contrast, recovery was absent in the RL group. This result provided a confirmation on two counts: first, since spontaneous recovery is the signature of the slow process, its occurrence in the untrained arm reinforced the view that slower, implicit processes forge an effector-independent motor representation that yields interlimb generalization. Second, it bolsters the view that interlimb generalization of visuomotor learning is asymmetric. We speculate that this occurs because access to the effector-independent memory representation is asymmetric.

Disorders and Stroke, Bethesda, MD; [2]Amazon.com, Inc., Barcelona, Spain; [3]Dept. of Electrical and Computer Engin., The Univ. of Texas at Austin, Austin, TX; [4]Dept. of Neurol., Univ. of Leipzig Med. Ctr., Leipzig, Germany; [5]Inst. of Neurosci. & Psychology, The Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Skill acquired in one task can transfer or generalize to another novel task. [1–3] We conducted a series of experiments to determine transfer between tasks during early motor skill learning, [4,5] when memories may still be fragile.[1] Subjects performed an explicit motor sequence task in an online naturalistic crowdsourcing environment. We evaluated transfer of skill acquired after a short training session in task A to task B. Across a set of experiments we parametrically changed the properties of tasks A and B. In experiment 1 (4 groups; total $n = 551$), we observed substantial performance transfer after only a single practice trial of A such that performance of task B was even better than performance at the end of practice of task A. Additional practice trials of task A did not enhance transfer. In experiment 2 (5 groups; total $n = 718$), we provided longer intervals between tasks, which did not enhance transfer. Finally, in experiment 3 (5 groups; total $n = 674$) we asked what content is transferred. To address this question, we manipulated the similarity between tasks A and B. We report that rapid transfer of procedural skill relied on the ability to extrapolate a parsing rule relating salient events within the practiced and transfer sequence rather than on the specific ordinal or transitional similarities between them. While data collection is ongoing, it appears that rapid generalization of skill in early motor learning can occur following a single trial of practice, may exhibit an offline contribution, and is dependent on similar salient rules between the tasks.

Title: Placebo Effects of tDCS on Cognitive and Motor Training

Authors: *N. K. HAIKALIS[1], P. WANG[1], A. HOOYMAN[1], L. LOSSNER[1], R. YANG[1], S. JEJUKAR[1], M. GODMAN[1], K. WOODBURN[1], A. DETTMER[2], S. Y. SCHAEFER[1];
[1]Biomed. Engin., [2]Psychology, Arizona State Univ., Tempe, AZ

Abstract: Studies using transcranial direct current stimulation (tDCS) to enhance cognitive and/or motor training often produce equivocal results. Differences in stimulation parameters (e.g., stimulation site, intensity, or duration) may contribute to mixed findings; It is thus plausible that placebo effects like expectations about tDCS may interact with the true 'treatment' effect of tDCS, resulting in mixed findings. We have recently shown that the general public has higher-than-neutral expectations about tDCS to enhance motor performance. Thus, the purpose of this study was to test whether there was a placebo effect of tDCS on cognitive and motor training.

Forty-seven participants (age:23.74 ± 4.37 years; 24 female) were randomly assigned to one of three groups: active anodal tDCS (n=19), sham tDCS (n=17), or no-tDCS control (n = 11). All participants completed a pre-test of the Shepard-Metzler Mental Rotation Task (MRT), followed by 20 minutes of training on the Corsi Block Tapping Task. Participants were re-tested on the MRT, measuring changes in cognitive (visuospatial) performance. Participants then completed 30 trials of motor training on a functional reaching task (measuring improvement in motor performance), followed by an exit questionnaire that measured their expectations about tDCS. The tDCS stimulation (20-min, 2mA) was applied to the right parietal area (P4) and paired with visuospatial training only for the sham and anodal tDCS groups.

