Abstract: Social communication deficits are a hallmark of many neuropsychiatric disorders, such as autism spectrum disorders. Social communication is controlled, in part, by the anterior hypothalamus (AH), making the AH a potential pharmatherapeutic target for alleviating social deficits in neuropsychiatric disorders. In Syrian hamsters, social communication includes a sterotyped flank marking behavior that is controlled by vasopressin V1a receptor activation in the AH. Injection of vasopressin into the AH induces flank marking and lesions of the AH or injections of V1a receptor antagonists decrease the expression of flank marking. Given these results, we hypothesized that activating or inhibiting the AH with chemogenetics would regulate flank marking in an opposing manner. Specifically, we predicted that chemogenetic activation of the AH would increase flank marking, while chemogenetic inhibition of the AH would decrease flank marking. To examine our hypothesis, we transduced adeno-associated viruses expressing either hM3Dq (i.e., Gq-linked DREADD; excitatory; $n = 9$), hM4Di (i.e., Gi-linked DREADD; inhibitory; $n = 7$), or mCherry (i.e., control virus; $n = 7$) into the AH of male hamsters. Three weeks after transduction, subjects were injected I.P. with either clozapine (0.1 mg/kg diluted in saline; note: dose of clozapine did not affect flank marking in controls) or vehicle in a counterbalanced design and then placed into either a clean cage or a cage recently marked by a same sex conspecific. Flank marking was then scored for 30 mins. We found, contrary to our predictions, that excitation of the AH led to decreased flank marking compared to controls and that inhibition of the AH led to increased flank marking compared to controls, independent of whether testing occurred in a clean cage or a cage containing conspecific odor. These data

suggest that the ultimate output of the AH has inhibitory action on flank marking and that V1a activation in the AH might act to inhibit that output. These results extend our previous data supporting a critical role of the AH in regulating social communication and further our understanding of the AH circuitry involved.

Title: Mesoscale hypothalamic network dynamics in social behavior

Authors: S. STAGKOURAKIS, G. SPIGOLON, J. KIM, M. FEYDER, *D. J. ANDERSON; Caltech, Pasadena, CA

Abstract: In the animal kingdom, aggression holds a unique position on the spectrum of social behaviors, as its expression has high metabolic costs and potentially life-threatening consequences. Whether the brain utilizes an exclusive strategy for eliciting this risky behavior remains unknown. Previous work has identified features in the control of this behavior, such as the finding that silencing of different hypothalamic nuclei halts the expression of aggression, raising questions over the operating principles of the functional network underlying its expression. Here, we performed simultaneous neural activity measurements throughout the hypothalamus and identified that aggression correlates with high levels of inter-region synchrony, not observed in other social behaviors. Following the expression of attack, recurrent aggressive episodes correlate with lower activity levels, albeit highly synchronous. Surprisingly, pan-hypothalamic synchrony persists even after the end of an aggressive encounter suggesting this feature as a marker of a generalized aggressive state. These results reveal the unique neural encoding properties of social behaviors at the level of the hypothalamus, and identify specialized features in control of an animal's most risky social behavior expression.

Title: Zfp189-mediated transcription in prefrontal cortex controls social behavior and promotes mature pyramidal neuron morphology

Authors: N. L. TRUBY[1], ***G. M. SILVA**[1], J. A. PICONE[1], H. E. WOOLARD[1], R. L. NEVE[2], X. CUI[1], P. J. HAMILTON[1];
[1]Virginia Commonwealth Univ., Richmond, VA; [2]Massachusetts GeneraL Hosp., Boston, MA

Abstract: Earlier work has correlated the expression of *Zfp189* within mouse prefrontal cortical (PFC) neurons with enhanced behavioral resilience to chronic social stress. However, the exact mechanisms through which *Zfp189* is able to manifest stress resilience remains unclear. The *Zfp189* gene product is a Krüppel associated box (KRAB) zinc finger transcription factor of unknown function. To directly interrogate the transcriptional function and gene targets of ZFP189, we reprogrammed the endogenous ZFP189^{WT} by replacing the repressive KRAB domain with an enhanced transcriptional activation domain (VP64-p65-Rta (ZFP189^{VPR}) or by removing the functional moiety entirely (ZFP189^{DN}). We demonstrate divergent transcriptional regulation at a *luciferase* target gene, *in vitro*. Upon packaging these ZFP189 variant constructs in herpes viral vectors (HSVs) and delivering to mouse PFC, we observe that mice infected with HSV-ZFP189^{VPR}, the variant with inverted transcriptional function relative to the pro-resilient ZFP189^{WT}, demonstrate dramatically reduced social behaviors when exposed to a subthreshold defeat stress. Other stress-related behavioral metrics, like elevated plus maze, remain unaffected. The infected PFC tissues were then microdissected and subjected to RNA-sequencing, providing insight into which ZFP189-gene targets might be mediating these effects. Lastly, we investigated the consequences of altered ZFP189-mediated transcriptional function on spine density and morphology in cortical pyramidal neurons. Mice were transcardially perfused with 4% paraformaldehyde, brain tissue was extracted and sectioned, and was then imaged on a Zeiss 880 Airyscan confocal microscope. We observed pyramidal neurons infected with either ZFP189^{WT} or ZFP189^{VPR} possessed greater spine density and mature spine morphology relative to the transcriptionally inert ZFP189^{DN} and GFP controls. Collectively this body of work indicates that *Zfp189* mediates stress resilience by acting as a transcriptional repressor at key target genes in PFC cortical neurons, which drive dendritic spine maturity and pro-social behaviors.

Title: Development of a novel automated behavior analysis system for multiple freely-moving marmosets

Authors: *T. YURIMOTO, T. INOUE, W. KUMITA, K. SATO, Y. KUROTAKI, E. SASAKI; Central Inst. For Exptl. Animals, Kawasaki-Shi, Japan

Abstract: Many behavioral abnormalities are caused by symptoms of many neurological disorders. The common marmosets (*Callithrix jacchus*) social behaviors are similar to those of humans than rodents, such as family-based herding and food-sharing behaviors. Recently, various genetically manipulated marmoset models of neurodegenerative diseases have been created. However, it is unclear when and how the new genetically modified marmoset models will develop symptoms. Therefore, an automated behavioral analysis system that accurately detects and quantifies the lifelong behaviors of the model animals is necessary. Using this system to detect behavioral changes before and after the onset of disease and abnormal signs in the very early stages. However, there are no reports of behavior analysis systems for multiple marmosets or large cages that can house marmoset families. This study developed a behavior analysis system that combines light detection and ranging (LiDAR), video tracking, and deep learning for automatically tracking and analyzing individual behaviors of multiple marmosets in a family cage were tracked and their behaviors detected. Three wild-type family marmosets were kept in a family cage (W820 × D610 × H1578 mm) in accordance with EU guidelines. At the front and back of the cage were installed acrylic panels for acquisition of images from cameras and LiDAR. Four LiDAR and four cameras were set up in front of the cage. LiDAR and video tracking by deep learning were used to detect the positions of individual marmosets and create trajectories for each scene. Each trajectory was identified by face recognition using deep learning, and over one month simultaneous tracking of multiple animals. In addition, the animal behaviors were detected by deep learning of video frames to determine their content and location. The behavior information was matched with the tracking information to identify which animal performed the behaviors. So far, the face recognition accuracy is more than 85%. In addition, we have confirmed that the creation of trajectories and the detection of grooming behaviors of three animals can be accurately done by comparing with visual inspection.

Currently, video frames of typical behaviors such as drinking, feeding, mating, lying down, stretching, purring, jumping, tongue flicking, and marking are collected as training data for deep learning. Using these training data, not only the individual trajectories but also the animals behaviors will be automatically classified.

Title: An interneuronal neuropeptidergic circuit modulates birdsong stability

Authors: *B. M. COLQUITT, M. S. BRAINARD;
Dept. of Physiol., UCSF Ctr. For Integrative Neurosci. and Howard Hughes Med. Inst., San Francisco, CA

Abstract: A hallmark of skilled behavior is consistent performance across renditions. Although the neural mechanisms that maintain stable performance have been extensively studied at systems and physiological levels, little is known about how the molecular properties of motor circuits influence skill stability. Songbird courtship song, a model for skilled behavior, is a highly structured vocalization that is learned and adaptively maintained throughout adulthood. To identify molecular pathways that influence song stability, we developed a dense gene expression profiling approach to characterize transcriptional responses across song neural circuitry to song destabilization following deafening. Song destabilization induced the largest expression changes in the motor output nucleus RA, including a strongly downregulated module of genes enriched in Pvalb and Sst-class GABAergic interneurons. Furthermore, this module showed an interaction in RA between song destabilization and singing rate, suggesting that the expression of these genes is coupled to both song stability and the amount of singing. The most highly modulated gene among these was corticotropin releasing hormone binding protein (CRHBP), whose product binds the neuropeptide corticotropin releasing hormone (CRH), a pathway previously implicated in neuronal excitability and plasticity. The CRH signaling pathway is expressed in non-overlapping neuronal populations in each song motor region and therefore could act as a local neuromodulatory pathway that influences song stability. Consistent with this role, genetic and pharmacological manipulation of the CRH pathway in the song motor

pathway resulted in bidirectional modification of song variability with CRHBP acting to maintain low variability and CRH acting to increase variability. These data indicate that singing engages an interneuronal neuropeptidergic pathway in motor circuits that maintains the consistency of song, thus providing a molecular mechanism to couple motor performance and stability.

Title: An amygdalocortical circuit for the integration of multisensory social cues

Authors: *A. NOWLAN, A. CORONA, C. KELAHAN, S. D. SHEA;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Many species, including mice, communicate using multisensory signals to coordinate social behaviors essential for survival. How social experience influences multisensory integration and supports dynamic behavioral goals is not well understood at the circuit level. For example, when newborn pups become separated from the nest, a mother relies on olfactory and auditory cues to motivate her retrieval of pups back to the nest. Co-housing a virgin female with a dam and her pups is sufficient to provoke maternal retrieval behavior and olfactory-auditory integration without pregnancy. In mothers and experienced virgins ('surrogates'), pup odor modifies activity within the auditory cortex (AC) to enhance the detection of pup distress calls and potentially improves retrieval performance. However, the underlying circuitry involved in olfactory-auditory integration and maternal behavior remains incomplete.Here we reveal that projection neurons from the basal amygdala (BA) target the AC, detect olfactory cues, and evoke experience-dependent changes to the neural activity within the AC. Using fiber photometry, we show that BA-AC projection neurons are sensitive to pup odor and are primarily active while the surrogate mother searches for an isolated pup. We find that optogenetic activation of the BA-AC terminals during the presentation of auditory stimuli elicits complex changes in the activity of auditory neurons. Both ongoing and auditory evoked activity was preferentially suppressed in pup-naïve females but enhanced in surrogate mothers. Our results suggest that relaying olfactory cues through the amygdala may enhance the perception of pup distress calls by conveying contextual features about the pup stimuli to the AC. These features might comprise the perceived

salience or valence of individual social cues or the animal's overall affective or behavioral state, however, these details remain undetermined. Nevertheless, the BA-AC circuit represents a novel avenue by which the amygdala modulates primary sensory cortex that warrants further exploration and may be particularly relevant to anxiety and autism spectrum disorders.

Title: Knockout of the autism-associated gene Shank3B leads to alterations in social and vocal behavior in female mice

Authors: *R. S. CLEIN[1], M. R. WARREN[2,1], J. P. NEUNUEBEL[1];
[1]Univ. of Delaware, Newark, DE; [2]Emory Univ., Atlanta, GA

Abstract: Autism spectrum disorder (ASD), a highly heritable neurodevelopmental disorder, is characterized by challenges in social interaction, verbal and non-verbal communication, and enhanced repetitive behaviors (Faras et al., 2010). While the exact etiology of ASD is unknown, multiple genetic alterations have been associated with autism-like behavior. For example, more than 50% of patients with Phelan-McDermid syndrome (22q13.3 deletion syndrome) have a syndromic form of ASD, and most have a chromosomal deletion on the *SHANK3* gene (Phelan & McDermid, 2012). Mice with a *Shank3B* deletion (Peca et al., 2011) show physiological and behavioral abnormalities, providing a promising model for the study of ASD. However, although equal proportions of males and females carry a 22q13 deletion (Tabet et al., 2017), most behavioral studies using mouse models of *Shank3B* deletion focus solely on males. Therefore, direct quantification of the innate social and vocal behavior of female mice with genetic modifications to the *Shank3b* gene is lacking. To that end, we used a sound source localization system to simultaneously record the social and vocal behavior of females and males in mixed-sex groups (2 males and 2 females per group) of either *Shank3b* knockout mice (KO; n = 6 groups, 24 mice) or wild-type controls (WT; n = 7 groups, 28 mice). Surprisingly, pairs of KO females interacted with each other more often than did pairs of KO males (Mann-Whitney, $U = 21$ $p < 0.01$). This pattern was not observed in WT animals (Mann-Whitney, $U = 66$, $p = 0.09$). When quantifying the time females spent interacting with each other, KO females interacted for longer than WT females (Mann-Whitney, $U = 28$, $p < 0.05$). Even during interactions between females

and males, the duration was longer in KO than WT mice (Mann-Whitney, $U = 22$, $p < 0.05$). Moreover, the inter-individual distances between pairs of KO females were significantly smaller than WT females, indicating that KO females were physically closer together during social interactions than their WT counterparts (Mann-Whitney, $U = 68$, $p < 0.05$). However, the inter-individual distances between females and males were similar in KO and WT mice (Mann-Whitney, $U = 49$, $p > 0.05$). Additionally, during social interactions, the vocal rate of WT females was higher than KO females (Kruskal-Wallis, $H = 20.67$, $p < 0.01$, Dunn-Sidak post hoc correction). Taken together, these results demonstrate altered vocal and social behavior in female mice with known modifications in the *Shank3b* gene and suggests that genetic alterations to the *Shank3B* gene differentially affect behavior in males and females.

Title: Investigating the acoustic directionality of mouse ultrasonic vocalization

Authors: *Y. MA[1], M. R. WARREN[1,2], J. P. NEUNUEBEL[1];
[1]Univ. of Delaware, Newark, DE; [2]Emory Univ., Atlanta, GA

Abstract: Across the animal kingdom, ultrasonic vocalizations (USVs) are used as a means of communication, navigation, and predation, and in some species, the directionality of the signal facilitates these processes (Jakobsen et al., 2015; Portfors et al., 2014). Previous research has shown that some species of bats and whales produce highly directional ultrasound beams to echolocate (Au, 1993; Surlykke et al., 2009). While numerous studies have demonstrated that mice produce USVs in a variety of social contexts (e.g., Warren et al., 2021), the directionality of these signals is less clear, as identifying the vocalizer in group settings is challenging. To that end, we used an 8-channel microphone array to localize and assign USVs to individual mice that were either in isolation (n=28) or socially interacting (male-female dyads, n = 13; 4-mouse, mixed-sex groups, n = 11). Across recordings, males emitted 82 – 100% of assigned vocalizations. To assess directionality, we used the position of the mice, position of the microphones, and the sound intensity of signals at each microphone. For each vocalization, we mapped the microphone positions on a Cartesian plane with the position of the vocalizer at the origin. We then computationally rotated the map such that the head of the mouse always faced 0

degrees, thus aligning the positions of the microphones relative to the source of the vocalization. The resulting maps were subsequently sectioned into 72 non-overlapping, equally-sized wedges and the average sound intensity was calculated for each wedge. USV intensity was strongest in the direction that the mouse was facing, and weakest in the opposite direction, suggesting a directional pattern. We next calculated a directional index (DI) for the male vocalizers in each recording, where a DI of 0 indicated an omnidirectional vocalization. On average, male mice produced USVs with DIs of 48.9, 23.7, and 24.3 when in isolation, dyads, and mixed-sex groups, respectively. To determine the DI values expected by chance, we conducted a permutation test. We demonstrated that across all behavioral contexts, the directionality of male-emitted USVs was significantly greater than chance levels (Z-test, all p's < 0.001). Overall, these findings directly demonstrate that male mouse USVs are directional and may provide additional insight on the communicative function of mouse vocalizations.

Title: Neural circuits underlying the effects of acute isolation on vocal and non-vocal social behaviors in female mice

Authors: *X. ZHAO, Y. CHAE, S. RABINOVICH, T. GRINBERG, S. CHU, Z. HE, A. SADANGI, K. A. TSCHIDA;
Cornell Univ., Ithaca, NY

Abstract: Social isolation is a potent stressor that adversely impacts both mental and physical well-being. Despite a wealth of studies demonstrating the impacts of chronic isolation on social behavior, it remains less clear how acute social isolation impacts the brain and behavior and whether these effects vary according to sex and social context. To investigate this question, we established a behavioral paradigm in which mice that were either group-housed or single-housed for three days interacted with a novel group-housed visitor, and their ultrasonic vocalizations (USVs) and non-vocal social behaviors were examined in three different contexts (female-female, male-female, and male-male interactions). In female-female trials with a single-housed resident, we observed a dramatic increase in the production of USVs, increased social interaction time, and the emergence of mounting accompanied by USV production as compared to trials with group-housed residents. In contrast, acute isolation drove only subtle effects on social behavior during male-female and male-male encounters. To explore the neural circuit basis for the effects of acute isolation on female social behavior, we are currently comparing c-Fos

activation in group-housed and single-housed females to test whether acute isolation enhances the activity of different populations of forebrain and midbrain neurons, including the preoptic area of the hypothalamus, the bed nucleus of the stria terminalis, the medial amygdala, and the periaqueductal grey (PAG). We are also combining these Fos immunostaining experiments with retrograde labeling from the PAG to identify forebrain neurons whose activity is potentiated by acute isolation and that project to the region of the PAG that contains neurons necessary to USV production. We anticipate that our findings will shed light on the forebrain-to-midbrain circuits that regulate the production of social vocalizations in female mice, as well as how acute isolation acts on these circuits to affect social behavior.

Title: Social isolation changes ultrasonic vocalizations and reduces dopamine and serotonin ventral tegmental area of healthy rats

Authors: *C. BROADFOOT[1], C. LENELL[2], C. A. KELM-NELSON[3], M. R. CIUCCI[2]; [2]Surgery-Otolaryngolgy, [1]Univ. of Wisconsin Madison, Madison, WI; [3]Dept. of Surgery, Div. of Otolaryngology, Univ. of Wisconsin Madison Dept. of Surgery, Madison, WI

Abstract: Vocal communication plays an important role in health and wellness. Of interest to our laboratory, are the effects of social isolation on vocal communication in disease states, such as Parkinson disease, and the ability of social enrichment to treat these deficits. However, the effects of social context such as isolation and enrichment, and the neural mechanisms governing these complex behaviors, is relatively unknown. As a crucial first step, we studied socially-motivated ultrasonic vocalizations (USV) in wild-type (*i.e.* healthy) rats. The catecholaminergic systems of the ventral tegmental area (VTA) are associated with social and reward processing and are suseptible to changes in social stress (isolation). The central hypotheses for this study

were that social condition would alter vocal communication by changing USV acoustics, non-motor behaviors (anxiety, anhedonia, and cognitive function) and affect catecholamine concentrations in the VTA. Specifically, we hypothesized that social isolation would decrease vocal function (loudness), increase the presence of anxiety and anhedonia, and decrease cognitive function. To test these hypotheses, twenty-four male wild type (WT) rats were randomized into 3 groups: 1) control, housed with a cage-mate, 2) socially-isolated, housed individually, and 3) socially-enriched, housed with a cage-mate and underwent social enrichment. Social enrichment involved grouping rats in a larger 'socialization' cage with another pair of cage mates 5x per week. USVs were recorded at 2 (baseline-prior to randomization), 4, 6, 8 and 10 month time points using an established elicitation mating paradigm. At each timepoint, all animals were also assessed for cognitive skills (novel object recognition test), anxiety levels (elevated-plus maze), and presence of anhedonia (sucrose preference test). Micro punches of the VTA were assayedfor levels of dopamine, norepinephrine, and serotonin and associated metabolites using high-performance liquid chromatography. A repeated measures ANOVA with factors of social condition and timepoint revealed that vocalizations of rats that underwent social enrichment produced calls that were louder ($p<0.01$) with greater duration ($p<0.001$) compared to the control and isolation rats. The results of the non-motor behavior analyses will be presented. Additionally, rats in the social isolation group had significant increases in levels of dopamine ($p<0.001$), HVA ($p<0.05$), and 3MT ($p<0.001$) as well as 5-Ht ($p<0.001$) in the VTA. This study suggests that chronic changes to social condition in adulthood affects both behavioral outcomes and neural mechanisms in healthy rats.

Title: Evaluating ultrasonic vocalizations as predictors of social behavior during group interaction

Authors: *C. M. KAWAR[1], R. S. CLEIN[1], M. R. WARREN[1,2], J. P. NEUNUEBEL[1]; [1]Univ. of Delaware Grad. Program In Behavioral Neurosci., Newark, DE; [2]Emory Univ., Atlanta, GA

Abstract: During social interaction, animals integrate a variety of sensory information, which influences future behavioral decisions. For example, vocalizations can alert conspecifics to predators or reproductive opportunities and then elicit distinct responses (Seyfarth et al., 1980; Macedonia, 1990; Evans, 1993). Mice produce ultrasonic vocalizations (USVs) associated with discrete behaviors (Sangiamo et al., 2020), however, it is unclear if USVs foreshadow specific actions. To investigate the predictive power of mouse USVs on social behavior, we recorded mixed-sex groups of freely interacting adult mice (n = 11, 2 males and 2 females per group; 12-21 weeks old, B6.CAST-Cdh23Ahl+/Kjn) for 5 hours using a sound source localization system. Though it has traditionally been challenging to identify individual vocalizers while mice are socially interacting, this 8-channel microphone array system allows us to assign vocalizations to individual mice. Using machine learning-based approaches (Kabra et al., 2013) to automatically categorize vocalizations and extract distinct behaviors in which two mice have unique roles as actor or recipient (i.e., approach, flee, investigate, chase, and mount), we found a significant interaction between particular social behaviors and the vocalization types that preceded (2-way ANOVA, $F = 4.78$, $p < 0.001$). A permutation test showed that specific vocalization types were produced at above-chance proportions when they preceded dominant behaviors (involving an actor courting or behaving aggressively toward a recipient), while other types were emitted at above-chance proportions when preceding submissive behaviors (involving an actor avoiding a recipient) (Z-tests, p-values < 0.001). We then trained multi-class support vector machines to distinguish behavioral role (actor versus recipient) based on the proportion of vocalization types the participants produced preceding the behaviors. While classifiers were unable to accurately distinguish the behavioral role of the mouse at above-chance levels for some behaviors (flee, approach, male-investigate-male, mount, female-investigate, and fight) we found accuracies significantly above chance for dominant behaviors (male-chase-male, male-chase-female, male-investigate-female; Z-tests, p-values < .0005). In sum, our results demonstrate that mouse vocalizations may predict specific subsequent behaviors.

Title: A novel, open-source, high-throughput monitoring system for maternal behavior in mice

Authors: *L. F. SCHUSTER[1], D. C. ANANTH[3], A. C. MAR[2], R. C. FROEMKE[1];
[1]Grossman Sch. of Medicine, Skirball and Neurosci. Institutes, Departments of Otolaryngology, [2]Neurosci. and Physiol., New York Univ., New York, NY; [3]Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Understanding the neural basis of maternal behavior requires a comprehensive analysis of the repertoire that parents express, under conditions that enable high-resolution monitoring of most if not all behaviors 24 hours/day for weeks to months. To achieve this, we designed a semi-automated habitat for mice using open-source tools, where behavioral data can be collected and saved near-continuously over 4+ months. Our system is soundproofed, temperature- and humidity-controlled, and supports neural recordings and gain-of-function and loss-of-function interventions. Our overall goal is comprehensive behavioral phenotyping throughout life and over generations.
To date we have monitored 10 wild type (WT) dams across 2-4 litters apiece, examining changes across different aspects of maternal care from litter to litter. While infanticide is quite common in first-time mothers, the incidence decreases in most dams with the second and subsequent litters. We found that even before birth of the first litter, quality of nest-making predicted degree and perseverance of infanticide. Those dams that continued to be infanticidal stopped this behavior when co-housed with experienced dams that were not infanticidal.
Previously we found that the neuropeptide oxytocin promotes long-term plasticity and mediates experience-dependent changes in neural circuits that increase the sensitivity to pup cues, thereby facilitating behavioral responses to pup distress. To understand the effects of genetic disruption of oxytocin signaling in maternal care, we monitored the first pregnancies of 2 oxytocin receptor knockout (OXTR KO) dams. These OXTR KO animals built subpar nests, spent less time interacting with their pups, and had high pup mortality rates compared to WT mice who raised successful first litters. Interestingly, WT dams who neglected or cannibalized their pups showed similar nest-building patterns and time spent in the nest as the OXTR KO mice.

Title: Within-neuron comparison demonstrates context-dependence of natural social signal processing in primate prefrontal cortex

Authors: *V. JOVANOVIC[1], L. A. DE LA MOTHE[2], K.-F. LEE[3], C. T. MILLER[1];
[1]Cortical Systems and Behavior Lab., Univ. of California San Diego, La Jolla, CA; [2]Psychology, Tennessee State Univ., Nashville, TN; [3]PBL-L, Salk Inst., La Jolla, CA

Abstract: Communication is an active exchange of social signals between individuals and yet the neural basis of primate communication has primarily been studied in head-restrained paradigms in which social signals are entirely divorced from the contexts in which they naturally occur. The few studies to examine the neural basis of vocal communication in freely-moving monkeys have yielded patterns of results that diverge notably from parallel experiments using more traditional, head-restrained approaches. Here we sought to directly test - within neuron - whether these observations reflect differences in experimental design or more fundamental insight into how the primate brain functions under natural conditions. We recorded the responses of the same individual neurons in marmoset prefrontal cortex (PFC) to acoustic stimuli, including vocalizations, across a series of contexts ranging from head-restrained passively-listening animals to freely-moving monkeys engaged in interactive conversational exchanges (i.e. active, natural communication). Consistent with previous reports in rhesus macaques, we observed robust responses to acoustic stimuli in PFC neurons when marmosets were in a traditional head-restrained context. When presenting the identical set of acoustic stimuli to freely-moving marmosets, PFC neurons likewise exhibited robust responses. However, the same individual neurons exhibited little to no response to the vocalization stimuli when subjects were engaged in their natural communicative exchanges. These results suggest that while mobility had little impact on the pattern of neural responses in primate PFC, actively engaging in natural communication profoundly affected the responses of these neurons. Further analyses indicated that contextual differences were not limited to stimulus firing rate, but rather several characteristics of neural activity distinguished PFC activity during natural communication from the other behavioral contexts. This suggests that key facets of active communication may not be replicable using the more reductionistic, head-restrained paradigms that typify previous experiments investigating neural basis of primate communication. Thus, we show the assumption that data in traditional, restrained paradigms of social signal processing reflect the natural analog is not strictly true. Explicating the neurobiology of communication in the primate brain likely necessitates that we examine neural activity as individuals actively engage in natural communication exchanges.

Title: Meta-analysis of how sex and dominance interact with social position to affect prosocial behaviors in marmosets (Callithrix jacchus)

Authors: *S. RIVERA[1], O. MEISNER[2], S. PARK[2], M. P. JADI[3], A. S. NANDY[4], S. CHANG[5]; [1]Hunter Col., New York City, NY; [3]Dept. of Psychiatry, [4]Dept. of Neurosci., [5]Dept. of Psychology, [2]Yale Univ., New Haven, CT

Abstract: Research in prosocial behaviors garnered much interest in the field of social neuroscience over recent years, but human research is limited in its ability to address the underlying neural mechanisms of these behaviors. Research in this domain using rodent models has furthered our understanding of the neural circuit mechanisms of social behaviors. However, the rodent model also faces limitations when it comes to modeling human social behaviors. For example, the fundamental mode of social communication between rodents (olfactory) is much different than the largely visual communication used by primates. Primate models have been beneficial to social neuroscience due to their complex social communication and environments that more closely resemble that of humans. More recently, the common marmoset (*Callithrix jacchus*) has emerged as a model system for investigating the neural bases of primate social behaviors. Despite evolutionarily diverging much earlier from humans compared to macaques or capuchins, they are cooperative breeding and a highly prosocial species that is small in size and easy to maintain in captivity. Though marmosets are potentially an excellent comparative model for human cooperative prosociality, their complex group dynamics also can stand as an obstacle. In this meta-analysis, we will investigate how sex and dominance interact with social role to affect prosocial behaviors in the common marmoset. As the identity of individual monkeys dictates much of marmoset social life, we will investigate how the sex, position within dominance hierarchy, and social role dictate which members of a colony are more likely to perform prosocial behaviors and if a correlation exists across this species. We are exploring previous research where prosocial and cooperative behaviors demonstrated and identify which individuals successfully display different types of prosocial behaviors in these experiments. As social experiments in marmosets tend to successfully elicit cooperative social behaviors in a subset of individuals, we aim to identify which individuals are most likely to engage in these behaviors. As the allocation of prosocial behaviors among members is variable, this investigation hopes to shed light on the complex social structures of marmosets to help inform future social neuroscience research in this species.

Abstract: Reproduction and survival in most primate species reflects management of both competitive and cooperative relationships. Here we investigated the links between neuroanatomy and sociality in free-ranging rhesus macaques. In adults (n=68), the number of social partners predicted morphology of mid-superior temporal sulcus and anterior insula, implicated in social decision-making and empathy, respectively. We found no link between brain structure and other key social variables such as status or indirect connectedness in adults, nor between maternal social networks or status and dependent infant (n=20) brain structure. Our findings demonstrate the size of specific brain structures varies with the number of direct social connections, and suggest this relationship arises during development. These results reinforce proposed links between social network size, biological success, and the expansion of specific brain circuits.

Med., Gainesville, FL; [5]Dept. of Biomed. Sci., Univ. of Missouri, Columbia, MO

Abstract: Endocrine disrupting chemicals, such as bisphenol A (BPA) and ethinylestradiol (EE2), are detected in the marine environment from plastic waste and wastewater effluent. However, their impact on reproduction in sexually labile coral reef fish is unknown. The objective of this study was to determine impacts of environmentally relevant concentrations of BPA and EE2 on behavior, brain gene expression, gonadal histology, sex hormone profile, and plasma vitellogenin (Vtg) levels in the anemonefish, *Amphiprion ocellaris*. *A. ocellaris* display post-maturational sex change from male to female in nature. Sexually immature, male fish were paired together and fed twice daily with normal food (control), food containing BPA (100 µg/kg), or EE2 (0.02 µg/kg) (n=9 pairs/group). Aggression towards an intruder male was measured at 1, 3, and 6 months. Blood was collected at 3 and 6 months to measure estradiol (E2), 11-ketotestosterone (11-KT), and Vtg. At the end of the study, fish were euthanized to assess gonad morphology and to measure expression of known sexually dimorphic genes in the brain. Relative to control, BPA decreased aggression, altered brain transcript levels, increased non-vitellogenic and vitellogenic eggs in the gonad, reduced 11-KT, and increased plasma Vtg. In two BPA-treated pairs, both individuals had vitellogenic eggs, which does not naturally occur. EE2 reduced 11-KT in subordinate individuals and altered expression of one transcript in the brain toward the female profile. Results suggest BPA, and to a lesser extent EE2, pollution in coral reef ecosystems could interfere with normal reproductive physiology and behavior of the iconic sexually labile anemonefish.

Title: The effects of Bisphenol A and Bisphenol S exposure on stress and sex steroid-sensitive protein expression in the murine hippocampus.

Authors: *K. NICHOLSON[1], J. WOODMAN[1], E. CHOLERIS[2], N. J. MACLUSKY[1];
[1]Biomed. Sci., [2]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Bisphenol A (BPA) is a potent endocrine disrupting chemical that interferes with the mechanisms of gonadal hormones such as estradiol and adrenal hormones such as glucocorticoids. Specifically, BPA is known to disrupt estradiol-mediated activation of intracellular cascades including the extracellular signal-regulated (ERK) and c-Jun N-terminal (JNK) kinases. These kinase cascades are also known to be glucocorticoid-sensitive while playing important roles in hippocampal protein synthesis, synaptogenesis, learning, and memory. Therefore, many industrial processes have since replaced BPA with structural analogues such as Bisphenol S (BPS). However, the effects of BPS exposure on these glucocorticoid and estradiol-sensitive mechanisms within the mammalian hippocampus remain unknown. This work aimed to compare the effects of BPA and BPS exposure on hippocampal expression of ERK, JNK, mitogen-activated protein kinase phosphatase 3 (MKP3-a phosphatase implicated in stress and depression), glial fibrillary acidic protein (GFAP), and postsynaptic density-95 (PSD-95). For 10 consecutive days, gonadally intact male and female CD-1 mice (2-3 months of age) were administered vehicle, BPA, or BPS-containing peanut butter at the tolerable daily intake (TDI) dose of 50 μg/kg/day as defined by the American Environmental Protection Agency. Female estrous cycles were tracked by daily vaginal lavages. On day 10, mice were sacrificed 4 hours after their final treatment for hippocampal extraction (n=9/group). Hippocampi were homogenized and analyzed through western blotting for changes in ERK, JNK, MKP3, GFAP, and PSD-95 protein expression. Significant effects of treatment and sex were observed for expression of 54 and 46 kDa isoforms of JNK, respectively. BPA-treated females exhibited a stress-like reduction in MKP3 expression in comparison to BPA-treated males. Females treated with BPA and BPS exhibit reduced total MKP3 expression in comparison to vehicle-treated female controls. ERK, GFAP and PSD-95 levels were unaffected by BPA or BPS treatment. Plasma corticosterone levels were measured using ELISAs (n=7-9/group). Females exhibited

higher plasma corticosterone concentrations than males, although no effects of treatment were detected. These findings may have important implications for sexually differentiated cellular and stress response mechanisms of bisphenols within the mammalian hippocampus. Our ongoing studies will further investigate the cellular interactions between glucocorticoids, estradiol, and bisphenols using in vitro and in vivo models.

Title: Oxytocin and lactationally-triggered embryonic diapause in mice

Authors: *J. L. MINDER[1,3,4], M. V. CHAO[1,3,4], R. C. FROEMKE[2,3,4];
[2]Otolaryngology, [1]NYU Med., New York, NY; [3]Skirball Inst. of Biomolecular Med., New York, NY; [4]Neurosci. Inst., New York, NY

Abstract: Embryonic diapause is a state in which the development of the pre-implantation embryo is halted until conditions become favorable for pregnancy progression (Fenelon et al., 2014). It is mediated by the hypothalamic-pituitary axis and results in the pausing of embryonic development at the blastocyst stage, with implantation into the uterine endometrium being temporarily blocked (Stouffer and Hennebold, 2014). Development resumes as normal upon a return to homeostasis. Diapause has been reported in many mammalian species, including suggestive reports in humans that underwent in vitro fertilization (Grinsted and Avery, 1996). Despite the long history of study and potential importance for fetal development, little is known about the initiating factors for diapause in rodents. We have been examining whether oxytocin (OT) might be involved in lactationally-triggered facultative diapause in C57 mice. OT is released from the posterior pituitary during the sensory stimulus of suckling, resulting in peripheral OT surges reaching the womb. First, we identified oxytocin receptor (OXTR) expression on mouse blastocysts. We also found that embryo implantation in the presence of OT is delayed in comparison to saline (n=79 embryos, p=0.009) using an in vitro embryo culture model of implantation (Bedzhov et al, 2014). When pregnancy ensues coincident with nursing a previous litter, we found that gestational times were extended by one week (n=3), as compared to gestation in the absence of nursing (n=12; p=0.004). A drop in estrogen levels in the mother is thought to contribute to halting embryo implantation (Stouffer and Hennebold, 2014). After

treating the hypothalamic cell line GT1-7 with the estrogen receptor antagonist 4-hydroxytamoxifen, OT mRNA levels were increased relative to saline-treated controls (n=11, p=0.005). This suggests that OT levels are increased in the mother during nursing. Finally, we found that without the OXTR, embryos may fail to implant at the right time and become reabsorbed. Only 5% of OXTR knock-out pups were born in litters that experienced diapause (n=3), as opposed to 33% of OXTR knock-out pups being born from normal pregnancies (n=9). We conclude that nursing induces diapause in mice, and that maternal OT levels increase during this state. Given that fewer OXTR KO pups were born in litters that experienced diapause, we hypothesize that OT levels serve as a timing cue for the embryo to enter a paused state in order to properly coordinate with the maternal uterine environment and to survive diapause. Understanding how OT levels might regulate reproductive state and embryonic development has major implications for reproductive medicine.

Title: Lps treatment alters gad67 mrna expression and gonadotropins concentrations in a sex- and age-dependant manner

Authors: *K. B. SMITH[1], J. ZHONG[1], N. ISMAIL[2];
[2]Ctr. for Neuroendocrine Studies, [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Puberty is a period of sexual and reproductive development, and neuronal reorganization and remodeling. Exposure to stress during this period can result in enduring effects on reproductive behaviour. Stress-induced HPA axis activation causes inflammatory cytokine release which contributes to downregulating the hypothalamic pituitary gonadal (HPG) axis. This downregulation may be caused by GABAergic inhibition to the pituitary gland, preventing the secretion of gonadotropins. The current study examined the acute and enduring effect of LPS treatment on GAD67 mRNA expression in the pituitary gland, and LH, FSH, interleukin-6 (IL6), and tumor necrosis factor alpha (TNFα) concentration in the blood of male and female mice. 160 male and female mice were treated with either saline or LPS at 6 (puberty) or 10 (adulthood) weeks of age and euthanized either 8 hours (acute effects) or 4 weeks (enduring effects) post-treatment. LPS treatment in adult males and females increased GAD67 mRNA expression and TNFα concentration, and decreased LH concentration at 8 hours

following treatment. LPS-induced upregulation of GAD67 mRNA expression was long-lasting at it was still present 4 weeks following treatment. LPS treatment in pubertal males and females increased IL6 concentration and decreased LH concentration only at 8 hours following treatment. We also identified sex differences in gonadotropin expression, where LPS-treated pubertal and adult females displayed less FSH concentration compared to males at 8 hours and 4 weeks following treatment. LPS-treated adult females also expressed lower LH concentration compared to male counterparts. Lastly, LPS-treated pubertal and adult males displayed greater IL6 concentration compared to females 8 hours post-treatment. Our data show important age and sex differences in stress-induced downregulation of the HPG axis. Moreover, although the upregulation of GAD67 mRNA persisted 4-weeks post LPS treatment in adult mice, it does not impact LH concentrations. Taken together, our findings show that the GABAergic pituitary inhibition is an important mechanism in stress-induced downregulation of the HPG axis, but in an age- and sex-specific manner. The presence of these sex and age differences implies that sex hormones may play an influential role upstream to the pituitary control of gonadotropin secretion.

Title: The role of suprachiasmatic VIP neurons in circadian rhythm regulation of the estrous cycle of female mice

Authors: *A. KAHAN, G. M. COUGHLIN, M. BORSOS, J. E. ROBINSON, V. GRADINARU;
Caltech, Pasadena, CA

Abstract: Female mice ovulate every 4-5 days at the beginning of the dark phase. The temporal specificity of this process points to a role for the circadian clock – and thereby the

suprachiasmatic nucleus (SCN), the circadian rhythm pacemaker – in ovulation. One key neuronal population in the SCN expresses vasoactive intestinal peptide (VIP); these neurons have both direct and indirect effects on gonadotropin-releasing hormone (GnRH) neurons, which control the release of reproductive hormones such as luteinizing hormone (LH). Although signaling from SCN^{VIP} to GnRH neurons has been hypothesized to control estrous cycle timing, it is unknown whether the activity of SCN^{VIP} neurons depends on the estrous state and how SCN^{VIP} neuronal signaling is relevant for ovulation. To address the first question, we recorded calcium-dependent fluorescence signals via fiber photometry (FP) from SCN^{VIP} neurons *in vivo* in female mice. In one data set, we recorded SCN^{VIP} FP activity over 24h (10 min/hr) for multiple days. In a separate data set we recorded SCN^{VIP} FP activity for 30 minutes at ZT10 (zeitgeber time), which corresponds to the LH surge onset, and for two hours during the transition from light to dark, ZT11-13. FP data showed that over the course of 24 hours, SCN^{VIP} activity is not dependent on the estrous cycle. However, longer recordings around ZT10-13 show estrous cycle dependency; at ZT11 these neurons are active at the rate of 0.7 ± 0.1 events/min while females are in estrus, higher by a factor of 1.4 compared to recordings from females in proestrus or diestrus ($P<0.05$), as confirmed by slice electrophysiology. These results suggest that SCN^{VIP} neurons are under hormonal control. To investigate the importance of SCN^{VIP} neurons for the regulation of estrous cycles, we experimentally manipulated the circadian rhythm by ablating SCN^{VIP} neurons through viral-mediated expression of Caspase-3, which triggers cell-autonomous apoptosis. We observed a significant decrease in estrous cycle regularity ($P<0.001$). In addition, dark-dark conditions with strict light exposures reduced fertility, as shown in reduced regularity of the estrous cycle ($P<0.005$) and oocyte release ($P<0.05$). When light was applied specifically at the LH onset, the fertility profile was rescued. Likewise, optogenetic and chemogenetic activation of SCN^{VIP} neurons during the same time window were able to partially rescue the estrous cycle irregularity arising from dark-dark conditions. These experiments provide new insights into the role of SCN^{VIP} neurons as regulators of ovulation occurrence, and suggest that SCN^{VIP} neuronal activity is also affected by the estrous cycle.

Title: The role of sex and ovarian cycles in trait variability across timescales and subjects

Authors: B. N. MARTIN[1], K. J. MOSHOFSKY[1], *A. BEERY[2,1];
[1]Smith Col., Northampton, MA; [2]UC Berkeley, Berkeley, CA

Abstract: Exclusive use of male subjects is common in animal research, based in part on the long-held assumption that females are more variable than males because of estrous cyclicity. Recent surveys of rat and mouse studies have found no evidence of different variability between the sexes for most outcomes, with males more variable slightly more often than females. These studies leave unresolved whether the sources of variability in males and females are similar. Similar variability could arise from high variability across days in females and high variability across individuals in males, or, males and females could have similar variability across timescales. There are indications that trait variability differs in male and female mice for body temperature but not food intake (Smarr et al. 2017, 2019). In the present study, we investigated the time-course of variability across several behavioral and physiological measures over 8 consecutive days of testing.
Female Syrian hamsters (*Mesocricetus auratus*) exhibit robust, precisely 4-day estrous cycles. Ovariectomized female hamsters were compared to intact (or sham operated) females and males. Measures included exploratory behavior and locomotion in an open field, novel object preference, sucrose preference and fluid intake, body mass, and internal body temperature. Sex differences were present in multiple traits, but as in other rodent species tested, there was no sex difference in the extent of inter-individual variability (assessed as coefficient of variation) between individuals in males and females. We also assessed the mean CV of each individual over time (intra-individual CV). Patterns of variation were trait specific rather than sex-specific; for example, males exhibited higher inter-individual variability in body temperature than females, but females had higher inter-individual variability in sucrose preference. Staging by estrous cycle phase did not reduce variability except for the most cycle-dependent trait (reproductive behavior), which was used as a positive control. This study extends the finding that females are not more variable than males to hamsters, and supports no consistent sex-specific patterns of variability within or across individuals in a variety of traits.

Abstract: Sex differences in the human brain emerge as early as mid-gestation and have been linked to sex hormones, particularly testosterone. We analyzed markers of early sex hormone exposure (polygenic risk score (PRS) for testosterone, salivary testosterone level around 3 months of age, number of CAG repeats in the androgen receptor (AR) gene, digit ratios and PRS for estradiol) in relation to cortical surface area expansion in a longitudinal cohort of 722 infants. We focused on surface area because it shows strong sex differences in infancy with males exhibiting larger surface area, on average, at birth and growing faster than females. We used an orthogonal polynomial with order 2 for mixed model regression analysis between our sex hormone markers and surface area. Analyses were performed separately in males and females. We found PRS for serum testosterone and right-hand digit ratio to be significantly associated with surface area, but only in females. PRS for testosterone in the most stringent p value threshold was associated with increased surface area expansion over time. Higher right hand digit ratio, which is indicative of low prenatal testosterone levels, was associated with reduced surface area throughout infancy. This is the first study to explore potential associations between gonadal steroid exposure during early life and infant brain surface area. The current work suggests that variation in testosterone levels during both the prenatal and postnatal period may contribute to cortical surface area development and predicts inter-individual variation in females, but not in males.