No online tDCS treatment effect on visuospatial training was observed; rather, a placebo effect was, such that the sham group demonstrated more improvement in MRT reaction times than the active tDCS ($\beta = 125.29$, $p = .046$) and the no-tDCS control ($\beta = 151.58$, $p = .037$) groups. Regarding motor training, no offline tDCS treatment effect was observed, such that the sham and active tDCS groups did not differ in performance improvement nor final performance at the end of training (all $p>.160$). However, the sham group improved more than the no-tDCS control group during training in two aspects of the functional reaching task (object manipulation, $p = .036$; object transfer, $p = .044$). Moreover, regardless of group, better final performance at the end of motor training was associated with higher expectations about tDCS ($p = .015$).

Thus, this exploratory study showed there is a measurable placebo effect of tDCS on both

cognitive and motor training. This placebo effect was stronger than the true 'treatment' effect of tDCS and was likely driven by participants' expectations about tDCS. Future studies should consider placebo effects in tDCS research and treatment, as the neural capacity for such effects is not well understood.

Title: Boost your brain? 100% oxygen supply improves motor learning processes during a visuomotor adaptation task.

Authors: Z. WANG[1], *G. SPIELMANN[1], N. JOHANNSEN[1], F. GREENWAY[2], *M. DALECKI[1];
[1]Sch. of Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Pennington Biomed. Res. Ctr., Baton Rouge, LA

Abstract: Normal-baric 100% oxygen treatment (100%NbOxTr) during first aid enhances neuronal survival rates in the human brain after heart attacks or strokes. However, whether motor learning processes of the brain can be improved by this treatment is not known. Motor learning (e.g., adapting to a visuomotor distortion) requires updating existing motor programs by integrating new cognitive and motor-related sensory information. Learning or reorganization of such capabilities is crucial for skill acquisition and neurorehabilitation. The present study examined the effects of 100%NbOxTr on visuomotor adaptation. Healthy young adults (m = 21 yrs.) were split into a 100%NbOxTr group (n=13) or a control group (mixed air; n=14) and performed a visuomotor adaptation task. During this task, participant's moved a pen along a horizontal tablet to move a cursor on a vertical display from a center target to peripheral targets. Peripheral targets (1.5 cm diameter) were presented in quasi-random order at 8 positions with 7.5 cm distance to the center target. Overall, 30 sessions were performed, and each session included 24 trials with 3 trials to each peripheral target. First, 4 sessions were performed with visual feedback correctly representing the pen position (baseline phase), followed by 20 sessions with 60° clockwise rotated visual feedback (adaptation phase), 3 sessions with correct visual feedback (after-effect phase), and 3 final sessions with distorted visual feedback (refresher phase). Gas

treatment was administered via nasal cannula (5 l/min) only during the 20 adaptation phase sessions. Variables of interest were initial direction error (IDE) and pathlength (PL) of the pen stroke to the target. Participant's mean baseline was subtracted from the subsequent phases for further analysis. ANOVA's (factors: group, session) were performed for each phase. For the baseline phase, no group-related differences were found for IDE and PL (all $p>0.05$). Significant group effects existed for adaptation and refresher phase (all $p\leq0.05$), with lower values in group 100%NbOxTr (adaptation: IDE -29%; PL -56%; refresher: IDE -25%; PL -60%) than in group mixed air. PL was also lower in the after-effect phase in group 100%NbOxTr (-46%; $p<0.05$). Our study shows that movement planning and execution-related characteristics of visuomotor adaptation were improved by 100%NbOxTr. Short-term consolidation of this effect sustained in refresher and partially in after-effect phases. Our finding suggests that 100%NbOxTr may improve neuroplasticity processes during motor learning tasks. This technique may provide promising potential for neurorehabilitation or skill training approaches.

Title: The role of effort in motor learning

Authors: R. MARBAKER, *A. AHMED;
Univ. of Colorado, Boulder, CO

Abstract: In previous research, reward and punishment, monetarily valued or as points-based scores, modulate the rate of learning, how much is retained, and how much of that learning is expressed (saved) upon re-exposure (Nikooyan 2014, Galea 2015). In other studies, cognitive effort induced by random task order during learning, enhanced savings after one week (Frömer 2016). The role of physical effort, the effort associated with completing the movement in the task, is not clearly understood. In this study, we investigate the effect of effort costs on the process of motor adaptation. Specifically, we asked whether increased effort costs would accelerate learning. Participants held the handle of a robotic arm and made 10 cm out-and-back reaching movements to one of eight possible targets evenly spaced about the center circle. Participants performed a visuomotor rotation (VMR) task, which consisted of five phases:

baseline, adaptation with a 30-degree visuomotor rotation, retention without visual feedback, washout, and savings during which they were exposed to the same 30-degree visuomotor rotation. To modulate effort costs, we modified a traditional VMR task so that the robot consistently opposed the hand motion with a damping force. Participants were divided into three groups: a high effort cost group where the damping constant was 20 Ns/m (N =10), a low effort cost group where the damping constant was 5 Ns/m (N = 4), and an error-dependent effort cost where damping on the following trial increased with increasing error on the previous reach (N=11). We hypothesized that the combined mechanisms of error-reduction and effort-reduction would accelerate learning for the error-dependent group. To quantify learning rates, we fit state-space models to individual subject data during adaptation and savings to quantify learning rates and retention factors. Preliminary findings show participants in all groups adapt to the VMR and exhibit savings. Error reduction over the course of adaptation appears positively correlated with the forces experienced during adaptation. Individuals who experienced greater forces during adaptation reduced their error to a greater extent. Further data collection will help elucidate the role, if any, of effort in driving or inhibiting motor adaptation.

Title: Implicit sensorimotor adaptation occurs during motor imagery, but execution potentiates it

Authors: *C. PAWLOWSKY, F. THÉNAULT, P.-M. BERNIER;
Kinanthropology, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: In error-driven sensorimotor adaptation, a sensory prediction error (SPE) emerges when the actual and predicted sensory feedback do not match. This discrepancy leads to adaptive motor responses. These predictive mechanisms, relying on the efference copy of the motor commands, have been shown to be involved in motor imagery (MI) when an action is internally simulated without moving. However, even if MI is commonly reported to improve motor performance, it is unknown whether it can generate SPE and lead to adaptive motor responses. Here, using a reaching task with single-trial visuomotor rotations in a within-subject design (n=30), it was hypothesized that providing a rotated visual feedback time-locked to the moment at which participants were asked to imagine reaching a target on trial n would lead to adaptive motor responses when actually reaching on trial n+1 (MI condition). In a Control condition, the

same rotated visual feedback was provided while participants were instructed to make a small non-specific inward arm movement following target onset, irrespective of its location, in order to prevent them from performing meaningful MI. In an Execution condition, participants physically performed the reaching movement on trial n while being provided with rotated visual feedback. Results revealed that the magnitude of the post-rotation bias in hand direction was largest in the Execution condition. Interestingly, smaller but significant adaptive biases opposite to the direction of the perturbation were also observed in the MI and Control conditions. This implies that SPEs can be generated in absence of movement execution. It also suggests that sensorimotor adaptation is further improved by movement execution and/or dynamic proprioceptive signals, probably reflecting refined state estimation.

Title: Smart dura: a large scale flexible semi-transparent interface for non-human primates

Authors: *T. BELLOIR[1], S. MONTALVO VARGO[2], D. J. GRIGGS[1], I. KIMUKIN[2], Z. AHMED[2], J. REDDY[2], S. FISHER[1], Z. ANDERSON[1], M. CHAMANZAR[2], A. YAZDAN-SHAHMORAD[1];
[1]Univ. of Washington, Seattle, WA; [2]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Studying large scale cortical circuits in non-human primates (NHPs) is important to gain insight on a variety of neural phenomena from fundamental mechanisms to neural disease and mechanisms of recovery. To do so, there is a need for chronically stable neural interfaces that are capable of recording neural activity with high spatial and temporal precision from large areas, while permitting the integration of additional modalities such as imaging or optogenetics manipulation. In that context, we have developed a novel neural interface, called *smart dura* that monolithically incorporates a micro-electrocorticographic (µECoG) array in an artificial dura. The µECoG arrays include recording electrodes that have been patterned on a Parylene C substrate embedded in polydimethylsiloxane (PDMS). PDMS is also the material used for the structure of the artificial dura since it is biocompatible, transparent and castable for realizing large and flexible structures. This original approach not only allows for large scale high density