Abstract: The reproductive axis has established layers of regulation: the gonadotropin releasing hormone (GnRH) neuron is controlled by Kisspeptin (Kiss), neurokinin B (NKB) and dynorphin A (DynA) which together comprise KNDy neurons in the hypothalamus. As neuropeptides, Kiss and DynA must be modified enzymatically in the extracellular space to modulate downstream signaling, though the enzyme(s) underlying this process remain elusive. Furthermore, Phoenixin (Phe), a hypothalamic neuropeptide plays a novel role in the regulation of the reproductive axis. Phe increases GnRH expression, GnRH receptor and Kisspeptin mRNAs, which ultimately supports GnRH secretion and ovarian cyclicity. We posit that EP24.15 (EC 3.4.24.15, thimet oligopeptidase, EP24.15) can serve the role as the metallo-endopeptidase for these neuropeptide regulators. EP24.15, expressed throughout the hypothalamus and other brain regions is best known for regulating GnRH by inactivation of binding to its cognate receptor. To validate the biochemical and physiological regulation of Kiss and DynA, we utilized a systems biology approach to hormone regulation by a high throughput pipeline including substrate scanning analyses to identify peptides, potential active site binding and cleavage sites by mass spectrometry, enzymatic kinetic parameters and *in silico* molecular modeling. Finally, we determined that EP24.15 and both Kiss and DynA immunoreactivities are co-expressed in the brain, identifying a functional neuroendocrine circuit whereby EP24.15 could regulate Kiss- or DynA -induced reproductive hormone secretion. Kiss and DynA immunoreactivities are co-expressed and localized with EP24.15 in the hypothalamus. To build upon mass spectrometry and kinetic analyses of EP24.15 cleavage of Kiss, DynA and Phoenixin we established high resolution 3D structural models of enzyme and substrate. Together, these data demonstrate that EP24.15 cleaves Kiss, DynA, and Phoenixin *in vivo* as an additional layer on the exquisite control mechanism of the mammalian reproductome. Similar analyses of Neurokinin B (NKB) demonstrated that while they are colocalized, NKB was not a substrate reinforcing the regulatory specificity of the enzyme in KNDy neurons and allowing for finer tuning of reproduction by EP24.15. Further investigating EP24.15 in neuropeptide metabolism and reproductive physiology will provide targets for modulating normal and aberrant reproductive function validating the high throughput reproductomics approach.

Title: Reciprocal changes in voltage-gated potassium and subthreshold inward currents help maintain firing dynamics of anteroventral-periventricular (AVPV) kisspeptin neurons during the estrous cycle.

Authors: *J. R. STARRETT[1], R. A. DEFAZIO[2], S. M. MOENTER[3];
[2]Mol. and Integrative Physiol., [3]Mol. and Integrative Physiology, Intrnl. Medicine, and Obstetrics and Gyne, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: The brain initiates ovulation via a gonadotropin-releasing hormone (GnRH) surge, a process that requires estradiol action on central circuits. This surge is induced by estradiol positive feedback, induced when high estradiol levels cause a switch from a pulsatile pattern, regulated by estradiol negative feedback, to a surge of GnRH secretion. This occurs on the afternoon of proestrus in rodents. Positive feedback is thought to be conveyed to GnRH neurons by kisspeptin-expressing neurons in the AVPV. Kisspeptin is a potent GnRH secretagogue, and AVPV neurons express higher amounts of kisspeptin mRNA on proestrus compared to cycle phases, such as diestrus, when estradiol negative feedback prevails. AVPV kisspeptin neurons also fire more action potentials and more action potential bursts (associated with peptide release) on the afternoon of proestrus. Combined, these factors are thought to increase excitatory signaling to GnRH neurons and thus stimulate a GnRH surge. The mechanisms facilitating the increase in AVPV kisspeptin neuron electrical activity on proestrus are not fully understood. We hypothesized changes in voltage-gated potassium (K^+) currents help regulate the excitability of these cells in a cycle-dependent manner. Whole-cell voltage-clamp recordings of GFP-identified AVPV kisspeptin neurons in brain slices from diestrous and proestrous mice revealed three sub-components of the voltage-sensitive K^+ current: fast-inactivating (A-type), slow-inactivating, and residual. During proestrus, the V1/2 of inactivation of the fast current was depolarized and the amplitude of the slow-inactivating component was reduced compared to diestrus; the residual component was consistent across both stages. Computational models were fit to experimental data, including published estrous-cycle effects on other voltage-gated currents. Surprisingly, computer simulations suggest proestrus-typical K^+ currents are suppressive compared to diestrus.

Interestingly, larger T-type, persistent-sodium, and hyperpolarization-activated currents during proestrus compensate for this suppressive effect by increasing excitability and enabling post-inhibitory rebound bursting. These findings suggest modulation of both voltage-gated K^+ and multiple subthreshold depolarizing currents across the negative to positive feedback transition maintain AVPV kisspeptin neuron excitability in response to depolarizing stimuli. These changes also enable firing following hyperpolarization, which may attenuate or reverse effects of inhibitory input, thus contributing to activation of this population leading up to the preovulatory GnRH surge.

Title: Relationship between action potentials and hormone release in gonadotropin-releasing hormone (GnRH) neurons is modified by gonadal feedback

Authors: *X. CHEN[1], S. M. MOENTER[2];
[1]Mol. and Integrative Physiol., [2]Mol. and Integrative Physiology, Intrnl. Medicine, and Obstetrics and Gyne, Univ. of Michigan, Ann Arbor, MI

Abstract: In vertebrates, the pulsatile release of GnRH from neurons in the preoptic area (POA) and hypothalamus plays a critical role in triggering secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. LH and FSH activate steroidogenesis, and steroids in turn exert feedback on GnRH release. Although long-term changes in episodic firing pattern of GnRH neurons resemble the pulsatile release of GnRH and LH, the relationship between short-term GnRH neuron firing and release, and how the relationship is influenced by gonadal feedback are unknown. We used voltage-clamp to control GnRH neuron membrane potential while monitoring GnRH release by fast-scan cyclic voltammetry in sagittal brain slices from gonad-intact (sham) and orchiectomized (ORX) male GnRH-GFP mice. GnRH release was detected in the POA at appositions of pairs of GFP-identified cells/processes. A train of 2, 5 or 15 action potentials (APs) with a constant interval of 213.9ms (median intraspike interval of spontaneous bursts) was used as command voltage to manipulate cell firing. To test if there was a refractory period for induced release, a second identical train was given to the cell four minutes after the first one. AP-triggered GnRH release began 0.6 to 79.4s after stimulation (mean 30 ± 3s, n=39 releases). GnRH release was trigged by

2APs in 50% of sham (4/8) and 70% of ORX (7/10) trials; the peak of the first triggered release was similar between sham (6.6±1.4 mM n=4) and ORX (7.2±0.6 mM n=5) groups. 5APs triggered release in 90% (9/10) of sham and 100% (10/10) of ORX trials. Preliminary data suggest amplitude of the first 5AP-triggered GnRH release may be increased by ORX (sham 10.7±2.6mM, n=5, ORX 20.6±2.9mM, n=6, p=0.09). In ORX mice, more GnRH was released after 5 than after 2 APs ($p<0.05$). All 15AP stimulations triggered GnRH release in both groups. The first 15AP-triggered release was greater than that following 5APs in sham (19.1±6.2 mM, n=4) but not ORX (19.8±3.2 mM, n=3) groups. The 2nd stimulation-triggered GnRH release was lower than the 1st in 77.7% (7/9) of cells given 5AP stimulation and 85.7% (6/7) of cells given 15AP stimulation, suggesting some depletion of releasable pool. In addition to triggered release, spontaneous releases were observed before (8-135s) and well after (105-445s) stimulations; these releases may be AP-independent (Endocrinology 156: 231) or arise from the un-patched cell of the pair. These results suggest coupling between GnRH neuron firing and release is stronger with increased stimulation, that a relative release refractory period may exist, and that ORX increases sensitivity of secretory mechanisms to APs.

Title: Serotonin stimulates preoptic area kisspeptin neuron activity in female mice

Authors: *R. PIET, A. ANELLO, C. BUO, J. DAKIN, R. BEARSS;
Kent State Univ., Kent, OH

Abstract: Ovulation is controlled by brain circuits that regulate the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus and luteinizing hormone (LH) from the anterior pituitary. Kisspeptin (Kiss1) neurons, which project to GnRH neurons, have emerged as key regulators of GnRH neuron activity and LH secretion. Kiss1 neurons located in the preoptic area (POA^{Kiss1}) of the hypothalamus are involved in generating the preovulatory surge in LH secretion that triggers ovulation. In addition to Kiss1, other neurotransmitters and neuropeptides likely regulate the preovulatory LH surge. Previous studies have indicated that serotonin (5HT) substantially contributes to generating the estrogen-induced LH surge in ovariectomized female rodents (Dow et al 1995, Psychoneuroendocrinology). Here, we hypothesized that the impact of 5HT on the LH surge results from excitatory effects on POA^{Kiss1} neuron activity. To address this question, we used mice that express Cre recombinase in Kiss1 cells and a Cre-dependent, genetically-encoded fluorescent calcium indicator GCaMP6f. In brain slices obtained from these

mice, we used live-cell epifluorescence imaging to determine changes in intracellular calcium concentrations $[Ca^{2+}]_i$ in multiple POA^{Kiss1} neurons simultaneously, as an index of their activity. In brain slices from female mice, 10 μM 5HT increased $[Ca^{2+}]_i$ (3.1±0.4% change in fluorescence) in 89% of POA^{Kiss1} neurons (n=74 cells in 7 slices from 4 mice). This effect was smaller in male mice where 48% of POA^{Kiss1} neurons showed $[Ca^{2+}]_i$ rises (0.5±0.3% change in fluorescence; n=54 cells in 5 slices from 3 mice). We next investigated if the effect of 5HT was mediated directly at POA^{Kiss1} neurons or via an indirect mechanism. Two successive 5HT applications evoked similar responses in POA^{Kiss1} neurons and the amplitude of the response to the second application was on average 83.1±12.4% of that of the first one, indicating that the effect of 5HT is repeatable. We then tested the effect of blocking action potentials in the slice using tetrodotoxin (TTX, 0.5 μM). 5HT-induced rises in POA^{Kiss1} neuron $[Ca^{2+}]_i$ in the presence of TTX were comparable to those evoked without TTX (n=68 cells in 7 slices from 4 mice; $p>0.37$, Wilcoxon test) and the response ratio was similar to that measured in control experiments (83.5±15.5%, $p>0.99$ Mann-Whitney test). Together these data indicate that 5HT stimulates the activity of POA^{Kiss1} neurons, likely through a direct mechanism. This effect is more prominent in females than in males. Our data suggest a potential mechanism through which 5HT might regulate the preovulatory surge in female rodents.

Title: Evidence that elevated agouti-related peptide signaling during undernutrition inhibits arcuate kisspeptin neurons in male sheep

Authors: S. L. SHUPING[1], A. N. RENWICK[2], K. HARLOW[1], J. R. SOMMER[1], *C. C. NESTOR[1];

Abstract: Proper energy balance is important to ensure reproductive success. While it is known that nutrient restriction impairs hypothalamic-pituitary function, the central mechanism whereby undernutrition inhibits reproduction remains to be fully elucidated. Given recent evidence in

sheep and mice that the majority of arcuate kisspeptin neurons express melanocortin 3 receptors (MC3R), anorexigenic neurons which produce agouti-related peptide (AgRP), an endogenous MC3R antagonist, may play an important role in relaying energy status to the reproductive axis. Since kisspeptin neurons are essential for reproduction and undernutrition increases AgRP expression, we hypothesized feed restriction would increase AgRP input to kisspeptin neurons and inhibit kisspeptin expression in MC3R-expressing neurons. We selected tissue containing the arcuate nucleus from wethers that were fed to maintain pre-study body weight (FM; n=4) or feed-restricted to lose 20% of pre-study body weight (FR; n=4). Using left brain hemisections (n=2/animal), we conducted dual-label immunofluorescence with primary antisera for kisspeptin and AgRP. Using right brain hemisections (n=2/animal), we conducted RNAscope for mRNA expression of kisspeptin and MC3R. Using immunohistochemistry, we observed significantly more AgRP close-contacts onto ARC kisspeptin cells in FR wethers (5.96 $\pm$ 0.9 contacts/cell) than in FM wethers (3.33 $\pm$ 0.2 contacts/cell). RNAscope analysis revealed significantly fewer total kisspeptin cells in FR animals (91 $\pm$ 15 cells) compared to FM animals (164 $\pm$ 17 cells), while there was no significant difference for total MC3R cells between groups (FM, 193 $\pm$ 21 cells; FR, 180 $\pm$ 30 cells). In addition, we observed significantly fewer cells co-expressing mRNA for kisspeptin and MC3R in FR animals (37.1 $\pm$ 6 cells) compared to FM animals (104.8 $\pm$ 9 cells). Furthermore, we observed that the integrated density (mRNA per cell) for kisspeptin in kisspeptin/MC3R cells tended to be lower ($p = 0.052$) in FR wethers (920737 $\pm$ 431678 AU) compared to FM wethers (2128366 $\pm$ 380764 AU). Together, we suggest that AgRP acts to inhibit kisspeptin neurons and plays a key role in relaying low energy status to reduce GnRH/LH secretion and ultimately impair reproduction.

Title: Study on the method of gene delivery to the hypothalamic arcuate nucleus using goats and newly established goat kisspeptin neuron cell lines

Authors: *F. MATSUDA[1], K. OKUDA[2], Y. SUETOMI[2], K. KOBAYASHI[3], S. OHKURA[2]; [1]Dept. of Vet. Med. Sci., The Univ. of Tokyo, Tokyo, Japan; [2]Grad. Sch. of Bioagricultural Sci., Nagoya Univ., Nagoya, Japan; [3]Section of Viral Vector Develop., Natl. Inst. For Physiological Sci., Okazaki, Japan

Abstract: Kisspeptin neurons located in the hypothalamic arcuate nucleus (ARC) is known to be the key regulator of pulsatile gonadotropin-releasing hormone (GnRH) secretion and the following gonadotropin pulses that stimulate gonadal activity in mammals. The goat is a good experimental animal not only for having similar characteristics with cattle but for the usefulness in physiological analyses. Important studies related to the regulation mechanism of hypothalamus-pituitary-gonadal (HPG) axis including the function of ARC kisspeptin neurons have been reported using goats. Optogenetic regulation of specific neurons have recently been developed, which is expected to be also effective to artificially regulate kisspeptin neurons in goats to further clarify their functions. In this study, we aimed to establish the method to introduce a light-gated ion channel gene into the hypothalamus using goats and newly established goat kisspeptin neuron cell lines. Experiment 1: In vivo analyses to establish the method to deliver genes into the goat ARC by adeno-associated virus (AAV) vector. AAV of four serotypes (AAV-1, 2, 5, and DJ), loading a light-gated ion channel (channelrhodopsin-2, ChR2) gene and a fluorescent protein gene (tdTomato), was generated. The AAV of each serotype was injected into four different parts of the ARC of castrated male Shiba goats (n = 3) with volume of 0.3 μl and flow rate of 0.03 μl/min. Three to four weeks later, brains were obtained and tdTomato fluorescence and immunoreactivity of kisspeptin in the ARC were examined. tdTomato fluorescence and kisspeptin-immunoreactivity were detected in the equivalent area of the ARC in adjacent sections, suggesting that ChR2 gene might be introduced into ARC kisspeptin neurons. tdTomato fluorescence was relatively stable and strong in AAV-1 and DJ serotypes, suggesting the advantage of these serotypes in introducing genes into goat brains. Experiment 2: In vitro analyses to evaluate the efficiency of gene delivery by AAV using immortalized kisspeptin neuron cell lines derived from goat ARC, GA28 and GA64. The AAV of four serotypes used in the Experiment 1 was added to GA28 and GA64 and after the 14 days of culture, cells with tdTomato fluorescence were counted by fluorescent activated cell sorting (FACS). As a result, the numbers of fluorescent cells were higher in AAV-2, 5, and DJ serotypes compared with control and AAV-1. Taken together, AAV-DJ was likely to be the most suitable serotype to deliver genes to ARC kisspeptin neurons in goats. The method introducing ChR2 into the goat hypothalamus by AAV we established in this study will contribute to further elucidate the function of ARC kisspeptin neurons.

Title: In vivo calcium imaging of arcuate nucleus KNDy neurons reveal the GnRH pulse generator in awake, mobile female mice

Authors: *A. M. MOORE, L. M. COOLEN, M. N. LEHMAN;
Biol. Sciences, Brain Hlth. Res. Inst., Kent State Univ., Kent, OH

Abstract: Reproduction is critically dependent on luteinizing hormone (LH) pulses driven by episodic release of gonadotropin-releasing hormone (GnRH). It is hypothesized that neurons in the arcuate nucleus (ARC) expressing kisspeptin, neurokinin B and dynorphin (KNDy cells) are capable of synchronized, episodic activity driving GnRH pulses, and thus constitute the so-called "GnRH pulse generator". However, without *in vivo* visualization of KNDy cell activity at a single-cell level this hypothesis remains unproven. Using *in vivo* calcium imaging we examined the activity of KNDy neurons at single-cell resolution in awake, freely moving ovariectomized female mice. Kiss1-Cre mice were stereotaxically injected with a Cre-dependent AAV containing the calcium indicator GCaMP6s into the unilateral ARC. A 500µm diameter Gradient-Index (GRIN) lens (Inscopix Inc) was inserted above the ARC and secured in place by attachment of an integrated baseplate to the skull. After 5 weeks of habituation, an Inscopix Miniscope was mounted to the baseplate and recordings were performed at 10Hz for 1 hour (n=5 mice). Serial blood samples were collected from the tail-tip every 3-4 minutes for analysis of LH release. Fluorescent traces were extracted from 12.2 ± 1.2 cells per animal using the PCA-ICA cell detection algorithm. The KNDy population exhibited episodic periods of elevated fluorescence across the recording period, with a duration of 77.0 ± 6.8 seconds and an interval of 4.1 ± 0.7 min. Our analysis showed that 75.2 ± 5.7% of these episodic events involved activation of all recorded cells, depicting complete synchronization of the population. All other events, in which only 7.1-71.4% of the recorded cells were activated, exhibited significantly lower amplitude and duration compared to events where 100% of cells were recruited ($p<0.05$). Importantly, LH pulses were always preceded by an event (within 3.1 ± 0.3 min) in which all cells were synchronously activated. Analysis of the order of activity onset and peak amplitude during synchronized events (from an average of 11.2 ± 0.9 synchronized events per animal) revealed a small population of cells that slowly activate to begin an event, followed by rapid activation of a separate population of cells that reach peak amplitude first. Cells first to activate

or first to reach peak amplitude comprised a separate population from those that did so later. Together, these data support that synchronized activation of KNDy cells drives pulsatile LH release and suggest the existence of discrete subsets of leader and follower cells that are activated during individual pulses.

Title: Locus coeruleus noradrenergic control of non-REM sleep substates

Authors: A. OSORIO-FORERO[1], R. CARDIS[1], G. VANTOMME[1], A. GUILLAUME-GENTIL[2], G. KATSIOUDI[3], C. DEVENOGES[1], L. M. FERNANDEZ[1], *A. LUTHI[1];
[1]Dep Fund Neurosci, [3]Ctr. for Integrative Genomics, [2]Univ. of Lausanne, Lausanne, Switzerland

Abstract: Noradrenergic neuromodulation of the mammalian brain is wake- and attention-promoting. Noradrenaline (NA) is released into the forebrain by the pontine locus coeruleus (LC). However, the LC is also active during non-REM sleep, playing roles in sleep spindle activity (Aston-Jones et al., 1981; Swift et al., 2018), sensory arousability (Hayat et al., 2019) and sleep-dependent memory consolidation (Gais et al., 2011). Still, how much NA is released during non-REM sleep, where it acts and what its roles are for non-REM sleep has remained under-investigated. We used the newly developed NA biosensors $GRAB_{NE1h}$ or $GRAB_{NE1m}$ (Feng et al., 2019) in combination with polysomnographic monitoring of natural sleep in C57BL/6J mice (either sex, 5-9 weeks-old). We observed recurrent fluctuations of the wake-promoting neurotransmitter NA in the primary thalamic somatosensory nucleus on the infraslow, ~50-seconds time-scale. These fluctuations occurred around mean NA levels greater than the ones of quiet wakefulness, while they declined steeply in REM sleep. Low NA levels coincided with a clustering of sleep spindle rhythms in the forebrain and with low heart rate, whereas high NA levels occurred when sleep spindles were rare and when heart rate increased. We addressed the origins of these fluctuations by using a) local thalamic pharmacology to antagonize noradrenergic signaling and b) closed-loop optogenetic LC activation or inhibition timed to NREMS or to moments of low and high spindle activity. Pharmacological blockade of noradrenergic signaling in thalamus suppressed infraslow variations in sleep spindle clustering

while leaving spindle properties intact. Using optogenetic LC activation or inhibition in dopamine-β-hydroxylase-Cre mice expressing hChR2(H134R) or Jaws in a Cre-dependent manner, we could suppress, lock or entrain sleep spindle clustering or heart rate variations. Noradrenergic modulation of thalamic but not cortical circuits seemed primarily required for sleep spindle clustering. Whole-cell patch-clamp recordings showed that local LC fiber-mediated NA release onto reticular thalamic nuclei or thalamic sensory neurons activated α1- or β-adrenergic receptors, respectively, to depolarize membrane potentials over the tens-of-seconds time scale. Noradrenergic signaling by LC thus divides non-REM sleep into substates that differ in terms of central (spindles) and autonomic (heart rate) physiological correlates. As these correlates parallel varying sensory arousability from non-REM sleep (Lecci et al., 2017; Cardis et al., 2021), we propose that LC signaling renders non-REM sleep more 'wake-like' on the close-to-minute-time scale

Title: Bilateral optogenetic stimulation of posterior parietal cortex leads to EEG activation and recovery of the righting reflex in a mouse model of coma

Authors: *R. MAO, M. CAVELLI, K. A. DRIESSEN, G. FINDLAY, G. TONONI, C. CIRELLI;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Years of experimental evidence points to the cerebral cortex as an essential brain structure in supporting conscious experience. Despite this, we still do not know whether posterior or frontal cortical areas alone are sufficient for consciousness, nor do we know the precise cortical mechanisms at work. To address these questions we first optimized in mice a protocol previously validated in rats, to induce a reversible state of profound, coma-like unresponsiveness via muscimol injections in the midbrain (Lanir-Azaria and Meiri et al., 2018). We then tested whether direct optogenetic cortical stimulation can reverse this coma-like state. CaMKIIα-Cre mice (3 males) were injected with rAAV5-Ef1a-DIO-hChR2(C128S/D156A-

EYFP) in the posterior parietal association area (PPtA, left or bilateral; from bregma, A/P -2.10, M/L ±1.50, D/V -0.60). Other CaMKIIα-Cre mice were crossed with Cre-dependent ChR2(H134R)/EYFP mice and adult offspring (CaMKIIα::ChR2) of both sexes were used (8 mice, 3 females). All mice were implanted with bilateral guide cannulas for muscimol injection in the midbrain, left or bilateral optic fibers for optogenetic stimulation of PPtA, EEGs and muscle electrodes, and cortical laminar silicon probes. In all mice (n = 11), muscimol injections in the midbrain induced a coma-like state characterized by loss of righting reflex, significantly reduced responsiveness to a battery of stimuli, and an EEG pattern dominated by slow waves and a high ratio of delta (0.5-4.5 Hz) to gamma (32-100 Hz) band power. All mice spontaneously exhibited recovery of righting reflex (RORR) after 1.5-4.5 hours and behaved normally the next day. In CaMKIIα::ChR2 mice the bilateral optogenetic stimulation of PPtA (0.3-4.7mW at cortex) during the coma-like state consistently led to EEG activation (decreased low frequencies, increased high frequencies) and full RORR. In the same mice, the same or stronger stimulation never resulted in EEG and behavioral activation under deep sevoflurane- dexmedetomidine anesthesia (1.0-1.5% sevoflurane, 70-100ug/kg dexmedetomidine), while brief stimulations were sufficient to wake up the animals from NREM sleep or REM sleep. In the mice that received unilateral stimulation during the coma-like state, full RORR or RORR attempts with partial EEG activation were observed. Unilateral stimulation was always able to wake up the mice from sleep. These results suggest that the direct activation of cortical pyramidal neurons in mouse posterior parietal area alone is sufficient for the recovery of consciousness.

Title: Sleep/wake changes in perturbational complexity in mice and rats

Authors: *M. CAVELLI, R. MAO, G. FINDLAY, K. DRIESSEN, T. BUGNON, G. TONONI, C. CIRELLI;
Dept. of Psychiatry, Univ. of Wisconsin, Madison, WI

Abstract: The Perturbational Complexity Index (PCI) and the related PCI^{ST} (ST = “state transitions”) are causal measures of spatiotemporal complexity in cortical event related potentials

(ERPs). In human subjects receiving transcranial magnetic or deep intracranial electrical stimulation, PCI and PCI^{ST} show reliable changes depending on the presence or absence of consciousness: they are high during wake and REM sleep, and low during dreamless NREM sleep and slow wave anesthesia (Casarotto et al., 2016; Comolatti et al., 2019). Here, we tested whether these measures also change across the sleep/wake cycle in mice and rats. Moreover, we tested the assumption that low PCI^{ST} values are linked to cortical bistability, which could disrupt causal interactions and lead to stereotypical evoked responses by promoting the occurrence of a large OFF period in response to stimulation. All animals were chronically implanted with cortical laminar probes (NeuroNexus or Neuropixels). The offspring of CaMKIIα-Cre mice crossed with Cre-dependent ChR2 (H134R)/EYFP mice (6 mice, both sexes) received optogenetic stimulation in the posterior parietal association area, and ERPs were recorded in posterior cortex. Rats (3 males) received electrical stimulation in primary sensory, motor and posterior associative cortex, and ERPs were recorded in ipsilateral or contralateral cortex. In each animal PCI^{ST} values were lower in NREM sleep than in wake or REM sleep (% relative to wake = 100: NREM sleep = 53.0 ± 22.2%; REM sleep = 87.7 ± 28.3%; ANOVA $F_{(2.4\ 17.4)} = 21.2$, $p < 0.0001$; NREM vs wake and NREM vs REM, both $p < 0.05$ after correction for multiple comparisons). In the same animals PCI^{ST} values were also low during deep anesthesia induced by sevoflurane and dexmedetomidine (29.5 ± 23.6% of wake). Consistent with results in humans, PCI^{ST} values and the Phase Locking Factor (PLF), which measures how long the evoked response remains phased locked to the original stimulus, were positively correlated ($r = 0.5$; $p = 5.9e^{-4}$). In both rats and mice, unit analysis showed that the early cortical response to stimulation is an OFF period that is most prominent during slow waves states. Together, these results show that PCI^{ST} values in rodents change across the sleep/wake cycle in a manner consistent with results obtained in humans. Low PCI^{ST} values are linked to the occurrence of OFF periods and short PLFs, which are believed to reflect the breakdown of causal interactions necessary for consciousness (Pigorini et al., 2015; Tononi et al., 2016).

Title: Sleep homeostasis in rat cortex and hippocampus

Authors: *G. FINDLAY[1], M. CAVELLI[1], W. MARSHALL[2], G. TONONI[1], C. CIRELLI[1]; [1]Psychiatry, Univ. of Wisconsin-Madison, Madison, WI; [2]Mathematics and Statistics, Brock Univ., St. Catharines, ON, Canada

Abstract: Slow waves are a defining feature of NREM sleep and reflect sleep need: cortical slow wave activity (CX-SWA) increases with time spent awake and decreases in the course of NREM sleep. Hippocampal slow wave activity (HC-SWA) and sharp-wave ripples, on the other hand, are hallmarks of NREM sleep but also occur in wake, and whether they reflect sleep need remains unclear. HC-SWA in cats (Lancel et al., 1992) and ripple occurrence in rats (Ponomarenko et al., 2003) increases after sleep deprivation (SD), but sharp waves (SPWs) were not analyzed. Although they often co-occur, SPWs and ripples are independent events produced by different synaptic networks (Buzsaki, 2015). Here we studied in rats how CX-SWA, HC-SWA, and SPWs change after SD.

Rats (6 males) were implanted with cerebellar-referenced Neuropixel probes in medial parietal association cortex (MPtA) and dorsal hippocampus. After 24h of baseline recording, rats underwent 6h SD by exposure to novel objects, followed by recovery sleep. SPWs were detected as large current sinks (>2.5 std. dev. above the mean current source density) in the stratum radiatum. Cortical and hippocampal signals were re-referenced to the white matter between MPtA and CA1 before computing CX-SWA and HC-SWA (0.5-4 Hz power spectral density). CX-SWA and HC-SWA in each rat were expressed as percentages of their respective baseline NREM medians.

CX-SWA increased in the first 2h after SD compared to circadian-time-matched baseline sleep ($n = 5$; $p = 0.001$, paired sample t-tests throughout) and declined from early to late recovery sleep ($n = 6$, $p = 0.002$). HC-SWA showed similar changes ($n = 5$, rebound, $p = 0.0002$; $n = 6$, decline, $p = 0.0002$), and increased from early to late SD ($n = 6$, $p = 0.002$ c.f. $p=0.102$ in cortex). HC-SWA rebound and decline were smaller than for CX-SWA ($n = 5$, relative rebound, $p = 0.006$; $n = 6$, relative decline, $p = 0.016$). Rate and amplitude of SPWs were elevated in the first 2h after SD compared to circadian-time-matched baseline sleep ($n = 5$, rate, $p = 0.003$; amplitude, $p = 0.013$), declined during recovery sleep ($n = 6$, rate, $p = 0.001$; amplitude, $p = 0.001$), with rate also increasing from early to late SD ($n = 6$, $p = 0.016$ c.f. $p = 0.074$ for amplitude). Although CX-SWA rebound and decline were strongly correlated ($n = 5$, Pearson's $r = 0.95$, $p = 0.012$), no similar correlation was present in the hippocampus, and hippocampal changes showed no consistent correlation with cortical changes.

Together, these results show that both HC-SWA and SPWs increase with time spent awake and decline during sleep. Their homeostatic behavior, however, seems weakly correlated with- and blunted relative to homeostasis of CX-SWA.

Title: A novel rhythm within REM sleep: hippocampal theta frequency, rapid movements and neocortical laminar LFP co-fluctuate in infraslow cycles

Authors: L. S. BUENO-JUNIOR, M. RUCKSTUHL, B. O. WATSON;
Dept. of Psychiatry, Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Rapid eye movement sleep (REM) has classically been divided into tonic and phasic microstates. To more finely determine this intra-REM structure, we recorded electrophysiologically from across the mouse S1 cortex and hippocampus at once using a linear silicon probe, while filming whisker and eye movements during sleep. We observed that rapid eye and whisker movements indeed burst in delimited periods, similar to the concept of phasic REM. However, hippocampal theta frequency (5-10 Hz, commonly used to delineate REM in rodents) was found to fluctuate in a non-binary fashion, contrary to what we would expect from the dichotomous concept of tonic REM vs. phasic REM. Interestingly, those fluctuations were at 0.02-0.06 Hz, an increasingly recognized brain rhythm known as infraslow. Rapid movements occurred preferentially at the crest of infraslow cycles, supporting this underlying periodicity. We additionally found that cross-frequency coupling between theta and high-frequency oscillations (HFO, 100-160 Hz) also fluctuates continuously in the infraslow range. This phenomenon varied in strength across our recording probe profile, being more evident in the hippocampus and either superficial or deep, but not intermediate cortical channels. Therefore, we expand the characterization of rodent REM to include co-fluctuations that span multiple frequency bands, and are anatomically uneven along cortical-hippocampal depths. We also demonstrate that the temporal structure of rodent REM is organized in continuous cycles of dozens of seconds, which could be speculated to govern mnemonic and homeostatic processes. Investigating these rhythms in other species may enable better dissection of REM and related disorders.

Title: Rem sleep microstates vary in neuronal activity across neocortex and hippocampus

Authors: *M. S. RUCKSTUHL, L. S. BUENO-JUNIOR, B. O. WATSON;
Dept. of Psychiatry, Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Traditionally, REM sleep is divided in human studies into phasic and tonic REM based on eye movement, and these microstates are thought to differ with regard to sensitivity to sensory stimuli. These microstates are believed to exist in rodents as well, as reflected in the heterogeneity of peak theta frequency during REM. However, we have found that peak theta frequency actually fluctuates continuously at an infraslow rhythm, suggesting that phasic and tonic REM exist on a continuum. Here we examine the impact of that continuum on neuronal activity across somatosensory cortex and hippocampus. We found that most neurons exhibit a phase preference for the peak of the infraslow rhythm, when theta frequency is highest. This concords with prior findings that firing rate tracks with theta frequency in awake animals and explains greater population activity during what is conventionally defined as phasic REM. We find that this is true across cell types and layers of neocortex and is not predicted by the baseline firing rate of a neuron. To better understand how cortical neurons work in concert, we performed a complementary analysis of assembly activity during REM sleep. We found that groups of consistently co-firing neurons tend to peak in activity during periods of high-frequency theta, and that assemblies detected during these periods are maximally dissimilar to assemblies detected during low-frequency theta. This exploration of neuronal activity during REM microstates informs our ongoing investigation of the structure of REM and sleep in general. This may lead to later insight about the impact of REM sleep on homeostasis and memory.

Title: The role of OLM interneurons in REM sleep dependent memory consolidation

Authors: *M. FRAZER, G. POE;
Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Forming and maintaining accurate spatial and contextual memories is important to an animal's ability to adapt to its environment. A growing body of evidence suggests that sleep is necessary for the proper consolidation of memory. Disordered sleep has numerous negative

effects on cognitive function, and is comorbid with nearly every common psychiatric illness. Thus, understanding why sleep is important to memory function is necessary for a full understanding of disorders in which sleep is affected. The role of rapid eye movement (REM) sleep, in particular, is contested and largely undetermined. Correlative studies suggest that depriving animals of REM results in deficits in spatial memory, and point to the necessity of the theta rhythm of REM. In waking, the theta rhythm is thought to temporally segregate inputs into the CA1, allowing for both encoding and retrieval; the role of REM theta, however, remains unknown. Hippocampal theta is driven by interactions between medial septal projections, pyramidal cells, and a diverse group of inhibitory cells. One such interneuron is the somatostatin-expressing oriens-lacunosum moleculare (OLM) cell, which fires spontaneously at the theta rhythm, and is phase-locked to theta peaks. Recent studies find that normal OLM cell activity is necessary for encoding spatial and contextual information during waking; the role they play in sleep-dependent consolidation, however, is unknown. To investigate the role of local inhibition in sleep-dependent consolidation, we have optogenetically silenced OLM interneurons selectively during REM sleep episodes, using a recently-developed mouse line specifically targeting OLM cells. We find that modulating OLM activity during REM sleep following acquisition of novel object place recognition (NOPR) tasks and contextual fear conditioning (CFC) disrupts typical consolidation. This suggests a role for OLM cells in consolidating hippocampal-dependent contextual tasks during REM sleep.

Abstract: Sleep is vital yet its regulation in the mammalian brain is poorly understood. The conventional view is that the cortex generates state-dependent brain oscillations, while subcortical brain structures control global sleep-wake switching. However, neocortex can locally generate sleep-like activity when homeostatic sleep pressure is high and bistable firing patterns in neocortex foreshadow sleep onset. In this study we tested if cortex contributes to vigilance state control and global sleep homeostasis. We performed chronic electrophysiological and passive infrared recordings to assess sleep and circadian rhythms in a transgenic mouse line (Rbp4-Cre;Ai14;Snap25$^{fl/fl}$), in which a subset of neocortical layer 5 pyramidal and archicortical dentate gyrus granule cells are functionally silenced by ablation of the synaptosome associated protein 25 (SNAP25). Laminar probe recordings from primary motor cortex showed layer-specific changes in neocortical dynamics during slow wave sleep in male cortical SNAP25-ablated mice. In addition, these conditional knockout mice (cKO, n=9) spent more time awake (Mean 13.8h ± SEM 0.4h) compared to Cre-negative controls (10.4 ± 0.4h, n=7, p<0.001, unpaired t-test, Cohen's d=2.96) and presented longer individual wake episodes. Following sleep deprivation, the level of frontal electroencephalographic (EEG) slow wave activity (SWA) during non-rapid eye movement (NREM) sleep, a measure of sleep intensity, was significantly lower in cortical SNAP25-ablated mice compared to controls (8 cKO mice: 136.77% ± 3.98%; 5 controls: 180.57% ± 5.13%; p<0.001, unpaired t-test, Cohen's d=-3.87). Circadian measures including period length, periodogram power, and the phase shift after a phase-delaying light pulse showed no significant differences between genotypes. Taken together, our study reveals an essential role for the cortex in sleep-wake regulation. Our data demonstrate that cortical SNAP25 ablation leads to a diminished homeostatic sleep drive without affecting core circadian parameters. These results support the possibility that cortical structures generate sleep drive locally, in an activity-dependent fashion, and raise the question of which mechanisms the cortex could use to generate, sense and/or integrate signals of sleep need. The next step will be to delineate these molecular mechanisms and to understand how the cortex interacts with established circuits of sleep–wake control. Further research on the cortical control of sleep will pave the way for a more comprehensive understanding of sleep regulation in the mammalian brain and help identify novel targets for the treatment of sleep disorders.

Title: Zona incerta Lhx6 neurons are most active during NREM and REM sleep and after prolonged waking

Authors: C. A. BLANCO-CENTURION[1], A. VIDAL-ORTIZ[2], ***P. SHIROMANI**[2];
[1]Psychiatry, Med. Univ. of South Carolina, Charleston, SC; [2]Res., Ralph H Johnson VA Med. Ctr., Charleston, SC

Abstract: Emerging data shows that GABA neurons in the zona incerta (ZI) play a prominent role in regulating sleep. Transfer of the orexin gene into ZI neurons blocks cataplexy in narcoleptic orexin-knockout mice (Liu et al., JNeurosci, 2011) and vGAT GABA neurons in the ZI anticipate onset of NREM (Blanco-Centurion et al., SLEEP, 2021). To identify the subtype of GABA neurons regulating sleep, we examine Lhx6 neurons. This study tests the hypothesis that Lhx6 neurons show peak calcium fluorescence during sleep, and that the fluorescence is further increased after prolonged waking. In Lhx6-cre mice (mice=4; all females; 4-5 mo), rAAV-DIO-GCaMP6s was delivered stereotaxically to the ZI (isofluorane anesthesia) and a GRIN lens, along with EEG and EMG electrodes were implanted. 21d later a miniscope (INSCOPIX) was attached, and after 3d of adaptation, sleep and fluorescence in individual Lhx6 neurons were recorded for 4h (baseline). On another day, the mice were kept awake for 6h (gentle handling; 9a-3p) and fluorescence in Lhx6 neurons was recorded for 2h during recovery sleep. The imaged data from the two recording periods (baseline and recovery sleep) was combined into a single data file and the change in fluorescence was determined against the mean image frame (F0). Previously, we and others found that the GCamP calcium fluorescence is a direct measure of action potentials and serves as a marker of activity. 97 neurons were automatically extracted (PCA-ICA analysis; blinded without knowledge of sleep state). In 66 neurons (68%) the average fluorescence was significantly higher during REM, NREM or both, compared to waking (Mixed Model ANOVA; SPSS25; $P<0.01$). In this population the fluorescence was significantly higher during recovery sleep compared to baseline ($P<0.001$) indicating increased activity of the sleep-active neurons during recovery sleep. With ensuing sleep, the increase in fluorescence gradually returned to baseline levels, attesting to the fluorescence as a marker of homeostatic sleep pressure. In 14 neurons (14%), fluorescence was highest in waking as compared to the other states during baseline, and in these neurons, fluorescence did not increase after sleep loss. Interestingly, six neurons (6%) were most active in waking and NREM but silent in REM (REM-off). This is the first study to measure fluorescence in individual neurons after sleep loss. We find that the fluorescence in two-thirds of ZI Lhx6 neurons is tightly linked to sleep, and that the

average fluorescence is further increased after prolonged waking. Microendoscopy is superior to indirect measures such as c-FOS or photometry in gauging sleep pressure in individual neurons.

Abstract: The transition from wakefulness to sleep is an initiation process of sleep behavior. Understanding the underlying neural mechanisms is particularly relevant for the development of new treatments for insomnia and other sleep disorders. Yet, brain circuits controlling this process remain poorly understood. Here we identified a novel population of glutamatergic neurons in the medulla that project to the preoptic area (POA), a prominent sleep-promoting region. Chemogenetic silencing of POA-projecting medulla neurons disrupts the transitions from wakefulness to Non-Rapid Eye Movement (NREM) sleep, whereas chemogenetic activation of these neurons promotes NREM sleep. Moreover, we show that optogenetic activation of medulla glutamatergic neurons or their projections in the POA reliably initiates NREM sleep in awake mice. Together, our findings uncover an excitatory brainstem-hypothalamic circuit that controls the wake-sleep transitions.

Title: Diversity and temporal structure of rat behavior across Pavlovian fear discrimination

Authors: *A. CHU[1], C. B. MICHEL[2], N. T. GORDON[2], A. M. DUBOIS[2], D. C. WILLIAMS[2], M. A. MCDANNALD[2];
[1]Psychology and Neurosci., [2]Boston Col., Chestnut Hill, MA

Abstract: In Pavlovian fear conditioning, a neutral cue is paired with an aversive stimulus, such as foot shock delivery. One result of this predictive relationship is that cue presentation will elicit a suite of defensive behaviors. The most commonly studied defensive behavior is freezing, a 'passive' defensive behavior defined by the absence of movement. Recent studies have revealed that shock-associated cues can also elicit 'active' defensive behaviors, such as darting, characterized by increased movement. Thorough ethograms of rodent defensive behavior have been confined to contextual fear conditioning procedures and lack temporal specificity. The goal of the current study was to construct a complete ethogram of rat behavior across Pavlovian fear discrimination. To do this, we tested 24 rats (12 females and 12 males) in a conditioned suppression procedure. Briefly, rats were trained to nose poke for food rewards. Rats then received 16 fear discrimination sessions in which three auditory cues predicted unique foot shock probabilities: danger (p = 1.00), uncertainty (p = 0.25), and safety (p = 0.00). Poke-reward and cue-shock contingencies were independent. During each trial, we captured individual images at a rate of 5 frames/s before and during cue presentation (2 s pre-cue, 10 s during cue, 12 s total). Initial observations show that rats exhibit a mixture of freezing and active behaviors such as locomotion during danger and uncertainty cue presentation. We will present a full analysis of behaviors such as freezing, locomotion, grooming, nose poking, and eating across cue presentation and across the 16 fear discrimination sessions. Additionally, we will scrutinize our findings for sex differences and for quantitative and qualitative differences in behavior elicited by danger and uncertainty cues. Our hand-scoring efforts will not only reveal fine organization of behavioral responding, but form the basis of a data set to train neural networks for behavior classification. Successful application of neural networks to behavior classification will permit highly-detailed, large-scale analysis of behavior to more completely reveal neural circuits supporting diverse threat behavior.

Title: The effect of sleep deprivation on fear extinction learning and memory

Authors: *A. R. FOILB[1,2], E. M. TAYLOR-YEREMEEVA[1], G. MISSIG[1,2], S. A. MADDOX[1,2], Y. DAI[3], K. J. RESSLER[1,2], W. A. CARLEZON, Jr.[1,2];
[1]Basic Neurosci., McLean Hosp., Belmont, MA; [2]Psychiatry, [3]Neurosci., Harvard Med. Sch., Boston, MA

Abstract: Sleep has a reciprocal relationship with fear- and trauma-related disorders. Sleep problems, including nightmares, difficulty falling or staying asleep, and restless unsatisfying sleep, are part of the diagnostic criteria for conditions such as Generalized Anxiety Disorder (GAD) and Post-Traumatic Stress Disorder (PTSD). Further, abnormalities in sleep patterns may contribute to, or exacerbate, the symptoms of these conditions and other co-morbid disorders. Existing research in rodent models demonstrate significant deficits in sleep as a result of fear learning, as well as improvements in sleep after extinction training. Prior studies on the inverse relationship, the impact of sleep on fear learning and extinction, have largely focused on disrupting the consolidation of memories immediately following learning. Here, we implanted male and female C57BL/6J mice with wireless telemetry transmitters (DSI) that allow for continuous collection of EEG, EMG, body temperature and locomotor activity. Vigilance states were tracked throughout fear conditioning, extinction training and recall testing. We used gentle handling to produce sleep deprivation, keeping mice awake for six hours prior to extinction training. Surprisingly, sleep deprived mice displayed enhanced extinction learning with reduced freezing to cue presentations during extinction and recall testing. Analysis of sleep data showed that sleep deprivation led to rebound slow wave sleep (SWS) and rapid eye movement (REM) sleep after extinction training, and that the retention of extinction memory correlated with the duration of rebound SWS in sleep deprived animals. In all animals, fear conditioning resulted in increased SWS and REM sleep during the dark phase, when mice are typically awake and active. Ongoing analyses will further investigate hourly changes in activity and sleep, as well as explore sex differences and a role of estrous cycle. Sleep is an ideal endpoint for preclinical neuroscience work, as it can be defined and assessed the same in the same ways in humans and animal models. Understanding the impact of stress and trauma on sleep will enable better alignment of neuroscience research and clinical studies and better treatments for a wide variety of psychiatric conditions.

Abstract: Episodic memories formed during infancy are rapidly forgotten, a phenomenon associated to infantile amnesia, the inability of adults to recall infantile memories. We previously showed that contextual experiences in infant rats are stored as latent memories and can be reinstated by reminders given later in life. We also found that infantile memory formation requires the dorsal hippocampus (dHPC) and biological mechanisms typically used in developmental critical periods. The development of parvalbumin interneurons (PVIs) is an important mechanism of critical periods in sensory functions. Furthermore, episodic memory formation in adult mice involve PVIs in the dHPC. Whether PVIs in the dHPC play a role in the critical period of memory development remains unknown. We used Inhibitory Avoidance (IA) to model contextual episodic learning in infant rats at postnatal day 17 (PN17), and biochemical, immunohistochemical, pharmacological and genetic approaches to determine the regulation and functional role of PVIs in the dHPC during infantile memory formation. We found that training significantly increased the levels of parvalbumin 48 hours after training. Chemogenetic inhibition of PV+ cells in the dHPC disrupted infantile long-term memory. While a bilateral dHPC injection of the positive GABAAR modulator diazepam after training led to long-term memory expression, chemogenetic activation of PV+ cells in the dHPC did not prevent infantile forgetting. We conclude that infantile episodic learning regulates the expression of PV protein in the dHPC where the function of PVIs is necessary for the storage of latent infantile memory. Furthermore, although like for sensory functions, diazepam can accelerate functional maturation, i.e., memory expression, the activation of PVIs is not sufficient to accelerate this developmental maturation.

Title: Aberrant Orbitofrontal Cortical Activation Interfered the Encoding of Pavlovian Fear Conditioning

Authors: *C.-F. SUN, C.-H. CHANG;
Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Hsinchu City, Taiwan

Abstract: The orbitofrontal cortex (OFC) can be subdivided into the lateral OFC (lOFC) and the medial OFC (mOFC). Previous studies have suggested that both subregions are involved in the modulation of negative emotions. However, the aberrant activities of the OFC on encoding the Pavlovian fear conditioning remain unknown. In Pavlovian fear conditioning, a neutral conditioned stimulus (CS), such as a tone, is associated with an aversive unconditioned stimulus (US), such as a footshock. After conditioning, the animals would demonstrate contextual fear to the conditioning chambers and cued fear to the tones. In this study, the mOFC or the lOFC was pharmacologically activated before fear conditioning on Day 1, followed by context test on Day 2 and tone test on Day 3 in Long-Evans rats. We found that animals under aberrant activation of either the mOFC or the lOFC showed normal within-session fear expression during conditioning. However, acquisition of contextual fear was impaired under mOFC activation, while the acquisition of cued fear was impaired under either the mOFC or the lOFC activation, that these animals showed lower freezing compared to controls during retrieval test. Together, our data revealed the importance of proper OFC activities in Pavlovian fear conditioning.

Title: Unilateral or Bilateral Activation of Lateral Orbitofrontal Cortex on Acquisition of Fear Extinction

Authors: *C.-C. SHIH[1], Y.-H. CHANG[1], R.-J. CHIOU[2], C.-H. CHANG[1];

Abstract: Dysfunction of fear expression and extinction is the reason of many anxiety-related disorders. By repeatedly presenting an initially neutral conditioned stimulus (CS; a tone) with an aversive unconditioned stimulus (US; a footshock), animals learn the association between the CS and US in Pavlovian fear conditioning. Afterward, repeated presentation of the CSs alone results in decrement of the conditioned fear response to CS, a process called fear extinction. Researches have indicated that both the amygdala and the medial prefrontal cortex (mPFC) play critical roles in the fear extinction. In addition, aberrant activities of the lateral orbitofrontal cortex (lOFC) have been observed in patients with anxiety-related disorders. Given the role of the lOFC in modulating fear expression and extinction, we hypothesized that activation of the lOFC would change the balance of neuronal activities in the amygdala and the mPFC, which causes a learning deficit in fear extinction. First, we unilaterally or bilaterally activated the lOFC with N-methyl-D-aspartate receptor (NMDA) immediately before the fear extinction procedure. We found that left and bilateral lOFC activation would lead to an initially low then gradually increased freezing behavior in the extinction learning process, whereas activation of the right lOFC did not. In addition, all experimental groups showed impaired acquisition of fear extinction during retrieval test. Next, we quantified the neuronal activities using c-Fos as an index in related brain regions during extinction acquisition. Our data suggested that pharmacological activation of the lOFC caused higher levels of c-Fos expression in non-GABAergic neurons in the ipsilateral lateral/basolateral amygdala and the ipsilateral mPFC in experimental groups. Meanwhile, higher activation levels of GABAergic neurons in the ipsilateral lateral amygdala and the ipsilateral medial intercalated cells were also observed in experimental groups. There was no significant difference in c-Fos expression in the central amygdala between experimental groups and control groups. Together, our results indicated that pre-extinction activation of lOFC changed the balance in neuronal activity in numerous extinction-related brain regions, which may have impacts on the expression of conditioned fear and may lead to the impairment of fear extinction acquisition.

Title: Sex-specific lateral septum circuits for threat memory acquisition

Authors: *K. ADCOCK BINION, A. N. YANKOGLU, S. BASU, E. K. LUCAS;
Dept. of Mol. Biomed. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Dysregulation of emotional learning and memory is a core feature of anxiety disorders. Women disproportionately experience anxiety disorders, leading us to hypothesize that emotional memory circuits may differ between the sexes. Using cued threat conditioning as a model for emotional memory, we found robust lateral septum (LS) activation after training in females but not males. Since the LS does not receive input from primary sensory regions conveying the conditioned and unconditioned stimuli, we next questioned which upstream regions recruit the female LS during threat memory acquisition. We bilaterally infused the retrograde tracer cholera toxin subunit B (CTb) into the LS of male and female animals one week prior to cued threat conditioning. In ongoing analysis, we are quantifying regional expression of CTb+ as well as CTb/FOS+ neurons throughout the brain. Thusfar, we have not observed any sex differences in input to the LS. We found that the ventral hippocampus (vHC) is the primary source of input to the LS, but vHC→LS projections are robustly activated during training in both sexes. However, we found that LS-projecting neurons in the lateral orbital cortex are activated by training in males but not in females, whereas LS-projecting neurons in the infralimbic cortex are activated by training in females but not in males. These data suggest that hardwiring of LS circuitry does not differ between the sexes, but sex-specific activation of upstream regions may drive sex-specific LS activation during threat memory acquisition. Future experiments will determine the causal relationship of LS circuitry on threat memory formation.

Title: The lateral septum drives sex-specific emotional memory encoding

Authors: *E. K. LUCAS[1], A. M. JEGARL[2], S. BASU[3];
[1]North Carolina State Univ., Raleigh, NC; [2]Yale Sch. of Med., New Haven, CT; [3]Cleveland Clin., Cleveland, OH

Abstract: The emotion of fear is a powerful trigger for memory storage, helping us avoid cues associated with dangerous outcomes. However, fear memories become maladaptive in common psychiatric diseases such as post-traumatic stress disorder, generalized anxiety disorder, panic disorder, and phobia. Women are twice as likely as men to experience these fear-based mental illnesses, suggesting that the neurobiological mechanisms underlying fear memory encoding may differ between the sexes. To explore this possibility, we quantified expression of the neural activity marker c-fos in select forebrain regions of mice subjected to auditory threat conditioning compared to naïve controls. While both sexes equally engaged canonical regions of cued threat memory circuit, such as basolateral and central amygdala, we found a robust female-specific increase of c-fos expression in the lateral septum (LS). We next employed chemogenetics for bidirectional modulation of LS activity during threat memory encoding and observed sex-specific effects on memory formation. In females, LS activation further enhanced threat memory encoding, whereas LS inhibition promoted threat memories that were more susceptible to degradation. In males, on the other hand, LS activation impaired, while LS inhibition enhanced, threat memory formation. To determine the downstream LS circuitry promoting threat memory, we used an activity-dependent tagging approach to express eYFP in neurons of the LS memory ensemble. Consistent with our c-fos data, significantly more tagged neurons were observed in trained females than trained males or naïve controls of either sex. Axons of LS memory ensemble neurons projected to canonical mediators of behavioral and physiological defensive responses, including the periaqueductal gray, lateral hypothalamus, and ventral hippocampus. Finally, we questioned whether LS neurons comprise a cued threat memory ensemble, and we found that LS neurons tagged during training were re-activated during cued memory recall. These data pinpoint the LS as a critical locus of sex-specific threat memory encoding that may promote women's susceptibility and men's resilience to fear-based psychiatric disease.

Title: Sex-specific neural networks of threat memory acquisition: a pilot study

Authors: *K. DU PLESSIS, E. K. LUCAS;
Dept. of Mol. Biomed. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Women are twice as likely as men to be diagnosed with posttraumatic stress and anxiety disorders, and greater symptom severity leads to worse clinical outcomes in women than in men. Dysregulation of emotional memory is a core feature of these disorders, suggesting that emotional memory processing may differ between the sexes. While decades of elegant studies have established circuits for the acquisition and retrieval of cued threat memory,the most common preclinical model of emotional memory, most of these studies excluded female subjects. Thus, it is currently unknown whether threat conditioning engages similar circuits to the same extent in females versus males. To investigate sex-specific circuits for emotional memory, we conducted whole-brain quantification of c-fos in adult male and female mice after cued threat conditioning compared to naive controls (n=3/group). Two-way ANOVA revealed that trained females exhibited higher activation of the central amygdala, cortical amygdala, and primary somatosensory cortex than trained males. Interestingly, we also observed greater activation of the anterior hypothalamic nucleus, midbrain, and superior colliculus in females relative to males independent of threat conditioning. To further analyze these basal and learning-dependent sex differences in regional activity, we generated cross-correlation matrices for all groups. We observed patterns of highly synchronized interregional activity in both naive and trained males that were not observed in females. In trained males, co-activation patterns were particularly pronounced between thalamic subregions. In contrast, thalamic activity in trained females was consistently uncoordinated with activity throughout the rest of the brain. Overall, this pilot study provides preliminary evidence of sex differences in the individual circuit components and broader neural networks involved in threat memory acquisition. Subsequent studies will elaborate on these findings through estrous cycle monitoring to account for estrogen- and progesterone-mediated effects on threat circuitry. In addition, future analyses will identify hub regions that exert disproportionate influence over network activity. By expanding our understanding of sex-specificity in threat memory networks, we aim to identify potential targets for clinical interventions that are better equipped to accommodate sex differences in memory systems.

Title: Evidence for a prefrontal - bed nuclei of the stria terminalis circuit that constrains contextual fear generalization.

Authors: *R. T. LINGG[1], S. B. JOHNSON[1], T. D. SKOG[2], D. C. HINZ[1], M. LIZARAZU[1], S. A. ROMIG-MARTIN[1], S. ELIASEN[1], N. S. NARAYANAN[4], J. J. Abstract: Generalization of fear is an adaptive neurobiological process conserved across species. Nevertheless, dysregulation of the neural systems that mediate fear generalization has been implicated in the development of a variety of stress-related psychiatric illnesses, including PTSD. It is well documented that glucocorticoid stress hormones modulate memory consolidation and contribute to fear generalization. However, little is known about the stress-modulatory systems that regulate endogenous glucocorticoid activity and how these are engaged to mediate fear generalization. Our prior work combining optogenetic, behavioral, and neuroendocrine approaches highlight the anteroventral bed nuclei of the stria terminalis (avBST) as an important interface between HPA-related information processing and prefrontal cortical regions tasked with the regulation of emotional memory. Here we used intersectional viral approaches to examine the role of a rostral prelimbic cortex (PL)-avBST pathway in regulating contextual fear generalization. We applied optogenetic methods for manipulating neural activity immediately following training on a modified single-trial inhibitory avoidance procedure in rats, as this post-training period is critical for mediating the emergence of long-term fear generalization. First, post-training inactivation of the rostral PL-avBST pathway with *halorhodopsin 3.0* (eNpHR3.0) for 10 min exaggerated corticosterone output provoked by the footshock given in the training context as compared to the control group. Forty-eight hours later, retention latencies were tested in the training and a novel context. Whereas both eNpHR3.0 and control groups showed high retention latencies in the training context, only the eNpHR3.0 group showed a high degree of generalization, as indicated by a similar retention level in the novel as training context. Next, we pre-exposed rats to a neutral context prior to footshock training to bias them toward generalization and activated the rostral PL-avBST pathway with *channelrhodopsin 2* (ChR2) for 10 min immediately after training. When tested 48 h later, only controls showed high retention levels for both contexts, indicating generalization, whereas the ChR2 group showed comparable retention for shock but not neutral context. Interestingly, corticosterone increases in the post-training period were not affected by pathway activation with ChR2. Together, these data provide evidence for a novel circuit regulating consolidation processes that limit stress hormonal activation in the aftermath of a traumatic event and fear generalization thereafter.

Title: Gut-brain signaling about metabolic state alters passive avoidance behavior in male rats: Potential contribution of A2 noradrenergic neurons

Authors: *C. M. EDWARDS, T. DOLEZEL, L. M. RINAMAN;
Dept. of Psychology, Florida State Univ., Tallahassee, FL

Abstract: Competing motivational drives coordinate behaviors essential for survival. For example, negative energy balance suppresses innate anxiety-like behaviors in rats. In this set of experiments, we explored the impact of metabolic state on learned avoidance behavior, and whether the "hunger hormone" ghrelin plays a role. Male and female rats were trained in a passive avoidance task where they learn to avoid a context paired with a single mild footshock. When rats later were tested for avoidance of the same context, male rats tested in an overnight food-deprived state and female rats (regardless of feeding status) displayed significantly less avoidance compared to male rats that were fed *ad libitum* prior to testing. However, when the fasting-induced increase in ghrelin signaling was pharmacologically antagonized before the test, fasted male rats displayed more passive avoidance compared to fasted, saline-injected controls. Based on prior evidence that prolactin-releasing peptide (PrRP)+ A2 neurons and glucagon-like peptide 1 (GLP1)+ neurons within the caudal nucleus of the solitary tract (cNTS) are "silenced" by overnight fasting, we examined whether these neurons were activated in rats re-exposed to the shock-paired context in fed vs. fasted conditions. Compared to controls, context re-exposure in fed rats activated PrRP+ neurons, but not GLP1+ neurons, and also activated neurons within the anterior ventrolateral bed nucleus of the stria terminalis (vlBNST), which receives dense input from PrRP+ terminals. Food deprivation prior to context re-exposure reduced activation of PrRP+ A2 neurons in both sexes, and this effect was partially reversed by ghrelin receptor blockade. Our results support the view that PrRP+ neurons innervating the vlBNST contribute to expression of passive avoidance in a manner that is modulated by metabolic state, including a potential role for ghrelin signaling, in male rats.

Title: Over- and under-segmentation of latent causes lead to different types of extinction failures

Authors: *I. AITSAHALIA[1], S. PISUPATI[1], A. LANGDON[1,2], Y. NIV[1,2];
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: Recent studies have proposed that individual differences in the failure to extinguish Pavlovian conditioned fear may emerge from differences in the inferred causal structure of the environment. Previous research has distinguished between individuals who attribute fear acquisition and extinction trials to a single cause and those who attribute these to different causes. Healthy participants in the latter group showed higher resurgence of fear than the former (Gershman and Hartley, 2015) while participants with PTSD were more likely to fall into the former category (Norbury et al. 2021). However, this delineation does not capture the full range of possible regimes that could contribute to differences in learning and fear extinction, especially in extinction tasks with both safe (CS-) and dangerous (CS+) stimuli. Here, we propose that inferred causal structures lie on a spectrum between too few and too many latent cause assignments, corresponding to "discrimination" failures (failures in distinguishing between safe and dangerous stimuli) and "over-accommodation" failures (failures in updating beliefs about stimuli that are no longer dangerous) respectively, with "good" extinction falling in between. Using simulations, we show that these extremes can be reached through changes in a parameter that controls beliefs about randomness in the world, captured in our model as a prior over observation probabilities. Starting out with a "deterministic" prior, i.e. a belief that probabilities are often all-or-nothing, leads to surprising observations being assigned to new causes. Creating too many latent causes can give the impression of rapid learning, but does not extinguish the original association, failing to generalize between acquisition and extinction trials. Such over-accommodating individuals could be more susceptible to spontaneous recovery of fear. On the other hand, a "stochastic" prior, i.e. a belief that probabilities are often close to chance, leads to attribution of disparate observations to a single cause and overgeneralization. The creation of too few latent causes leads to poor discrimination between stimuli and therefore poor extinction performance through the generalization of fear to safe stimuli. Our proposed delineation of latent cause regimes clarifies the mapping between erroneous inference of causal structure and different types of extinction failures. Moreover, we relate these regimes to a single parameter, the observation prior, that can reflect cognitive distortions or an individual's past experiences.

Title: Learning a state-space map

Authors: *O. BEIN[1], N. W. SCHUCK[2], R. RAGHU[1], Y. NIV[1], A. J. LANGDON[1];
[1]Princeton Univ., Princeton, NJ; [2]Max Planck Inst. for Human Develop., Berlin, Germany

Abstract: Goals drive how we represent the environment. If trying to cross the street, we might represent and base decisions on the speed of different cars, while when evaluating which car is more aesthetically pleasing, color might be more important. In the computational framework of reinforcement learning, the information relevant to a given decision is referred to as 'state', and a task can be described as a map of such states. This map is composed of a set of states, with transitions between them, and rewards and costs associated with some states and not others. Much research has been devoted to understanding how values are learned based on a given state representation. However, only recently researchers started to focus on understanding how the state representation itself is learned. Recent research has implicated the orbitofrontal cortex (OFC) in representing well-learned states (Schuck, Cai, Wilson & Niv, 2016), especially when relevant state information is partially unobservable (i.e., has to be recalled from memory rather than being perceptually available). Here, we used the same task to investigate the process of initially constructing the representation in the OFC: participants (N=27) were scanned using fMRI while they read the task instructions, practiced the task, and then performed it for hundreds of trials. The arbitrary nature of the task ensured that state representations had to be constructed de novo. In particular, participants observed stimuli composed of a superimposed house and a face, and made young/old judgements about either the face or the house. Knowing which category to judge, namely, what is the current 'state', required information from the previous trial, and therefore this aspect of the state was unobserved. Behaviorally, error rates and reaction times decreased with learning, indicating that participants learned and honed an effective state representation. Neural analyses include univariate activation, functional connectivity, and multivariate pattern analysis (MVPA classification and representational similarity analysis, RSA). Our analyses are focused on an OFC region of interest, as well as on the hippocampus and sensory brain regions, with the goal of understanding the circuit involved in learning a map of states to guide decisions.

Title: Changes in reward identity disrupt the reset of reward predictions and reveal model-based influences on reward prediction errors in dopamine neurons

Authors: S. K. HAROOTONIAN[1], Y. K. TAKAHASHI[2], T. A. STALNAKER[2], L. E. MUELLER[2], G. SCHOENBAUM[2], Y. NIV[1], A. LANGDON[1];
[1]Princeton Univ., Princeton, NJ; [2]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: The phasic activity of midbrain dopamine neurons is thought to encode the model-free prediction error signal posited by the temporal-difference (TD) reinforcement learning algorithm. In this interpretation, dopaminergic prediction errors are sensitive only to differences in the value of outcomes, irrespective of the form in which these outcomes are delivered. Recent findings, however, have challenged this idea by showing that unexpected reward identity—for example, a receiving a chocolate-milk reward rather than an equally valued vanilla-flavored reward—can elicit phasic increases in dopamine activity (Takahashi et al., Neuron, 2017). These results demonstrate that changes in reward identity alone are sufficient to produce significant prediction-error responses in dopamine neurons. Here, we present a model-based multi-prediction TD learning algorithm (Langdon et al. Curr. Opin. Neurobiol. 2018) to account for reward-identity-dependent responses of midbrain dopamine neurons in a task in which the identity and timing of rewards are systematically manipulated (Takahashi et al., SfN 2019). In particular, we focus on accounting for both the responses to changes in reward identity and the "reset" of reward predictions when a reward is obtained earlier than predicted (i.e., the fact that dopamine neurons do not show an omission signal at the original time of reward). Importantly, the data show that omission responses are restored when the identity of the now-early reward is also changed. In our model, we account for this identity-specific reset of reward predictions through model-based inference, in which only the specific prediction that is no longer relevant after the delivery of an early reward is reset, a mechanism that relies on the congruence between the expected and actual identity of the outcome. Our results suggest that dopamine neurons have access to complex, multi-dimensional reward expectations, in which multiple identity-specific predictions about reward outcomes can be sustained in parallel. Overall, our results provide compelling evidence

that prediction error responses in dopamine neurons do not correspond to simple model-free errors in scalar value expectations, but correspond instead to errors in model-based predictions about the specific reward outcomes expected in a task.

Title: A unified framework for reversal learning based on latent cause inference

Authors: *S. PISUPATI[1], J. R. TAYLOR[3], Y. NIV[1,2], S. M. GROMAN[3,4];
[1]Princeton Neurosci. Inst., [2]Psychology, Princeton Univ., Princeton, NJ; [3]Psychiatry, Yale Univ., New Haven, CT; [4]Neuroscience, Med. Discovery Team on Addiction, Univ. of Minnesota, Minneapolis, MN

Abstract: Reversal-learning tasks have been extensively used to quantify cognitive flexibility across species by requiring subjects to adapt choice behavior to changing contingencies. Although reversal-learning tasks are traditionally thought to measure response inhibition, recent work suggests that this task may measure multiple interacting processes such as reward-based learning, change-point inference and rule/task-space learning (Izquierdo et al.'17, Groman et al.'19). Here, we present a model of reversal learning that unifies these processes based on the normative framework of latent-cause inference, in which individuals infer hidden or "latent" causes that dictate the relationship between cues, actions and outcomes in the task. Reversal learning in this model involves learning the structure of these causes, online inference about their change-point dynamics, and learning associations and response policies contingent on these causes.Our model accounts for several empirically observed features of reversal learning, such as abrupt rather than gradual changes in response policy, learning of new associations rather than unlearning of old ones, and a dissociation between abandoning previously rewarding actions and

learning to exploit newly rewarding ones. In addition, it predicts the existence of "interference" events where ambiguous evidence leads an agent to infer that an old cause has returned, and incorrectly perform the old response policy long after a new one has been learnt - a feature whose occurrence we confirm by fitting the model to a dataset of rodents performing a probabilistic reversal learning task (Groman et al. '19). Further, we use our model to understand the influence of prior experiences on reversal learning, and to interpret the effects of viral ablations of select projections to and from the orbitofrontal cortex, an area previously associated with latent cause inference. Our model offers a unified probabilistic view of multiple facets of reversal learning, and is of particular relevance to the application of reversal paradigms to psychiatric conditions involving the resurfacing of old behaviors after prolonged periods of time, such as relapse in addiction.

Title: Discovery of hierarchical representations in goal-directed behaviour

Authors: *M. SILVA, L. FUENTEMILLA, J. MARCO;
Univ. of Barcelona, Barcelona, Spain

Abstract: Goal-directed behavior relies on the ability to learn the relational structure of a complex environment. Prior research showed that humans can quickly acquire a map-like representation of multiple events that are associated by a uniform transition probability. Here, we examined how the acquisition of such topology structure can lead to the discovery of hierarchical representations hidden in a relational structure. We recorded scalp electroencephalography (EEG) while participants were asked to find out optimal paths that linked sequence of fractal pictures to a reward. Critically, picture sequences and paths coalesced around clusters or ‘communities’ of mutually predicting stimuli, thereby eliciting the emergence of hierarchical event memory representations for picture images, those that linked within and those that linked between (i.e., boundaries) communities. By implementing model-based analysis on behavioral and on EEG data, we demonstrate that the acquisition of memory representations containing such community structure precedes the discovery of the hierarchical topology hidden in the same structure. These findings provide important insights of the organizational principles that allow optimal goal-directed behavior via relational learning in humans.

Ctr., Los Angeles, CA

Abstract: Memory formation is a dynamic process where single memories are stored, updated and integrated within the framework of other pre-existing memories to drive adaptive behavior. Previously our laboratory and others have shown that when two memories are acquired close in time, the recall of one leads to the recall of the other, a phenomenon referred to as memory linking. Memory linking is mediated by an overlap between the neuronal ensembles encoding these memories. However, little is known regarding the dendritic plasticity mechanisms that regulate memory linking and other memory integration phenomena. Here, we investigate the integration of two distinct contextual memories to study the role of somatic as well as dendritic plasticity within the retrosplenial cortex (RSC). We demonstrate that overlapping RSC neuronal ensembles are recruited to encode contextual memories acquired close in time (neuronal co-allocation). Moreover, individual neuronal firing as well as patterns of coactivity in RSC are more stable across context explorations within the same day vs 7days apart (conditions that drive contextual memory linking). We also show that this overlap in RSC neuronal ensembles is necessary and sufficient for linking contextual memories. Using structural as well as functional 2 photon imaging, we next investigated whether the exploration of a novel context causes branch-specific dendritic plasticity within RSC neurons such that the future dendritic plasticity is biased to the same dendritic segments (dendritic co-allocation). Longitudinal calcium imaging of RSC dendrites demonstrated that the same dendritic branches are activated when two contexts were

visited same day vs 7 days apart. We also found that structural plasticity in the form of spine addition and clustering was biased to the same dendritic branches under these conditions. These results demonstrate that contextual memory linking drives dendritic activation as well as plasticity within the same RSC dendritic branches. Finally, to further test the role of RSC dendritic co-allocation in contextual memory linking, we developed an optogenetic tool that allows the tagging as well as manipulation of previously activated dendrites. Using this system, we demonstrate that branch-specific reactivation of RSC dendrites alone was sufficient to link two contextual memories. These data demonstrate a key role for RSC dendritic co-allocation in contextual memory linking. We show that contextual learning results in branch-specific dendritic plasticity in RSC that biases future memory allocation to the same dendritic segments, and that this dendritic co-allocation is critical for memory linking.

Title: Medial entorhinal cortex lesions produce delay-dependent disruptions in memory for elapsed time in rats

Authors: A. VO[1], N. TABRIZI[1], T. HUNT[1], K. CAYANAN[1], S. CHITALE[2], L. ANDERSON[2], S. TENNEY[2], A. WHITE[2], M. SABARIEGO[2], *J. HALES[1];

Abstract: Our awareness and experience of elapsed time is important for remembering and organizing events in a temporal context as well as for planning future actions. Several studies have supported the role of the hippocampus in temporal organization of episodic memory with the finding of hippocampal time cells that fire sequentially throughout a temporal gap. This sequential firing has recently been identified in the medial entorhinal cortex (MEC), an area that directly projects to the hippocampus, which suggests that the MEC may provide temporal input to the hippocampus that is integral for episodic memory formation and maintenance. The behavioral relevance of such firing remains unclear, however, as previous research has rarely used time as a meaningful variable or utilized tasks that depend on the MEC. In our study, we

investigated whether the MEC is necessary for rats to perform a time duration discrimination task (TDD), in which they were taught to distinguish between 10-s and 20-s delays. During every trial in the figure 8 maze, rats were held in a delay box at the end of the central arm for 10 or 20 seconds. At the end of the delay, rats were allowed to turn left or right, but they only were rewarded for making a left turn after a 10-s delay or a right turn after a 20-s delay. After reaching a 90% performance criterion in two out of three consecutive test days, rats were randomly assigned to receive an excitotoxic MEC-lesion or sham-lesion surgery. After a two-week recovery period, we found that MEC-lesioned rats were significantly impaired on the TDD task in comparison to sham-lesioned rats and did not return to performance criterion. This impairment was specific to the longer 20-s delays, suggesting an important role for the MEC in memory for elapsed time longer than 10 seconds possibly due to an increased reliance on long-term memory resources for processing prolonged time intervals.

Title: Characterizing hippocampal CA1 network activity in the context of trace conditioning at multiple inter-stimulus intervals

Authors: *H. NAMBISAN, A. G. KAMBADUR, U. S. BHALLA;
Natl. Ctr. for Biol. Sci. (NCBS-TIFR), Bangalore, India

Abstract: The hippocampus plays a crucial role in associating discontiguous events and in the consolidation and encoding of memory. Recent research has shown that the hippocampus is functionally relevant for the creation and maintenance of different types of sequences. Of particular interest is the idea that some clusters of cells take up specific encoding tasks, termed ‘place cells’ and ‘time cells’. In previous work using trace eyeblink conditioning (TEC) protocol, where two events occur one after the other and are separated by an inter-stimulus interval (ISI) or

trace interval, we observed the emergence of time tuning in cells of the hippocampal CA1 pyramidal layer following learning of the trace association (Modi et al., eLife 2014). Time-cell remapping has been observed for learning tasks involving delay periods (W. Mau et al., Curr. Biol. 2018) but these take place over tens of seconds and do not address multiple simultaneous representations. Here, we seek to understand the time-cell formation, remapping, multiple representations, and extinction in the context of a series of trace timing tasks with multiple individuals and interleaved durations. Using TEC as the behavioral context, we investigate how the dorsal hippocampal CA1 network activity changes to encode new time scales of trace for a pair of a conditioned stimulus (CS: light) and an unconditioned stimulus (US:air-puff). We used head-fixed GCaMP6f mice (n=6 imaging, n=6 behavior) to train them on varying trace intervals (250 ms, 350 ms, 450 ms, and 550 ms). Each animal was first trained to criterion on the 250 ms trace over a few sessions on consecutive days. The trace duration was successively incremented once the animal reached the criterion. After learning the 550 ms trace, the animals went through 3-4 sessions of interleaved trials consisting of 6 blocks of 5 trials alternating between the 250 ms and 550 ms traces, for a total of 60 trials. Finally, the animals went through CS-only extinction sessions. We used an implanted cranial window to carry out in vivo 2-photon calcium imaging on head-fixed mice using a custom-built galvo-scan microscope. We recorded ~100 cells for each animal across ~25 sessions spanning the behavioral training, and also monitored locomotion using a rotary encoder on a treadmill. The behavior data suggests that the animals take longer to associate the first interval but are comparatively quicker to associate subsequently expanded trace intervals. We present our findings on the emergence and stability of time-cell sequences and how the sequential activity changes with the expansion of the trace intervals.

Title: Learning to anticipate: hazard rate updating in mice and monkeys

Authors: *N. N. ODEAN[1], M. SANAYEI[3], J. GOLDBAS[4], G. M. STINE[1], D. M. WOLPERT[2], M. N. SHADLEN[5];
[1]Neurosci., [2]Columbia Univ., New York, NY; [3]Sch. of Cognitive Sci., Inst. for Res. in Fundamental Sci., Tehran, Iran, Islamic Republic of; [4]New York Univ., New York, NY; [5]Neurosci., Howard Hughes Med. Inst. - Columbia Univ., New York, NY

Abstract: Anticipation of events allows us to infer cause/effect, test predictions, express and understand language and music. Its formal realization is the hazard rate, h(t): the probability of an event at t, given it has yet to occur. Monkeys and humans are known to produce faster reaction times (RT) to stochastic cues when h(t) is larger, and a neural representation of h(t) is observed in macaque parietal cortex (Janssen & Shadlen 2005). The mechanisms responsible for establishing these dynamical neural responses are unknown. We reason they might be tractable in the mouse. We therefore sought to determine whether mice exhibit anticipatory behavior consistent with hazard rate timing.

Mice were trained to wait in a central port for a "go" cue before moving to a second port to collect a reward. Initially, the wait time, τ, was uniformly distributed ($0.5 < \tau < 2.5$ s). After learning this unimodal distribution, $U(\tau)$, the mice were switched to a bimodal distribution, $B(\tau)$: $p=0.45$ that τ is from the 1st mode (0.5-0.75 s), $p=0.45$ that τ is from the 2nd mode (2.25-2.5 s), and $p=0.1$ that it is distributed uniformly between them. The hazard rate associated with $U(\tau)$ increases monotonically with waiting time; for $B(\tau)$ it is triphasic, rising for each mode and falling in between. One rhesus macaque was trained on a saccade task using $B(\tau)$ to facilitate comparison with past results.

We measured the RT of the mice after exposure to these schedules. For $U(\tau)$, RT decreased monotonically as a function of wait time. For $B(\tau)$, RT showed a triphasic pattern. These patterns are broadly consistent with anticipation mirroring the hazard rate. When $B(\tau)$ was introduced, RT decreased for trials from the first mode within the first session (rank sum $p<0.0001$), while RT in the second mode did not. The monkey, similarly, responded most quickly to trials from the first mode early in training and to trials from the second mode when fully trained. The effect of wait time on learning could also be seen in the slowing of RT in the sparsely sampled intermode epoch. RT slowed first for τ at the beginning of this epoch. Even late in training, mice exhibited changes in RT that were influenced by the wait time in the preceding trial. Thus they continue to adjust their behavior to potential changes in temporal milieu. For example, following a trial with τ drawn from the intermode epoch, mice responded faster than expected on the next trial.

These observations provide preliminary support for hazard rate timing by mice. They begin to constrain the class of models that can explain how temporal regularities are learned.

Title: The 'Expected Value' (not the surprising outcomes) of risky choices drives subjective pleasure of risky decision making in patients with Impulse Control Disorder

Authors: *B. LIEBENOW[1], A. JIANG[1], E. DIMARCO[1], L. P. SANDS[1], M. MOYA-MENDEZ[3], M. S. SIDDIQUI[2], I. HAQ[4], K. T. KISHIDA[1];

Abstract: Dopaminergic signals have been implicated in heightened impulsive motivation and positive feelings initially associated with addictive stimuli. Impulse control disorder (ICD) is a behavioral addiction consisting of the sudden onset of increased risky decisions induced by dopaminergic therapies (DT) used to treat Parkinson's disease (PD). The connection between dopamine, ICD, and the experience of risky decision making is not understood. We hypothesized that patients with a history of ICD have increased motivation to take risks and that heightened dopamine-related signals increase the pleasure associated with those decision outcomes. We investigated the experience of risky decision making in patients with PD and a history of ICD (ICD, n = 18) compared to patients with PD and no history of ICD (non-ICD; n = 11), on and off their DT. All participants performed a 'Sure-bet vs. Gamble' Choice Task where they choose to either gamble or take a sure bet on a series of independent trials; on one-third of all trials, participants reported how they felt about the outcome. We fit each participant's behavior to Rutledge et al.'s 'happiness model' to predict subjective feelings about decision outcomes. Parameters in the model include: certain rewards (CR), expected value of the gamble (EV), and reward prediction errors over outcomes (RPE). No difference in the rate of gamble decisions or earnings were observed across groups; however, the ICD group showed a significant baseline bias towards subjective ratings of "very good" compared to non-ICD over all decisions and outcomes (on or off DT: $p < 0.001$). DT reduces positive feelings about these decisions in both ICD and non-ICD ($p < 0.001$). The EV of a gamble significantly increases positive feelings about gambles taken and related outcomes in ICD vs. non-ICD (on or off DT: $p < 0.001$). This effect is enhanced by DT in ICD ($p < 0.001$), but diminished by DT in non-ICD ($p < 0.001$). RPEs about decision-outcomes drive subjective ratings in both groups with no difference observed across ICD versus non-ICD off DT. However, DT appears to diminish the impact of RPEs in ICD ($p < 0.001$) and enhance the effect of RPEs in non-ICD ($p < 0.001$). Together, we show that enhanced positive experiences associated with risky decisions in patients with a history of ICD is driven by the anticipation of potential outcomes rather than experienced outcomes and that this effect is enhanced in the presence of DT. These results suggest that, in ICD, the reinforcing effects of dopamine may be most strongly associated with the onset of risky behavior and not on the outcome of these decisions, an effect that would lead to continued poor decision making in the face of adverse outcomes.

Title: Multi-shell diffusion-weighted magnetic resonance imaging for the study of white matter structural connectivity in treatment-resistant depression.

Authors: *C. K. JOHNSON[1], R. E. JONES[2], T. DURAN[2], H. E. DOUGLAS[1], P. GLIGOROVIC[1], K. T. KISHIDA[2];
[1]Wake Forest Baptist Hlth., Winston Salem, NC; [2]Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: Of the more than 300 million people diagnosed with depression worldwide, ~30% are classified as treatment-resistant (TRD). This occurs when a person fails to respond to conventional treatments, including a combination of psychotherapy with antidepressants and/or antipsychotics. The most effective intervention for TRD is electroconvulsive therapy (ECT), however, the mechanisms by which it alleviates symptoms of depression remain unknown. Several neuroimaging studies on depression, as well as those investigating effects of ECT, have demonstrated a difference in characteristics of white matter in the brains of depressed and non-depressed individuals and changes in white matter structure following ECT in individuals with

TRD, indicated by metrics such as fractional anisotropy (FA) and mean diffusivity (MD). However, results of these studies are inconsistent, primarily due to small sample sizes in some and imaging techniques that do not provide enough fine detail to reliably determine subtle differences in white matter structure, particularly where multiple fibers cross in a single voxel. Our approach uses multi-shell diffusion-weighted magnetic resonance imaging (DW-MRI), which includes multiple diffusion directions sampled along multiple spheres to provide high angular contrast necessary for distinguishing crossing fibers. Here, we conduct an observational study in which DW-MR images are collected from participants with no history of depression, those with mild/moderate depression, and those with severe TRD who are seeking ECT. Analysis of these images confirms that white matter structural integrity is diminished, as indicated by lower FA and higher MD, in cases of severe TRD (n = 8), and, to a lesser extent, in cases of mild/moderate depression (n = 11), when compared with images collected from individuals without depression (n = 25). Furthermore, our imaging approach allows us to detect significant differences in FA between participants with mild/moderate depression and those with TRD. Following ECT, we will use these techniques to identify with greater specificity than previously reported the white matter tracts most affected by this treatment for TRD and determine how they might track with functional changes in the brain and improvement of clinical symptoms. Finally, we will extend our work to include fitting penalized and cross-validated regression models to determine if it is possible to predict the effectiveness or side effects of ECT treatment. Together, our preliminary and ongoing work will further elucidate the mechanisms of ECT, thus allowing for better understanding of depression and, ultimately, higher quality of care for patients.

Title: Slower learning from punishments and altered mapping of prediction errors to affective responses in patients with depression

Authors: *R. E. JONES[1], L. P. SANDS, III[1], A. JIANG[3], H. E. DOUGLAS[4], P. V. GLIGOROVIC[4], K. T. KISHIDA[2];
[1]Neurosci., [2]Physiol. and Pharmacol., Wake Forest Univ. Sch. of Med., Winston Salem, NC; [3]Wake Forest Sch. of Med., Clemmons, NC; [4]Psychiatry and Behavioral Med., Wake Forest Baptist Hlth., Winston-Salem, NC

Abstract: Major depressive disorder is characterized by persistent sadness and anhedonia, as well as deficits in cognitive function and decision-making. It is hypothesized that dopaminergic projections throughout mammalian reward circuitry encode temporal difference reward prediction error (TD RPE) signals, which quantify the difference between received and expected outcomes. Human functional magnetic resonance imaging (fMRI) studies have demonstrated reduced RPE responses to rewarding stimuli in the ventral striatum and ventral tegmental area in patients with depression; however, the neurocomputational components of punishment learning and how these may be altered in depression are less well understood. Standard computational reinforcement learning (RL) models equivocate rewards with punishments and thereby are unable to capture how humans, and especially patients with depression, may react non-linearly to these different classes of outcomes. We provide evidence suggesting that rewards and punishments are tracked by independent, valence-specific neural systems, though the bearings of such a valence-partitioned RL (VPRL) model on behavioral phenotypes in depression remains an open question. To address this, we conducted experiments in which healthy controls (HC; n=19), patients with depression (PwD; n=10), and patients with treatment-resistant depression (PwTRD; n=8) completed a probabilistic reward and punishment task while scanned with fMRI; participants reported how they felt about their outcomes on 33% of trials. We fit a standard TD learning model and a VPRL model to participant choice behavior and found that VPRL best captured how humans learn from rewards and punishments across cohorts. In this framework, PwD and PwTRD showed a specific decrease in their learning rate to punishment prediction errors (PPEs). We regressed RPEs, PPEs, and expected values (EVs) on participants' subjective ratings and determined that the three cohorts were best differentiated according to the influence of negative RPEs, positive PPEs, and the EV of the chosen and unchosen actions on subjective ratings. Our results demonstrate that how humans learn from rewards and punishments differentially impacts subjective feelings during decision-making, and that this mapping of learning signals to affective dynamics may be altered across depression severities. Our data collection and model-based fMRI analysis are ongoing. As our sample size increases we will investigate brain regions of interest that may track RPE and PPE signaling and how activity in these systems might be altered in depression.

Title: Time perception deficits are associated with individual differences in clinical presentation and comorbidities of Parkinson's disease

Authors: *E. DIMARCO[1], R. SADIBOLOVA[3], R. E. JONES[1], A. JIANG[1], B. LIEBENOW[1], I. U. HAQ[4], M. S. SIDDIQUI[2], D. B. TERHUNE[3], K. T. KISHIDA[1];

Abstract: Striatal dopamine is commonly understood to mediate time perception and is the target of dopaminergic therapies (DT) prescribed to treat Parkinson's disease (PD); however, the role of dopamine in the intersection of timing and the non-motor symptomology of PD is incompletely understood. We hypothesize that specific deficits in interval timing will be associated with heterogeneity in PD presentation and comorbidities. To investigate, we recruited patients with PD (n = 19) to complete a temporal bisection task (interval durations: 500ms - 1100ms) while on and off their prescribed DT. We applied psychometric functions (PFs) to estimate temporal precision and accuracy for each participant in each medication state. Their timing performance was subsequently investigated in the context of different clinical features (e.g., age, PD duration, DT profile, comorbid depression diagnoses) and each patient's score on the Questionnaire for Impulsive-Compulsive Disorders in Parkinson's Disease–Rating Scale (QUIP-RS). We applied linear regression models with these clinical features as predictors and timing performance as outcome variables to examine how dopaminergic dysfunction related to interval timing performance. Although the PD patients on vs. off DT did not significantly differ in their timing ability ($p > 0.05$), we observed that longer PD duration of diagnosis (distribution = 1 – 8 years, $p < 0.01$) was associated with decreased temporal precision regardless of medication state. We additionally found that patients with suprathreshold QUIP-RS scores ($n = 11$, $p < 0.01$) showed increased temporal overestimation bias, and that patients with a depression diagnosis ($n = 4$, $p < 0.05$) showed increased bisection point error compared to euthymic subjects. This association between PD comorbidities and temporal deficits further highlights how PD symptom heterogeneity may be accounted for. Finally, patients who were prescribed poly-DT demonstrated an increase in proportion of correct responses and decreased bisection point error compared to patients prescribed Levodopa monotherapy ($n = 11$, $p < 0.01$). Together, these results demonstrate that non-motor PD symptoms are associated with specific changes in interval timing behavior consistent with changes in dopaminergic system function. This suggests that simple time perception tasks may be used to quantify and investigate specific mechanisms

underlying individual differences in the clinical presentation of PD; and, that investigating individual differences in time perception in PD patients may provide insights into the mechanisms of timing more generally in humans.