electrophysiological recording, it also equips our interface with optical access and chronic stability. Here we discuss *in vivo* experiments to assess the utility and electrophysiological recording capacity and performance of our *smart dura*. Electrical recordings were acquired acutely in macaque sensorimotor cortex using arrays with electrode diameters ranging from 20 to 40 µm. We will discuss acute electrophysiological recordings from our interface in response to tactile stimulation on each finger of the monkey's right hand, enabling mapping its digit representation. The transparency of our interface allowed us to photochemically induce a focal ischemic lesion targeting a specific digit location determined with the somatotopy map. Electrical activity recorded before, during and after the lesion produces somatotopy maps that reveal the predicted functional changes of the lesioned circuits. These experiments show that our *smart dura* is capable of recording electrophysiology signals while maintaining optical access over large regions of NHP cortex (up to 300 mm^2). In addition, demonstrating the somatotopy maps acquired with our interface is a proof of concept that we can link a sensory function to the corresponding circuit activity, as well as induce a targeted lesioning of the underlying circuit. Our *smart dura* is well suited both for acute and chronic experiments and has the potential to accommodate higher recording sites density. Paired with complimentary stimulation modalities, it can be used to study more complex large-scale neural phenomena associated with the behaviors and cognitive abilities of non-human primates.

Title: The influence of pre-processing methods on the reconstruction of continuous speech from stereo-electroencephalography

Authors: *M. VERWOERT[1], M. C. OTTENHOFF[1], S. GOULIS[1], J. P. VAN DIJK[2], A. COLON[2], S. TOUSSEYN[2], L. WAGNER[2], P. KUBBEN[1,3], C. HERFF[1];

Abstract: Reconstructing speech directly from neural signals has the potential to be an intuitive tool for restoring communication in individuals who have lost the ability to speak. Recent advances have been made to reconstruct speech with techniques that are fast enough to be applied in real-time for a closed-loop brain-computer interface (BCI) system. However, the reconstructed speech has yet to reach high intelligibility and the feasibility of reconstructing speech with stereo-electroencephalography (sEEG) has not been extensively studied. Here, we evaluate if sEEG can be used for speech synthesis and how different pre-processing techniques impact the quality of the reconstructed speech. We aim to gain an understanding of the underlying neural processes and contributing regions within the sparse sampling provided by sEEG. We simultaneously recorded sEEG and acoustic data in epileptic patients undergoing assessment for resective surgery, while articulating 100 uniquely prompted Dutch words continuously for five minutes. The acoustic data was transformed into the frequency domain using Fast Fourier Transform to create a speech spectrogram. The sEEG data samples were divided into overlapping windows which were time-aligned to the corresponding speech spectrograms. A timeframe of 400ms of neural data centered around the spectrogram was considered for the reconstruction. Regression approaches were applied to reconstruct the complete speech spectrogram from the neural data alone. We further investigated the influence of several pre-processing techniques on the reconstruction and on signal quality metrics. Results show that the speech spectrogram can be reconstructed using sEEG. We furthermore found that local referencing methods are beneficial compared to broader referencing in terms of apparent signal quality, however, this does not necessarily translate to improvements in the reconstruction of speech. This work encourages the potential use of sEEG electrodes for a speech neuroprosthesis and contributes to the knowledge on sEEG pre-processing methods.

Title: The brain interchange evaluation kit allows bench-top preparation for clinical studies with a wireless implantable brain-computer interface

Authors: *M. SCHUETTLER, C. STOLLE, M. OBERT, F. KOHLER, T. LEDWIG, J. F. QUICENO QUINTERO, J. RICKERT;
Cortec GmbH, Freiburg Im Breisgau, Germany

Abstract: We developed a brain-computer interface which is an implanted device that wirelessly communicates with a personal computer. The device is capable of brain recording and stimulation on 32 channels and allows the investigation of new closed-loop neuromodulation therapies. To de-risk clinical studies, clinical researchers can evaluate the system using a bench-top version of the implant. Together with an electronic representation of brain implanted electrodes, this bench-top implant comes as a kit suitable for investigation of system behavior, such as programming features (C, C++ or Python using an application programming interface API), stimulation output, recording properties, noise and timing aspects, wireless connectivity, etc. The bench-top implant can also be connected to electrodes in saline, e.g. for investigation of artifact pickup when stimulation and recording is carried out at the same time. Besides these in-vitro evaluations, the bench-top implant can be connected to patients having implanted electrodes with externalized leads as a first feasibility phase towards a complete implantation study. By this way, clinical brain-computer-interface studies can have two de-risking phases: 1. In-vitro system setup, programming and evaluation, 2. Connection of the bench-top version of the implant to externalized leads of electrodes implanted in patients, to eventually begin the 3. phase: chronic implantation of the electronic implant.