Title: Orbitofrontal beta-gamma rhythms influence reward processing and obsessive-compulsive behaviors

Authors: *S. GROVER, J. A. NGUYEN, V. VISWANATHAN, R. M. REINHART;
Dept. of Psychological & Brain Sci., Boston Univ., Boston, MA

Abstract: Many characteristic symptoms of various neuropsychiatric illnesses can be conceptualized as abnormalities in reward processing. This is particularly the case for disorders of compulsivity where computational models of decision-making have identified abnormalities in feedback-guided, goal-directed behavior. These abnormalities can be localized to a frontostriatal circuit consisting of the orbitofrontal cortex (OFC) and the striatum. Recent work in human electrophysiology has identified rhythmic activity in the high beta-low gamma (20-35 Hz) range as an index of reward processing. However, it is not conclusively known whether these rhythms originate from the OFC, and whether they selectively influence reward processing. In a randomized, double-blind, sham-controlled design, we entrained activity in the medial

orbitofrontal cortex (mOFC) using high-definition transcranial alternating current stimulation (HD-tACS) while human participants (N=60) performed a probabilistic reinforcement learning task. Personalized entrainment was performed at the peak beta-gamma frequency for every individual at which reward-related modulation could be observed in the electroencephalography (EEG). We found that personalized beta-gamma neuromodulation of the mOFC selectively modulated reward-guided behavior while leaving punishment-guided behavior intact. Our results provide direct evidence that beta-gamma rhythms are selectively associated with reward processing, and that the OFC is a likely source of these rhythms. Next, we examined the translational potential of beta-gamma rhythmic neuromodulation in the OFC. In a second randomized, double-blind, sham-controlled experiment (N=68), we examined the effect of chronic (over 5 days) mOFC neuromodulation on subclinical obsessive-compulsive symptoms. These symptoms were quantified at baseline, immediately after the fifth day of neuromodulation, and after 1 month, 2 months and 3 months post modulation. We observed a rapid reduction in obsessive-compulsive symptoms when mOFC was entrained at personalized reward-related beta-gamma frequencies. Critically, these improvements sustained over the next three months motivating the viability of this approach in clinical populations. Together, our results suggest that beta-gamma rhythms constitute the temporal code facilitating reward processing in the OFC, and that its chronic modulation can be used to reduce obsessive-compulsive symptoms. We speculate about the computational operations facilitated by beta-gamma rhythms, and examine the likelihood that beta-gamma rhythms facilitate connectivity between the OFC and the striatum.

Title: Learning rate mediates effects of glutamate on depression

Authors: *H. PARK[1], S. KIM[1], D. YOON[1], J. KIM[2], B. JEONG[1];
[1]KAIST, Daejeon, Korea, Republic of; [2]Caltech, California, CA

Abstract: Various learning paradigms have been used to show impairment in depression. However, neuro-computational mechanisms of abnormal decision-making in depression remain unclear. 52 subjects underwent 30 minutes of functional magnetic resonance spectroscopy (MRS) and performed both punishment-specific and reward-specific two-armed bandit decision-making tasks. Participants had to estimate the probability of some fractal stimuli to be associated

with reward or punishment. Dynamic accuracy and computational parameters of learning rate were compared with Patient Health Questionnaire-9 (PHQ9), which is depressive scale, using linear regression. Functional MRS focused on glutamate complex (Glx) in anterior insula (AI) and medial prefrontal cortex (mPFC) were performed to identify altered neurochemical change in depression. Time to reach threshold accuracy was negatively correlated with PHQ9 (r=-0.32, p=0.03). Model analysis consistently showed that a higher learning rate predicted higher PHQ9 performing linear regression (CI=[44.7 64.7]). Glx concentration in AI had a positive correlation with PHQ9 (r=0.44,p<0.001), but not with glutamate in mPFC (r=-0.11,p=0.45). Mediation analysis revealed that learning rate fully mediates effects of Glx on PHQ9 (p<0.05). Glutamate concentration abnormality in AI made depressive, which is mediated by higher learning rate.

Title: Reward-motivated memory processes and their underlying neural mechanisms change with age

Authors: *A. O. COHEN[1], M. M. GLOVER[3], X. SHEN[4], K. N. AVALLONE[1], C. V. PHANEUF[1], L. DAVACHI[5], C. A. HARTLEY[2];
[2]Psychology, [1]New York Univ., New York, NY; [3]Wayne State Univ., Detroit, MI; [4]Temple Univ., Philadelphia, PA; [5]Dept Psychology, Columbia Univ., New York, NY

Abstract: Motivationally salient events are often prioritized in memory. In adults, memory for high-reward memoranda is related to increased connectivity involving mesolimbic dopamine systems, centered around the ventral tegmental area (VTA), the anterior hippocampus, and cortical areas both during and after encoding. More generally, dopamine-dependent plasticity in the hippocampus is critical for memory formation. Converging evidence from cross-species studies suggests that subcortical dopamine signaling is increased during adolescence, which may lead to stronger memory representations of rewarding events relative to mundane events. Additionally, given the distributed neural circuits that have been implicated in reward-motivated memory enhancements, it is possible that the underlying neural mechanisms change across age. To test these hypotheses, 89 participants ages 8 to 25 years-old completed a reward-motivated encoding fMRI paradigm with baseline and post-encoding active rest periods and returned 24-hours later for a behavioral memory retrieval test. We find that reward motivation enhances specific associative memory across age and leads to a boost in more general source memory during adolescence. Neuroimaging analyses suggest that reward-motivated encoding is supported by interactions between the prefrontal cortex and VTA across age, particularly in older participants. We also find that putative offline post-encoding consolidation mechanisms change with age such that experience-dependent increases in anterior hippocampus-VTA connectivity show a stronger relationship with reward-motivated memory benefits in younger participants. Taken together, our findings suggest that reward motivation enhances memory somewhat differently across age and that there may be age-related shifts from “offline” subcortical to “online” systems-level circuits supporting reward-motivated memory processes.

Title: Maternal education is associated with functional segregation of the fetal connectome.

Authors: K. M. COOK[1], **C. SITRIN**[2], *J. DE ASIS-CRUZ[1], S. D. BARNETT[1], D. KRISHNAMURTHY[1], C. LIMPEROPOULOS[1];
[1]Children's Natl., Washington, DC; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Parental education is consistently linked to children's cognitive and behavioral functioning including childhood IQ, executive functioning, and emotional processing as well as long-term outcomes of academic achievement, employment, and even prevalence of health concerns such as obesity. Despite this link and clear brain-behavior interactions, it is not known when in development education-driven differences become detectable in the brain. Moreover, the collinearity of socioeconomic status (SES) variables such as education and income, alongside the effect of greater neighborhood SES, makes it difficult to disentangle the effect of parental education later in development. To investigate these gaps, we utilized a cohort of fetuses from the DC/MD/VA area who underwent in utero, resting state fMRI scans. A total of 110 scans from 95 healthy fetuses between 19-40 weeks gestational age (GA; median: 34.93) were analyzed. Median education for participating pregnant mothers was 16 years, with 33% possessing a graduate degree. To assess neighborhood SES variables, we used participant reported zip code at the time of admission. Abstracted Census data suggest a median household income of $84,892, 12.8% live below the poverty line with an average 2021 SocioNeeds Index score of 21.3. Graph theory-based functional network metrics calculated from the fMRI data included clustering coefficient (*C*), characteristic path length (*L*), modularity (*Q*), global efficiency (*GE*), local efficiency (*LE*), normalized L (γ), normalized C (λ), and small-world-ness (σ). We utilized weighted Spearman Rank Correlation, controlling for GA at time of scan, to assess the relationship of education and SES indicators with brain network metrics. Statistically significant associations were observed for maternal education. Both *C* (r=-0.22) and *LE* (r=-0.24), metrics reflecting network segregation/specialization, were statistically significant for maternal education after controlling for gestation age, with both exhibiting a negative relationship. No connectivity metrics were significant for any of the Census data. Our findings show that relationships between emerging functional brain network structure and maternal education are detectable in utero, and that higher levels of education are associated with a diminished clustering coefficients and local efficiency - the latter of which we've observed decreases with fetal maturation in our prior work. Thus, even when controlling for GA, our findings suggest fetuses whose mothers have more education exhibit greater maturation (as measured by decreased network segregation) compared to those whose mothers have less education.

Title: Structural and functional features of the adolescent brain in multiple cognitive domains

Authors: *C. HUMPHRIES[1], Y. LI[1], J. J. BERO[1], A. KUMAR[1], S. NAG[1], H. LEE[2], W.-Y. AHN[3,4], S. HAHN[3], H. KIM[5], D. LEE[6,2];

Abstract: In recent years, a growing number of MRI studies have found associations between individual psychological variables on the one hand and structural or functional characteristics of specific brain areas on the other hand. For example, a study of emotional development might show a relationship between a metric of emotional maturity and the volume of the amygdala. One open question is whether the findings from these correlational studies probe unique associations of neuroanatomical and neurophysiological features with specific cognitive domains (e.g., memory, attention, sensory processing), or whether there are instead a few underlying sources of variation that appear across multiple domains.
To address this question, we selected a sample of 60 publications from the literature that investigated brain features associated with a wide variety of psychological variables, ranging from general cognitive and social skills to disorders, such as depression and anxiety. The modalities used in these papers were grouped into three broad categories: measurements of volume or surface-based structure, functional connectivity, and DTI metrics (e.g., FA values). The metrics from the MRI data used in these previous studies were recalculated using an independent MRI dataset collected from 459 adolescents aged 10 to 15 years, which included structural T1- and T2-weighted scans, a diffusion-weighted scan, and resting-state fMRI. For each of the previous studies, regions of interest (ROI) were chosen that matched the brain regions reported in the paper. Modality-specific metrics were then calculated for each ROI, and the resulting values were then normalized to z-scores. If a paper found an association between a psychological variable and multiple ROIs or modalities, then the resulting values were combined into a single measure using principal components analysis (PCA). In the end, we derived 74 metrics, each associated with a different psychological variable. The metrics were then analyzed using a hierarchical clustering analysis and PCA. The results showed three main clusters of

correlated metrics comprised of a variety of different psychological variables. In addition, the first 5 PCs of these metrics accounted for approximately 40% of their variance. These results suggest that multiple cognitive and emotional traits might be related to diverse functional and anatomical measures of the brain during adolescence.

Title: Maternal Pre-pregnancy Body Mass Index is Associated With Newborn Offspring Hypothalamic Mean Diffusivity: A Prospective Dual-Cohort Study

Authors: *J. RASMUSSEN[1], J. J. TUULARI[3], S. NOLVI[3], M. LAVONIUS[3], H. MERISAARI[3], L. KARLSSON[3], S. ENTRINGER[4], P. D. WADHWA[2], H. KARLSSON[3], C. BUSS[4];
[1]Univ. of California, Irvine, Long Beach, CA; [2]Univ. of California, Irvine, Irvine, CA; [3]Inst. of Clin. Med. Univ. of Turku, Turku, Finland; [4]Charité – Universitätsmedizin Berlin, Berlin, Germany

Abstract: Introduction Genomic, preclinical, and pharmacological studies all support the hypothalamus (HTH) as a critical regulator of energy (im)balance in the context of obesity. Further, a rich body of animal literature suggests that maternal obesity during pregnancy elicits structural changes to the developing offspring HTH, with implications for offspring obesity risk. Yet, the relationship between maternal BMI and the *newborn* human HTH remains unknown due to a lack of validated *in vivo* methods of measurement of HTH integrity. Recent evidence in adult humans supports HTH Mean Diffusivity (MD) as a replicable neuroimaging phenotype

associated with obesity. Here, using an international (Finland and California, USA) multi-site diffusion tensor imaging (DTI) dataset, we leverage this phenotype to test the hypothesis that maternal pre-pregnancy BMI is associated with newborn offspring HTH MD.
Methods HTH MD was independently quantified in two separate BMI-matched cohorts (up to Class I Obesity; BMI_{Range}=17-35) using a high-resolution atlas-based definition of HTH. A total of N=229 mother-child dyads were available for analysis ($N_{Site,1}$=152, Age at MRI=26.7+/-8.1 days, Gestational Age at Birth=39.9+/-1.2wks, $N_{M/F}$=82/70, BMI=24.9+/-4.3; $N_{Site,2}$=77, Age at MRI=25.6+/-12.5 days, Gestational Age at Birth=39.3+/-1.5wks, $N_{M/F}$=43/34, BMI=24.2+/-3.8). The association between maternal pre-pregnancy BMI and newborn offspring HTH MD was tested separately in each of these cohorts using linear regression controlling for gestational age at birth, postnatal age at scan, sex, whole white matter mean diffusivity, and quality control criteria. In post-hoc tests, additional potentially confounding factors including socioeconomic status, ethnicity, and obstetric risk, were adjusted for.
Results The distribution of maternal pre-pregnancy BMI was comparable across sites but differed in ethnicity and socioeconomic status in a geographically predictable manner. A positive linear association between maternal pre-pregnancy BMI and newborn offspring HTH MD was observed at both sites ($b_{Site,1}$ = 0.17, $p_{Site,1}$= 0.01; $b_{Site,2}$ = 0.22, $p_{Site,2}$=0.03) and remained significant after adjusting for cohort-relevant sociodemographic and clinical factors.
Discussion These findings demonstrate an association between maternal BMI and offspring hypothalamic microstructure consistent with animal literature. In addition to further replication and generalization, future studies aimed at identifying putative pathways in order to better inform primary intervention strategies are warranted.

Title: Quantifying waveform shape of EEG alpha and mu oscillations across development

Authors: *A. S. BENDER[1], N. SCHAWORONKOW[2], B. VOYTEK[2,3,1,4];
[1]Neurosciences Grad. Program, [2]Dept. of Cognitive Sci., [3]Halıcıoğlu Data Sci. Inst., [4]Kavli Inst. for Brain and Mind, UCSD, La Jolla, CA

Abstract: Neural oscillations in the human brain are most prominent in the alpha band (8-13 Hz) as detected with EEG. While alpha oscillations in occipital cortex and mu oscillations in sensorimotor cortex occur at similar frequencies, it has been difficult to analyze mu oscillations due to their weaker amplitude relative to alpha oscillations. Because neural oscillations are commonly nonsinusoidal and the nonsinusoidal features have been shown to reflect underlying physiological and pathophysiological characteristics (Cole et al., 2017), quantifying the differences in waveform shape between alpha and mu oscillations may inform understanding of the physiological distinctions between these oscillations. In this study, we aim to quantify changes in waveform shape of both alpha and mu oscillations across development. We analyzed an open dataset of high density, resting-state EEG from 1205 participants (ages 5-21) of the Healthy Brain Network Biobank (Alexander et al., 2017). We used spatio-spectral decomposition to extract oscillatory components with enhanced signal-to-noise ratio in the alpha band. The spatial patterns for each of these components, which represent how each oscillatory source maps onto the electrodes, were matched to alpha and mu template patterns to identify whether each component represented an alpha or mu oscillation. We then used the bycycle package (Cole & Voytek, 2019) to quantify waveform shape features on a cycle-by-cycle basis. Using this approach, we found that the peak and trough of alpha waveforms were significantly less asymmetrical than those of mu waveforms ($t(1157)=12.9, p<0.001$), confirming that alpha and mu oscillations can be differentiated by their waveform shape. Additionally, we confirmed that alpha waveforms increase in frequency ($r=0.51, p<0.001$) and decrease in amplitude ($r=0.13, p=0.018$) across age, while there are no significant changes across age to waveform shape features. Mu waveforms, on the other hand, increase in frequency ($r=0.43, p<0.001$) and become more asymmetrical with age ($r=0.19, p<0.001$), but have no significant change in amplitude ($r=0.018, p=0.66$). The fact that alpha and mu oscillations undergo different changes during development suggests that the developmental modifications to physiological and pathophysiological characteristics underlying each of these oscillations are unique.

Abstract: Spatiotemporal dynamics in infant sleep spindles follow a longitudinal maturational pattern from 3 to 6 months of age
Authors: A. PATHAK*, S. E. PETERS, L. MULLER, A. A. BENASICH, T. J. SEJNOWSKI
Sleep spindles are patterned bursts of oscillatory brain activity seen in the EEG, associated with NREM sleep, that are known to play a key role in information processing, neuroplasticity, and ongoing cortical development. Previous work (Muller et al.,eLife,2016) in our lab suggests that sleep spindles travel across the cortex as a neural traveling wave (nTW) rotating in the Temporal-Parietal-Frontal (TPF) direction via long and short-range cortical white matter tracts. Here we examine the same typically developing infants at 3 and 6 months using high resolution EEG acquired at each age during a daytime nap. We tested the hypothesis that traveling spindle waves are present and follow a maturational pattern. This developmental period is characterized by a high rate of active cortical myelination that follows a spatiotemporal trajectory from posterior to anterior and medial to lateral regions over the ages of ~3 to 10 months. We hypothesize that the developing topography and spatiotemporal dynamics of infant sleep spindles are associated with cortical myelinating fibers. Hemispheric differences in the rate of myelination in the developing cortex have been shown with delayed onset and a faster rate of myelination in the right hemisphere. The thin cranium at these ages allows EEG to capture neural activity with relatively high spatial resolution. By applying a phase-based method for detecting traveling waves in noisy multichannel data, we quantify the relative proportion of nTW patterns across these ages. Our computational algorithms for detecting rotating nTWs allowed us to characterize and classify the spatiotemporal patterns during thousands of episodes of spindle activity in several hours of sleep recordings at each age point. Our results show a significant increase in rotating waves from 3 to 6 months (n = 37, 21 females) in the TPF direction ($p<0.0001$). Interestingly, we observe the reverse trend in the opposite Temporal-Frontal-Parietal (TFP) direction across cortex, with a significant decrease in the wave activity from 3 to 6 months ($p<0.0001$). The nTW spindle analyses by hemisphere suggest greater individual variability in the nTW measure across ages in the left hemisphere as compared to the right, which is in line with a longer average myelination window in the left hemisphere. In this ongoing work, we will examine the hemispheric and sex differences at each age in a larger cross-sectional sample, along with behavioral data collected concurrently in this sample.

Title: Learning-induced reorganization of neural representations in a biologically inspired neural network reveals developmental dynamics of numerosity representations

Authors: *P. MISTRY[1], R. LEI[1], G. YOUNG[1], V. MENON[2];
[1]Stanford Univ., Palo Alto, CA; [2]Stanford Univ. Sch. Med., Palo Alto, CA

Abstract: We implemented in-silico experiments to investigate plausible mechanisms of how learning induced numerosity representations emerge and evolve at a neuronal level over a key developmental period. We used a biologically inspired network (CORNet-S) developed for visual neuroscience whose architecture with 4 blocks (V1, V2, V4, inferior temporal cortex) maximized a composite Brain-score benchmark. A numerosity classification task was tested on this network pre-trained for object recognition. Subsequently, the network was trained on numerosity recognition and was probed at a neural level to measure various aspects of representational dynamics with learning. We show that as in some previous studies, spontaneous numerosity tuned neurons emerged in the pre-trained network. A key contribution of our study was to track the evolution of representational dynamics at a neuronal level with training. The spontaneously emergent neurons were not critical in the formation of subsequent representations and the improvement in accuracy was correlated to the dropping off of spontaneous neurons. Training reorganized the network with rapid representational drift in these neurons after even a single epoch of training. With training, a larger proportion of new neuronal groups became sensitive to specific numerosities, but continued to show representational drift with learning, manifested as an evolving mix of transient and persistent neurons. This continuous drift, possibly contributing to learning, was more pronounced at higher layers (V4 and IT). Using multidimensional scaling we found that the distributed representations in higher layers were predicated on two dimensions, one encoding magnitude, and the other encoding distance from the mid-point of the stimuli space (mid-point anchoring, similar to what has been demonstrated in numerical estimation tasks). The representational drift was smaller when measured at a distributed level compared to a neuronal level. Collectively this conveyed a learned cognitively plausible distributed representation almost independent of spontaneously emergent neurons. All of these aspects of drift were significantly correlated with classification accuracy. The biologically plausible network and cognitively plausible representations provided a unique environment for understanding how learning induced developmental changes may be manifested. This informs future considerations of training paradigms, and validates a platform to examine the neuronal basis for individual differences and mathematical learning difficulties, otherwise impossible to study at a neuronal level during this critical stage of development.

Title: Association of Wisconsin Card Sorting Test with Structural and Functional MRI in Healthy Adults

Authors: *I. CHI[1], A. YANG[1,2,3];
[1]Inst. of Brain Science, Natl. Yang Ming Chiao Tung Univ., Taipei Country, Taiwan; [2]Digital Med. Center, Natl. Yang Ming Chiao Tung Univ., Taipei Country, Taiwan; [3]Dept. of Med. Research, Taipei Veterans Gen. Hosp., Taipei Country, Taiwan

Abstract: Background: The human brain is extremely abstract, and it is difficult to quantify the amount of consciousness and thought. Fortunately, the invention of scientific tools in the last decade has given us the opportunity to explore the world of thought and ideas without boundaries. In the theory of mind, thinking is subdivided into very different abilities, and cognitive functions are the most important of them. **Data and Methods:** The data used in this study were obtained from the Taiwan Aging and Mental Illness (TAMI) database. A total of 290 healthy adults aged 20 to 60 years were used. Each subject underwent a functional magnetic resonance imaging scan and cognitive function was assessed by the Wisconsin Card Sorting Test. The Pearson's product-moment correlation coefficient was used to identify significant brain areas. A corrected p-value was used to determine whether it was statistically significant, and stepwise analysis in multiple linear regression was used to develop a predictive model of cognitive function based on brain imaging metrics. **Results:** In the prediction model of cognitive function based on gray matter volume, the results showed that the important brain regions were the inferior frontal gyrus, the rectus gyrus, the right and left superior parietal gyrus, the angular

gyrus, and the caudate nucleus in the orbital region. In the predictive model of white matter bundle integrity, the right superior cerebellar peduncle was the most important, and the next most important areas were the medial lemniscus and the left posterior thalamic radiation. In terms of functional connectivity of the whole brain, the important brain regions are the right superior limbic gyrus, the pontine brain and the left and right brainstem.**Conclusion:** Using different structural and functional approaches, the resulting brain regions were found to be important areas that affect abstract thinking ability and participate in higher-level cognitive coordination, internal conceptualization and processing. **Key words:** cognitive function, Wisconsin Card Sorting Test, resting-state functional magnetic resonance imaging, diffusion tensor imaging, global functional connectivity

Title: Suvn-5107002, a potent serotonin and weak dopamine modulator demonstrating antipsychotic effects with no motor side effects

Authors: *A. SHINDE, S. PETLU, N. NATH, A. RAYA, J. THENTU, P. ACHANTA, K. BOJJA, J. TADIPARTHI, V. GRANDHI, H. TALAKANTI, R. ABRAHAM, R. KALLEPALLI, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Recent interest in the role of serotonin (5-HT) in antipsychotic drug action is based mainly upon the fact that antipsychotic drugs are potent 5-HT_{2A} receptor antagonists and relatively weaker dopamine D_2 antagonists. These agents share in common low extrapyramidal side effects at clinically effective doses and greater efficacy to reduce negative symptoms. SUVN-5107002 is a lead compound with potent affinity at SERT transporter and 5-HT_{2A} receptor with weak affinity for dopamine receptors is being proposed for the treatment of psychosis. *In vitro* pharmacological properties of SUVN-5107002 were evaluated in radioligand binding assay and cell based reporter gene assay. The pharmacokinetic profile was evaluated in rats and dogs. Non- radiolabeled assay was used to assess the occupancy of test compound at SERT, 5-HT_{2A}, 5-HT_{1A} and D_2 receptors in rats. Brain microdialysis assay was used to assess the effects on the cortical levels of monoamine neurotransmitters. Functionality at SERT, 5-HT_{2A}, D_2 and 5-HT_{1A} receptor was evaluated by both *in vitro* and *in vivo* methods. SUVN-5107002 has potent affinity at SERT, 5-HT_{2A}, 5-HT_{1A} and weaker affinity at D_2 receptors. It showed antipsychotic and antidepressant effects in animal models. The efficacy doses were devoid of

motor impairment i.e., a clear separation between the doses which produced efficacy and side effects. From the current research we conclude that SUVN-5107002 has therapeutic potential for antipsychotic and antidepressant effects without inducing debilitating side effects associated with antipsychotics or antidepressants.

Title: Activating $mGlu_3$metabotropic glutamate receptors rescues schizophrenia-like cognitive deficits through metaplastic adaptations within the hippocampus

Authors: *S. DOGRA[1], B. J. STANSLEY[1], Z. XIANG[1], R. G. GOGLIOTTI[3], F. NICOLETTI[4], C. W. LINDSLEY[1], C. M. NISWENDER[1], M. E. JOFFE[1], P. CONN[2];

Abstract: Polymorphisms in *GRM3*, the gene encoding the $mGlu_3$ metabotropic glutamate receptor, are associated with impaired cognition and neuropsychiatric disorders such as schizophrenia. However, the mechanisms through which $mGlu_3$ receptors regulate synaptic plasticity and cognition are not known. Recent studies have provided evidence for a functional partnership between $mGlu_3$ and $mGlu_5$, prompting the current set of studies to investigate concerted actions between $mGlu_3$ and $mGlu_5$ in the enhancement of hippocampal synaptic plasticity and cognition. In this study, we performed a series of experiments in c57BL6 and cell-specific KOs of *Grm3* and *Grm5* to evaluate the role of $mGlu_3$ in hippocampal synaptic plasticity and cognition. We showed that $mGlu_3$ receptor activation enhanced trace fear conditioning, an associative learning task disrupted in patients with schizophrenia. Interestingly, it also reversed the deficits in cognition induced by subchronic administration of NMDA antagonist phencyclidine. To gain mechanistic insight of *in vivo* phenomenon, studies using selective pharmacological tools showed that activation of $mGlu_3$ receptor-induced metaplastic changes, biasing afferent stimulation to induce long-term potentiation at SC-CA1 synapse through a $mGlu_5$ receptor-dependent mechanism. Further, $mGlu_3$-mediated enhancement of LTP required CB1 receptor-dependent depression of inhibitory transmission onto pyramidal neurons. Selective deletion of either $mGlu_3$ or $mGlu_5$ from hippocampal pyramidal cells eliminated the effects of $mGlu_3$ activation on hippocampal LTP and cognitive enhancement reveal a novel mechanism by which $mGlu_3$ and $mGlu_5$ interact to enhance cognitive function. These studies suggest the potential utility of developing approaches to positively modulate $mGlu_3$ receptor function for treating cognitive disruption in schizophrenia and other psychiatric diseases.

Title: Roluperidone (MIN-101) Causes Brain Region-Specific Neurotransmitter Release, Increased Brain Activity and Functional Network Connectivity in the Rat Brain Related to Negative Symptoms in Schizophrenia

Authors: *R. HODGSON[1], N. ENGLISH[1], J. RUSSO[1], D. RADL[1], M. PAPAKOSTA[1], H. SUN[1], Z. CHERUVALLATH[1], J. MCLAUGHLIN[1], K. KOZMINSKI[1], J. SCHACHTER[1], A. SHATILLO[2], J. OKSMAN[3], R. KOZAK[1], H. MONENSCHEIN[1], H. SCHIFFER[1];

[1]Takeda, San Diego, CA; [2]Charles River Discovery, Kuopio, Finland; [3]Charles River Labs, Kuopio, Finland

Abstract: The lack of consistent and robust efficacy in treatments of negative symptoms in schizo-phrenia (SCZ) is a large burden for patients and represents an unmet need to develop novel therapies. Understanding polypharmacology, neurotransmitter release and brain circuit modulation of compounds demonstrating some efficacy in treating negative symptoms in SCZ patients will facilitate new drug development efforts. Roluperidone (MIN-101) is currently in clinical development by Minerva to treat negative symptoms in SCZ and previously demonstrated clinical efficacy in treating negative symptoms in SCZ in a phase 2b trial. MIN-101 shows a unique poly-pharmacology believed to drive its clinical efficacy: antagonizing serotonergic 5HT2A, sigma-2 and adrenergic alpha 1 receptor without direct binding to dopamine receptors. However, comprehensive preclinical data characterizing the MIN-101 mechanism of action are not publicly available. Studies focusing on structural and functional imaging and non-invasive electrophysiology implicate perturbations of the frontocortico-temporal circuits and disruption of cortico-striatal loops to negative symptoms in SCZ. We performed *in vivo* microdialysis and functional (f)MRI studies in naïve rats to obtain more insight into the neuropharmacological mechanism of MIN-101 and its impact on neurotransmitter chemistry and neurocircuitry. An acute oral dose of MIN-101 (1 mg/kg) significantly increased dopamine, norepinephrine and serotonin release in the hippocampus compared to vehicle dosing, but not in the striatum or prefrontal cortex. Additional less prominent changes in glutamate or acetylcholine release were observed and GABA release was unaffected. The brain activation pattern upon intravenous MIN-101 administration (1 mg/kg i.v.) was measured in rats using BOLD functional MRI (fMRI). In addition, the resting state functional connectivity changes induced by MIN-101 were studied. MIN-101 produced an acute and region-specific effect on the BOLD signal, showing strong activation of the medial prefrontal cortex (mPFC) and striatum. Interestingly, striatal activation was sustained during the whole 30 minutes measurement time in contrast to a sharp mPFC activation, which was followed by a signal decay in 10 min. No meaningful difference in BOLD signals was detected in hippocampus and thalamus. In resting state functional connectivity analysis, MIN101 significantly increased network connectivity over time. Our studies demonstrate that MIN-101 modulates hippocampal and cortical-striatal circuitry in naïve rats, which has been linked to negative symptoms in SCZ.

Title: Investigating the effects of acute and chronic exercise on cognitive dysfunction in a preclinical model of relevance to schizophrenia

Authors: *J. FLETCHER, T. WIGHT, J. GIGG, J. C. NEILL, B. GRAYSON, M. K. HARTE; Univ. of Manchester, Manchester, United Kingdom

Abstract: Cognitive impairment associated with schizophrenia remains an unmet clinical need. Increasing evidence indicates parvalbumin interneurons (PVI) and their associated perineuronal nets (PNN) play a key role in cognition. Reductions in PVI and PNN have been observed in schizophrenia patients and in vivo models of relevance to schizophrenia. Aerobic exercise has been correlated with both cognitive and PVI improvements in disease models, although the effect on PNN is unknown. This study aimed to investigate the behavioural and pathological outcomes in an acute and chronic model for exercise. 80 female lister hooded rats were dosed with sub-chronic phencyclidine (scPCP, 2mg/Kg, i.p.) or vehicle bi-daily for 7 days. Following a 1 week washout, baseline recognition memory was tested using the novel object recognition task (NOR). The difference between time spent at the novel and the familiar object was divided by total exploration to find the discrimination index (DI). Rats were subsequently exercised on individual running wheels for 1 hour/day. For the acute exercise cohort (AE), cognition was assessed immediately after exercise using NOR. The chronic exercise cohort (CE) were exercised 1 hour/day, 5 days/week. CE rats underwent NOR testing 24 hours after completing 3 and 6 weeks of exercise. After exercise, scPCP exercise (PE) and scPCP sedentary (PS) were tested with a continuous NOR (cNOR) protocol, comprising of 11 trials of NOR without intervention. CE brains were taken for immunohistochemistry (IHC), the prefrontal cortex was stained for parvalbumin (PV) and PNN. The baseline NOR test for AE and CE revealed scPCP treated rats had reduced DI compared to controls. In AE, all groups, apart from PS, spent significantly more time at the novel object, indicating acute exercise recovered scPCP induced cognitive impairment. This recovery was also seen in the PE group in the CE study at 6 weeks but not at 3 weeks, signifying separate mechanisms for AE and CE. In the first 4 trials of the cNOR, both PE and PS rats had intact recognition memory. However, in the final 4 trials, PS DI had decreased compared to PE, suggesting memory formation of PS rats is susceptible to distraction. IHC analysis revealed PV and PNN density decreased in scPCP treated rats relative to vehicle controls. Within treatments, exercise increased PV density and reduced PNN density. This study highlights the role of PVI and PNN in scPCP induced cognitive impairment and the ability of

aerobic exercise to reverse cognitive impairment and PVI pathology. Studies to investigate the wider mechanisms, including changes to PNN, are ongoing.

Title: Auditory steady-state response (40Hz) in rodents, a new tool for drug discovery in schizophrenia?

Authors: *J. VOLLE, C. HABERMACHER, V. DUVEAU, A. EVRARD, C. ROUCARD, Y. ROCHE;
SynapCell, Saint Ismier, France

Abstract: Schizophrenia is a severe psychiatric disorder associated with persistent alterations of diverse neurocognitive functions, leading to lifelong psychosocial disabilities. Although schizophrenia has long been considered as a condition that specifically impairs the higher-order functions, recent research has demonstrated that basic sensory processing is also impaired, especially in the auditory modality. Neurophysiological approaches have provided evidence that most schizophrenic patients exhibit a wide range of clinically measurable dysfunctions in the processing of auditory stimulations, including the Auditory Steady-State Responses (ASSRs) which is one of the most consistent functional biomarker across schizophrenic patients. ASSRs consist in cortical electrophysiological oscillations entrained by the frequency and phase of a periodic auditory stimulus presented at a rhythm in the gamma range (that is, 30-80Hz). ASSRs are believed to reflect the interplay between cortical pyramidal neurons and parvalbuminergic interneurons. Consistent with the theory of imbalance between cortical excitation and inhibition in schizophrenia, patients show reduced power and phase locking, to stimuli presented at 40Hz. In recent years, we have developed the characterization of ASSRs in mice and rats to propose a translational solution for drug candidates. In this work, we particularly studied the 40Hz-ASSR modulations in a rat model of schizophrenia, induced by a glutamatergic antagonist MK-801. We will show in this poster how MK-801 (0.1, 0.15, 0.2mg/kg) induces a dose-dependent reduction of the 40Hz-ASSR phase locking in the cortex of rat and how antipsychotics (such as clozapine) modulate this pharmacological effect. We propose the 40Hz-ASSR phase locking as a specific translatable biomarker useful for the preclinical identification, selection and validation of new innovative therapeutics in psychiatric disorders.

Title: Abnormal Perineuronal Nets and Gamma Band Oscillations in Mice with Vitamin D Deficiency

Authors: S. YU, *T. KIM;
GIST (Gwangju Inst. of Sci. and Tech.), Gwangju, Korea, Republic of

Abstract: Abnormal gamma-band oscillations (GBO) are possible mechanisms for cognitive dysfunction in patients with schizophrenia (SZ). In our brain oscillations, fast-spiking (PV) neurons are a pivotal component of GBO, and they are surrounded by perineuronal nets (PNNs), which are net-like extracellular matrix. Several studies showed that PNNs enable PV to make fast-spiking and GBO, and recent research suggested that a lack of vitamin D disrupts the PNNs integrity in the brain. However, the direct effect of vitamin D deficiency on GBO remains unknown. Here we hypothesized a decrease of PNNs by a vitamin D deficiency diet might change the power of GBO. First, we measured the evoked or spontaneous EEG power at the gamma range frequency in 4 to 6-month-old male PV-Cre mice. Then, the mice were grouped into control and vitamin D deficiency with normal and vitamin D depleted-diet for 6 weeks, respectively. To examine the impact of reduced PNNs on GBO, we injected chondroitinase ABC (chABC), an enzyme that digests PNNs, intracerebrally in the frontal cortex and measured optogenetically evoked GBO. Finally, we injected SB-3CT, an inhibitor of matrix metalloproteinase 9 (MMP-9), to rescue abnormal phenotypes in vitamin D deficiency. Immunohistochemistry was performed for PV neurons and PNNs, and analyzed with CellProfiler software. Our preliminary results showed that PNNs decreased in the vitamin D deficiency group, and the optogenetically evoked GBO decreased simultaneously. In contrast, spontaneous GBO increased in the vitamin D deficient group. Interestingly, after PNNs were reduced by chABC, the power of the evoked GBO decreased, and the spontaneous GBO increased

immediately. Vitamin D deficient mice treated with MMP-9 inhibitor demonstrated no changes in GBO and PNNs, Taken together, we suggest that the vitamin D deficiency could result in the decreased ability to generate GBO, especially around 40 Hz, by reducing PNNs. These results are reminiscent of the decreased auditory steady state response (ASSR) at 40Hz in schizophrenia. In addition, the relationship between vitamin D deficiency and schizophrenia has been suggested. Accordingly, the reduced PNN might be a necessary and sufficient condition for the reduced ASSR in schizophrenia.

Title: Gamma band LFP activity in a cognitive control task is decreased after NMDAR blockade in primates

Authors: A. M. HUYNH[1], *D. A. CROWE[1], R. K. BLACKMAN[2], M. V. CHAFEE[2];
[1]Augsburg Univ., Minneapolis, MN; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: We measured local field potentials in the prefrontal and parietal cortices of monkeys to investigate the effects of NMDAR blockade (using phencyclidine; PCP) on gamma power during a cognitive control task. Hypofunction of NMDAR has been shown to be associated with schizophrenia-like symptoms. We utilized a task, the dot-pattern expectancy task (DPX), that isolates a specific deficit in patients with schizophrenia. Monkeys given PCP show the same pattern of errors on this task as patients with schizophrenia. In the DPX task two stimuli (the "cue", which could be either 'A' or 'B', and then the "probe", which could be either 'X' or 'Y') were displayed sequentially, separated by a delay period. The animal made a response based on the combination of these two stimuli. The four categories of 'Cue-Probe' pairs were 'AX', 'AY', 'BX', and 'BY'. 'AX' trials, 69% of the total, required a target response, the movement of a joystick to the left. The three other trials require a non-target response, a joystick movement to the right. Monkeys given PCP and patients with schizophrenia perform selectively worse on 'BX' trials. To study the effects of NMDAR blockade on neural signals related to this cognitive control task, we injected monkeys on alternate days with saline or 0.25 - 0.30 mg/kg PCP, and subsequently recorded local field potentials while the animals performed the DPX task. We converted the field potentials into power time courses (49 frequencies from 1-100 Hz) using a

wavelet analysis and then averaged across frequencies into five frequency bands. Our analysis here focuses on gamma power during the probe period of the task.In general, we observed that gamma power increased shortly after the display of the probe stimulus. In both the PCP and control conditions, gamma power increased faster after the display of 'X' probes than for 'Y' probes. Overall, gamma power was lower under the PCP condition during the end of the delay period in parietal but not prefrontal cortex. PCP administration reduced the stimulus-locked increase in gamma power in both brain areas, though it did not tend to alter the timing of such activity. Interestingly, probe-related differences in gamma power, as shown by a decoding analysis, were generally not affected by PCP.

Title: Examining differential cancer rates in severe mental illness

Authors: *A.-R. HAMOUD[1], J. RETHMAN[1], S. KHUDER[1], J. MELLER[2], J. RIEGLE[2], R. MCCULLUMSMITH[1];
[1]The Univ. of Toledo, Toledo, OH; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Schizophrenia is a devastating psychiatric disorder that has a global prevalence of about 1%. Interestingly, overall cancer rates in schizophrenia are lower than the general population. Previous epidemiological studies of cancer rates in schizophrenia did not fully account for confounding variables such as smoking and substance abuse. We sought to confirm lower cancer rates in schizophrenia and explore mechanisms responsible for this unexpected observation.
Cell culture studies have shown dysregulation of kinase networks driven by antipsychotic administration with a focus on Dopamine 2 Receptor antagonism. Gene expression analysis of cancer cells treated with antipsychotic drugs has shown decreased expression of kinases involved in cell survival, proliferation, and drug resistance including AKT and PIM kinases. We hypothesize that typical antipsychotics are competitive inhibitors of AKT and PIM kinases. We postulate that inhibition of these and other kinases by antipsychotics accounts for reduced cancer incidence in patients with schizophrenia.

We applied a three-pronged approach to answer this question: 1) Epidemiological confirmation of reduced cancer incidence rates in patients with schizophrenia, 2) bioinformatics analyses of perturbagen structural moieties and gene expression data, and 3) in vitro kinase activity drug screening. Epidemiological data confirmed reduced risk of cancer incidence in patients with schizophrenia when accounting for age and smoking rates using the Healthcare Cost and Utilization Project (HCUP). Bioinformatics analyses of perturbagen structure and transcriptional profiles suggest a medication effect, as opposed to genetic factors (such as single nucleotide polymorphisms risk alleles for schizophrenia), as a main contributor to the observed decrease in cancer rates. In vitro kinase activity and protein expression will be measured in A549 cancer cells. In summary, we have identified AKT and PIM kinases as possible novel targets of typical phenothiazine antipsychotics. Taken together, our data suggest that phenothiazine antipsychotics act directly on protein kinases to lower cancer risk.

Informatics, Yale Sch. of Med., New Haven, CT

Abstract: In order to build biologically ever-larger detailed reconstructions and simulations of large-scale neuronal circuits, the Blue Brain Project (BBP) and Yale University have added many new features to the NEURON simulator to improve efficiency and accessibility for massively parallel operation. Having been developed for the past 45 years, NEURON carries with it a substantial amount of legacy code which initially limited structural changes and prevented fast adoption of features from modern architectures. During the last two years, members from BBP, Yale university, and SUNY Downstate have organized regular discussion groups to consolidate ideas for advancing the state of NEURON source. As part of this developer community, we have made significant progress towards making NEURON into a modern, performant, portable and maintainable simulation environment including the following major developments: 1. A new build system using CMake in place of autotools; 2. Addition of documentation to nrn.readthedocs.io; 3. The introduction of an officially supported Python wheel for NEURON with automatic deployment on PyPi to enable installation of NEURON via pip; 4. Integration of CoreNEURON, an accelerated compute engine for NEURON providing more than 7-fold acceleration on NEURON simulations using CPUs; 5. Development of NMODL Framework, a source-to-source compiler for the domain-specific languages NMODL uses to describe biological models simulated in NEURON, allowing translation to C++, CUDA, OpenACC, ISPC, and LLVM IR backends to enable acceleration on a large variety of computing systems; 6. Addition of intracellular reaction-diffusion "chemophysiology" to electrophysiology; 7. Additional frontend development via GUIs and declarative language (NetPyNE).

Title: Quantum machine learning applied to neuropsychiatric genomics datasets: proof-of-concept and biological interpretation

Authors: *P. S. EMANI, J. CHAPMAN, J. WARRELL, A. DONAGHEY, M. B. GERSTEIN; Mol. Biophysics and Biochemistry, Program in Computat. Biol. and Bioinformatics, Yale Univ., New Haven, CT

Abstract: Massively parallel classical computing continues to address computations on increasingly large datasets in genomics and neuroscience. However, the question remains whether alternate computing paradigms, such as quantum computing (QC), can capitalize on the promise shown on some algorithms to offer relative speedups or more efficient representations. Any gains need to be demonstrated on biologically and clinically relevant datasets, with complex interactions between many features. Accordingly, we explore functional genomics datasets from schizophrenia cases and controls from the PsychENCODE consortium, using quantum machine learning (QML) methods. Specifically, we aim to classify samples from the human prefrontal cortex according to neuropsychiatric disease status, based on sample gene expression. This is a complex classification problem, with a high-dimensional underlying structure. QML methods encompass many algorithms constructed as analogues to classical ML methods, including neural networks. We construct multiple versions of published quantum neural networks (QNNs), using the IBM Q library. Given that current QC hardware is limited in the number of quantum bits (qubits), we employ dimensionality reduction strategies: using a smaller set of genes known to be correlated with disease status; and using the top principal components of the full gene expression matrices. While the analysis was mostly done with QC simulators, we also run trained QNNs on a commercial quantum computer for validation. We further explore other aspects of QML: (1) representational differences relative to classical networks; and (2) biological interpretation. We compare the results of QNNs to classical NNs with a comparable number of parameters, using classification metrics. Additionally, we have designed a probabilistic classical NN whose architecture mimics that of the QNNs for a careful analysis of representational differences. Finally, we perform a saliency analysis to quantify the sensitivity of the best models to the input features, which are either genes or linear combinations thereof. We find (on PsychENCODE data) that QNNs can perform at an accuracy comparable to classical NNs, sometimes even improving upon the latter, with a certain degree of stochasticity in the model predictions. The representations are inherently different, and the saliency evaluation of features provides a more agnostic measure of shared biological information. We find differences in the saliency, with some of the QNN saliencies recapitulating the correlations of features with case/control status. Ongoing work is delving into the nature of these discrepancies.

Abstract: Comparison of brain samples representing different developmental stages often necessitates registering the samples to common coordinates. Although the available software tools are successful in registering 3D images of adult brains, registration of perinatal brains remains challenging due to rapid growth-dependent morphological changes and variations in developmental pace between animals. To address these challenges, we propose a multi-step algorithm for the registration of perinatal brains. First, we optimized image preprocessing to increase the algorithm's sensitivity to mismatches in registered images. Second, we developed attention-gated simulated annealing (Monte Carlo) procedure capable of focusing on the differences between perinatal brains. Third, we applied classical multidimensional scaling (CMDS) to align ("synchronize") brain samples in time, accounting for individual development paces. We tested this multi-step algorithm on 28 samples of whole-mounted perinatal mouse brains (P0 - P9) and observed accurate registration results. Our computational pipeline offers a runtime of several minutes per brain on a personal computer and automates brain registration tasks including mapping brain data to atlases, comparison of averaged experimental groups, and monitoring brain development dynamics.

Title: Modular neuromechanical model of Aplysia feeding behavior

Authors: *A. S. LIAO[1], R. SUKHNANDAN[1], Q. CHEN[2], B. KUNDU[3], J. P. GILL[2], G. SUTTON[3], P. J. THOMAS[2], V. A. WEBSTER-WOOD[1,4], H. J. CHIEL[2];

Abstract: Animals exhibit behavioral flexibility in response to a dynamic environment. The coordination between the nervous system and periphery transforms sensory information into muscle activation to induce mechanical responses. The feeding behavior of the model organism *Aplysia californica* demonstrates this flexibility by switching between three behaviors - biting (an attempt to grasp an object), swallowing (grasping and ingesting food), rejection (egestion of inedible material) - based on mechanical and chemical stimuli. Understanding the neuromechanical principles underlying this behavioral flexibility is key to uncovering the mechanisms behind multifunctionality.

We developed an *Aplysia*-inspired neuromechanical model with a Boolean-like neural controller, first-order muscle models, and 1D biomechanical equations of motion. This model qualitatively demonstrated all three feeding behaviors and could flexibly switch between them depending on mechanical and chemical stimuli [1]. Furthermore, the simplified model components enabled the model to perform simulations faster than real time, but at the cost of physiological details in the components. Depending on the focus of the research application, components of the model may need to be altered to suit the level of complexity required.

Using a demand-driven complexity approach, we extended our original neuromechanical model to have three customizable modules: neural circuitry, muscles, and mechanics. This enabled us to qualitatively compare the simulation results between our original 1D mechanical model of the feeding apparatus and a 2D version as well as between our original first-order muscle model and a Hill-type muscle. With the new module versions, the model reproduced mechanical outputs that differed in the transient response but were qualitatively similar overall to that from the original model. However, the module replacement process was sensitive to model parameters and required hand tuning to match the original model's results.

Our modular modeling framework allows a demand-driven complexity approach to neuromechanical modeling of *Aplysia* feeding behavior. It is easily extensible, and each module can be replaced with alternative models that are more biologically realistic. We will explore the effect of incorporating more physiologically accurate neuron and muscle models on model output and quantitatively compare our modeled behavior to animal experimental data. Additionally, we are developing deep-neural-network-based algorithms for automatically tuning model parameters to match experimental data.

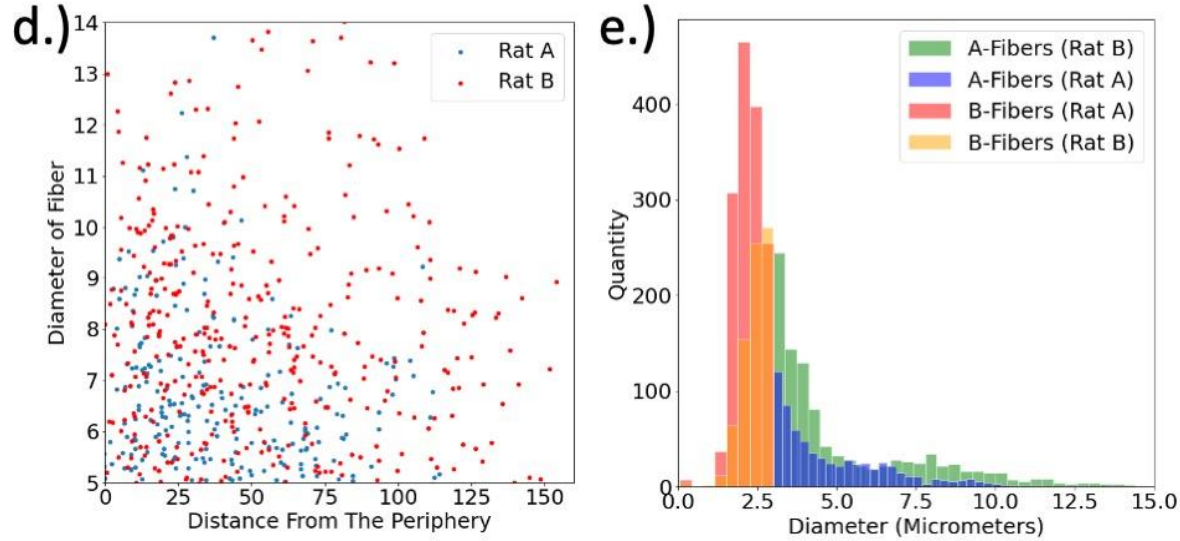
Title: Analysis of the Spatial Distribution of Myelinated Fibers in the Vagus Nerve for Spatially-Variant Targeted Neuromodulation



Authors: *A. CHO[1], H. JEONG[2], I. AY[3], G. BONMASSAR[4];
[1]Harvard Univ., Cambridge, MA; [2]Athinoula A. Martinos Center, MGH, Cambridge, MA; [3]Dept Radiol, Massachusetts Gen. Hosp., Boston, MA; [4]Harvard Med. Sch., Charlestown, MA

Abstract: Introduction: Vagus Nerve Stimulation (VNS) is an FDA-approved method for the therapeutic use of drug-resistant epilepsy, migraine, cluster headache, and depression. The vagus nerve contains both afferent and efferent fibers. Current VNS technologies are fiber non-selective: although the therapeutic effects of VNS are linked with the stimulation of the large afferent fibers, unintended stimulation of the efferent fibers results in adverse effects. This project aims to study the anatomy of the vagus nerve to develop new simulation technologies of the afferent A-fibers by modeling and characterizing the vagal fibers to minimize the current VNS side effects. **Methods:** Two cervical right vagus nerve samples of healthy adult male Wistar rats (350-450 g) were obtained and prepared on a Transmission Electron Microscopy (TEM) grid for imaging (HT7800, Hitachi, Japan). The images were preprocessed for noise removal, stitched, segmented, and morphed into a circle using MATLAB (MathWorks, MA, USA). The TEM images were adjusted for contrast for segmentation, masked based on B&W thresholds, partitioned, and manually cleaned up. ImageJ based on the color threshold was used to determine the diameters and locations of each fiber and blood vessel. A-fibers were defined as myelinated fibers with a diameter of 3 μm or greater, while B-fibers were determined to be myelinated fibers with a diameter of less than 3 μm **(1.c)**. Python and Prism8 (GraphPad, California, USA) software were used for quantitative distribution analysis. **Results and Discussion:** Rat 1's vagus nerve had an estimated diameter of 256.63 μm, whereas Rat 2's diameter was approximately 319.95 μm (Fig 1.c). 63.52% of Rat 1's A-fibers and 52.66% of Rat 2's A-fibers were located in the outer half of the nerve (Fig 1.d.e). **Conclusions:** The rat VNS segmentation allowed for the spatial characterization of the vagus nerve fibers and revealed a 2D

toroidal spatial distribution. This unique toroidal spatial distribution observed in our results dramatically simplifies the design of a focal and minimally invasive stimulator.

c.)	Rat A	Rat B

Title: Wearable Networks of Multijoint Elastic Elements for Upper-Extremity Neurorehabilitation

Authors: *P. RYALI[1], B. MALIZIA[1], Y. GHANI[1], D. MCDERMED[1], J. HE[1], C. CELIAN[2], J. L. PATTON[3];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]Shirley Ryan AbilityLab, Chicago, IL; [3]Sensory Motor Performance Prog, Rehab Inst. Chicago, Chicago, IL

Abstract: Wearable robotic interfaces can not only make humans move better but can also help them train better -- offering an attractive modality for neurorehabilitation on post-stroke or spinal cord injured populations. Here, we present the advantages and demonstrate two neurorehabilitative applications of a passive orthosis, the ExoNET, which uses structural optimization with impedance (equilibrium point) control to tune moment arms and pretension properties of a network of elastic elements to satisfy desired upper-extremity torques.Tunable spring designs, such as the ExoNET, can not only provide assistive forces but also have the potential to mechanically amplify the errors made by the user. For example, destabilizing forces surrounding a reaching path can provide error augmentation, which has been shown to enhance motor recovery in brain-injured individuals. Another example is to reshape movement variability with an unstable limit push field that makes disturbance forces surrounding the boundary of a desired region. A crucial design variable is the number of impedance elements available at each joint, and there is a tradeoff where the system is more complex and bulky with more elements, but it is more accurate at approximation. Here we explore this variable. We measured the ExoNET's abilities to approximate upper extremity error augmentation and limit push forces for up to 5 elements at each joint. For error augmentation, errors averaged 4.120, 2.090, and 0.023 Nm for 1, 3, and 5 elements. For limit push, errors averaged 0.004, 0.002, and 0.001 Nm. Not only is it evident that accuracy increases with the number of elements, error augmentation fields require more elements, and they dramatically improved when 5 elements were used. Meanwhile, limit push may only require 1 element per joint. This work demonstrates the ExoNET's potential to perform complex and clinically significant tasks in assisting rehabilitation, and warrants further study.

Title: Sparse high-dimensional decomposition of non-primary cortical spectrotemporal receptive fields

Authors: *S. MUKHERJEE[1], B. BABADI[1,2], S. A. SHAMMA[1,2,3];
[1]Dept. of Electrical and Computer Engin., [2]Inst. for Systems Res., Univ. of Maryland, College Park, MD; [3]Dept. d'Études Cognitive, École Normale Supérieure, PSL Univ., Paris, France

Abstract: Characterizing neuronal responses to natural stimuli remains a central goal in sensory neuroscience. In auditory cortical neurons, the stimulus selectivity of elicited spiking activity is summarized by the neurons' spectrotemporal receptive fields (STRF). Canonically, the STRF can be inferred from spiking responses to a diverse range of auditory stimuli by reverse-correlation, assuming a linear relationship between spectrotemporal features of the stimuli and response. Alternatively, point process generalized linear models of stimulus-driven spiking can be applied to infer STRFs with greater predictive capacity.
Both approaches fundamentally seek to directly map the spectrotemporal features of auditory stimuli to neuronal responses. Though effective in characterizing primary auditory cortical responses, directly estimated STRFs of neurons in non-primary areas can be quite intricate, a reflection of mixed selectivity in neuronal responses. The complexity of non-primary STRFs poses challenges in interpreting the representation of spectrotemporal features in later stages of the auditory pathway.
To address this challenge using a point process model of neuronal spiking, we propose estimating receptive fields of non-primary auditory cortical neurons with respect to a high-dimensional model of the primary-cortical representation of auditory stimuli. Moreover, we employ a greedy estimation algorithm to capture the salient primary-cortical features that drive spiking responses. We additionally relate the resulting sparse cortical receptive fields to corresponding spectrotemporal features, and hence describe a biologically plausible hierarchical decomposition of non-primary STRFs. In application to simulated data, we validated that our proposed analysis can recover the cortical receptive field with statistical confidence. Additionally, in application to spiking activity of neurons in the ferret posterior ectosylvian gyrus, our proposed method yields highly predictive models of neuronal responses to both artificial and natural stimuli.

Systems, Univ. of California San Diego, La Jolla, CA; [4]Luxembourg Ctr. for Systems Biomedicine, Univ. of Luxembourg, Belval, Luxembourg

Abstract: In the dynamic metabolic landscape of a neuron, mitochondrial membrane morphology can provide critical insight into the energetic state of the cell. Theoretical calculations of functional outputs like ATP often represent mitochondria as idealized geometries and therefore can miscalculate the metabolic fluxes. To analyze mitochondrial architecture in neurons of mouse cerebellum neuropil, 3D reconstructions of synaptic and axonal mitochondria were generated using serial transmission electron microscope tomography images. We created high quality meshes from manual tracings of the membranes using new procedures in 3D computer graphics modeling software in order to produce minimal distortion from the original volumes with a granularity of 1.6 nanometer isotropic voxels. The resulting *in silico* representations were subsequently quantified by differential geometry methods in terms of the mean and Gaussian curvatures, surface areas, volumes, and membrane motifs, all of which can alter the metabolic output of the organelle. Finally, we identify structural motifs that are present across this population of mitochondria. These anatomical reconstructions are highly accurate and lay the foundation for future studies of the internal mitochondrial physiology and metabolism in neurons using Monte-Carlo techniques to simulate the biochemical interactions that takes place in the mitochondrial compartments.

Title: A computational model to simulate vascular arborization based on neuron cytoarchitecture

Authors: *B. S. KUMAR, S. M. CHANDRAMOHANAN, S. G. RAJAPPA, V. S. CHAKRAVARTHY;
Indian Inst. of Technol. Madras, Chennai, India

Abstract: The electrical activity of the neurons in the brain is highly dependent upon timely and adequate blood supply from the cerebral vascular network. Since cerebral blood flow in turn is dependent on neural activity, it is understood that there is a bidirectional interaction between the neural and the cerebrovascular system. Therefore, there is an anticipation, supported by experimental evidence, that even the development of both neural and cerebrovascular systems should be interdependent. To understand the effect of activity and density distribution of the neurons on the development of vascular arborization, we propose a computational model known as the Vascular Arborization Model (VAM). We considered four segments of tissue volume from the murine cortex, wherein each segment has the dimensions: 100μm X 100μm X 800μm. The neurons and non-neural cells were distributed randomly in the volume, constrained by experimental data. The vascular network originates from a parent root node and grows to span the tissue volume based on the cytoarchitecture of the neural and non-neural cells of the cortex. There are two stages of vascular arborization: (i) Growth phase and (ii) Settling phase. In the growth phase, each terminal vessel grows closer to the neurons in its domain such that the mean squared distance (MSE) between the vascular terminal node and the neurons in its perfusion domain is minimized. When the MSE reaches a minimum, the vessel splits into two smaller vessels. The former perfusion domain is also split into two sub-domains, while the two child vessels proceed to perfuse the two newly formed subdomains. This process occurring iteratively results in vascular arborization. During the settling phase, the fully grown vascular network is rearranged to ensure optimal path length and wire length. The simulated vascular network grown from a single root node to a vast network could approximate the biological vascular network reasonably well. The microvascular volume density and the total vascular volume density estimated from the model were in close agreement with the experimental studies. The mean

Euclidean distance between vessels and neurons in the model was close to 14μm, the biologically observed value. The model also shows that the neural densities do not covary with the vascular density along the depth of the cortex, but predicted a high correlation between neural areal density and microvascular density when compared over a global scale (across animals and regions). Moreover, the range of estimated vessel radii that resulted in this vascular volume density agreed with the range of arteriolar diameter observed experimentally in rats and mice.

Title: Quantitative methods to evaluate motor thalamic deep brain stimulation-induced gait ataxia with computer vision

Authors: *D. C. P. MARTICORENA, M. BLUMENFELD, A. BRINDA, B. REBECCA, J. D. KRIEG, L. SCHROCK, S. E. COOPER, J. MATSUMOTO, M. D. JOHNSON;
Univ. of Minnesota - Twin Cities, Minneapolis, MN

Abstract: Thalamic deep brain stimulation (DBS) is often used to decrease motor manifestations of Essential Tremor, but can be impeded by stimulation-induced gait ataxia. To further understand the neurophysiology of DBS-induced gait ataxia and avoid its emergence with DBS therapy, it is important to have methods that can quantify features of gait ataxia in a subject-specific manner with granularity beyond current clinical rating scales. In this study, we developed a markerless pose estimation approach to reconstruct a subject’s pose in real space for complex gait analysis during a DBS programming session. The apparatus includes a triad stereo camera system which captures heel-to-toe ambulation toward and away from the system. The collection methods involved activating the cameras (30 fps, 2160p) to collect ambulation videos for a given evaluation. Within the 2D videos taken from each camera, the subject's shoulders, elbows, wrists, hips, knees, and ankles were labeled using DeepLabCut, a markerless pose estimation tool. Given potential error derived from spurious labels attributable to loose clothing and occluded joints, a 10-sample median-difference-threshold filter was used to create a probability distribution of individual labels based on temporal consistency, identify low-probability labeled joints j (σj > 5), and eliminate them. Empty entries were refitted with a piecewise cubic Hermite interpolating polynomial. The resulting vectors were then smoothed

with a 3-point moving average filter. The camera intrinsics (focal point, FOV, etc.) and extrinsics (orientation with respect to one another) were calibrated on the basis of eight images of a distinctly-oriented checkerboard to minimize reprojection errors using linear least-squares, with average pixel reprojection error less than 0.4 pixels. To capture the real-world coordinates of the subject's joints, the filtered two-dimensional joint coordinate matrices were triangulated using a linear least-squares triangulation algorithm. These results serve as an initial estimate for the non-linear least squares optimization triangulation, which factors in camera extrinsics, joint depth, temporal consistency, and anthropomorphic constraints, which fits joint estimates onto a consistent model of the subject. This optimization greatly reduced error in pose reconstruction, and therefore increased the accuracy in related gait analysis. This low-cost, objective, and granular gait assessment method is poised to provide insight into subject-specific DBS optimization efforts to better elucidate the neural pathways involved in the induction of gait ataxia with DBS

Title: Development and time interval learning of hippocampal-cortical co-culture model in vitro

Authors: *C. CHANG, K. SHIMBA, T. ASAHINA, T. FURUKAWA, K. KOTANI, Y. JIMBO;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Phenomenon and connection in brains have long been in interest of neuroscientists. In vitro cultural networks, consists of randomly connected neurons, have long been used to investigate basic properties of neuronal networks, and have provided insights about network level information processing and memory formation. In vitro studies have shown abilities of in vitro neuronal networks performing pattern separation, blind source separation, spatiotemporal memory and temporal interval learning by dissociated neuronal cultures. Dissociated neuronal cultures consisted of randomly connected neurons evenly spread over cultured area. Artificial

information can be given by electrical stimulation, optical stimulation or both. Studies have report modification of network activity for several seconds to minutes, shown by modification in network burst activities or spike events on recorded electrodes pairs. However, in brains, information and messages are transferred over layers of networks and processed across several structures. Considering above situation, in this study, we took advantage of microfluidic technologies and develop an in vitro model to separate neurons derived from separate brain structures, cortex and hippocampus. Specialized connection between cortical and hippocampal structures have been well-known for long-term memory formation, consolidation and memory recall. Cortical and hippocampal cells were plated into two different cell chambers to keep cell properties of the original structure. Communication between separated networks were performed by microstructures to allow axonal passage but restrain somatic entrance, forming a heterogenous network model to study memory formation by external stimulation in vitro. Hippocampal and cortical co-cultures showed communication between networks by sharing similar starting time of burst activities, on the other hand, hippocampal and cortical bursts showed different rhythms of local burst activities, suggesting localized network functions remained in each network. Memory formation by external stimulation was tested by time interval learning between cortical and hippocampus culture. Time interval training was designed as giving series of electrical stimuli first in cortical cultures, followed by another series of stimuli in hippocampal cultures. After training, direct evoked response by test stimulation in cortical culture showed significantly shortened duration of firing activity, and lasted for over 20 mins, suggesting the possibility of time interval learning to modify cortical-hippocampal connection by modifying network activity in cortical culture.

Title: Stimulation-pattern dependence in the activation of Arc mRNA in live neurons

Authors: *D. KIM, H. MOON, B. LEE, J. SHIM, H. PARK;
Dept. of Physics and Astronomy, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Immediate early genes (IEGs) are genes that are rapidly induced by neural activities. The expression of IEGs such as Arc, c-fos, and Egr1 has been used to investigate the relation among external stimuli, neural activities, and memory formation. Inside cells, there exist signaling pathways where the chain reaction of enzymes leads to synaptic plasticity including gene expression and regulation. For electrically stimulated neurons, specific patterns are known to induce synaptic plasticity. But the relation between various stimulation patterns and gene expression in live cells is still in question. In this research, we investigated the effect of electrical stimulation on the expression of Arc mRNA in hippocampal neurons cultured from the Arc-PBS x PCP-GFP mice. We found that there are correlations among the pattern of the stimulation, calcium ion influx, phosphorylation of transcriptional factor CREB, and gene expression. Neurons stimulated by burst stimulation showed the highest Arc transcription rate and calcium influx at theta frequency. And Arc-positive neurons showed higher CREB phosphorylation levels than Arc-negative neurons.

Title: Neural inhibition with a miniature magnetic coil

Authors: *H. YE, L. BARRETT;
Loyola Univ. Chicago Dept. of Biol., Chicago, IL

Abstract: Numerous neurological dysfunctions are characterized by undesirable nerve activity. By providing reversible neural blockage, electric stimulation with implanted electrode holds promises in the treatment of these conditions. Externally applied electric currents have been used in inhibiting axon conductance and ganglion cell activities in clinical practices. However, there are significant limitations to its application, including poor bio-compatibility and decreased efficacy during chronic implantation. Magnetic coil with miniature size can mitigate these problems, by coating it with biocompatible material for chronic implantation. Via electromagnetic induction, the miniature magnetic coil could induce local electric field for neural stimulation. However, it is unknown if miniature coils could be effective in blocking neural

activity and if so, what are the underlying mechanisms. Here we report that a submillimeter magnetic coil could reversibly blocked action potentials in the unmyelinated axons from marine mollusk *Aplysia californica*. Biophysical modeling confirmed that the miniature coil induced a sufficient electric field in the vicinity of the targeted axon. Using a multi-compartment model of *Aplysia* axon, we found that the miniature coil caused a significant local depolarization in the axon, altered activation dynamics of the sodium channels, and prevented the traveling of the invading action potentials. We also report that the miniature coil could reversibly block ganglion cell activity, regardless the firing frequency of the neurons, or the presence of the ganglion sheath. The inhibitory effect was local to the soma, but was sufficient in blocking the neuron's functional output. Using a multi-compartment model of *Aplysia* ganglion neuron, we found that the high-frequency magnetic stimuli altered the ion channel dynamics that were essential for the sustained firing of action potentials in the soma. Results from this study produce several clinical insights to further develop the miniature coil technology for neural control by targeting axons or ganglion cells. With improved biocompatibility and capability of emitting high-frequency stimuli, micro coil provides an appearing alternative for electric blockage of neural activity.

Title: On the design of electrical stimulus parameters for selective activation of retinal ganglion cells

Authors: *J. PAKNAHAD[1], M. HUMAYUN[2], G. LAZZI[3];
[2]Biomed. Engin. and Ophthalmology, [3]Electrical Engineering, Biomed. Engin. and Ophthalmology, [1]USC, Los Angeles, CA

Abstract: Retinal degenerative diseases such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD) first affect the outermost layer of the retina, photoreceptors, and eventually lead to the damage of the innermost layer of the retina, consisting of retinal ganglion cells (RGCs). Retinal prosthetic systems have been developed with a tremendous influence on the life of patients suffering from the blindness for decades. Epiretinal implants aim at electrically stimulating targeted surviving retinal neurons and particularly RGCs with a relatively

longer functionality compared to outer retinal neurons such as bipolar cells (BCs) and photoreceptors. Several electrical stimulation strategies have been proposed and developed to augment the efficacy of current epiretinal prosthetic devices. However, there are still many challenges to be addressed such as simultaneous activations of various RGCs subtypes in response to electrical stimulation. The ability to selectively target subtypes of RGCs that carry particular visual information such as color and contrast would significantly enhance the performance of retinal prosthetic systems. In this study, we applied the 3D Admittance Method (AM)-NEURON computational platform to study the frequency response (up to 200 Hz) of the developed RGCs models, A2-monostratified and D1-bistratified, to a range of symmetric and asymmetric charge-balanced stimulus pulses. We further analyzed the response of RGCs as a function of modulations in charge amplitude over a range of stimulus pulses at 200 Hz. Our results indicate that D1 cells are more responsive to high stimulus frequency using symmetric, asymmetric short cathodic-first, and asymmetric long anodic-first biphasic pulses relative to A2 cells. Interestingly, asymmetric long cathodic-first stimulus pulses alter the excitability of RGCs such that A2 cells can better follow high rates of firing at high frequency compared to D1 cells. While the differential biophysical properties slightly changed the response of the cells, we found the soma size to be a predominant factor leading to this differential response of RGCs at high frequency across stimulus pulses. The differential sensitivity of stimulus strength-dependent response of RGCs at high frequency to various stimulus waveforms offers a great opportunity for selective activation of individual RGCs. This enables the possibility of encoding additional visual information such as color in future retinal prosthetics systems.

Title: Evaluating the Effect of Retinal Degeneration on Response of ON and OFF Cone Bipolar Cells to Extracellular Electrical Stimulation: A Computational Study

Authors: *S. FARZAD, J. PAKNAHAD, P. KOSTA, E. ISERI, G. LAZZI;
USC, Los Angeles, CA

Abstract: Bipolar cells (BCs) play critical roles in the visual signal processing through retinal layers by transmitting the signals from photoreceptors to ganglion cells (GCs). In retinal degenerative diseases, such as retinitis pigmentosa (RP), first photoreceptors start to degenerate,

followed by neuronal remodeling and topological alterations, which finally leads to loss of inner neurons such as BCs and GCs. Due to the loss of photoreceptors, the remaining cells go through intensive functional and morphological adjustments. Computational modeling of retinal cell response to electrical stimulation allows us to design stimulation strategies and improve the performance of current retinal prosthetic devices. Previous works either utilize single compartment-based simplified neuron models or use morphology of healthy retinal cells. With the aid of retinal connectomics databases of a healthy and an early stage degenerated retina, we can accurately model cells and compare their responses to electrical stimulation of varying stimulus parameters. Retinal connectomes are built by slicing the rabbit retina tissue in 70nm-thick slices, manually annotating different cell types, and generating 3D morphologies of retinal cells by connecting the annotations across all the slices. This way, the connectome databases provide an accurate and realistic of the cell morphologies, synapse information, and network topology details. Using the Admittance method (AM)-NEURON multi-scale modeling platform, we aim at analyzing the impact of retinal degeneration on neuronal activities induced by electrical stimulation. Leveraging this computational model, we compared the response generated in the healthy and degenerated ON-BCs morphologies due to electrical stimulation. Interestingly, we found that the degenerated ON-BCs have slower time constants compared to the healthy ON-BCs at the terminals. This may indicate the decreased average peak membrane potentials and therefore the less likelihood of neurotransmitter release at the presynaptic terminals of the degenerated cells relative to the healthy cells using short stimulation pulses. Characterizing the influence of retinal degeneration on BCs' response to electrical stimulation would allow us to effectively design stimulation strategies and enhance the efficacy of current retinal prosthetic systems.

Title: Optogenetic modulation of electrical coupling

Authors: *V. LERNER, M. LONDON, Y. YAROM;
The Edmond and Lily Safra Ctr. for Brain Sci., Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Theoretical studies show that the number of neurons in an electrically coupled network can be experimentally estimated by comparing the membrane potential decay in a single neuron in two conditions: (1) following a brief stimulation to this neuron and (2) when the

stimulation is applied to all the electrically coupled neurons. The use of optogenetics may provide the experimental protocol to examine this prediction. Surprisingly, in cortical PV interneurons, we found that the voltage decay is identical in both conditions. We hypothesize that this results from temporary decoupling of the electrical connections between the neurons due to activation of Channelrhodopsin-2 (ChR2). We further examined this possibility on the electrically coupled network of the inferior olive, where subthreshold voltage oscillations occur when cells are electrically coupled. Indeed, during light activation of ChR2, expressed in inferior olive neurons, the subthreshold oscillations were eliminated, indicating a reduction in gap junction conductivity. Since it is well documented that gap-junction conductance is pH sensitive and that activation of ChR2 affects the pH, we suspect that this mechanism reduces coupling in the network. This finding may have implications on the interpretation of many experiments which use ChR2 to manipulate the activity of neurons that are electrically coupled.

Title: Frequency dependent electrical stimulation of the prefrontal and anterior cingulate cortices provides pain modulation in rats

Authors: *H. F. XU, Y. LIU, B. VEMULAPALLI, H. J. JEE, Q. ZHANG, J. WANG;
New York Univ., New York, NY

Abstract: As pain consists of both sensory and affective components, its treatment solely by pharmaceutical methods, such as opioids, remains difficult. While electrical stimulation is a promising alternative to pharmaceutical treatment, greater exploration into its targets and parameters of use, particularly its use in the brain, is required to support clinical application. We studied how electrical stimulation of the prelimbic-prefrontal cortex (PL-PFC) and anterior cingulate cortex (ACC) at different frequencies affects pain modulation within these two cortical regions in awake, freely-moving rats. In male Sprague-Dawley rats, we implanted stimulating electrodes in the PL-PFC, a region that provides top-down regulation of pain, and the ACC, a region that processes pain affect. To evaluate the effects of electrical stimulation frequency on prefrontal control of acute pain, we conducted a Hargreaves test by providing acute thermal stimulation to the plantar surface of the hind paw of a rat. We simultaneously administered electrical stimulation at a range of frequencies (0, 20, 40, 60, 80, 120 Hz) to the PL-PFC,

contralateral to the paw receiving thermal stimulation and recorded the paw withdrawal time as a measure of nociceptive pain response. We used the conditioned place aversion (CPA) assay in a standard two chamber setup to determine the rats' aversive response under stimulation of the PL-PFC and ACC at low (20 Hz) and high (120 Hz) frequencies. We found that lower frequency stimulations (20, 40, 60 Hz) of the PL-PFC prolong the withdrawal latency in the Hargreaves test, whereas high frequency stimulation (120 Hz) decreases withdrawal latency. Meanwhile, electrical stimulation of the PL-PFC decreased aversive response at low frequencies (20 Hz) and increased it at high frequencies (120 Hz). An opposite trend was observed in the ACC, as low-frequency stimulation increased aversive response, whereas high-frequency stimulation decreased aversive response. These results demonstrate that electrical stimulation can be used to modulate the sensory and aversive components of pain, and furthermore, such modulation is dependent on both brain targets and on stimulation frequencies.

Title: Treatment efficacy and technical advantages of ipsilateral temporary spinal nerve root stimulation for unilateral postherpetic neuralgia

Authors: M. HUANG[1], Q. CHEN[2], S. WU[1], J. HUANG[1], W. SUN[1], S. YANG[1], ***T. NGUYEN**[2], X. QIAN[2], L. XIAO[1];

Abstract: Objectives: Post-herpetic neuralgia (PHN) is a common complication after herpes zoster infection (HZ). Whilst temporary spinal cord stimulation (tSCS) has been shown as an effective treatment for drug-resistant PHN, recent data suggests ipsilateral temporary spinal nerve root stimulation (tSNRS), a relatively newer technique, as a safe and viable alternative for treating PHN affecting unilateral dermatomes. However, there is no direct comparison on the treatment efficacy of tSNRS to the traditional tSCS. The current retrospective study aimed to describe the technical parameters and the therapeutic effects of tSNR for patients with unilateral PHN, and to compare them with those treated with tSCS.
Materials and Methods: 160 patients with unilateral PHN treated with tSCS (n=109) or tSNRS (n=51) were included in this single-center study. Technical factors between two groups, such as

procedure time, radiation dosage, number of electrodes used, and average cost were compared. Treatment efficacy, measured by analgesic coverage, pain visual analog scale (VAS), total analgesic agent consumption, Pittsburgh sleep quality index (PSQI), and physical and mental quality of life, was also compared between two groups at baseline, post-procedure, and 3 months after stimulation treatment.
Results: Patients who underwent tSNRS reported significant improvement in pain level, sleep quality, and overall quality of life immediately post-procedure and at the 3-month follow-up. This effect was comparable to the tSCS group. However, tSNRS was able to achieve this therapeutic effect with less stimulation sessions than tSCS. The overall cost, procedure time, number of implanted electrodes, and intraoperative radiation exposure were also significantly less in the tSNRS group than those received tSCS.
Conclusions: Whilst tSNRS provides similar therapeutic effect comparing to tSCS for patients with unilateral PHN, it offers several technical advantages. These advantages include shorter procedure time, less radiation exposure, less implanted electrodes, more effective stimulation, and lower overall cost.

Dept. of Electrical and Computer Engin., Durham, NC

Abstract: Techniques to study brain activities have evolved dramatically, yet tremendous challenges remain in acquiring high-throughput electrophysiological recordings minimally

invasively. Here, we develop a soft neuroelectronic probe that is both filamentary and actively multiplexed. Specifically, onsite active multiplexing using miniaturized flexible silicon transistors achieves 256 neuroelectrodes on a filamentary substrate in only a 2.3×0.3 mm^2 area. A novel single-transistor multiplexing acquisition circuit further reduces noise from the electrodes. The filamentary form factor integrated with a rollable contact pad design allows the entire device to be also injectable through syringe injection, enabling minimally invasive probe delivery. Acute auditory experiments in rats successfully validated the ability of the array to record neural signals with high accuracy of tone decoding. Together, these results establish soft, injectable neuroelectronic probes as promising devices for neuroscience research and clinical applications.

Title: Learning to See Again: Using the optokinetic response to assess functional recovery after optic nerve injury

Authors: A. HERMANS, A. GORMAN, S. TAJNAI, ***S. HENLE**;
Carthage Col., Kenosha, WI

Abstract: The zebrafish (Danio rerio) eye has many anatomical similarities to the human eye but is unique in its ability to regenerate the optic nerve. Optic nerve regeneration is typically measured with histology. To better understand the functional regeneration of the optic nerve we investigated the optokinetic response (OKR) assays. The assay relies on the conserved ability to track movement across the whole field of vision in order to keep the visual acuity of the moving object. The response is unconditioned and reproducible, allowing it to be used for a visual assay. To perform an OKR assay, a fish is placed in a 3D printed drum with bars pulled by a motor controlled by an Arduino to elicit the OKR, a more cost-effective alternative to previous methods. Measuring changes in ocular angles recorded during the OKR assay, the zebrafish's visual function can be quantified. Previously, the ocular angles for adult zebrafish had to be manually measured in FIJI and then run through an R program to create a graph. We have also developed an automated imaging pipeline to analyze OKR in adult fish to speed up the process

and allowed for more fine-tuned OKR measurements over time. This will allow us to both better understand the process of optic nerve regeneration, and provide a new assay for measuring optic nerve regeneration that does not require sacrificing the animal.

Title: Osteopontin drives retinal ganglion cell resiliency in glaucomatous optic neuropathy

Authors: *K.-I. TOMA[1], M. ZHAO[1], B. KINDE[1], C. TAN[1], Y. HU[2], Y. HAN[1], X. DUAN[1]; [1]Univ. of California San Francisco, San Francisco, CA; [2]Dept. of Ophthalmology, Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: Retinal ganglion cells (RGCs) project from the retina to the central nervous system via the optic nerve, are representing the earliest step in visual processing. Damage to the RGCs or their axons in the optic nerve can lead to permanent vision loss. We and others have demonstrated that RGCs are not uniformly susceptible to injury and that certain RGCs appear to be more resistant to cellular death for acute injury. These studies showed that both the alpha-RGCs and the intrinsically photosensitive-RGCs expressing melanopsin (M1-RGCs) are more resistant in the ONC model and more chronic forms of injury. We further have previously demonstrated that alpha-RGCs preferentially express osteopontin (OPN, also named SPP1). It is critical for conveying increased resiliency and regeneration in combination with growth factors under ONC. However, the RGC subtype-specific survival has been explored to a lesser degree in mouse models of chronic injuries. Here, we explored RGC subtypes and subclasses with differential survival responses to elevated intraocular pressure (IOP). Furthermore, we assessed if similar mechanisms may protect certain RGC subtypes from chronic injury as occurs in glaucomatous disease states compared to acute injury in ONC models. For this, we employed two complementary models, the microbead occlusion model, and the silicone oil-induced ocular hypertension model, to induce and sustain elevated IOP to recapitulate the debilitating glaucomatous disease states that affect humans. We found that chronic ocular hypertension leads to significant loss of RGCs, with preferential survival of alpha-RGCs, and more specifically, survival of the alpha-ON-RGCs. We found that the OPN that is expressed in alpha-RGCs, is

critical for this resiliency as knockdown of OPN in alpha-RGCs abolishes this preferential survival, and over-expression of OPN in non-alpha-RGCs induces survival. We provide mechanistic insight into the molecular players that specifically drive alpha-RGC survival in the context of chronic glaucomatous injury. Finally, we demonstrated that OPN is expressed, and its expression is correlated with disease severity in the human retina. Our study demonstrated the novel role of OPN in promoting RGC resiliency in a mouse experimental glaucoma model. This work highlights how intrinsic properties of different RGC subsets equip them with differential survival abilities, which may be exploited to prevent premature and permanent vision loss in glaucoma.

Title: The planar cell polarity pathway is required to terminate adult neurogenesis in-vivo

Authors: *S. J. HACK, W. S. BEANE;
Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: Understanding how to initiate the regrowth of axons and other neural structures following injury is a central goal of regenerative medicine. However, successful implementation of translational therapies will require more than how to initiate neurogenesis *in-vivo*. Understanding how neuronal growth self-terminates will be equally critical, as small alterations in growth regulation can easily result in carcinogenesis. To date, few studies have investigated the elusive process by which adult neurogenesis ceases. One of the few model systems where this is being investigated is planarians, which are flatworms capable of regenerating their entire CNS (including brain). Our previous work shows the planar cell polarity (PCP) pathway plays a key role in restricting or stopping neurogenesis during planarian regeneration. Specifically, loss of PCP signaling results in the formation of ectopic photoreceptor neurons and hyperplasia throughout the entire nervous system, concurrent with elevated levels of mitosis weeks after new growth is normally considered finished. In this study, we sought to determine which neural sub-populations and adult stem cell (ASC) subtypes require PCP signaling to terminate their growth. The PCP pathway has long been implicated in regulating cell size, proliferation, cell migration, and tissue patterning, and is a known human tumor suppressor gene associated with several

cancers. Our data suggest that PCP loss has variable effects on different neuronal subtypes, with some populations not being affected, some increased, and some decreased. For example, pan-neural and photoreceptor neuron markers reveal significant increases in the number of both neurons and neural synapses, while markers specific for chemosensory and GABAergic neurons show no increase and dopaminergic neuron numbers are decreased. Ongoing investigations are characterizing the requirement for PCP in specific neural populations and neural ASCs. Because very little is known about the mechanisms governing termination of neurogenesis, these investigations will give insights into how tissues 'know' when they have been properly patterned and scaled. Furthermore, understanding how neuronal growth stops will be crucial for translating future *in-vivo* therapies. This work was supported by NSF grant #1652312.

Title: Inhibition of NFkB signaling promotes neuron regeneration in the mammalian retina

Authors: *I. PALAZZO[1], L. TODD[2], S. BLACKSHAW[3], A. J. FISCHER[1];
[1]Neurosci., The Ohio State Univ. Neurosci. Grad. Program, Columbus, OH; [2]Biol. Structure, Univ. of Washington, Seattle, WA; [3]Johns Hopkins Univ, Sch. Med., Baltimore, MD

Abstract: Loss of vision is caused by irreversible death of retinal neurons. Müller glia (MG) are the primary support cell of the retina and are capable of reprogramming into progenitor cells with potential to regenerate neurons following retinal damage. The capacity for MG mediated retinal neuron regeneration varies widely across species. In lower vertebrate species, MG undergo a neurogenic reprogramming event that results in regeneration of functional neurons to restore loss of vision. However, in mammalian systems, MG undergo a reactive "gliotic" response associated with activation of inflammatory gene networks, and do not regenerate neurons. NFkB signaling is a master regulator of a pro-inflammatory response in the nervous system. The goal of this study was to investigate the role that NFkB signaling plays in regulating the neurogenic vs. gliotic response in MG after damage in the mammalian retina. We investigated patterns of NFkB activation in the mammalian retina after NMDA-mediated excitotoxic damage using an NFkB-eGFP reporter mouse line, as well as probing for NFkB

signaling components in single cell RNA-seq (scRNAseq) libraries from damaged mouse retinas (Hoang et al. 2020). Additionally, we utilized an Ascl1 overexpressing mouse line (GlastER-cre/LNL-tTA/tetO-Ascl1-GFP) (Jorstad et al., 2017) to investigate neuron regeneration after NMDA damage. We performed intraocular injections of NMDA and a pharmacological inhibitor of NFkB signaling (PGJ2) followed by immunohistochemistry or scRNAseq library preparation to identify retinal neuron regeneration and transcriptomic networks underlying the response, respectively. We find that NFkB signaling is rapidly activated in Müller glia cells after NMDA damage, and that this activation is dependent on the presence of microglia in the retina. Additionally, inhibition of NFkB signaling decreases macrophage populations within the retina. We find that inhibition of NFkB signaling promotes Ascl1-mediated retinal neuron regeneration by 30%. Further, inhibition of NFkB signaling repressed damage induced upregulation of reactivity gene networks as well as gene networks that drive reactive Müller glia back to a quiescent state, which underlies the increase in neurogenesis from these cells. In conclusion, these data indicate that inhibition of NFkB signaling suppresses a pro-inflammatory response and promotes neurogenic reprogramming of Müller glia in the damaged mammalian retina.

Title: Purification and characterization hPSC-derived striatal progenitor subpopulations for transplantation in Huntington's Disease

Authors: *F. J. MOLINA-RUIZ, P. SANDERS, C. GOMIS, G. BOMBAU, M. GALOFRÉ, S. ARTIGAS, C. INTRONA, V. MONFORTE, J. M. CANALS;
Biomed. Sci., Univ. of Barcelona, Barcelona, Spain

Abstract: Huntington's disease (HD) is a movement disorder primarily characterized by the degeneration of striatal medium spiny neurons (MSNs). Cell replacement therapy to substitute degenerated neurons is a promising strategy to cure this devastating disease. The efficient differentiation of human pluripotent stem cells (hPSCs) to MSNs is a critical step in the implementation of cell therapy strategies for treating HD. Current *in vitro* striatal differentiation protocols are inefficient and generate heterogeneous cell products, which have a risk of undesired results following transplantation. Here we show a robust immunomagnetic cell sorting pipeline that uses a novel cell surface marker to select striatal neuroblast (NB) subtypes from a heterogeneous cell population differentiated in vitro from hPSCs. Our findings demonstrate that the use of this cell surface marker is a consistent method to isolate NBs which rapidly differentiate into mature striatal neurons expressing Dopamine Receptor (DR)-D1 and DR-D2. In addition, cell sorting of the heterogeneous differentiated hPSCs under different conditions produces specific NB subtypes related to striatal MSN sub-populations. Furthermore, following transplantation of these sorted committed NBs into adult mouse striatum we show evidence of graft survival and integration into the host tissue without graft overgrowth. In conclusion, we demonstrate that the cell selection process results in high-yield enrichment of different striatal NB subtypes under different conditions, and a reduction of cell product heterogeneity and batch-to-batch variation in different hPSC lines. We anticipate that the use of this pipeline for striatal NB selection prior to transplantation could accelerate the implementation of safe and reproducible cell products as part of future clinical cell replacement strategies for the restoration of functional deficits in HD.