Title: Galvanic stimulation evokes more natural neural responses than pulsatile stimuli.

Authors: C. STEINHARDT, ***G. FRIDMAN**;
Johns Hopkins Univ., BALTIMORE, MD

Abstract: Implantable pulse generators used ubiquitously in neural implants are constrained to delivering charge balanced biphasic pulses to modulate neural activity. Until recently low frequency galvanic (non-pulsatile) current modulation has not been possible without violating charge injection safety constraints. Safe direct current stimulator (SDCS) implant technology (Aplin and Fridman, 2019) supplants this restriction allowing for ionic galvanic current (iGC) modulation of the neuronal activity delivered via electrolyte-filled flexible conduits. The effects of iGC and pulsatile neuromodulation of the peripheral vestibular system have been examined experimentally in both behavioral assays and single afferent recordings. We developed a vestibular afferent computational model and replicated the experimental results of both stimulation paradigms in-silico. In verification with experimental data, pulsatile stimulation trains evoked a wide range of neural firing rates. Also, in agreement with previously obtained experimental data iGC could smoothly excite or inhibit neural activity while maintaining natural stochasticity of inter-spike intervals. The computational model allowed us to identify the complete range of neural responses to both pulse trains and iGC modulation that would not be possible otherwise. Pulse-train effects on the neural firing rate strongly depend on the pulse rate, pulse amplitude, and spontaneous activity of the neuron. For sub-threshold amplitudes (<~60uA), pulse-effects add to produce a single spike for multiple pulses, with threshold defined as the minimum amplitude at which a single pulse will evoke a single action potential. For supra-threshold mid-range amplitudes (~60-250uA) pulses evoked a single spike for each pulse at low pulse rates (<~150pps). At higher pulse rates however pulse-evoked AP refractory period interferes with the subsequent pulse to evoke one AP for every two pulses. High amplitudes (<250uA) will block the ability of subsequent pulses to produce spikes at higher rates (<~250pps). Spontaneous activity strongly interferes with the ability of pulses to evoke spikes. In contrast, iGC delivery changes the afferent's extracellular membrane potential. Depending on the polarity of the iGC, it smoothly depolarizes or hyperpolarizes the resting membrane potential, effectively modulating the threshold of AP generation in response to its synaptic inputs. This ability to modulate sensitivity of the afferent to its inputs could account for the improvement in behavioral assays that use iGC over its pulsatile correlate.

Title: Radiculopathy treated with Kilohertz Frequency Alternating Current Stimulation

Authors: *L. DEWBERRY[1], K. PORCHE[2], K. ALLEN[2], K. J. OTTO[1];
[1]Univ. of Florida, Gainesville, FL; [2]university of florida, gainesville, FL