Title: Using multi-omics prediction and in vivo screen to explore transcriptional regulation of optic nerve regeneration

Authors: *C. QIAN[1], C. QI[1], Y. XIN[2], F.-Q. ZHOU[3];
[2]Wilmer Eye Inst., [1]Johns Hopkins Sch. of Med., Baltimore, MD; [3]Orthopedic surgery and Neurosci, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Weak inherent axonal regrowth in the adult mammalian CNS hampers circuitry reconnection and functional recovery after various types of injuries or axonopathies. Emerging evidence showed that developmentally downregulated transcriptomic and epigenomic regulators, including Klf6/7, Sox11, Jun, Myc, Uhrf1 and Lin28, functioned to promote CNS axon regeneration sufficiently. Some developmentally upregulated factors such as Klf4/9 and Rest functioned to inhibit CNS axon regeneration. We thus hypothesize that manipulating developmentally regulated transcriptional factors (TFs) in retinal ganglion cells (RGCs) may act to promote optic nerve regeneration. An advanced integrative bioinformatics analysis approach was established to explore a mouse retinal embryonic and postnatal developmental deep-sequencing dataset (GSE87064) including RNA-seq, ChIP-seqs of histone markers and ATAC-seq. The RNA-seq was used to sort out differential TFs across development. By characterizing both the chromatin accessibility transition and active enhancer regions, a motif-based footprinting analysis (notches in the ATAC peaks) was utilized to predict TF-promoter as well as TF-enhancer-gene regulations. We then used a scoring algorithm to identify a group potential candidate TFs that might be manipulated to enhance optic nerve regeneration. Among all the candidate TFs, several novel targets were predicted with prioritized score in interacting with the regeneration-related transcriptome via either promoter or enhancer regions. Besides, some well-known regeneration promoting TFs, such as Sox11, Myc, Ascl1, Fos and Id2, also received high scores. Next, we are going to perform the in vivo screen with intermediate throughput of candidates in optic nerve axon regeneration. We will use CRISPRa and traditional ORF overexpression to explore the positive targets. Meanwhile, we will use CRISPRi, Cas13 and traditional shRNA interference through AAV2 infection to reveal the role played by suppressive targets in CNS regeneration.

Title: Hey1 and Id2b regulate Müller glia's injury-response threshold and the proliferation of Müller glia-derived progenitors in the zebrafish retina

Authors: *A. SAHU, S. DEVI, J. JUI, D. GOLDMAN;
Michigan Neurosci. Inst. and Dept. of Biol. Chem., Univ. of Michigan, Ann Arbor, MI

Abstract: The zebrafish and mammalian retina share structure and function; however, only zebrafish can regenerate a damaged retina. Key to this regenerative response is Müller glia (MG), which responds to retinal injury by reprogramming and dividing to produce multipotent retinal progenitors that regenerate all major neuron types. In the uninjured retina, Notch signaling is restricted to quiescent MG. However, following retinal injury, it is suppressed in injury-responsive MG and this suppression is necessary for retina regeneration. Studies suggest that MG engages in a regenerative response when exposed to injury-derived signals that exceed a certain threshold (MG's injury-response threshold). This threshold appears to be controlled by Notch signaling since pan-retinal Notch inhibition recruits normally quiescent MG near the injury site to participate in the regenerative response. Notch signaling inhibition is also associated with the proliferation of MG-derived progenitors. Using a combination of ATAC-seq and RNA-seq, we show that Notch controls MG's injury-response threshold by regulating the expression and chromatin accessibility of certain regeneration-associated genes. Intersection of RNA-seq gene lists obtained from injured MG and Notch inhibited uninjured MG identified 89 regeneration-associated genes that are regulated by Notch signaling in the uninjured retina. Importantly, 2 Notch target genes, *hey1 and id2b*, were found to mediate the effects of Notch signaling were also found to regulate MG's regenerative response. Using a combination of gene inactivation and transgenic overexpression studies, we show that *hey1* regulates MG's injury-response threshold, while *id2b* regulates the proliferation of MG-derived progenitors. Furthermore, using morpholino and CRISPR mediated gene suppression, transgenic overexpression studies, along with epistasis experiments, we show that notch ligands, Dll4 and Dlb, act through Notch3 receptor to regulate *hey1* and *id2b* expression. Importantly, these studies show that Hey1 suppression is sufficient to lower MG's injury-response threshold, while Id2b regulates the proliferation of MG-derived progenitors.

Title: Evaluation of functional repair process in iPSC-derived in vitro model of damaged neuronal network

Authors: *S. SHIOMOTO[1], W. LIN[1], K. MURAMATSU[1], T. HOSOYA[1], K. SAWADA[2]; [1]Biomed. Business Ctr., Ricoh Company, Ltd., Kawasaki-shi, Japan; [2]Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Neurodegenerative diseases cause abnormalities at different scales of the nervous tissue, from neuron subcellular structures to neuronal network functions. The repair of damaged neurons and their networks has been found to be difficult in the mammalian central nervous system (CNS). Therefore, there is a great need for new treatment methods that promote recovery from neuronal damage. However, the mechanisms for neuronal repair is poorly understood and replicating the human CNS microenvironment remains a challenge. Here, we combined human induced pluripotent stem cell (hiPSC)-derived neurons with microengineering to assess the functional connectivity of neuronal networks and their repair after disconnection.
Using hiPSC-derived neurons, two spatially separated clusters of cells were placed on a microelectrode-array. Neurites were observed to elongate between the co-cultured clusters, and the establishment of functional connections was evaluated by analyzing synchronized bursts within and between the two distinct networks. Cutting the neurites between the two clusters induced a desynchronization of the bursting activity, indicating that the neuronal networks had been damaged. Further culture of the damaged networks for a week induced the neurites to extend again beyond the severed area. Synchronous bursts reappeared between the two clusters, thus demonstrating that functional connection could be repaired over time.
Our results provide a method that can be used to evaluate the process and outcome of disrupting and repairing functional connections between two populations of neurons. This approach is expected to be useful in developing screening assays to evaluate the efficacy of drugs that reduce damage or promote functional recovery, and in understanding the mechanisms of brain plasticity and regeneration.

Title: Optic Nerve Regeneration Lipidomics: A Comparison of Four Phospholipid Profiles

Authors: *S. MEEHAN[1], E. NEAG[2], S. K. BHATTACHARYA[3];
[1]Univ. of Miami, Miami, FL; [2]Osteo. Med., Michigan State Univ., East Lansing, MI; [3]Bascom Palmer Eye Inst., Univ. of Miami Sch. of Med., Miami, FL

Abstract: Purpose As the quantity of discovered regenerative factors increases, we can evaluate regenerative processes from multiple perspectives. Successful optic nerve regeneration requires axon membrane expansion. The neuronal membrane contains more than 50% of phospholipids and is a likely source of significant shifts in regeneration. A comparison of phospholipid lipid profiles may provide insight into the essential lipid species and properties for regeneration.
Methods We evaluated four regenerated lipid profiles at 7 days and 2 weeks of regeneration: 2 pharmacological (Zymosan and Wnt3a), 1 biophysical (optogenetics - transgenic channel rhodopsin (ChR)), and a Phosphatase and Tensin homolog (PTEN) Cre-Lox knockout. Raw mass spectrometry files were obtained from Metabolomics Workbench and analyzed using LipidSearch. Significant lipid species and properties were determined using Metaboanalyst and Lipid Ontology (LION).
Results Of the four lipid profiles, the optogenetic transgenic mouse showed no significant specie or ontology shift between ChR groups and was omitted from the comparisons. Phospholipid classes were compared between regeneration, vehicle, and control groups. Zymosan group had 3/12 and 0/12 significant classes at 7 and 14 days post crush, respectively. Wnt3a had one significant class (LPC) at 15 days. PTEN KO had no significant phospholipid classes. At the species level, Zymosan group had 24/762 and 117/796 significant species at 7 and 14 days post crush, respectively. Wnt3a group had 1/286 and 15/286 significant species at 7 and 15 days, respectively. PTEN KO had 19/561 and 2/561 significant species at 7 and 14 days, respectively. Comparing all three lipid profiles showed no matched significant species. However, Wnt3a and Zymosan had two matched crush-specific lipids: PG(22:6/22:6) and PG(18:1/22:6). Zymosan and PTEN had one matched lipid specie: PI(17:0/20:4) with opposite shifts. Comparing all three lipid ontology profiles, at 7 days post crush, there is a consensus of upregulated lysophospholipids (LPE/LPC) and decreased alkyl- and acyl-phosphoethanolamines. At ~2 weeks, both Zymosan and PTEN KO groups had decreased lysophospholipids while Wnt3a maintained increased lysophospholipids.
Conclusions Based on this approach of optic nerve regeneration phospholipid profile comparisons, total phospholipid classes and single species may not provide insight into regeneration. Single phospholipid species may be associated with injury-specific shifts. The lipid ontology comparison provided the most insight into axon regeneration. Lysophospholipid and phosphoethanolamine regulation may be a clue in regenerative capacities.

Title: Neuroregenerative neurotrophic effect mediated by agents that promote cytidine diphosphate diacylglycerol biosynthesis

Authors: W. KANG, A. D. S. TCHAMNA, ***A. S. UNDIEH**;
CUNY Sch. of Medicine, City Col. of New York, New York, NY

Abstract: CDP-diacylglycerol (cytidine disphosphate diacylglycerol) is a critical intermediate in the biosynthesis of phosphatidylinositols for various cell signaling and structural functions. Receptors utilizing phosphatidylinositol-4,5-bisphosphate (PIP2) in signal transduction may couple through phospholipase C to induce PIP2 hydrolysis with release of inositol phosphate and diacylglycerol second messengers, or the receptors may couple through phosphatidylinositol-3-kinase (PI3K) to convert PIP2 into PIP3 which activates downstream intracellular signaling mediators. Neurotrophic factor receptors, especially the brain-derived neurotrophic factor (BDNF)-sensitive TrkB receptor, depend on both of these PIP2 cascades for normal function. We previously showed that a number of chemically diverse pharmacological agents could increase the biosynthesis of CDP-diacylglycerol with onward conversion of the nucleolipid into enhanced production of phosphatidylinositides in neural tissues (Undie, 1999; Tyeryar et al, 2007; 2009). Here, we surmised that a strategy to promote cellular PIP2 availability from increasing CDP-diacylglycerol could boost PIP2-associated receptor signaling events with physiologic consequences. To test this, cortical primary neurons obtained from neonatal rat pups and grown in culture for 7 days were mechanically injured using a commercial neuronal injury device. Injured neuronal populations were immediately exposed to predetermined concentrations of chemical compounds known to promote the synthesis of CDP-diacylglycerol. After 3 days, the cultures were immunostained with *Tub3* antibodies to mark neuronal soma and processes, followed by quantitative assessment of neuronal regrowth into the region of injury. As observed, multiple CDP-diacylglycerol-promoting compounds, including some dopaminergic agents and some clinical antidepressants, boosted the regenerative regrowth of injured rat cortical neurons in culture. For comparison, the regenerative effect of SKF38393 (1-phenyl-7,8-dihydroxy-2,3,4,5-tetrahydro-1H-3-benzazepine HCl) at 30 uM concentration was comparable to the effect of BDNF 40 ng/ml. Hence, in addition to direct stimulation of neurotrophin receptors, boosting PIP2 substrate availability could lead to neuroregenerative neurotrophic effects in neural tissue. The direct role of TrkB receptor signaling in these drug effects is being investigated.

Title: The role of MMP2 in zebrafish retinal regeneration

Authors: L. BATIS[1], J. WILKINSON[1], P. GARRETT[2], K. FRIEDEL[1], J. SAAVEDRA[2], K. PAYNE[3], B. TONKS[4], *E. SANDQUIST[1];

Abstract: Cell transplantation therapy has the potential to remedy presently incurable neurodegenerative diseases and injuries of the retina. However, low cell survival and retention is observed following transplantation to the retina. Disrupted environmental architecture and the presence of growth inhibitory molecules can reduce the efficiency of transplanted cells. Replicating regenerative stem cell niches such as those observed in zebrafish may improve cell survival and retention following transplant. Further, the use of developing zebrafish allows for live visualization of cell migration, an important step for stem cell integration following transplant. Matrix metalloproteinase-2 (MMP2) is promotes cell migration during development, with some evidence of involvement in regeneration. The objective of this study was to confirm whether MMP2 plays a role in retinal repair. Following photolesion to the zebrafish retina at three days postfertilization, the expression of MMP2 was measured at 1, 2, 3, 5, and 7 days post lesion. Results demonstrated that the gene was upregulated in the eye compared to controls. Significant changes in MMP2 expression indicates that further investigation of MMP2 in retinal regeneration is warranted. A second goal was to explore the validity of larval, rather than adult, zebrafish as a model for retinal regeneration. Immunohistochemistry to detect proliferating cell nuclear antigen (PCNA) was used to measure cell proliferation in the retina following injury. To identify proliferative Müller glial cells, *Tg(alpha-1 tubulin:EGFP)* zebrafish were used. This can determine whether Müller glia are the source of new cells, as is seen in adults, or if the cells originate in the ciliary marginal zone, which is responsible for normal retinal development. Future experiments will use live imaging to characterize the migration patterns of retinal stem cells during regeneration, as well as the effects of loss of MMP2 on this process. The ability to live image retinal stem cell migration *in vivo* will be an additional tool available to scientists as they investigate the mechanisms of regeneration. A better understanding of the manner in which stem cells migrate within their environment during repair, such as with matrix metalloproteinases, will lead to optimized cell delivery methods and improved prognosis for patients with retinal disease.

Title: Lysosomes self-regulate their axonal transport through TRPML1-mediated zinc release, directly inhibiting motor protein motility

Authors: *T. F. MINCKLEY[1], A. M. DISCHLER[1], D. H. FUDGE[2], E. GHAZVINI ZADEH[3], W.-H. LI[3], K. VERHEY[4], S. M. MARKUS[5], Y. QIN[1];

Abstract: Accurate delivery of cargo over long distances through axonal transport requires precise spatiotemporal regulation in neurons, and in this work, we identify a novel role of zinc (Zn^{2+}) as a signaling molecule in axonal transport. First, we developed a novel, sub-nanomolar sensitive genetically encoded Zn^{2+} sensor, GZnP3, that has 13-fold dynamic range, and is able to detect cytosolic fluctuations in Zn^{2+} between 100 pM and 100 nM, characterized both *in situ* and *in vitro*. Using this sensor, both cytosolic and subcellularly-targeted, we established via confocal microscopy that the lysosomal ion channel, transient receptor potential mucolipin 1 (TRPML1), was permeable to physiological levels of Zn^{2+}. We found that primary rat hippocampal neurons have lysosomes with high concentrations of Zn^{2+} and pharmacological activation of TRPML1 can release this intracellular pool of Zn^{2+} into the cytosol. In addition, TRPML1-mediated Ca^{2+} signals were much smaller and shorter-lived in neurons than in HeLa cells. Conversely TRPML1-mediated Zn^{2+} signals were completely absent in HeLa cells, leading us to believe that TRPML1-mediated Zn^{2+} release from lysosomes may play an important role in neuronal health. Further we found that TRPML1-mediated Zn^{2+} release was more robust in neurites as compared to the soma. This led us to investigate the role of TRPML1 activation on axonal transport and we found that TRPML1-mediated Zn^{2+} release inhibited bidirectional axonal transport of lysosomes.

We were able to replicate this inhibition of lysosomal axonal transport by depolarization-induced Zn^{2+} influx. *In vitro* ATPase assays using purified motor protein and preformed microtubules were used to determine that both dynein and kinesin were inhibited by physiological increases in Zn^{2+}. We therefore propose a novel model for Zn^{2+} as a brake signal on axonal transport, wherein lysosomes can self-regulate their transport through TRPML1-mediated Zn^{2+} release.

Title: Muscleblind-like proteins selectively associate with kinesin motors through their zinc-finger domains to regulate RNA transport

Authors: *R. HILDEBRANDT[1], K. MOSS[2], L. KNUDSON[2], A. JANUSZ-KAMINSKA[2], K. LIN[2], T. SAXENA[1], L. DENES[1], G. J. BASSELL[2], E. T. WANG[1];

Abstract: Localization of mRNAs to axons and dendrites supports efficient control of local protein synthesis and maintains proper neuronal function. RNA-binding proteins (RBPs) and cytoskeletal motors are important for mediating this process. One such family of RBPs are the Muscleblind-like proteins (MBNLs), splicing factors with cytoplasmic functions, including localization of RNA targets to various subcellular locations. Previous studies have shown that depletion of MBNLs by expanded CTG repeats in myotonic dystrophy may cause RNA mis-localization; however, mechanisms and domains responsible for MBNL-mediated RNA localization remain uncharacterized. Through live imaging of primary mouse cortical neurons, we observed MBNL-containing granules moving at speeds consistent with microtubule transport. Thus, we hypothesized that MBNL associates with a kinesin motor to mediate RNA localization. To elucidate these potential MBNL-kinesin associations, we utilized assays designed to identify novel kinesin-cargo interactions. We found that tail domains of Kif1bα and Kif1c selectively associate with MBNL and, surprisingly, these interactions depend on MBNL C_3H zinc-finger (ZnF) domains in a non-RNA binding dependent manner. Subsequent experiments with other C_3H ZnF-containing proteins suggest a common mechanism for kinesin association. MBNLs have been shown to localize RNAs to membranes, indicating a potential role for MBNL in facilitating not just transport, but terminal anchoring. Indeed, we found that MBNL mutants lacking unstructured domains (exon 3 and C-term) no longer co-fractionate with membranes and do not efficiently form cytoplasmic granules. Finally, we found that dominant negative expression of kinesin tails or functional depletion of MBNL by CTG repeat over-expression in a neuronal cell model causes mis-localization of nucleolin (*Ncl*) RNA, revealing a functional target that may be perturbed in myotonic dystrophy. Overall, these findings advance our understanding of kinesin-RBP interactions and how RNA transport is mediated in neuronal systems.

Title: The role of schizophrenia-associated MAD1L1(Mitotic Arrest Deficient-1 like 1) in neuronal development

Authors: B. GOO, D. MUN, S. KIM, T. THI MY NHUNG, B. SUH, Y. WOO, S. KIM, *S. PARK;
Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of

Abstract: The neurodevelopmental hypothesis of schizophrenia is evidenced by the alteration of ventricle sizes and cortical volumes in patients. Until now, novel schizophrenia risk genes have been revealed via multiple genome-wide association studies (GWAS). Although GWAS has identified an association between *MAD1L1* (*Mitotic Arrest Deficient-1 like 1*) and the predisposition of schizophrenia, the molecular mechanisms underlying this association remain unclear. Here, we report the novel functions of *MAD1L1* in neuronal development. First, we found that MAD1 (gene product of *MAD1L1*) is an important regulator of neuronal polarity in migrating neurons. Our data revealed that polarity defect caused by *MAD1L1*-deficiency affects neuronal migration and neurite outgrowth. Positioning of Golgi apparatus, which determines the cellular polarization, was notably changed by *MAD1L1*-deficiency in migrating neurons. Second, we observed that endogenous MAD1 is enriched at the Golgi apparatus in neurons. When we induced knockdown of MAD1, significant changes in morphology and trafficking functionality of Golgi apparatus were observed. Finally, we identified kinesin-like protein KIFC3 as a novel protein-protein interaction partner of MAD1 by yeast-two-hybrid screening. Our data also show that MAD1-KIFC3 collaborates to maintain the integrity of the Golgi apparatus in developing neurons, critical for proper migration and differentiation. Collectively, our findings suggest that *MAD1L1* has a novel function in neuronal development, which might be further relevant to schizophrenia pathophysiology.

Abstract: The largest mammalian CNS nerve terminal, the calyx of Held (CH), provides strong and temporally precise excitation of target principal cells of the medial nucleus of the trapezoid body (MNTB). The CH exhibits hallmark developmental features of strengthening and pruning necessary to yield monoinnervation of MNTB neurons. Using serial block-face scanning electron microscopy (SBEM) of tissue collected from neonatal littermate mice (24-48 hr sampling), we previously found that between postnatal (P) days 2 and 4, most of the 10-20 small pioneering inputs on each cell are pruned while 1-3 terminals grow at rates of 200 μm^2 per day. By P6, 75% of principal cells are monoinnervated. During CH formation, collateral processes of variable length extend from the edges of the developing terminal and are known sites of Ca^{2+} entry. Although we found no evidence of direct interaction between CHs along the principal cell soma, collaterals largely occupy shared territories. However, little is known about the function of the calyceal collaterals. Our lab is interested in the direct interaction among developing inputs that lead to the emergence of a dominant CH. Here, we sought to examine the temporal dynamics of synaptic organization in the MNTB as it relates to the ultrastructure revealed with SBEM. We employed lattice light-sheet (LLS) microscopy which offers rapid and high-resolution image acquisition with minimal bleaching. Acute coronal brainstem slices (300-600 μm thickness) were collected in neonatal mice ranging from P0-14. Following the 4D image acquisition, data was imported into syGlass ™, a custom software package designed in-house, for immersive virtual reality (VR) aided-analysis. Processes were manually tracked in syGlass™ to reveal the growth dynamics of CHs and their associated processes, including filopodia- and growth cone-tipped terminal arbors. We found these collaterals form a fluid field around each CH as well as exhibit an age-dependent relationship in their motility that rivals or exceeds rates of axonal extension described elsewhere in the CNS. Growth cones, perhaps the most dynamic structure in this system, extend fastest during the ages of CH expansion yet slow after monoinnervation is established. Moreover, live imaging and ultrastructural analysis presented here establishes that CH arbors repeatedly form transient associations between developing terminals and such contacts may serve a communicative role in circuit formation. These data are effective in

monitoring the navigation patterns of assembling neural circuits in an intact system and reveal the dynamic nature of growth and retraction of developing neurite reorganization.

Title: Schwann cells provide iron to axonal mitochondria and its role in nerve regeneration

Authors: *B. S. MIETTO[1], P. JHELUM[2], K. SCHULZ[3], S. DAVID[4];
[1]Inst. of Biol. Sci., Federal Univ. of Juiz de Fora, Juiz de Fora, Brazil; [2]Ctr. for research in neuroscience, The Res. Inst. of the MUHC, Montreal, QC, Canada; [3]Ctr. for Res. in Neurosci., Montreal, QC, Canada; [4]McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Iron is an essential co-factor for several metabolic processes, including the generation of adenosine triphosphate (ATP) in mitochondria, which is required for axonal function and regeneration. However, it is not known how mitochondria in long axons, such as those in sciatic nerves, acquire iron *in vivo*. Due to their close proximity to axons, Schwann cells (SCs) are a likely source of iron for axonal mitochondria in the peripheral nervous system. Here we demonstrate the critical role of iron in promoting neurite growth *in vitro* using iron chelation. We also show that SCs express the molecular machinery to release iron, namely, the iron exporter, ferroportin (Fpn) and the ferroxidase ceruloplasmin (Cp). In *Cp* knockout (KO) mice, SCs accumulate iron, because Fpn requires to partner with Cp to export iron. Axons and SCs also express the iron importer transferrin receptor 1 (TfR1), indicating their ability for iron uptake. In teased nerve fibers, Fpn and TfR1 are predominantly localized at the nodes of Ranvier (NR) and Schmidt-Lanterman incisures (SLIs), axonal sites that are in close contact with SC cytoplasm. We also show that lack of iron export from SCs in *Cp* KO mice reduces mitochondrial iron in axons as detected by reduction in mitochondrial ferritin, affects localization of axonal mitochondria at the NR and SLIs, and impairs axonal regeneration following sciatic nerve injury.

These finding suggest that SCs contribute to the delivery of iron to axonal mitochondria, required for proper nerve repair.

Title: Mutations in UNC-33, a microtubule associated protein, causes defects in transport of autophagic vacuoles in neurites of C. elegan's neurons: impact of microtubule organization on axonal autophagic flux

Authors: *R. JAUREGUI, **A. HOLGADO**;
Dept. of Biol. Sci., St. Edward's Univ., Austin, TX

Abstract: Autophagy is an important process for maintaining homeostasis wherein cells degrade intracellular components to enable nutrients to be utilized in other ways. Neurons are postmitotic cells that rely on this process to ensure that dysfunctional proteins, organelles, and aggregates are safely degraded. Neurodegenerative diseases such as Alzheimer’s disease display characteristic intracellular aggregates that make autophagy a target of research. Neurites are elongated, polarized projections that enable communication between neurons. Collapsin Response Mediator Protein-2 (CRMP-2), along with it's ortholog UNC-33 in *C. elegans*, are responsible for proper microtubule assembly and neurite elongation. UNC-33 has been shown to form a complex with UNC-44 and UNC-119 to secure microtubules to the cortex of neurons. Proper microtubule organization enables the functioning of the autophagic pathway and ensures that synaptic dysfunctional proteins are safely degraded and recycled in the cell. Our study aims to understand the role that UNC-33 has in the autophagic process. In vivo confocal imaging of the *C. elegans'* AIY neuron with the aid of a tandem LGG-1 marker was used to count and track individual autophagic vacuoles (AV) and their flux through the autophagy pathway. This tandem marker contains a pH sensitive, two color fluorescent marker that, when fused with degradative cellular compartments such as lysosomes and endosomes, quenches the green signal and shows a single red puncta. Images of red and green AV’s were randomized and blindly scored for location, number, and maturity. Each control or experimental group analyzed contained n>27 animals. Statistical examinations of the results demonstrated that two *unc-33* mutants alleles *unc-33(e204)*

and *unc-33(mn407)* are found to have a significantly higher number of LGG-1 positive puncta in their AIY neurites. The *unc-33* mutants also possess a higher number of mature autolysosomes in the AIY neurites when compared to wild type. *unc-44(hrt-2)* mutants show a similarly higher number of AV in the AIY neurite. This study further validates the role that *unc-33* plays in maintaining homeostasis by enabling transport of autophagosomes through neurites. A better understanding of how autophagosomes are able to clear dysfunctional proteins has important implications on how scientists may be able to remedy the aggregates seen in neurodegenerative diseases such as Alzheimer's Disease.

Title: Defects in autophagy flux related to microtubule associated protein UNC-33 mediate changes in basal and starvation-induced autophagy

Authors: *E. CARRILLO, E. HOLECHEK, A. OTT, A. HOLGADO;
St. Edward's Univ., Austin, TX

Abstract: Autophagy is the intracellular degradative process responsible for the recycling of inefficient proteins or organelles. Regulation of autophagy is essential for axonal development and maintenance via CRMP-2/UNC-33, a microtubule associated protein (MAP) that contributes to neuronal development and transport of autophagosomes. Together with UNC-119 and membrane-associated Ankyrin (UNC-44), UNC-33 forms a ternary complex that anchors microtubule bundles to the cortex and inhibits microtubule sliding, herein referred to as the ternary microtubule associated cortical complex (MACC). Deficiencies in cargo degradation and autophagy flux produced by *unc-33* mutants have the potential to contribute to the development of neurodegenerative diseases, such as Alzheimer's. Our laboratory studies autophagic flux via the cleavage of the double fluorescently tagged autophagosomal protein LGG-1/LC3 in *C. elegans unc-33 mutants*. We predict that lack of UNC-33 will result in defects in autophagy flux.To test this hypothesis we monitored autophagosome maturation and pathway flux using western blotting techniques and measured the levels of the double fluorescently tagged autophagosomal protein CERULEAN-VENUS-LGG-1(dFP)(MW 75) versus the monomeric

fluorescent protein (mFP)(25 kDa). We compared induced autophagy via starvation against basal autophagy. The cleavage of dFP into mFP upon arrival at the lysosome was used to construct a ratio of 25 kDa/75 kDa herein defined as the index of autophagy flux. Analysis of westernblot densitometry showed that *unc-33* mutants undergoing induced autophagy have an increase in the index of autophagy flux. In basal autophagy, there was a decrease in the index of autophagy flux. Additionally, *unc-104(e1265)* mutants appeared to have similar indices to wildtype. Together, these results suggest that UNC-33 and the ternary MACC may play a notable role in autophagy flux and clearance of cargo compared to the kinesin motor protein UNC-104. These results are indicative of the role UNC-33 plays towards neuronal autophagy and neurodegenerative disorders.

Title: Investigating the effects of infection of Pseudomonas aeruginosa on the regulation of the expression of neuronal GFP driven by the unc-33 promoter in C. elegans

Authors: *A. CARRASCO-PENA[1], S. AVANT[1], E. TORRES[1], K. SALAZAR[1], A. HOLGADO[2];

Abstract: Schizophrenia’s familial transmission and heritability have been known for several decades, although the relationship between the disorder and genetic components have been made evident, it has been difficult to identify the particular causative molecular players involved. It has been hypothesized that environmental and genetic factors have contributed to the development of Schizophrenia particularly through the disruption of the mammalian target of rapamycin (mTOR) pathway. *Pseudomonas* is an aerobic and gram-negative bacteria that belongs to the *Pseudomonadaceae* family which is often found in soil and water. *Pseudomonas aeruginosa* is commonly described as an antibiotic resistant and opportunistic pathogen that causes infection in plants and animals with the inclusion of humans. *Pseudomonas aeruginosa* has been shown to be pathogenic to *C. elegans* nematodes. Genes, including *daf-16*,activate the nematode’s immunity upon the pathogen's presence. It is proposed that infection with *Pseudomonas aeruginosa*

activates the DAF-2 signaling pathway as well as induces autophagy. Our previous findings support the hypothesis that external factors, such as temperature, play a role in the regulation of the expression of GFP driven by the *unc-33* promoter. In our studies, we incubated *C. elegans* at 16°C and 25°C and found that those developing at a high temperature had a lower expression of neuronal GFP as an indicator of the activity of the *unc-33* promoter. In contrast, nematodes that develop at 16°C show a high expression of GFP in the nerve ring. Herein we will study the effects of environmental stressors such as *Pseudomonas aeruginosa* infection on the expression of GFP driven by the *unc-33* promoter. To this end, *C. elegans* hermaphrodites were incubated at 16°C in a plate seeded with OP50 or *Pseudomonas aeruginosa* until they reached the L3/L4 stage. Confocal microscopy was then utilized and the head of the *C. elegans* hermaphrodites were imaged to determine GFP expression driven by the *unc-33* promoter in the nerve ring and glial cells. The analysis of the quantification of twenty five worms per condition has shown that *C. elegans* infected since embryo with *Pseudomonas aeruginosa* have decreased neuronal GFP driven by the *unc-33* promoter. While neuronal expression is reduced due to infection, GFP glial expression is increased. This study provides insight into the role that infection has on regulating the expression of GFP driven by the *unc-33* promoter, shedding some light into external factors controlling one of the molecular players (UNC-33/CRMP2/DPYSL2) shown to be repressed by polymorphic variations in patients suffering from schizophrenia.

Abstract: Disruptions in embryonic brain development can manifest as altered postnatal brain structure and function, leading to neuropsychiatric illness. One such disruption is mutation in Chromodomain helicase DNA binding protein 8 (*Chd8*); a gene that encodes an ATP-dependent chromatin remodeler. Heterozygous *Chd8* loss of function mutations result in macrocephaly in both humans and mouse models, and autism in humans. However, how *Chd8* haploinsufficiency impacts brain structure across cortical development is unknown. Importantly, previous work demonstrated that increases in brain volume are observed across several brain regions including the cortex, requiring a whole brain imaging approach to study the mutation's effects. Here, we employ magnetic resonance imaging (MRI), tissue clearing technology, and light-sheet microscopy to acquire MR and 3D cellular resolution images in intact whole brains from a mouse model with a single heterozygous point mutation in *Chd8* leading to truncated protein (*Chd8*$^{+/-}$). Our goal is to quantify neural progenitors and neuronal cell-types within annotated areas of the developing neocortex in *Chd8*$^{+/-}$ mice and their sex-matched wild-type (WT) littermate controls to determine the cell types that drive this ASD-associated cortical hyper-expansion. At present, we have generated 2 littermate pair brain MR images at postnatal day 4 (P4) (60µmx60µmx60µm). We found increased cortical volume in *Chd8*$^{+/-}$ mice(7%) relative to WT littermate controls in both males and females, replicating previous work. Additionally, we have generated 3D cellular high resolution (0.75µmx0.75µmx4µm) images from 5 littermate pairs at P4 labeled with upper- (*Brn2*) and lower-(*Ctip2*) layer neuronal markers. Using NuMorph, a suite of image analysis tools developed in our lab, we have registered one of these images to the Allen Developing Brain Atlas and quantified all the nuclei in the cortex. We detected about 13.8 million cortical nuclei comprised of 21% each of upper- and lower-layer neurons. These results demonstrate cortical volume increases in *Chd8*$^{+/-}$ mouse brains. Moving forward, we aim to perform similar analyses for 9 biological replicates per sex and per genotype at P4 and other early developmental timepoints to elucidate the cellular basis and spatial localization of brain overgrowth in our mouse model, leading to a better understanding of how genetic variation can affect cortical development and alter risk for neurodevelopmental disorders.

Title: Deficits in social touch in genetic and environmental mouse models of autism

Authors: *T. CHARI[1], A. HERNANDEZ[2], C. PORTERA-CAILLIAU[3];
[1]Dept. of Neurology, Neurosci. Interdepartmental Program, David Geffen Sch. of Med., [2]Dept. of Neurology, CARE Scholars Program and CARE Sci. Engin. and Math Summer Program, [3]Dept. of Neurol. and Neurobiology, David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: Social withdrawal/social anxiety in individuals with autism spectrum disorders (ASD) may result from hypersensitivity to social touch, such as hugging or shaking hands. Social touch deficits have been relatively understudied in rodent models of ASD, and the circuits involved have not been identified. We designed a novel assay to investigate the behavioral responses associated with social touch and differences between ASD mice and healthy controls. A *test* mouse, head-fixed but free to run on an air-suspended polystyrene ball, is allowed to voluntarily (whisker-whisker) or forced (snout-snout) to interact with an inanimate object or with a *visitor* mouse (familiar or stranger) head-fixed on a moving platform. Each social interaction type (order is randomized) occurs in several bouts to mimic typical mouse to mouse interactions. We use high speed videos (50 FPS) to analyze avoidance behaviors and aversive facial expressions with custom MATLAB routines and DeepLabCut (Mathis et al. 2018). We tested two ASD models, the genetic model of Fragile X Syndrome (*Fmr1*$^{-/-}$ mice) and the environmental maternal immune activation (MIA) model (progeny of dams injected with Poly I:C at E12.5). We find that ASD mice in both models spent more time running in the direction away from the stranger mouse during forced and voluntary social touch interactions compared to 'no-contact' or voluntary object interactions. Healthy control mice (*Fmr1*$^{+/+}$ mice or progeny of dams injected with phosphate buffered saline) showed significantly less avoidance during social touch than with object touch (and less avoidance compared to ASD mice). Furthermore, we observed a significant increase in aversive facial expressions (orbital tightening, prolonged whisker protraction) during forced social touch compared to both voluntary social and object touch in both *Fmr1*$^{-/-}$ and MIA mice, while there was no difference in healthy controls across conditions. We also observed that autism model mice demonstrate gaze avoidance during object and social touch, a behavioral phenomenon also observed in ASD individuals. We conclude that our novel social touch assay for mice shows a strong applicability for investigating maladaptive behaviors to social touch in models of autism. In the future, we intend to use Neuropixels silicon probes to record the activity of behaviorally relevant neuronal populations in the barrel field of primary somatosensory cortex (S1BF) and the basolateral amygdala (BLA) during social touch to correlate neuronal activity with behavioral changes in autism models.

Title: Human infant gut microbiomes may influence social behavior in mice

Authors: *H. DUBEY, A. WHITE, S. LIU, R. KNICKMEYER;
The Inst. for Quantitative Hlth. Sci. & Engineering, Michigan State Univ., East Lansing, MI

Abstract: Background: The gut microbiome has pleotropic effects on our body with recent research suggesting individual variation in gut microbiome composition may influence brain development and increase risk for some psychiatric and neurodevelopmental disorders. This includes work by our group showing that certain features of the infant gut microbiome are associated with fear reactivity. Given the observational nature of our human infant studies, it remains unclear whether the human infant gut microbiome causes individual differences in fear reactivity. To address this gap, the present study was undertaken to investigate whether transplant of gut microbiota from human infants into germ-free pregnant mice altered anxiety-related behaviors, social behaviors, and cognition in their offspring.
Methods: Pregnant Swiss-Webster germ-free mice were divided into four groups. Group 1 (BIF group) was inoculated with a mixed human fecal slurry derived from infants with relatively high levels of *Bifidobacterium*. Group 2 (BAC group), was inoculated with a mixed human fecal slurry derived from infants with relatively high levels of *Bacteroides*. Group 3 (SPF group) received fecal slurry from specific pathogen free mice (SPF group) and group 4 (GF group) received autoclaved fecal slurry from SPF mice. Offspring were assessed in the elevated plus maze (EPM), novel object recognition, and three-chamber sociability tests between 6-8 weeks of age. Both males and females were studied (N = 13, 6, 4, 7, 4, 4, 6, and 5 for BIF males, BIF females, BAC males, BAC females, SPF males, SPF females, GF males, and GF females, respectively).
Results: No statistically significant group differences were observed when males and females were combined. In sex stratified analyses, SPF male mice spent more time with the familiar mouse in phase 2 of the social interaction tests than BIF male mice (*$p<0.05$) or BAC male mice (**$p<0.01$), but all 4 groups spent a similar amount of time with the novel mouse. Germ free males appeared more similar to the SPF males, but did not differ significantly from any other group. Sex stratified analyses of the EPM and novel object recognition test did not indicate and significant group differences.
Conclusion: Results suggest that male mice carrying humanised infant gut microbiomes may

differ in their social behaviour compared with SPF and GF mice. Our next step will be to examine histopathological and imaging data from these mice to determine if behavioural changes are accompanied by changes in brain volumes, resting-state connectivity, myelination, and dendritic morphology.

Title: Toward Understanding the Molecular Basis of Prenatal Stress as an Environmental Risk Factor for Autism Spectrum Disorder

Authors: J. T. DUNN[1,2], **A. GUIDOTTI**[2], *D. R. GRAYSON[2];
[1]Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL; [2]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: It has long been posited that symptoms of autism spectrum disorder (ASD) may be the consequence of an imbalance of excitation and inhibition (E/I) in the brain. However, the E/I profile of neural substrates for ASD-relevant behavioral endophenotypes remains largely undefined on the molecular level with respect to the etiological risk factor of prenatal stress. We examined the behavioral and molecular endophenotypes of adult offspring of C57BL/6J dams subjected to prenatal stress during gestation. We chose to examine this genetic background as it is commonly used in the generation of preclinical models for the study of ASD. Pregnant C57BL/6J dams underwent three 45-minute restraint stress sessions per day from gestational day 9 to parturition. Male and female offspring of the stressed dams (PRS mice) and non-stressed dams (NS) underwent ASD-relevant behavioral testing in adulthood. The differential expression of genes related to excitatory and inhibitory neurotransmission was evaluated in the medial prefrontal cortex, amygdala, hippocampus, nucleus accumbens (NAc) and dorsal striatum of male PRS mice using qRT-PCR. Adult PRS mice demonstrated reduced sociability along with increased marble burying behavior relative to NS control mice. The PRS mouse behavioral phenotype coincided with aberrant expression of glutamate and GABA marker genes (e.g. Grin1, Grin2b, Gls, Gat1, Reln) in brain regions with putative involvement in social behavior. We tested drugs with known epigenetic properties (e.g. clozapine (5 mg/kg) + 18-hr washout) and observed the successful pharmacological rescue of the male PRS mouse sociability deficit. This result is consistent with the hypothesis that genes that govern sociability are epigenetically regulated. Analysis of the expression levels of genes relevant to epigenetic regulation using NanoString fluorescent barcoding indicated that those genes which encode enzymes that alter histone

methylation and acetylation revealed alterations in clozapine-treated PRS NAc samples compared to the NAc of vehicle-treated PRS mice. The identification of etiology-specific mechanisms underlying clinically relevant behavioral endophenotypes provides alternative targets for the development of novel pharmacotherapies for treating ASD.

Title: Development of the midbrain and social behavior in theMonodelphis domesticaanimal model

Authors: *I. PEREZ[1], E. I. ALANIZ[1], A. MENDIOLA[2], A. MAR[1], J. L. VANDEBERG[3], M. GIL[4];
[1]Psychological Sci., [2]Hlth. and Biol. Sci., [3]Sch. of Med. South Texas Diabetes and Obesity Inst. and Dept. of Human Genet., [4]Psychological Sci. and Inst. for Neuroscience, Sch. of Med., Univ. of Texas Rio Grande Valley, Brownsville, TX

Abstract: The Brazilian short-tailed opossum (*Monodelphis Domestica)* is an understudied animal model, compared to the *Mus musculus,* and has been identified as an ideal candidate for studying neurodevelopment (VandeBerg, & Robinson, 1997). *Monodelphis* is an ideal animal model to study neurodevelopment because the embryo develops outside the pouch of the mother providing easy noninvasive access to track changes across different developmental stages (Mate et al., 1994). Having this noninvasive access provides an opportunity to study natural midbrain development, which has implications for typical behavior and neurodevelopmental disorders. The objective of the present study is to compare the area and volume of the *Monodelphis* midbrain across four different developmental stages as well as describe any changes in behavior. We utilized Zen and ImageJ software to perform area analyses of different stages of brain development (Mironov, 2017). As expected, based on our preliminary results, the embryonic day 14 specimen had the smallest area in the midbrain, area= 27260.36 μm ^2, m= 381.376. At postnatal day 1 (~24 hrs after birth) the midbrain area increased to 49917.28 μm^2, m= 404.12; increases continued on postnatal days 6 and 27 to 81866.66 μm^2, m=166.016 and 98442 μm^2, m= 227.734, respectively. Dissections were also performed from the midbrain at two developmental time points, PND0 (at birth) and PND1 (24 h post-birth). Tissue was then lysed and protein extracted for spectrophotometry and western immunoblotting (WB), and ImageJ software was used to quantify band densities. We have determined that extraction of the midbrain from a neonate (PND1-5) yields approximately 1,000,000 cells. After adjusting with a

loading control, the WB procedure yielded a brighter band for a target protein tyrosine hydroxylase (TH) at PND0 (band density = 0.97) compared to PND1 (band density = 0.19). Thus, our data suggest that TH protein levels are highest at birth and then decrease over subsequent developmental time points. Regarding behavior, aggression appeared to increase as post-weaning pups matured to adolescence and young adulthood. Interestingly, in litters with fewer animals, there was decreased expression of aggressive behavior in later stages in comparison to the litter with the most animals. There was no significant difference in the means for general motor activity and social behavior. Our study provides support for the use of the *Monodelphis Domestica* for the study of early neurodevelopment and neurodevelopmental disorders. A future goal is to analyze glia and neuronal number across different early neurodevelopmental stages using stereological techniques.

Abstract: Non-human primate (NHP) models are critical for understanding typical development and alterations in social attention in neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD). The goal of this study was to characterize the developmental trajectories of

social attention neurocircuits in infant rhesus macaques and their behavioral correlates. Longitudinal brain structural MRI scans were acquired at 2, 4, 8, 12 and 24 wks in 31 male infant macaques (equivalent to 2-24 mos in human infants), and at 16 and 20 wks in 21 of the subjects, all living in social groups. T1- and T2-MRI images were acquired using a 3T MRI scanner and analyzed for volumetric changes in the ventral and dorsal attention networks (VAN: V1,V3, lateral intraparietal area -LIP-, frontal eye field -FEF-; DAN: V1, V3, temporoparietal junction -TPJ-, ventrolateral prefrontal cortex -vlPFC-), and other regions involved in social attention (i.e. caudal temporal parieto-occipital area -TPOc-; area PG associated region in the superior temporal sulcus -STS-). Measures of social visual attention were collected from a subset of subjects (n=11), using: (1) focal observations (ethogram), (2) rating scales of atypical social behaviors (juvenile macaque Social Responsiveness Scale -jmSRS-, adapted from the human SRS, widely used for ASD diagnosis), (3) measures of visual orientation / following / attention with the Schneider Neonatal Assessment for Primates (SNAP), and (4) eye-tracking measures of visual attention to social vs. nonsocial stimuli. Our results showed increased social ($F_{(5,14.695)}$=10.802; p=1.66x10^{-4}) and solitary play ($F_{(5,25.714)}$=10.792; p=1.10x10^{-5}) behaviors by 12 wks, when infants increase independence, exploration and social interactions. These changes were paralleled by region-specific changes in developmental trajectories of social attention neurocircuits, although the strongest volumetric growth was observed in most brain regions between 2 and 8-12 weeks. Our findings suggest that during the first 8-12 wks, social attention brain networks undergo rapid and robust structural changes that parallel important social behavior milestones (increased play and independence from mother) in infant macaques. The neural changes likely support the infant's adjustment to independence and refined attention to relevant social visual cues for appropriate social interactions in complex social environments. Understanding how normative social attention and underlying brain networks develop in a NHP model can help elucidate the roots of brain-behavior pathogenesis of human neurodevelopmental social derailments, such as those in ASD.

Title: Delay discounting but not probability discounting promotes choice inflexibility in males in a mouse model of 16p11.2 hemideletion

Authors: *G. R. ROJAS, L. S. CURRY-POCHY, A. T. HELLER, N. M. GRISSOM;
Univ. of Minnesota, Minneapolis, MN

Abstract: People with neurodevelopmental disorders have previously been demonstrated to have an impaired ability to associate actions with their outcomes (Sinha et al., 2014). 16p11.2 hemideletion is a copy number variant which is associated with the diagnosis of multiple neurodevelopmental diagnoses, including autism spectrum disorder, language disorder, and attention deficit hyperactivity disorder. Mice modeling hemideletion of the syntenic 16p11.2 region display altered reward-seeking behavior and concomitant changes in striatal neurobiology. However, it is unknown whether altered reward-seeking behavior reflect slower or more uncertain value updating, versus other factors such as impulsivity. We asked whether 16p11.2 hemideletion impacts the ability of mice to learn about choice contingencies in a series of discounting tasks, and how animals reduce uncertainty when introduced with different tasks. We had mice modelling 16p11.2 hemideletion undergo delay and probability discounting in order to observe how mice adapt to different types of incrementing costs. Our design of delay and probability discounting presented animals with two choices: a small immediate reward or a large delayed/risky reward. Animals learned that blocks of trials either started with no delay/risk but increased delay/risk as mice progressed through a session ("Worsening") or started with a large delay/risk but decreased delay as mice progressed throughout a session ("Improving"). We gave mice amphetamine during the last rounds of probability discounting in order to examine if mice shift choice according to the order of the task (St Onge et al., 2009). In our current results, we found male 16p11.2 hemideletion mice, but not female 16p11.2 hemideletion mice, preferentially choose to experience large delays to receive more reward, suggestive of slower value updating, but not choice impulsivity per se. As training continued, male 16p11.2 hemideletion mice adjusted to delays with increased training, indicating long-term adaptation to shifting schedule demands. We are currently examining if animals exhibit differences in how they explore the chamber during different choice epochs.

Title: Murine influenza A virus disrupts immune profiles in the maternal gut and placenta but not the fetal brain

Authors: *A. M. OTERO[1], A. M. ANTONSON[2];
[1]Neurosci. Program, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Animal Sci., Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Maternal immune activation (MIA) during pregnancy is linked to neurodevelopmental disorders, such as schizophrenia and autism, in offspring. The majority of animal models initiate MIA using pathogen mimetics, which induce a controlled innate immune response. In this study, we use a mouse model of live H3N2 influenza A virus (IAV), which is moderately pathogenic and activates both innate and adaptive immune responses. As respiratory IAV infection is known to cause downstream immune dysregulation in the intestine, we hypothesized that this would contribute to inflammation in the fetus. Small intestine, placenta, and fetal brains were collected from C57BL/6NTac mice on gestational day 17, seven days post inoculation (dpi) with IAV (n=17) or saline (n=15), across four identical replicates. Despite no detectable virus in the small intestine, respiratory IAV infection upregulated the gene encoding RORγt, the main transcription factor for T_H17 and ILC3 cells of type III immunity. RORγt$^+$ type III immune cells release pro-inflammatory IL-17 cytokines, which are implicated in MIA-driven developmental abnormalities. However, transcription of *Il17a*, *Il17f*, and *Il17ra* was unaltered in maternal intestinal tissue regardless of treatment, as was production of IL-17A protein. To investigate if IAV-induced MIA impacted the fetus, we looked at immune profiles in the placenta and fetal brain. The placenta, which acts as a physical and immune barrier between dam and fetus, demonstrated altered immune profiles in infected dams. However, neuroinflammatory genes in the fetal brain were not significantly different between groups. Our results demonstrate that a moderately pathogenic IAV infection upregulates type III immune cells in the maternal gut at seven dpi with no significant difference in IL-17 production. Furthermore, changes in the placental immune response, but not fetal, suggest the placenta remains a resilient barrier during moderate maternal infection. Our data confirm the necessary use of live pathogens in MIA modeling to evaluate the complete immune response and improve translation to the clinic.

Title: Effect of genetic background in a mouse model of autism due to ASH1L mutation

Authors: *C. M. PAPENDORP[1], D. A. HAQUE[1], L. A. GOICOURIA[1], J. S. LIU[2];
[1]Neurosci., [2]Neurol., Brown Univ., Providence, RI

Abstract: Autism spectrum disorder (ASD) is a heterogenous condition with a broad spectrum of severity. While most studies of ASD use targeted disruption of a single gene, in affected humans, multiple genetic interactions are likely at play. Absent, small, or homeotic-like (ASH1L) is a highly penetrant ASD-associated gene. Humans with ASH1L mutations have variable phenotypes: while some may have mild ASD/intellectual disability (ID) and few other symptoms, others have severe ID, no verbal communication, intractable seizures, and multiple congenital anomalies. To study how loss of ASH1L leads to ASD, I use mice with a gene-trap (gt) mutation in ASH1L, rendering the mice hypomorphic for ASH1L. Previous studies have reported that homozygous loss of ASH1L is lethal at birth. I find that on an inbred C57BL/6J background, homozygous ASH1L$^{gt/gt}$ die around weaning age ($p = 0.0025$ at P21, Chi squared test for expected versus observed allelic frequencies, n = 61 mice from 10 litters). This lethality reflects the fact that humans are heterozygous for ASH1L mutations. However, when backcrossed three times to the outbred CD1 strain, I discovered that ASH1L$^{gt/gt}$ mice survive to adulthood at normal Mendelian ratios (no difference by Chi squared test at P21, n = 68 mice from 9 litters). While previous studies on a C57BL/6J background had reported that ASH1L is required for fertility in mice, on a CD1 background, ASH1L$^{gt/gt}$ mice are fertile and bear offspring. Motivated by the association of ASH1L with ASD, I examined neuroanatomical phenotypes caused by loss of ASH1L. While BL/6 ASH1L$^{gt/gt}$ mice are microcephalic, CD1 ASH1L$^{gt/gt}$ may be microcephalic or macrocephalic. To see if changes in brain size are accompanied by differences in neuronal morphology, I performed Golgi staining in 2-month-old mice. While ASH1L$^{gt/+}$ mice on a BL/6 background have normal morphology of layer V pyramidal cells compared to BL/6 wild type, ASH1L$^{gt/gt}$ mice on a CD1 background have decreased soma size and fewer intersections by Sholl analysis compared to CD1 wild type (n = 6 mice per genotype/background, 3 or more cells per mouse). Because about 30% of people with ASH1L mutations have seizures, I also examined differences in seizure frequency and baseline EEG power spectra between ASH1L mutant and wild type mice on the BL/6 and CD1 backgrounds (n = 6 mice per genotype/background). Overall, I find striking effects of genetic background on lethality, fertility, and brain structure and function in a mouse model of ASD due to ASH1L mutations. This study underscores the importance of considering genetic background in mouse studies of ASD and provides clues about the wide spectrum of severity in ASD due to ASH1L mutations.

Title: Neuro-immune signatures in chronic low back pain subtypes

Authors: *Z. ALSHELH[1], L. BRUSAFERRI[1], A. SAHA[1], E. MORRISSEY[1], P. KNIGHT[1], M. KIM[1], Y. ZHANG[2], J. HOOKER[1], D. ALBRECHT[1], A. TORRADO-CARVAJAL[1], M. PLACZEK[1], O. AKEJU[2], J. PRICE[1], R. EDWARDS[3], J. LEE[1], R. SCLOCCO[1], C. CATANA[1], V. NAPADOW[1], M. L. LOGGIA[1];
[1]Dept. of Radiology, Athinoula A. Martinos Ctr. for Biomed. Imaging, [2]Dept. of Anesthesia, Critical Care and Pain Med., Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [3]Dept. of Anesthesiology, Perioperative and Pain Med., Brigham and Women's Hospital, Harvard Med. Sch., Boston, MA

Abstract: We recently showed that patients with different chronic pain conditions demonstrated elevated brain and/or spinal cord levels of the glial marker 18kDa translocator protein, which suggests that neuroinflammation might be a pervasive phenomenon observable across multiple etiologically heterogeneous pain disorders. Interestingly, the spatial distribution of this neuroinflammatory signal appears to exhibit a degree of disease specificity, suggesting that different pain conditions may exhibit distinct “neuroinflammatory signatures”. To explore this hypothesis, we tested whether neuroinflammatory signal can characterize putative etiological subtypes of chronic low back pain patients based on clinical presentation. Specifically, we explored neuroinflammation in patients whose chronic low back pain either did or did not radiate to the leg (i.e., “radicular” vs. “axial” back pain). Fifty-four chronic low back pain patients, twenty-six with axial back pain (43.7±16.6 y.o. [mean±SD]) and twenty-eight with radicular back pain (48.3±13.2 y.o.), underwent PET/MRI with [^{11}C]PBR28, a second-generation radioligand for the 18kDa translocator protein. [^{11}C]PBR28 signal was quantified using standardized uptake values ratio. Functional MRI data were collected simultaneously to the [^{11}C]PBR28 data 1) to functionally localize the primary somatosensory cortex back and leg subregions and 2) to perform functional connectivity analyses. PET and functional MRI measures were compared across groups, cross-correlated with one another and with the severity of “fibromyalgianess”. Furthermore, statistical mediation models were employed to explore possible causal relationships between these three variables. For the primary somatosensory cortex representation of back/leg, [^{11}C]PBR28 PET signal and functional connectivity to the thalamus were: 1) higher in radicular compared to axial back pain patients, 2) positively correlated with each other and 3) positively correlated with fibromyalgianess scores, across groups. Finally, 4) fibromyalgianess mediated the association between [^{11}C]PBR28 PET signal and primary somatosensory cortex-thalamus connectivity across groups.Our findings support the

existence of “neuroinflammatory signatures” that are accompanied by neurophysiological changes, and correlate with clinical presentation in chronic pain patients. These signatures may contribute to the subtyping of distinct pain syndromes and provide information about inter-individual variability in neuro-immune brain signals, within diagnostic groups, that could eventually serve as targets for mechanism-based precision medicine approaches.

Title: Panaxytriol inhibits lipopolysaccharide induced microglia activation

Authors: G. HIRAMATSU[1], *D. UTA[1], K. MIHARA[2], T. KUME[1];
[1]Dept. Applied Pharm, Univ. Toyama, Toyama, Japan; [2]Kim's Korean Ginseng Co. Ltd, Kyoto, Japan

Abstract: Introduction: In neurodegenerative diseases, brain inflammation is triggered, and activated microglia produce inflammatory mediators that damage surrounding neurons. Therefore, suppression of activated microglia can be an effective therapeutic target in neurodegenerative diseases. Then, we focused on panaxytriol, an Nrf2 pathway activator contained in *Panax ginseng* extracts, as an inhibitor of activated microglia. Since the effect of panaxytriol on microglia activation has not been revealed so far, we investigated its effects of the lipopolysaccharide (LPS)-induced microglia activation both *in vivo* and *in vitro*. Methods: C57BL/6Ncr mice intracerebroventricularly injected LPS were used as a brain inflammation mouse model. Panaxytriol was simultaneously administrated with LPS. We performed immunostaining and measured spontaneous behavior activity. BV-2 cell was utilized *in vitro* study and nitric oxide (NO) production was detected as an index of activation by griess assay. The expression levels of the inflammatory cytokine mRNA and protein were detected by real-time PCR and Western blotting, respectively, and translocation of NF-κB to the nucleus was detected by immunocytochemistry. Results: In a brain inflammation mouse model induced by

LPS, Iba1 positive cells were increased and morphological change of Iba1 positive cells were observed. GFAP positive fluorescence intensity was increased. Spontaneous behavior was decreased. Simultaneous intraventricular injection of panaxytriol with LPS suppressed the increase of Iba1 positive cells, morphological change, and the increase of GFAP positive fluorescence intensity. Similar to the response to LPS, microglia were more sensitive to panaxytriol than astrocytes. Therefore, we investigated the mechanism of inhibitory effect of panaxytriol on microglia activation. In BV-2 cell, LPS increased NO production and iNOS expression. Panaxytriol suppressed the increase of NO production and iNOS expression by simultaneous treatment with LPS. In addition, panaxytriol suppressed the increase of proinflammatory cytokine mRNA expression induced by LPS. To investigate the mechanism of inhibitory effect of panaxytriol on microglia activation, we investigated the involvement of the MAPK pathway. Panaxytriol treatment had no effect on MAPK pathway. Panaxytriol suppressed the translocation of NF-κB into nucleus induced by LPS. Conclusion: These results suggested that panaxytriol suppressed microglia activation by suppressing the NF-κB signaling pathway. Taken together, panaxytriol can inhibit brain inflammation and may be useful as a therapeutic agent against neurodegenerative diseases.

Title: Impact of neonatal opioid exposure and withdrawal on the adult innate immune response in female mice

Authors: *C. LEMCHI[1], C. J. BROWN[2], J. R. FERRANTE[1], J. E. MENGAZIOL[1], A. D. DUNN[1], J. A. BLENDY[1];
[1]Systems Pharmacol. and Translational Therapeut., Univ. of Pennsylvania, Philadelphia, PA; [2]Hamilton Col., Clinton, NY

Abstract: Every year, thousands of pregnant women are prescribed prescription pain relievers, resulting in prenatal exposure to opioids. Babies born to an opioid-dependent mother experience neonatal opioid withdrawal syndrome (NOWS); a combination of somatic withdrawal symptoms including high pitched crying, sleeplessness, irritability, gastrointestinal distress, and in the worst cases, seizures. The long-term effects of chronic morphine treatment during early life are not

well characterized, particularly the effect on microglia activation and neuroinflammation. Determining the impact of neonatal opioid exposure and withdrawal on the innate immune response in adulthood will lead to new understanding and therapy of NOWS. We developed a novel morphine exposure and withdrawal paradigm to test if opioid exposure, over the human equivalent of all three trimesters, dysregulates the neuroimmune response to opioids, either at birth or later in adulthood. Female mice (n=34) were exposed to either morphine or saline during embryonic development (E0-E21) and treatment was continued via injections upon birth to postnatal day 14. On PND 15, 24 h after the final morphine or saline injection, pups showed significant signs of withdrawal including somatic signs, increases in ultrasonic vocalizations and thermosensitivity. In addition, several immune-related mediators are elevated in cortex, including complement component 1q (C1q), a protein complex which is part of the innate immune system. C1q elevation in newborn mice might have functional relevance for the development of long-term consequences of NOWS due to its role in synaptic pruning, however whether this elevation persists in adulthood is not known. Further, elevation of C1q has not been reported in adults after exposure to opioids. We found that elevation of C1q is not maintained in adulthood, following chronic morphine exposure (PND 90-595), but we see a significant downregulation of expression in cortex following an exposure paradigm of escalating doses of morphine (20-100 mg/kg for 5 days; which induces dependence as evidenced by withdrawal symptoms in adults. These finding reveal disordered neuroimmune regulation in female mice exposed to NOWS, suggesting susceptibility to autoimmune disorders or reoccurring infections later in life, and aid in providing important targets for the development of rational treatment approaches for NOWS.

Title: Cultured microglia exhibit time-dependent recovery after ethanol exposure

Authors: *B. BISHOP, C. KEISLING, A. HARMSWORTH, D. DONLEY;
Harding, Searcy, AR

Abstract: Microglia are central nervous system-resident immune cells that activate in response to dyshomeostasis. Upregulation of phagocytosis and the release of inflammatory cytokines are

two markers of activation. Ethanol has been identified as a cause of microglial activation. Therefore, an examination of the microglial responses to ethanol contributes to a better understanding of microglia function during insult. Published research demonstrates that microglial cells exhibit decreased phagocytosis and increased inflammatory cytokine production in response to ethanol exposure. While an increase in cytokine production is consistent with activation, decreased phagocytosis is indicative of microglia damage. Ethanol exposure is typically transient as compared to other activating signals such as misfolded proteins in neurological disorders. The long-term effects of ethanol exposure and their ability to recover after simulation is not well understood. To model the transient nature of ethanol exposure, we treated immortalized mouse microglial cells with 25 mM or 100 mM ethanol for two hours in the same plate as control cells. To measure activation, phagocytosis was quantified by engulfment of fluorescent latex beads, tumor necrosis factor-alpha (TNF-a) production was measured by ELISA, and metabolism was measured using a Seahorse XF-HS metabolic analyzer. Data was analyzed using an ANOVA. We found that microglial phagocytosis is impaired, metabolic capacity is altered, and TNF-a is increased by two-hour ethanol exposure. To address the ability of cells to recover after ethanol exposure, we changed the culture media after the two-hour stimulation and allowed cells a recovery period of 0, 12, or 24 hours. Our data suggests partial, time-dependent recovery upon removal of ethanol marked by a recovery of phagocytosis. We found that markers of inflammation including TNF-alpha production and glycolytic flux indicate a low-level activation that resolves over time, but in the absence of changes in cell proliferation. Together, these data suggest that cells are recovering and not being replaced. Future studies aim to explore the mechanism(s) of recovery and will contribute to the understanding of the dynamic responses of microglia during dyshomeostasis.

Title: Myeloperoxidase is a pro-oxidant enzyme in microglial cells that shapes the response to extrinsic stimuli

Authors: *S. EWING[1], D. DONLEY[2], A. WILCOX[1], B. BISHOP[1];
[2]Biol., [1]Harding Univ., Searcy, AR

Abstract: Microglial cells are the resident immune cells of the central nervous system. Reactive oxygen species (ROS) are highly reactive molecules that result from cellular metabolism and participate in cell signaling. In microglia, excess ROS causes oxidative stress, which is hypothesized to promote neurodegenerative diseases. The pro-inflammatory enzyme myeloperoxidase (MPO) is a known pro-oxidant enzyme in immune cells such as neutrophils but has not been widely studied in microglial cells. In addition, buildup of the Alzheimer's Disease-associated protein, beta-amyloid (Abeta) is associated with oxidative stress on microglia. However, the link mechanism(s)of how oxidative stress associated with Abeta develops in microglia are still not fully understood. Abeta is predominantly found in 2 forms: AB-40 and AB-42. AB-42has been found to be more toxic than AB-40. The goal of this study was to determine the impact of myeloperoxidase on the development of microglial oxidative stress in response to extracellular Abeta. To measure ROS, cultured microglial cells were stained with the fluorogenic dye, DCFDA, that detects ROS. Following staining, the cells were either treated with HBSS (as a control) or treated with hydrogen peroxide (as an ROS generator). After treatments, myeloperoxidase inhibitor-I was added to half of the samples. Data was continuously collected for two hours following initial treatment. Results show that the MPO inhibitor decreases the production of reactive oxygen species in hydrogen peroxide-treated microglial cells when compared to controls. These data indicate that myeloperoxidase could account for a major portion of the oxidative stress in microglial cells during neurological diseases. When microglia are exposed to toxic substances, such as AB 40 or 42, they produce inflammatory cytokines, such as Tumor necrosis factor alpha (TNFa). An ELISA assay was used to measure cytokine production. Inhibiting myeloperoxidase decreased cytokine production significantly across all samples indicating that myeloperoxidase could account for the majority portion of TNF-a production in microglial cells in response to pro-inflammatory stimuli. Given the connection between ROS and metabolism, we also measured the impact of MPO inhibition on the metabolic activity of microglia. Direct injection of a MPO inhibitor into control and AB 40or 42 treated cells increased glycolysis and decreased oxidative phosphorylation. However, MPO inhibition had a larger effect on control cells than cells stimulated with Abeta. Together these data show that myeloperoxidase impacts the oxidative state of the cell and participates in their response to external stimuli.

Title: Changes to microglial cell morphology in response to early post-natal environment as seen in a rodent model of Necrotizing enterocolitis (NEC)

Authors: V. CHAWLA[1], L. C. SIEBOLD[2], *C. G. WILSON[3];
[1]Neonatal-Perinatal Med., [3]Lawrence D. Longo MD Ctr. for perinatal biology, [2]Loma Linda Univ., Loma Linda, CA

Abstract: NEC presents with high mortality and neuro-developmental impairment in neonates. Gut-brain interactions may be key to NEC-related neuroinflammation and microglial cells in the CNS are key elements of neuroinflammation. Microglial morphology has a phenotypical spectrum, ranging from ramified to ameboid forms determined by micro-environment and patho-physiologic state. Microglia transition from ramified to more ameboid shapes in acute inflammatory states. Morphometric differences have the potential to differentiate and measure inflammation/restorative states when studying the effects of NEC on the brain. We hypothesized that microglial cells in the brainstem of rat pups with NEC have a compact, pro-inflammatory phenotype, compared to larger, ramified microglial cells in healthy rat pups.We compared two groups, 1) Healthy full-term breastfed rat pups housed with the dam and 2) NEC exposed pups delivered prematurely on embryonic day 21 via C-section and exposed to a NEC protocol that included repetitive hypothermia, hypoxia, lipopolysaccharide and hyperosmolar feeds. Intestinal injury was graded based on villous damage. Brainstems were removed, stained for IBA1, and analyzed using *ImageJ*. NEC incidence in the exposure group was 45% (n=38). Exposed rat pups had smaller brains compared to breastfed pups ($p<0.05$, n=50). Microglia in brainstems of breastfed pups had larger hull area, span, perimeter, bounding circles, radii, and increased "roughness" suggesting a resting (non-inflammatory) state compared to denser, compact (pro-inflammatory) microglia in NEC-exposed pups ($p<0.05$, n=170). We saw no correlation between brain size and microglia size suggesting that microglial cell parameters are independent of brain weight. Exposure to early postnatal risk factors was associated with smaller brains—emphasizing the importance of early developmental windows in long-term neurological outcomes. NEC-exposed microglia showed significant reduction in cell ramification and increased circularity indicating brainstem inflammation begins early postnatally.

Title: Cortical microglia gene and protein expression changes in human alcohol use disorder suggest shifts in microglial phenotype

Authors: *L. QIN, R. P. VETRENO, F. T. CREWS;
Bowles Ctr. Alcohol Studies, Sch. Med, Univ. North Carolina, Chapel Hill, NC

Abstract: Microglia are essential for CNS homeostasis, synapse regulation, and innate immune signaling that could contribute to neuroplasticity and neurodegeneration. Microglial genes and proteins were determined in orbital frontal cortex (OFC) of individuals with alcohol use disorder (AUD) and age-matched moderate drinking controls using RT-PCR and immunohistochemistry (IHC). In AUD OFC, we found significant increases in mRNA levels of microglial markers CD11b (207%) and CX3CR1 (337%). However, Iba1, CD68, and P2RY12 mRNA were not changed. Microglial marker protein assessment using IHC revealed increases in Iba1+ (13-fold), CD68+ (4-fold), CD11b+ (Mac1: 1.4-fold; OX42: 2-fold), CX3CR1+ (3-fold), and P2RY12+ (2-fold) immunoreactivity in the AUD OFC, compared to control subjects. Microglia in alcoholic

brain showed varied morphologies, including enlarged cell bodies, intensified staining, and activated morphology. In contrast, the microglial marker TMEM119, which is widely used in transgenic mice, was reduced in AUD OFC. TMEM119 mRNA and protein (IHC) were reduced by 47% and 51% in the AUD OFC, relative to controls. TMEM119 microglial morphology is ramified, similar to morphology associated with resting-trophic microglia. This differs from most other markers. Control TMEM119+IR cells show a ramified morphology that in AUD is faint with fewer cells. The six other microglial markers (Iba1, CD68, Mac1, OX42, CR3CR1, and P2RY12) show dark staining rounded microglial morphology associated with activation. These data are consistent with shifts in microglial phenotype from a resting state to an activated state with associated changes in gene expression, including loss of TMEM119 expression and morphological phenotype. AUD altered microglia may contribute to changes in synapses and neurocircuitry associated with AUD-induced changes in brain function.

Title: Complement proteins and myeloid cells support optic nerve regeneration via myelin clearance

Authors: *S. L. PETERSON, K. A. WONG, C. SUN, A. CATACORA, L. I. BENOWITZ; Boston Children's Hosp., Boston, MA

Abstract: Axon regenerative failure in the mature CNS contributes to functional deficits following traumatic injuries, ischemic injuries, and neurodegenerative diseases. Although neuro-immune interactions modulate many CNS functions, potential contributions of the classical complement cascade and myeloid cells to CNS axon regeneration (or its failure) are largely unknown. We recently reported (SfN 2017) that genetic deletion of complement C1q, C3, or CD11b (CR3) attenuates retinal ganglion cell (RGC) axon regeneration following experimental mouse optic nerve injury (ONI), suggesting that complement proteins and $CR3^{+}$ myeloid cells are each required for axon regeneration. However, the underlying mechanisms for this

regeneration effect remained unclear. The classical complement cascade is initiated by C1q, and C3b is a downstream opsonin that binds to CR3 receptor on myeloid cells (resident microglia, infiltrating monocytes, neutrophils) to induce phagocytosis. In the current study, we characterized the complement and myeloid cell response to ONI, and tested the hypothesis that complement and phagocytic myeloid cells support RGC axon regeneration by altering the local environment of the injured optic nerve. To achieve this, we performed protein and molecular analyses (markers: C1qa, C3, CD11b, Iba1/Aif1, CD68, CD206, CD45, P2RY12, MBP) on optic nerves and retinas from mice with and without ONI (uninjured, 1d, 3d, 5d, 7d, 14d), and with and without complement manipulation ($CR3^{-/-}$, $CR3^{+/+}$, WT, anti-C1q, IgG). Our data show that classical complement proteins C1q and C3 and $CR3^{+}$ myeloid cells each increase markedly near the ONI site. Further, axon regeneration results from local injections of C1q function-blocking antibody experiments confirmed that complement acts primarily within the optic nerve to support axon regeneration. In the optic nerve, we observed an MBP-negative area that expanded from the injury site over time and closely corresponded to an area that was densely populated with $CR3^{+}$ and $CD68^{+}$ myeloid cells, including some that contained internalized MBP. Interestingly, this region also contained an increased density of regenerating axons. Finally, our data indicate inefficient myelin clearance (increased myelin debris remaining near the ONI site) in $CR3^{-/-}$ mice compared to $CR3^{+/+}$ controls. Collectively, these results suggest that classical complement proteins and myeloid cells act within the optic nerve to support RGC axon regeneration through phagocytic removal of growth-inhibitory myelin debris. These results emphasize the importance of the axonal compartment and highlight a beneficial role for the innate immune response in CNS repair.

Title: Transcriptome & Mitochondrial Analysis of ASD Children Compared to Healthy Controls

Authors: *M. CANNON[1], S. GANESHAN[2], V. ALVAREZ[3], M. VUYISICH[4], G. BANAVAR[4];
[1]Northwestern, Chicago, IL; [2]MitoSwab Religen, Plymouth Meeting, MA; [3]CES, Medellin, Colombia; [4]VIOME, Los Alamos, NM

Abstract: Autism has been described as a gastrointestinal and neurological condition that is represented by impairments in language and social situations. Recently reported increases in the occurrence of Autism Spectrum Disorder (ASD) have resulted in increased research into the environmental differences between areas with a high occurrence, as in the “Western” diet populations, and a more locally derived diet population, wherein the rate appears to be significantly less. Thirty autistic children (USA) ages 6 to 21, were sampled at three different intervals: prior to any intervention, post-xylitol intervention, and post-probiotic intervention. The sampling consisted of buccal swabs for Mitoswab testing, and saliva for metatranscriptomics to determine the entire range of microorganisms and the metabolome. In addition, a “Blue Zone” subject component that included 30 Colombian children, ages 6-16, and who were healthy and within normal behavior standards, also had buccal swabbing and salivary sampling performed for comparison. Their saliva samples were analyzed metatranscriptomically and artificial intelligence was utilized to discern important differences in the microbiome that included bacteria, archaea, fungi, and viruses, and microbial functions. Significant differences were noted, and also seen in the temporal data, demonstrating shifts that may have been precipitated by the interventions, with both the probiotics and the polyols. Particular bacterial strains were significantly more prevalent in the autism subject group including a strain that reduces neurotransmitters by enzymatic degradation. This provided supporting evidence to the hypothesis that the occurrence of autism may also be influenced by low Gamma Amino Butyric Acid (GABA) levels during development. Also, of interest was the un-expected finding that verbal skills dramatically increased in 6 of the 30 ASD subjects following xylitol supplementation.

Title: Genetic susceptibility and high fat diet-induced obesity underlie changes in neurobehavior, white matter microstructure, and hippocampal metabolites in C57Bl/6 mice

Authors: W. ZENG[1], T. CHU[1], J. GAO[1], E. GOZAL[1], R. JAGADAPILLAI[1], G. N. BARNES[2], ***J. CAI**[1];
[1]Pediatrics, [2]Neurol., Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: Introduction: Accumulating evidence indicates that obesity-related cognitive deficits and mood disorders are associated with white matter (WM) impairment. Increased energy intake and reduced high-fiber food consumption (*e.g.* high fat diet, HFD), as well as genetic susceptibility, are major driving forces for the epidemic of obesity. It remains unclear whether HFD or genetic susceptibility plays a significant role in obesity-relevant brain complications. C57BL/6J mice, but not C57BL/6NJ mice, develop impaired glucose homeostasis control and reduced insulin secretion due to a natural deletion of nicotinamide nucleotide transhydrogenase exons, thus may be particularly proned to HFD-induced effects. Therefore, we adopted C57BL/6J and C57BL/6NJ mice to evaluate the gene-environment interaction on neurofunction, WM integrity, and brain metabolites. We hypothesized that diet and genetic susceptibility exert diverse effects on impairments of neurofunction, WM integrity, and brain metabolism. Methods: 3-week-old male C57BL/6J and C57BL/6NJ mice were fed a normal-fat diet or a HFD for 12 weeks or 24 weeks. Body weight (BW) and non-fasting blood glucose were monitored weekly. Fasting glucose and intraperitoneal glucose tolerance test were performed before sacrifice. Behavioral tests, including elevated plus maze, open field, Y-maze, object recognition test, and object location tasks, were conducted. WM microstructure and hippocampal metabolites were assessed by diffusion tensor imaging and magnetic resonance spectroscopy. All data are presented as mean ± SD and analyzed by two-way ANOVA with diet-by-strain interaction. Significance was set at $p<0.05$. Results: HFD exposure increased BW but reduced glucose intolerance in both strains, suggesting that the decrease in glucose intolerance was independent from their genetic differences. Short-term HFD exposure induced anxiety-like behavior only in C57BL/6J mice; while long-term HFD exposure caused cognitive decline in both strains. Decreased fractional anisotropy and increased radial diffusivity were observed in genu corpus callosum for both strains after long-term HFD exposure, suggesting a compromised WM integrity elicited by HFD. Both short- and long-term HFD exposures significantly elevated the myo-inositol and choline to creatine ratios in hippocampus for both strains, indicating glial activation and inflammation in the brain. Conclusions: HFD causes impairments in glucose intolerance, cognition, callosal WM integrity, and hippocampal metabolism. Diet-by-strain interaction exerts adverse effect on anxiety-like behavior.

Title: Neonatal sepsis leads to ependymal cell injury and a loss of subventricular zone neurogenesis

Authors: *A. A. EPSTEIN[1], B. RIKARD[2], V. JAIN[3], A. S. CHAO[1], K. ABDI[2], N. YOUNGE[1], K. PEGRAM[1], S. GREGORY[3], E. J. BENNER[1];

Abstract: Preterm neonates are at high risk of brain injury leading to neurodevelopmental impairments. Prematurity-specific mechanisms of neonatal neurological disease are not well-defined and no therapies are available at this time. The subventricular zone (SVZ) is part of the germinal matrix critical for postnatal brain development. The SVZ includes multiciliated ependymal cells forming a barrier between the cerebral spinal fluid and neural stem cell niche. Notably, high rates of neurodevelopmental impairments are associated with complications of premature birth, including necrotizing enterocolitis and bowel perforations. Our laboratory has developed a clinically relevant rodent model where experimental bowel perforation on postnatal day 5 (P5) lead to neonatal sepsis that replicates brain injuries seen among preterm-born infants. These injuries include white matter injury as well as motor deficits. In this study we aim to describe neural stem cell niche responses to neonatal sepsis in the animal model. We employed single cell transcriptomics to demonstrate broad shifts in SVZ ependymal, glial, and neural progenitors in septic mice compared to littermate controls. qPCR was utilized to measure localized inflammatory cytokine production. Immunohistology (IH) of SVZ whole mount and primary ependymal cell cultures were used to validate observations from transcriptomic data. Single cell transcriptomics identified changes in the SVZ with increased frequency of inflammatory cells and decreased progenitor populations and ependymal cells following 2 days of sepsis. IH confirms sepsis-induced localized periventricular microglial activation. IH of SVZ whole mounts confirms ependymal cell degeneration using FoxJ1-EGFP tg-mice expressing green fluorescence protein in ependymal cells, as well as broad loss of cilia visualized using electron microscopy. Sepsis leads to increased mRNA expression of IL-1 and TNFalpha in SVZ compared to control littermates. NFκB-specific signal transduction and cytokine expression follows LPS stimulation of ependymal cells in culture, thus replicating ependymal cell activation in vitro. Our animal data suggests that inflammation and sepsis lead to an injury impacting the neural stem cell niche during a critical time of neurodevelopment. This previously undescribed injury may be an important molecular mechanism linking sepsis and poor neurodevelopmental outcomes in human infants.

Title: Alteration of glycosphingolipid levels and its implications on neuroinflammation

Authors: *A. CHEONG, S. RYAN, L. LEE, D. OFENGEIM, J. PROTO;
Rare and Neurologic Dis. Res., Sanofi, FRAMINGHAM, MA

Abstract: Glycosphingolipids (GSLs) are one of the most abundant lipid molecules in the CNS. Synthesized within the Golgi, the conversion of ceramide to glucosylceramide (GL1), the major precursor of complex GSLs, is the rate-limiting step of the GSL biosynthesis pathway. GSLs can modulate a variety of cellular functions including cell proliferation, signal transduction, and glial cell activation and GSL dysregulation is implicated in numerous human inflammatory and metabolic diseases. While murine models of CNS disease have been used to understand various aspects of lipid biology and nervous system homeostasis, human-cell based systems are critical for advancing therapeutics. In particular, a better understanding GSL biology in the context of neuroinflammation is critical for generating precise therapeutics for neuroinflammatory disorders. In this study, we employed an *in vitro* iPSC-derived triculture system composed of astrocytes, neurons, and microglia to examine the effect of acute inhibition of GL1 synthesis during homeostatic and inflammatory conditions. We performed RNA sequencing analysis to examine the impact of GSL modulation in both an acute setting and after immune activation by endotoxin. Following immune activation of the tri-culture system, the data show global transcriptional changes including the induction of interferon-related (*ISG15*, *SOCS1*) and HLA class II (*HLA-DRB1, HLA-DQB1*) genes. Multiple synaptogenesis related (*VAMP2*, *SYN1*, and *GRM2*) gene expression levels were also altered indicating an impact on neuronal functions. In the absence of inflammatory stimuli, acute reduction of GL1 synthesis had only modest effects on gene expression compared to vehicle alone. However, GL1 inhibition subsequent to endotoxin stimulation resulted in profound gene expression changes. This included marked downregulation of genes related to synaptogenesis and cytoskeletal signaling. Taken together, this data supports the use of human iPSC-derived triculture systems as models for interrogating cell-cell interactions under healthy (homeostatic) and disease (inflammatory) conditions. Furthermore, this study underscores the importance of including neuro-immune perturbations in these types of models. Acute reduction of GL1 reflected the importance of achieving balanced glycosphingolipid levels when exposed to inflammatory stimulus and further signified the importance of glycosphingolipids in maintaining a balanced intracellular metabolic homeostasis in the CNS. A better understanding of this relationship will give rise to new opportunities for developing precise therapeutics towards inflammatory and metabolic diseases.

Title: Fibrosis of PDGFRβ+ cells following spinal cord demyelination is exacerbated with age

Authors: *B. LOZINSKI, Y. DONG, E. JELINEK, W. YONG;
Clin. Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: The process of remyelination is the endogenous response in demyelinating diseases such as multiple sclerosis (MS). However, in people with MS remyelination is heterogeneous and often insufficient for functional recovery. Remyelination failure is known to be a result of aging and of the inhibitory lesion environment. Fibrosis of the CNS following immune mediated injury has recently been shown to effect the glial cell response. Fibroblasts are a possible source of CNS fibrosis and produce collagen that is capable of impairing oligodendrocyte progenitor cell migration. Other stromal cells found in the CNS, such as pericytes and smooth muscle cells, have also been suggested to both respond to demyelination and produce various other extracellular matrix (ECM) molecules including laminins and proteoglycans. However, it is unclear how fibrosis affects remyelination, and if fibrosis impairment of remyelination worsens with age. We hypothesize that PDGFRβ+ cells responding to demyelination form a fibrotic scar that is inhibitory to oligodendrocyte lineage cells and this is exacerbated with age. To test this hypothesis, we used the lysolecithin model to demyelinate the ventral white matter of the spinal cord in young (2-3 months) and middle-aged (12 months) mice. PDGFRβ+ cells formed a scar area by 7 days post induction (dpi); the scar area persisted throughout the lesion site up to 21 dpi. Cells of the oligodendrocyte lineage were scarce in areas occupied by PDGFRβ+ cells at all time points. In middle-aged mice, the scar area was larger than in young mice and corresponded with reduced oligodendrocyte repopulation. Oligodendrocyte lineage cells were determined by Olig2+PDGFRα+ for OPCs, and Olig2+CC1+ for mature oligodendrocytes. Collectively, age was found as a significant factor that influenced the response of PDGFRβ+ fibrotic cells following demyelination and the scar area they formed were less hospitable to oligodendrocyte lineage cells. Further studies are needed to determine how this response impairs remyelination and if it can be targeted for therapeutic intervention.

Title: Spontaneous Remyelination in the regenerating optic nerve

Authors: *S. DE LIMA[1], T. ZHANG[1], N. P. BISCOLA[2], N. ZHANG[4], L. A. HAVTON[3], P. A. ROSENBERG[5], L. I. BENOWITZ[6];

Abstract: In the past 10 years, several groups have achieved appreciable optic nerve regeneration by activating the growth potential of mature retinal ganglion cells (RGCs). We previously showed that, with appropriate stimulation, some RGCs can extend axons from the eye to subcortical visual target areas (de Lima et al., PNAS, 2012), and that some regenerating axons become myelinated and re-establish the electrically excitable domains required for action potential propagation (Marin, de Lima et al., J.Neurosci, 2016). A more recent study reported an absence of spontaneous remyelination of regenerating axons in the optic nerve, and that stimulating myelination requires modulating GPR17 and microglia (Wang et al., 2020). However, we report here that after inducing regeneration (by combining PTEN deletion in RGCs with the growth factor oncomodulin + cAMP elevation), myelination of regenerating axons occurs spontaneously in the vicinity of the injury site and to a lesser extent distally. A longitudinal study using immuno-electron microscopy reveals that: 1) regenerating axons (identified by GAP-43 immunostaining or anterograde tracing with cholera toxin subunit B, CTB) show wraps of myelin as early as 2 weeks post-injury; 2) all regenerating axons reach the threshold diameter (≥ 300 nm) to become myelinated by 9 weeks, although not all axons that attain this diameter become remyelinated; and 3)regenerating axons that become myelinated exhibit a normal g ratio. We also investigated the dynamics of the oligodendroglial population from 3 days post-injury(dpi) to 42 dpi using as a marker Olig2, a transcriptional factor expressed by oligodendrocytes regardless of their state of differentiation. At the injury site, there is a75% drop in the number of Olig2+ cells 3 dpi, though at 42 dpi the number of Olig 2+cells is somewhat closer to normal. These results show that areas close to the injury site are more efficiently remyelinated than in distal areas, that some regenerating axons that reach the

appropriate threshold become myelinated, that remyelinated axons can reach a normal g ratio, and that the remyelination process observed in our study occurs in parallel with an increase in the total number of oligodendroglia.

Title: Pdgfr inhibitor regulates both ng2 glia and microglia: role of ng2 glia in ethanol-induced brain dysfunction

Authors: *J. ZOU[1], L. G. COLEMAN, JR[2], F. T. CREWS[3];
[1]Univ. North Carolina, Chapel Hill, Chapel Hill, NC; [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Prof Pharmacol & Psychiat, Skipper Bowles Ctr. Alcohol, Chapel Hill, NC

Abstract: NG2 glia are a distinct glial cell population distributed throughout brain. They are identified by the expression of specific markers such as chondroitin sulfate proteoglycan 4 (CSPG4) and platelet-derived growth factor alpha (PdgfRα). However, the role of NG2 glia in ethanol-related brain dysfunction remains unknown. The present study used a PDGFR inhibitor CP673451 to dissect NG2 glia in contributing to ethanol-induced neuroimmune signaling and neuronal gene expression in a hippocampal-entorhinal cortex (HEC) slice culture. The concentration-dependent studies show that treatment of CP673451 at lower concentration (100nM) for 4 days induced specific loss of NG2 glia without disrupting the other types of cell signatures, for example: CSPG4 (Control:100±1; CP100nM4D:34±3); PdgfRα (Control:100±2; CP100nM4D:21±1); Iba-1 (Control:100±4; CP100nM4D:109±3); Sall1 (Control:100±2; CP100nM4D:96±0.3); GFAP (Control:100±3; CP100nM4D:145±1) and NeuN (Control 100±1; CP100nM4D:138±4). However, PDGFR inhibitor CP673451 at higher concentration (1000nM) depleted both NG2 and microglia markers and cell numbers as indicated by mRNA levels and IHC staining. To uncover the functional role of NG2 glia in ethanol-induced brain dysfunction, we treated the slices with lower concentration of CP673451 (100nM) for 4 days to induce the selective loss of NG2 glia, either copresence of ethanol (100mM) or pretreatment for 4 days followed by 4-day ethanol exposure. The results indicated that ethanol alone significantly

increased the expression of NG2 glia gene CSPG4 and PdgfRα. The loss of NG2 glia (both copresence and pretreatment) significantly reduced ethanol-induced neuroimmune signaling, for example (from an experiment with 4-day pretreatment of CP673451 followed by 4-day ethanol without CP673451): IL-1β (Control:100±5; CP100nMW4D:145±14; EtOH4D:187±8; E+CP100nMW4D:55±3, $p<0.001$). The loss of NG2 glia also significantly blocked ethanol-induced expression of neuronal genes (NR2A, NR2B and PSD95). Interestingly, myelin-associated protein genes such as PLP and MBP were markedly potentiated after NG2 ablation in response to 4-day ethanol. Together, these results reveal the unique role of NG2 glia in ethanol-induced neuroimmune signaling and neuronal activity. Our results also suggest that PDGFR inhibitors may offer a unique tool to selectively explore the physiological and pathological role of NG2 glia during ethanol exposure.

Title: Tet1 isoform-mediated regulation of immune response pathways in neural cells.