Abstract: We evaluated the ability of kilohertz frequency alternating current (KHFAC) stimulation of the sciatic nerve to block behavioral evidence of pain and disability in a rat model of sciatic nerve lumbar disc herniation. Approximately 90% of clinical sciatica is caused when an intervertebral disk is herniated or slips. When this happens, nucleus pulposus (NP) slips out from the protective ring of the annulus fibrosus and causes inflammation of the nerve root through both compression and inflammatory signaling factors present in the NP. KHFAC applied to a nerve causes a nerve conduction block which is rapidly reversible when applied for less than 5-10 minutes. If applied to an injured sciatic nerve, KHFAC may limit hyperalgesic signals reaching the central nervous system, thereby limiting painful sensation from the innervated area distal to the stimulation. To mimic a physiologic radiculopathy, autologous tail NP was harvested and placed upon the right L5 nerve root. Male Lewis rats (3 mo.) (n=24) were separated into 3 groups: NP injury + KHFAC (n=7), NP injury + sham cuff (n=6), and sham injury + sham cuff (n=5). 6 rats were used for baseline measurements only. The surgeon was blinded to group assignment until the NP placement step. Electrode cuffs were placed around the ipsilateral sciatic nerve trunk. During blocked trials, a 50 kHz, 1 mA peak-to-peak sinusoidal waveform was delivered via the sciatic cuff. An optically isolated stimulus isolation unit (model 2200; A-M Systems) was used in conjunction with a high-pass filter circuit to limit direct current contamination of the waveform. Prior to surgery and for 2 weeks following surgery, animal tactile sensitivity, gait, place preference, and standing weight distribution were evaluated. Tactile sensitivity was evaluated through Chaplan's method for von Frey filaments. Gait was measured by recording freely moving animals. Gait kinematics were assessed using DeepLabCut and dynamics through force plate readings. The researcher testing behavior was blinded. 50 percent Paw withdrawal thresholds show that KHFAC applied to a distal cuff electrode can treat allodynia caused by this NP model. Without KHFAC, injured animals had increased mechanical sensitivity compared to baseline ($p<0.05$). Thresholds obtained with KHFAC were significantly higher than unstimulated thresholds ($p<0.01$), indicating KHFAC decreased hypersensitivity. Following our hypothesis, KHFAC decreases hypersensitivity but does not cause additional gait disability. This supports the idea that KHFAC applied to a peripheral nerve may be able to treat chronic pain resulting from sciatica.

Title: Mechanisms of electrical stimulation of spinal cord micro circuits: Rebound suppression after acute transection

Authors: M. K. CHARDON, *M. JOHNSON, A. A. MAHROUS, J. MILLER, C. HECKMAN; Physiol., Northwestern Univ., Chicago, IL

Abstract: Spinal cord stimulation is widely used in patients with chronic pain, and electrical activation of spinal circuits has potential as an assistive therapy for individuals with spinal injury (Formento et al., 2018; Harkema et al., 2011; Minassian et al., 2004; Roy, Harkema, & Edgerton, 2012). However, the neurophysiology of spinal stimulation is still relatively unknown. Here we explore the mechanisms of direct electrical stimulation (DES) of the dorsal surface of the spinal cord. We use DES to stimulate the dorsal surface of the lumbar enlargement and record the behavior of the canonical motor micro circuit (CMM) of the ankle flexor and extensor pair (Sol/TA) in the decerebrate cat. CMMs are comprised of Ia sensory axons, interneurons (IN) and motoneurons (MN), are repeated segmentally throughout the spinal cord and form the basis of reciprocal inhibition between agonist/antagonist muscle pairs and their proper function is critical for inter-joint coordination. Stimulation of the Sol/Ta CMM (10Hz-40Hz, 500µA, 5s) generated distinct force patterns comprised of 3 phases: an initial transient spike at the start of the stimulus, a profound inhibition during the duration of the stimulus and a long (< 15 s) sustained phase (rebound) after removal of the stimulus in the Sol muscle, as well as a single phase, strong activation during the stimulation period, in the TA muscle. The force responses of TA and Sol are essentially mirror opposites during stimulation due to their reciprocal inhibitory relationship. The rebound force in Sol could illustrate the activation of persistent inward currents (PICs) in spinal motoneurons (MNs) or the interaction among inter neurons, allowing strong muscle activation when the stimulation ceased (rebound). We also previously showed that these patterns could be modulated by electrode location, favoring activation of TA or Sol. In the acute thoracic transection (T12) the responses change : transection abolished rebound activity in the Sol muscle but did not alter the interplay between Sol and TA. Rebound could not be induced even at stimulation intensities 4 times the stimulation used on the intact spinal cord suggesting dependence on a supra spinal mechanism. These results suggest that the excitatory/inhibitory balance between motor pools can be effectively modulated by electrical stimulation of the CMM via dorsal spinal stimulation and that there exists a fundamental difference between intact and transected spinal cord.