Authors: E. JASHIM[1], G. LUPICA-TONDO[2], C. B. GREER[3], E. GAMAZON[4], ***G. A. KAAS**[4];
[1]Belmont Univ., Nashville, TN; [3]Pharmacol., [4]Genet. Med., [2]Vanderbilt Univ., Nashville, TN

Abstract: Ten eleven translocation (TET) dioxygenase enzymes have emerged as key regulators of inflammation—both under normal and pathological conditions. Recently, we reported that two isoforms of *Tet1* are co-expressed in the adult mammalian brain, and their disruption results in opposite effects on physiology and cognition (Greer *et al*. 2021). In addition, we find that suppression of the full length, canonical isoform ($Tet1^{FL}$) in neurons induces a robust immune response, suggesting it might normally function to suppress neuroinflammation in the brain. To investigate these findings further, and in a more tractable system, we have now generated *Tet1* isoform mutant Neuro2A (N2a) cell lines using CRISPR-Cas9 editing. We find that loss of $Tet1^{FL}$ expression in N2as is sufficient to upregulate many immune-related genes, including *Nfkb1, Nfkb2, Tnfa, and IL-7.* Surprisingly, we also find that *pan-Tet1* loss reduces the expression of these same genes, whereas loss of the opposite isoform, *Tet1 Short* ($Tet1^{S}$), only mildly changes their transcript levels. Together, our results reveal that each isoform serves a unique, oppositional role in the regulation of inflammation in neural cells. Moreover, given that

many immune pathways contribute to neural physiology, these data suggest that *Tet1* isoforms may influence brain function, in part, through the epigenetic regulation of immune response genes.

Title: SRI-42127, a novel small molecule inhibitor of the RNA Regulator HuR, potently attenuates glial activation in a model of neuroinflammation

Authors: *R. CHELLAPPAN, A. GUHA, Y. SI, T. KWAN, B. NABORS, N. FILIPPOVA, X. YANG, A. S. MYNENI, S. MEESALA, A. S. HARMS, P. H. KING;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Glial activation with production of pro-inflammatory mediators is a major driver of disease progression in neurological conditions ranging from acute traumatic injury to chronic neurodegenerative disease. Our prior work has shown that the RNA regulator HuR plays a major positive role in regulating glial production of pro-inflammatory mediators through its interaction with adenine- and uridine-rich sequences (ARE) in the 3' untranslated region (3' UTR) of the mRNA. Upon binding to the ARE, HuR promotes RNA stabilization and increases translational efficiency of the transcript. We have developed a small molecule inhibitor of HuR, SRI-42127, that blocks its ability to dimerize and translocate to the cytoplasm, two steps necessary for proper function. Here, we test the ability of this inhibitor to attenuate glial activation and neuroinflammatory responses using lipopolysaccharide (LPS) as a model of neuroinflammation. Methods: Cultured murine microglial and astroglial cells were stimulated with LPS and treated with SRI-42127. Cellular localization of HuR was determined by single-cell flow cytometry and immunohistochemistry (IHC). Cytokine production was measured by qPCR and ELISA. RNA kinetics were measured in LPS-stimulated BV2 microglial cells after actinomycin D treatment. A luciferase-based reporter assay was used to assess promoter function of select cytokine genes. Glial migration was assessed with a transwell assay. For in vivo assessment, mice were injected with LPS intraperitoneally (i.p.) followed by SRI-42127 (10 mg/kg). Brains were assessed for

cytokine mRNA expression by qPCR, neutrophil and monocyte infiltration by flow cytometry, and microglial activation by Iba1 fluorescence intensity with IHC. Results: SRI-42127 blocked HuR cytoplasmic translocation in glial cells and the concomitant production of pro-inflammatory cytokines including IL-1β, IL-6, TNF-α, iNOS, CXCL1, and CCL2. There was marked suppression of TNF-α and IL-1β promoter activity and a mixed effect on RNA kinetics of select cytokines. Glial cell migration was suppressed. In vivo, SRI-42127 blocked induction of cytokine mRNAs and the infiltration of neutrophils and monocytes in all regions of the brain. Microglial activation was attenuated. Conclusion: SRI-42127 suppresses neuroinflammatory responses by activated glia through its inhibitory effect on HuR function. Systemic administration of SRI-42127 suppresses CNS neuroinflammatory responses including the recruitment of peripheral immune cells into the CNS. These findings open up a new avenue of therapeutic development for the many neurological diseases driven by neuroinflammation.

Title: Sting signaling in peripheral sensory neurons confers protective immunity against listeria monocytogenes infection

Authors: *A. S. ANDRIESSEN[1], S. BANG[1], A. MCGINNIS[1], R.-R. JI[1,2,3], C. R. DONNELLY[1,4];
[1]Anesthesiol., Duke Univ. Ctr. for Translational Pain Med., Durham, NC; [2]Cell Biol., [3]Neurobio., Duke Univ. Med. Ctr., Durham, NC; [4]Duke Cancer Inst., Durham, NC

Abstract: STING signaling in peripheral sensory neurons confers protective immunity against *Listeria monocytogenes* infection
Amanda S. Andriessen, Sangsu Bang, Aidan McGinnis, Ru-Rong Ji, Christopher R. Donnelly
Listeria monocytogenes (*L.m.*) is a bacterial pathogen responsible for the foodborne illness listeriosis, which is among the most frequent causes of death and is responsible for the highest

hospitalization rate among all foodborne illnesses. Importantly, *L.m.* is among the most common causes of bacterial meningitis and/or meningoencephalitis among newborns, and once *L.m.* crosses into the central nervous system (CNS), lethality exceeds 50%, even with aggressive medical treatment. Notably, the mechanism used by *L.m.* to bypass the blood-brain barrier to enter the CNS is poorly understood. STING is a sensor of host-derived double-stranded DNA and bacterially derived cyclic dinucleotides. *L.m.*, an intracellular pathogen, potently activates STING in immune cells, which initiates or amplifies a protective immune response. Interestingly, we recently demonstrated that STING is highly expressed by pain-sensing peripheral sensory neurons (nociceptors). Given that the peripheral afferents of nociceptors are present within virtually all barrier tissues and are frequently used by viral pathogens as a conduit to enter the CNS, we hypothesized that *L.m.* may infect nociceptors, and STING signaling in nociceptors may confer protective immunity against *L.m.* To test this hypothesis, we co-cultured sensory neurons with fluorescently labeled *L.m.* and performed live-cell imaging, which revealed robust infection of nociceptors by *L.m. in vitro*. Additionally, administration of *L.m.* in mice leads to robust infection of nociceptors *in vivo*. To evaluate whether STING signaling in peripheral sensory neurons confers protective immunity against *L.m. in vivo*, we performed a *L.m.* challenge experiment in signaling-deficient STING global knockout mice (STING-goldenticket mice, or STING-gKO) and mice lacking STING selectively in peripheral sensory neurons ($STING^{fx/fx}$; $Na_v1.8$-Cre; STING-cKO), as well as their wildtype (WT) littermates. Interestingly, both STING-gKO and STING-cKO exhibited significantly worse survival compared to WT controls, but not relative to one another. Collectively, these data suggest that STING signaling in peripheral sensory neurons confers protective immunity against *L.m.*, and ongoing work is aimed at uncovering the mechanism responsible for these effects.

Science, Korea Univ., Seoul, Korea, Republic of; [4]Dept. of Physical Therapy, Col. of Hlth. Sci., Korea Univ., Seoul, Korea, Republic of

Abstract: Osteoarthritis (OA) is a progressively degenerative joint disease, causing structural degradation of articular cartilage and adjacent connective tissue elements. This eventually induces pain and loss of joint function. Despite the considerable medical need, treatment options for the pain are insufficient. Substance P (SP) is well known to involve the induction of neurogenic inflammation and pain transmission in arthritis through activation of neurokinin 1 (NK1) receptor. The aim of this study is to investigate and compare the effect of two different neurokinin 1 (NK1) receptor antagonist, GR82334 and L-732,138 on arthritic pain in rats with MIA-induced OA.
Monosodium iodoacetate (MIA 4 mg/50 μl) was injected into the right knee joint cavity of Sprague-Dawley rats (180-200g) to induce OA. Two different NK1 receptor antagonist, GR82334 (10 μM diluted with 30 μl of saline) and L-732,138 (10 μM diluted with 30 μl of saline), was injected into the ipsilateral knee joint cavity using 30-gauge insulin syringe at 7 and 14days after MIA injection. Before and after NK1 antagonist administration, paw withdrawal threshold (PWT), knee joint diameter, knee bending test, and weight bearing were measured for determining hyperalgesia, edema, movement evoked pain and functional difference of hind limbs. Maximal Possible Effect (MPE) from the value of PWT and Area Under the Curve (AUC) of MPE were calculated to compare the effect of NK1 receptor antagonist between the groups. PWT significantly increased after administration in both GR 82334 group and L-732,138 group, while GR82334 group showed more rapid and dramatic analgesic effect compared to that of L-732,138 group in MPE and AUC graph. However, both GR82334 and L-732,138 did not reversed the reduction of weight load of inflamed leg and increased knee joint score on the ipsilateral hind-limb after MIA injection.
The present data showed that two different NK1 receptor antagonist, GR82334 and L-732,138 alleviate mechanical hyperalgesia in hind paw of rats with MIA induced OA through mediating the activity of the peripheral nociceptor, decreasing the excitability of the spinal cord. The finding suggests NK1 receptor antagonist as a potential mediator and drug target in OA, but each NK1 receptor antagonist has its characteristics and results in different effects under same condition, despite the same function.

Title: The effects of daily melatonin administration on the tissue reactions to neural implants

Authors: *K. WOEPPEL[1], Q. YANG[1], D. KRAHE[2], T. CUI[3];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Pittsburgh, pittsburgh, PA; [3]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Intracortical microelectrode arrays that record neural activities are key component of brain computer interface and neurophysiological studies. Despite their potential, recording quality often suffers from low yield and signal degradation. Host immune cells respond to the implant, encapsulating the foreign material and generating reactive oxygen and nitrogen species (RONS). The RONS serve as signals to other cells, amplifying the response, while also damaging both the device and native neurons. Pharmacologic methods of improving the long-term electrode performance by controlling the extent of RONS in the tissues have been investigated. One particularly interesting antioxidant is melatonin, a natural hormonal antioxidant which can modulate cellular responses through native receptors, while also having the ability to directly scavenge free radicals. Daily melatonin administration before and after electrode insertion resulted in enhanced electrode performance over 16 weeks. However, the short-term effects of melatonin have not been investigated. In this works, we use a combination of approaches including two photon microscopy, post mortem histology, and gene sequencing were employed to provide a better mechanistic understanding how melatonin affects the host tissues after short term implantations. In the two photon experiments, mice expressing green fluorescent protein in their microglia were given daily melatonin injections while the reactions of the microglia to the implant were visualized in real time. Characteristically, microglia attempted to encapsulate the implant. However, the microglial responses were slowed when melatonin was administered, with probe coverage decreased from 51.8% in control animals to 25.1% in treated animals at four days post implant. Postmortem histology and gene sequencing were used to examine the responses of the brain to the implant after one week. Staining of the tissues shows reduced astrocytic activation, decreased apoptosis, and elevated neural counts near the electrodes when the animals were treated with melatonin. We are currently underway in our attempts to determine the gene expression levels for implanted mice treated with melatonin or vehicle.

Title: Hypoxic regulation of gene expression in T98 glioblastoma multiforme cells by RNA sequencing identifies IRE1 as a target for therapy

Authors: *B. WHITE[1], Y. LIU[3], H. HAKONARSON[3], R. J. BUONO[2];
[2]Dept. of Biomed. Sci., [1]Cooper Med. Sch. of Rowan University: Rowan Univ. Cooper Med. Sch., Camden, NJ; [3]Ctr. for Applied Genomics, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Glioblastoma multiforme (GBM) is the most common primary brain cancer and carries a very poor prognosis. Intra-tumoral hypoxia is associated with dysregulation of various genes, including those involved in carbon metabolism, angiogenesis, and immunosuppression. These alterations characterize a subpopulation of cells that is particularly aggressive and resistant to multimodal therapy. IRE1, an endoplasmic reticulum stress sensor involved in the unfolded protein response, has been implicated in the increased angiogenic activity demonstrated in other cancer cell lines subject to hypoxia, including U87 GBM cells (Drogat et al., 2007). In our study, human T98G cell lines were cultured in a humidified incubator at 37° C and 5% CO_2 and were grown in normoxia (21% O_2) or hypoxia (95% N_2, 5% CO_2) for 72 hours. Three independent cultures (n=3) were used for each condition. Total RNA was harvested, and global gene expression was evaluated via RNA sequencing. RNA-seq alignment files were generated using the Illumina DRAGEN Bio-IT Platform (version 3.3.7), and the FASTQ alignment files were processed through Rsubread in Bioconductor package (version 2.0.0) to generate feature counts per sample. These counts were then processed through both DESeq2 (version 1.26.0) for differential expression analysis. *P* values were calculated using gene set enrichment analysis (GSEA) with Bonferroni correction. Gene Ontology and KEGG analyses were performed to identify processes and pathways enriched in hypoxia. The DrugBank database was queried to identify molecules targeting gene products upregulated in hypoxia. Hypoxia in T98G cells led to upregulation of genes implicated in multiple biological processes including canonical glycolysis, focal adhesion, and extracellular matrix reorganization. We document 690 genes and 11 associated KEGG pathways that demonstrated significant enrichment ($p \leq 0.01$) in hypoxia, including the IRE1-mediated unfolded protein response. DrugBank database analysis identified five molecules targeting gene products upregulated in hypoxic T98G cells: tenecteplase (5

targets), succinic acid (7 targets), artenimol (13 targets), copper (22 targets), and fostamatinib, a tyrosine kinase inhibitor targeting the IRE1 protein encoded by *ERN1*. In conclusion, this gene discovery study showed hypoxic upregulation of genes involved in multiple pathways associated with neoplastic behavior. The IRE1 protein showed enrichment in hypoxic T98G cells, corroborating results in another GBM cell line and suggesting a potential therapeutic target. The IRE1 inhibitor fostamatinib may hold therapeutic potential and warrants further preclinical study.

Title: G protein-coupled estrogen receptor blockade decreases cell viability and increases apoptosis of glioblastoma cells

Authors: *C. E. GUTIERREZ-ALMEIDA[1], J. M. DUEÑAS-JIMENEZ[2], S. H. DUENAS-JIMENEZ[1], A. SANTERRE[3];
[1]Neurociencias, [2]Fisiologia, Univ. De Guadalajara, Guadalajara, Mexico; [3]Biologia Mol., Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Background: Glioblastoma remains one of the most difficult to treat and worst prognosis tumors. Patients who undergo the standard treatment of surgical resection, chemotherapy, and radiation have 16 to 18 months of survival and a high recurrence rate. Different reports have shown that female patients have a survival advantage over males who have a higher glioblastoma incidence. The reason for these sex differences is believed to be associated with estrogens. G protein-coupled estrogen receptor (GPER) is a seven-transmembrane-domain receptor. This receptor participates in the estrogen rapid non-genomic signaling such as the activation of mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK), phospholipase C (PLC), and phosphatidylinositol 3-kinase (PI3 K) pathways, crucial pathways for cancer development. Rat tumor Leydig cells (R2C) express GPER and suffer apoptosis after GPER agonist G1 treatment, in vitro, and in vivo. GPER is also expressed in human squamous oral carcinoma cell lines (SCC4 and HSC-3), and the antagonist G15 induces apoptosis through caspases activation. Nevertheless, it is presently unclear the role of GPER in Glioblastoma. Objective: This study aimed to evaluate the role of GPER in C6 glioblastoma cells viability and apoptosis after the administration of GPER agonist (G1) and its antagonist (G15). Methods: C6 rat glioblastoma cell line was treated with a GPER agonist (G1,

10nM, for 48 hours) and antagonist (G15, 10μM, for 48 hours). Cell viability was evaluated using an MTT assay. To determine apoptosis, we evaluated caspase-3 expression by immunofluorescence and ELISA. Results: MTT assay showed C6 cell viability decreased after treatment with G1 in combination with G15 compared to control. Furthermore, G1, in combination with G15, significantly increased the percentage of C6 caspase-3 immunostaining cells and G15 (10μM) alone compared to control. Also, caspase-3 protein expression increased significantly in C6 cells treated with G1 and G15 compared to control. Conclusion: The GPER antagonist (G15) decreases cell viability while increasing caspase-3 protein levels. Our results demonstrate that GPER blockade promotes C6 cells apoptosis, thus showing the role of this receptor in cell death in glioblastoma cells.

Abstract: Non-coding RNAs, including microRNAs, support the progression of glioma. miR-21 is a small, non-coding transcript, involved in regulating gene expression in multiple cellular

pathways, including the regulation of proliferation. High expression of miR-21 has been shown to be a major driver of glioma growth. Manipulating the expression of microRNAs is a novel strategy in the development of therapeutics in cancer. In this study we used CRISPR genome editing technology to disrupt the miR-21 coding sequence in glioma cells. We found that targeted deletion of miR21 resulted in the upregulation of many downstream target mRNAs involved in proliferation. Phenotypically, miR21 deficient glioma cells showed reduced migration, invasion and proliferation *in vitro.* In an immunocompetent mouse model, miR-21 knockout tumors showed reduced growth resulting in an increased overall survival. In summary, we show that by knocking out a key miRNA in glioma, these cells have decreased proliferation capacity both *in vitro* and *in vivo*. Overall, we identified miR-21 as a potential target for CRISPR-based therapeutics in glioma.

Title: Selective HDAC6 inhibitor ITF3756 down-regulates PD-L1 in Gli36R cells, boosting the PBMCs-mediated immune response

Authors: *L. TAIAROL[1], M. KRAVICZ[1], M. RIZZUTO[2], L. BARBIERI[2], M. COLOMBO[2], C. STEINKÜHLER[3], E. MESSUTI[1], A. BENTIVEGNA[1], F. RE[1];

Abstract: Glioblastoma multiforme (GBM) is a severe IV grade astrocytoma with high degree of recurrence attributable to GBM stem cells (GSCs) and to the immunosuppressive microenvironment. Immunotherapy gained a lot of attention due to its ability to prevent metastatization and relapse better than conventional therapies. Immune checkpoint (ICs) such as Protein Death-1 and its ligand (PD-L1) are negative modulators of T-cells and Natural killer cells

(NKs) immune surveillance, being able to switch off the immune response eliciting immune escape of GBM. Histone deacetylases inhibitors (HDACis) are promising epigenetic modulators emerged as a therapy for various malignancies by modulating the expression of ICs. Here, we have characterized a nanoformulation of ITF3756, a selective HDAC6 inhibitor, on two *in vitro* models of GBM: Gli36ΔEGFR-2 (Gli36R) cells, which are resistant to chemotherapy and carry an EGFRvIII variant mutation present in 27-54% of GBMs, and PZG7, GSCs isolated from human biopsy. Results were compared with normal human astrocytes (NHA) as controls. ITF3756, dissolved in 7.5% PBS/DMSO, was formulated in liposomes (LIP-ITF) composed of cholesterol and sphingomyelin 1:1 added with 1.5 mol% of 1,2-dimyrystoil-snglycero-3-phosphate and prepared by extrusion procedure. LIP-ITF had a diameter of 125.3±1.5 nm with a PDI <0.2 and a surface charge -22.02±3.06 mV which make them stable and homogeneous drug vehicles. The cytotoxic effect of LIP-ITF was evaluated by MTT assay. Results showed that after 24 h both PZG7 and NHA were quite tolerant to LIP-ITF until the dose of 25 μM, while Gli36R started to be sensitive from 10 μM. Since HDACs relate to ICs expression, we have investigated the effect of LIP-ITF on PD-L1 in Gli36R at the doses of 25 and 50 μM using Tubastatine A, a known HDAC6 inhibitor, as a positive control. The mean reduction after 24 h of PD-L1 was about 70%, indicating that this drug might be an excellent candidate for immunotherapy. To confirm this hypothesis, we performed a live-imaging experiment using the Operetta System that involved PBMCs (T-cells and other mononuclear immune cells isolated from healthy donors' peripheral blood) co-cultured with Gli36R cells treated with 25 μM LIP-ITF for 24 h. Intriguingly, the treatment amplified the immune response of PBMCs against cancer cells in respect to untreated cells and we can speculate this effect was mainly due to the decrease of PD-L1 expression. Taken together, these unprecedented results lay the foundations for further studies aimed to better define the potential of ITF3756 for immunotherapy of GBM and its formulation in multifunctional LIP to boost blood-brain barrier crossing and tumor targeting.

Title: Cytotoxicity effects of mesoporous SiO_2 nanoparticles functionalized with folic acid and loaded with temozolomide in glioma cell lines.

Authors: *C. RODRÍGUEZ-PÉREZ[1], M. MANRÍQUEZ-RAMÍREZ[2], A. GONZALEZ-AGUILAR[1], E. ORTIZ-ISLAS[1];
[1]Natl. Inst. of Neurol. and Neurosurg., MEXICO CITY, Mexico; [2]ISIQIE, Natl. Polytechnic Inst., Mexico City, Mexico

Abstract: Glioblastoma multiforme is known as the most frequent primary brain tumor, which develops and originates in the non-neuronal glial cells of the brain. Despite the advances in the treatment, the median survival of patients is of 15 months. Currently, temozolomide is a first-line chemotherapy drug concomitantly with radiotherapy. Temozolomide, is a derivative of imidazotetrazine, it can cross the blood-brain barrier and at physiological pH, is converted by hydrolysis to the active form and then it is converted to 5-aminoimidazole-4-carboxamide and methyl diazonium ions. The formation of these methyl diazonium ions causes methylation at the guanine sites of the N7 and O6 atoms and the adenine site of the N3 atoms, leading to DNA double helix breakage, cell cycle interruption, and consequently cell death caused by cytotoxic DNA damage. The amount of temozolomide reaching the brain tumor is low (2%) relative to the total dose of drug circulating in the blood and the half-life is noticeably short (approximately 1.8 h). An alternative approach to improve the treatment of gliomas is use nanomaterials as drug carriers. The surface modification of nanomaterials has allowed them to preferentially accumulate in tumors and release drugs, making them interesting candidates for treat glioblastoma. In this study, we evaluated the cytotoxicity *in vitro* of temozolomide release of SiO_2 nanoparticles functionalized with folic acid in different human cell lines of gliomas (LN18, U87 and M059K) using MTT assay. The aim of functionalizing the silica nanoparticles with folic acid is that the nanoparticles can differentiate between cancer cells and healthy cells. The cytotoxic effect of temozolomide-SiO_2 nanoparticles was dose-dependent and clearly increased the cytotoxic effect of the drug alone. These results, suggest that these silica nanoparticles functionalized could have an important role in glioblastoma cancer treatment avoiding probably many side effects of chemotherapeutic drugs.

Title: Tumor-associated glial cells, macrophages, and extracellular matrix. Morpho-molecular dynamics in the mouse GL261-C57/Bl6J model of glioblastoma

Authors: A. VIRTUOSO, I. VISCOVO, R. CIRILLO, G. CIRILLO, ***M. PAPA**, C. DE LUCA; Dept. of Mental, Physical Hlth. and Preventive Med., Univ. della Campania Luigi Vanvitelli, Napoli, Italy

Abstract: Glioblastoma multiforme (GBM) is the most common primary brain tumor, associated with poor prognosis: scarce chances of long-term survival and rapid clinical worsening with state-of-the-art treatments. The microenvironment in the GBM comprehends as key cellular components microglia, macrophages, and astrocytes. Recent studies showed their involvement in nurturing tumor cells and grant GBM invasiveness. In the present study, we aim to characterize the time-related changes in the GBM landscape, using a syngeneic mouse model of primary GBM. GL261 glioma cells were injected in the right striatum of immuno-competent C57Bl6J mice and animals were sacrificed after 7, 14, and 21 days (7D, 14D, 21D). The tumor development was assessed through 3D tomographic imaging.Brain tissues were processed using immunohistochemistry, immunofluorescence, and western blotting. Our results showed how tumor progression temporally changes the morphology of astrocytes and microglia/macrophages. In the early stages, the proliferating tumor (Ki67+) appeared with a speckled distribution. The proliferating elements triggered astrocyte activation (GFAP+, glial fibrillary acidic protein) surrounding the GBM cells. The phagocytic cells, microglia, and macrophages (Iba1+, Ionized calcium-binding adaptor molecule 1), on the other hand, were scarcely represented and the brain architecture was conserved. A dense multilayer of reactive astrocytes with a morphological gradient of activation towards the well-defined tumor bulk is evident at 14D. At the same timepoint, we observed the increase of the phagocytic elements in the peritumoral area. The cellular changes may prompt the release of extracellular matrix (ECM) proteins and proteases to favor the GBM invasiveness locally and across the contralateral hemisphere. Metalloproteinase 9, fibulin, and tenascin C expression were affected at this stage. Accordingly, CD133+ glioma stem cells migrated out of the bulk at 21D, while the necrotic primary lesion was being infiltrated by macrophages. Protein expression of the specific microglial marker TMEM-119 (transmembrane protein 119) was downregulated, suggesting diminished activity of tumor-associated-resident microglia and increased contribution of circulating invading macrophages. The present study emphasizes the role of functional changes in the microenvironment during the GBM progression, fostering the studies on novel multi-targeted, time-dependent therapies in an experimental model similar to the human disease.

Title: Tsp-1 mediated glioma-network integration in high grade glioma

Authors: *M. NEGUSSIE[1], S. KRISHNA[2], S. HERVEY-JUMPER[2];
[2]Neurolog. Surgery, [1]Univ. of California, San Francisco, San Francisco, CA

Abstract: Glioma exists in the complex neural circuitry of the brain, making the interface between neoplastic and healthy neurons and glia potentially damaging to long range neural networks and stimulatory to tumor growth. Thrombospondin-1 (TSP-1), an astrocyte derived neurogenic factor expressed by glia of the normal brain, has been found to be upregulated in intratumoral regions with high network functional connectivity (HFC). This modified cell signaling represents cancer cell hijacking of normalphysiology with direct impact on tumor biology. There is emerging evidence that neuronal activity influences glioma proliferation and gliomas promote neuronal hyperexcitability. In humans, we have recently shown that bidirectional cellular interactions between gliomas and neurons alter cognitive circuit dynamics and ultimately patient survival. Previously, a subpopulation of human high-grade glioma cells which are enriched for tumor cells with synaptogenic potential were identified (HFCIDHwtGBM). We studied the mechanisms of TSP1 signaling in three different established glioma models (1) HFC-IDHwtGBM hippocampal neuron co-culture, (2) HFC-IDHwtGBM + induced neuron organoids, (3) patient derived xenografts (PDX) for in vivo GCaMP calcium imaging. This project aims to test the hypothesis that increased TSP-1 secretion from HFC-IHDwtGBM cells plays a central role in the maintenance of an invasive and proliferative tumor phenotype when compared with control conditions. Our results show that TSP-1 silencing using a lenti shRNA knockdown construct decrease the proliferative and invasive phenotype of HFC-IHDwtGBM cells evidenced by the reduced expression of Ki67 and MET markers, respectively in hippocampal neuron co-culture and PDX tissue specimens. Further, the HFC-IDHwtGBM cells lacking TSP-1 exhibit a less synaptogenic and integrative potential tested via hippocampal neuron co-culture and induced neuron organoid models. We hope our study guides future work focused on preventing the infiltration of tumor cells into healthy brain tissues.

Title: Primary brain tumour cells live morphological analysis and association with cancer stem cell biomarker SOX2 and CD133

Authors: *Z. HUMA[1,3], I. ABBAS[4,5], I. KHAN[4], D. HUSSEIN[6], S. WAZIR[2], S. AYUB[7]; [1]IBMS, [2]Khyber Med. Univ., Peshawar, Pakistan; [3]Anat., Rehman Med. Col., Peshawar, Pakistan; [4]Khyber medical university, Peshawar, Pakistan; [5]Anat., Northwest Sch. of Med., Peshawar, Pakistan; [6]King Abdulaziz Univ., Jeddah, Saudi Arabia; [7]Hayatabad Med. Complex, Peshawar, Pakistan

Abstract: ABSTRACT: Primary Brain Tumour Cells Live Morphological Analysis and association with cancer stem cell biomarker 'SOX2' and CD133**Background:** Despite recent advancements mortality rates remain high for brain tumour patients in Pakistan which being a developing nation lacks proper healthcare facilities. Majority of brain tumour patients suffer greatly and eventually die despite standard methods of treatment used. To understand brain tumour complexities and develop effective strategies for prevention and treatment proper documentation and research in this field is imperative. Primary cultures developed from patient derived tissues are indispensable tools for studying the biology of disease and for carrying out pre-clinical testing. Developing primary brain tumour cell lines from Peshawar based patients to study the biology of brain tumours will set the framework for research in the field of neuro-oncology for our people as there is paucity of research in this field in our country.**Methods:** Primary brain tumour cell lines were established with tumour samples from Hayatabad medical complex and Northwest general hospital. The tissue samples were processed in the cell culture laboratory and dissociated tumour cells were cultured in growth media and incubated at 37°C in 5% CO2.The attached monolayer cells were analyzed for various morphologies. Immunofluorescence was performed on the cultured cells as well as original tumour tissue for detection of stem cell biomarker SOX2.**Results:** Cell lines were developed from three samples of primary brain tumours which included two gliomas and one meningioma. The cell counts over a four-week period revealed that glial cell type was the dominant morphology at end of 4th week. SOX2 expression was found in all cells and tissues but higher in cells with a mean percentage of 45% as compared to tissue having mean percentage expression of 11.3%.**Conclusion:** Primary cultures from brain tumour developed. Morphological analysis of the primary brain tumour cultures demonstrated the presence of different cell types with glial type being dominant in our 3 samples. SOX2 was detected in cultured cells and original tumour tissue in all samples. No apparent correlation was found between dominant morphology and SOX2 expression with tumour aggressiveness.Keywords Primary brain tumours, Cell culture, Brain tumour stem cells, SOX2.

Title: Neurodegeneration of retinal ganglion cells in a mouse model of Alzheimer's Disease

Authors: L. PÉREZ DE SEVILLA MÜLLER[1], A. M. CHEN[1], *N. BRECHA[1,2];
[1]Neurobio., David Geffen UCLA Sch. of Med., Los Angeles, CA; [2]Res. Admin., Veterans Admin. Greater Los Angeles Hlth. Syst., Los Angeles, CA

Abstract: Introduction: Visual alterations are common in AD patients with a substantial impact on the quality of life. Retinal abnormalities in AD include loss of retinal ganglion cells (RGCs), including the intrinsically photosensitive RGCs (ipRGCs). We have tested if there is a loss of RGCs, including ipRGCs in the AD mouse model, APPswe/PS1DE9.
Methods: Double transgenic mice on the genetic background of C57BL/6J and C3H harboring the chimeric mouse/human APP (APPSWE) and mutant human presenilin 1 (PS1ΔE9) genes, and their aged-matched WT littermates, were purchased from the Jackson Laboratories (Bar Harbor, ME, strain #004462). Both APPSWE and PS1ΔE9 mutations are associated with early-onset Alzheimer's disease. The "humanized" APPSWE and PS1ΔE9 mutations mediate expression of the human Aβ peptide and presenilin 1. Retinas from mice at 10 and 12 months of age were used. Non transgenic female littermates and C57bl/6J were used as controls. To label and quantify the entire RGC population we have used RBPMS antibodies and for ipRGCs, specific ipRGC antibodies.
Results: Our data show a reduction in the number of RGCs in the ganglion cell layer and in the inner nuclear layer, and significant loss of RGCs in the superior and inferior retinal regions. These findings are in agreement with reports of RGC degeneration in the superior quadrants of the retina in AD patients. The near-complete loss of ipRGC dendrites in a 10-month-old APP_{swe}/PS1ΔE9 transgenic mouse model is consistent with postmortem studies in human AD retinas.
Conclusion: Symptoms referable to the visual system may be the earliest signs of AD and dementia. Damage or loss of ipRGCs in the retina might account for many AD-related visual dysfunctions, including impaired ocular motility, a reduction in amplitude of the PLR, and circadian alterations of melatonin. With ipRGC dysfunction occurring in the pre-symptomatic AD stages that precede cognitive decline, *in vivo* measurements of ipRGC function with chromatic pupillometry may be a potential biomarker for early diagnosis and progression of AD.

Its use in AD screening may provide information on the state of the CNS, sampled via ipRGCs, and become a promising tool for clinical evaluation for the onset, control, and progression of AD.

Title: Unraveling disease mechanisms in a novel, humanized mouse model of late-onset Alzheimer’s

Authors: *K. KOTREDES[1], A. OBLAK[2], C. PREUSS[1], R. PANDEY[1], P. R. TERRITO[3], S. J. SUKOFF RIZZO[4], G. CARTER[1], M. SASNER[1], G. R. HOWELL[5], B. T. LAMB[6];
[1]The Jackson Lab., Bar Harbor, ME; [2]STARK Neurosci. Res. Inst., [3]Radiology and Imaging Sci., Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Dept. of Neurobio. and Dept. of Med. - Aging Inst., Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [5]Jackson Lab., Bar Harbor, ME; [6]Stark Neurosciences Res. Inst., Indianapolis, IN

Abstract: OBJECTIVE:Late-onset Alzheimer’s disease (LOAD) is the most common form of dementia without an approved therapy. Current animal models do not fully recapitulate LOAD and thus are not ideal for therapy development. Hence, the Model Organism Development and Evaluation for Late-onset AD (MODEL-AD) Center is developing and distributing novel mouse models carrying human-relevant risk factors. Characterization of aging mice that better phenocopy human disease will reveal more appropriate molecular targets useful in the treatment of LOAD. METHODS:Two risk factors of LOAD, humanized *APOEε4* and *Trem2*R47H*, were incorporated into C57BL/6J mice to produce the LOAD1 mouse strain. The effects of expressing an additional genetic factor, humanized amyloid-beta (Aβ) allele (to form the LOAD2 strain), was investigated. Cohorts of mice were aged on multiple sites to 4-, 12-, 18-, and 24-month timepoints. In half, high-fat diet replaced normal mouse chow. A phenotyping pipeline designed to qualify neurodegenerative disease states observed in humans was implemented to measure behavior, cognition, and wellness. *In vivo* imaging of brain perfusion and metabolism, was also performed, as was post-mortem analyses of blood chemistry, neuropathology, transcriptomics, metabolomics, proteomics, spatial profiling, and electrophysiology. RESULTS:LOAD2 mice show increased CSF neurofilament-light in 12-month animals and KC/GRO plasma KC/GRO in 18-month animals, however no overt hippocampal pathology nor differences in long-term

potentiation were observed. Expression of human amyloid did not yield plaque formation in 18-month mice. High-fat diet increased frailty scores and weight in all cohorts irrespective of genotype. In 18-month-old LOAD2 mice, high-fat diet reduced activity and exploratory drive. Correlation of transcriptional profiling with human AMP-AD modules determined individual and synergistic effects between genetic and environmental risk factors. Continuing efforts dissect the downstream effects of sex, age, genotype, and diet via RNAseq, neuropathology, and *in vivo* imaging of brain tissue are in progress, as are proteomic and metabolomic assays on brain homogenates and plasma. CONCLUSIONS:The MODEL-AD consortium has established the LOAD2 mouse model to study the effects of genetic and environmental risk factors of LOAD. This strain serves as a platform for the incorporation of additional AD risk factors (both genetic and environmental) to more closely align phenotypes in the mouse to outcomes observed in the clinic. Here we show the evidence of emerging disease pathology in an animal model exposed to genetic and environmental risk factors.

Title: Neuronal vulnerability in prefrontal and visual cortex in Alzheimer's disease analyzed by multiplexed immunofluorescence

Authors: *M. VARGHESE[1], S. S. IN[1], W. CHANG[2], S. KRITZER[1], C. M. FREIRE-COBO[1], B. WICINSKI[1], E. MCDONOUGH[3], L. LOWERY[3], M. MEDALLA[2], J. I. LUEBKE[2], D. E. MEYER[3], P. R. HOF[1,4];

Abstract: Neurons in the prefrontal cortex (PFC) are more susceptible to degenerative changes in aging and Alzheimer's disease (AD) compared to neurons in the primary visual cortex (V1).

Whether interaction of neurons with other cells in their vicinity or protein expression in specific neuronal and non-neuronal cell populations contribute to differential vulnerability of neurons remain open questions. Postmortem brain samples from the PFC and V1 of human subjects with AD (clinical dementia rating CDR 3, Thal stage 3-4, Braak stage V-VI), mild cognitive impairment (CDR 0.5, Thal stage 1-3, Braak stage I-V) and age-matched healthy controls (CDR 0, Thal stage 0-1, Braak stage I-II) were used to prepare tissue microarrays. These tissue microarrays were subject to multiplexed immunofluorescence detection (MxIF), with markers of cellular identity, neuropathology, oxidative stress and inflammation. The images were processed using machine learning-based segmentation and classification algorithms, to detect and classify cells based on their expression of various markers. Tissue retention on the slides across the 13 rounds of MxIF was well-preserved for most of the samples in the study. Qualitative assessment of MxIF images showed robust expression of cellular markers Hu-antigen D for neurons, glial fibrillary acidic protein and aldehyde dehydrogenase 1 family member L1 for astrocytes, ionized calcium-binding adapter molecule 1 for microglia, and collagen IV for vasculature. Cellular stress markers (3-nitrotyrosine, cleaved caspase-3) and pathological markers (amyloid beta, phospho-Ser202/Thr205 tau and TAR DNA-binding protein 43) were also detected. Further analysis is underway to determine whether neuron density is changed, which specific subtypes of neurons are affected in AD, and if pathological or oxidative stress markers are altered in specific neurons, glia, or vasculature in AD. We will also investigate whether previously reported cortical layer-specific susceptibility can be replicated using this method. The outcomes from this study will provide information on *in-situ* cellular interactions and protein changes that contribute to neuronal vulnerability in aging and AD.

Title: Transcriptomics of Alzheimer's Disease determined from dried whole blood on filter paper

Authors: *M. BABIC, A. DIAZ, K. SCULLY, J. YEAKLEY, B. SELIGMANN;
BioSpyder Technologies, Inc., Carlsbad, CA

Abstract: Blood contains a complex mixture of cells that are exposed to local signals and metabolic states in all parts of the organism. As such, the overall transcriptomic state of such cells can reflect disease states in various parts of the body, and individual biomarker signals that correlate to specific conditions can be teased out. This is true even for complex conditions such as Alzheimer's Disease (AD), for which several transcriptomic signatures have been published. However, determination of such signatures presents significant technical challenges and costs: blood samples have to be collected, nucleated cells separated, RNA extracted, reverse-transcribed, RNA-seq normalizations performed before sequencing, and the final dataset has to be analyzed by expert bioinformaticists. We have developed a novel approach in which a targeted transcriptomic assay, TempO-Seq®, is applied to small samples of dried blood spots on filter paper, collected noninvasively by simple finger sticks. Rich transcriptomic data, up to the whole transcriptome, can be generated from a <5 mm^2 sample of a blood spot, which is added directly into the assay with no extraction or reverse transcription. Dried blood spots are stable at room temperature, allowing easy handling and shipping, properties that are especially important in poor or medically underserved areas. The assay is simple and inexpensive, with a single technician easily processing >400 samples in parallel in <4 hours of hands-on time. Since only targeted probes are sequenced, bioinformatics is fully automated; the final product is a table with read counts corresponding with levels of each RNA, without any need to analyze sequences directly at any point. The assay also possesses single-base specificity, which allows detection of expressed SNPs, mutations, splice variants, etc. A version of the assay can be utilized to measure DNA as well, finding mutations, unexpressed SNPs, and other alleles of interest. In this report, we show whole blood transcriptomic signatures of AD, comparing to controls, and to Parkinson's Disease patients. Preliminary data indicates that both AD and mild cognitive impairment induce changes in expression level of the non-receptor tyrosine kinase BMX, as well as changes in beta-catenin and FGFR signaling pathways. We also demonstrate detection of alleles of interest from the same dried spots using a DNA genotyping assay.

Sch. of Med., Boston, MA; [5]Rush Alzheimer's Dis. Ctr., Rush Univ. Med. Ctr., Chicago, IL; [6]Hinda and Arthur Marcus Inst. for Aging Res., Harvard Med. Sch., Boston, MA

Abstract: Association of Alzheimer's Disease and Related Dementias (ADRD) with fractures and low bone mineral density (BMD) are often observed prior to cognitive decline. A prior network analysis of ovariectomy-induced bone loss in mice highlighted the involvement of SNCA, and other literature supports its role in ADRD peripheral effects including insulin resistance and reduced gut motility. We hypothesized that SNCA would have a role in the ADRD-bone association. We conducted a transcriptomic analysis of SNCA using blood gene expression data from the Framingham Heart Study (FHS) Offspring cohort at exam 8 (N = 2,311, average age = 66, 54% female) for 17,873 transcripts, and whole blood (N = 104, average age = 65) and bone biopsy (N=84, average age = 65) gene expression data for 28,867 transcripts from a study of postmenopausal women in Norway. We performed co-expression analysis with FDR correction and pathway and network analysis of significantly co-expressed genes. In the FHS cohort, we also performed a WGCNA (Weighted gene co-expression network analysis) in a subset of participants with two bone assessments available (N = 1,350) for 4,220 transcripts, as their variance was in the top quartile of transcript variability. We found a strong enrichment for mitophagy and ubiquitination among co-expressed genes across all data sets, with top correlated candidates including FBXO7, ADIPOR1, and PINK1. WGCNA of the FHS blood data revealed a module containing SNCA, FBXO7, and ADIPOR1 that showed a significant inverse correlation between the intramodular connectivity, a statistic which measures gene connectivity in the same module, and change in femoral neck BMD. Additionally, SNCA was itself highly connected (intramodular connectivity above the 75th percentile for the module) and significantly associated with change in femoral neck BMD with inverse correlation. All three genes have been implicated in neurodegenerative disease pathogenesis, and our results further link SNCA to mitochondrial and protein degradation along with fat homeostasis. This analysis highlights a potential role of SNCA in ADRD interactions with peripheral tissue, given similar co-expression patterns in bone and peripheral blood that will be further explored using the SNCA interactome in brain transcriptomic data sets in the future.

Title: Single-nucleus chromatin accessibility and transcriptomic characterization of Alzheimer's disease

Authors: *S. MORABITO[1], E. E. MIYOSHI[2], N. MICHAEL[2], S. SHAHIN[2], A. C. MARTINI[2], E. HEAD[2], J. SILVA[2], K. LEAVY[2], M. PEREZ-ROSENDAHL[2], V. SWARUP[2]; [1]Mathematical, Computat. and Systems Biol., [2]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: The gene-regulatory landscape of the brain is highly dynamic in health and disease, coordinating a menagerie of biological processes across distinct cell types. The genetic, molecular, and cellular underpinnings of many complex multifactorial neurological diseases such as Alzheimer's Disease (AD) are not fully understood, hindering our ability to design effective therapeutics. Here, we present a multi-omic single-nucleus study of 191,890 nuclei from the prefrontal cortex in late-stage AD, profiling chromatin accessibility and gene expression in the same biological samples and uncovering vast cellular heterogeneity. We independently identified neuronal and glial cell types using two orthogonal genomics techniques and performed an integrated analysis to clarify the relationship between the epigenome and the transcriptome at cellular resolution. We found that the cellular composition of the cortex was significantly altered in AD in both neuronal and glial populations, highlighting a significant decrease of homeostatic microglia. We identified cell-type-specific, disease-associated candidate cis-regulatory elements and their candidate target genes, including an oligodendrocyte-associated regulatory module containing links to AD-associated genetic risk genes including *APOE* and *CLU*. Furthermore, we characterize the cis-regulatory architecture in specific cell types at a subset of AD genetic risk loci defined by genome-wide association studies, demonstrating the utility of this multi-omic single-nucleus approach for contributing to our understanding of AD genetics. We performed integrated pseudotime trajectory analysis in oligodendrocyte, microglia, and astrocyte populations, revealing disease-relevant transcription factors, such as SREBF1, and their regulatory targets throughout disease-associated activated glial responses. Finally, we introduce single-nucleus consensus weighted gene co-expression analysis, a co-expression network

analysis strategy robust to sparse single-cell data and perform a systems-level analysis of the AD transcriptome.

Title: Neuronal cell cycle re-entry mice and their relevance to late-onset Alzheimer's disease

Authors: *K. PARK[1], R. PANDEY[2], G. CARTER[2], K. STANGIS[1];
[1]Central Michigan Univ., Mount Pleasant, MI; [2]The Jackson Lab., Bar Harbor, ME

Abstract: Alzheimer's disease is the most prevalent form of dementia, affecting 6 million individuals in US alone. There is an urgency for identifying novel druggable targets. There is no treatment available for modifying the disease progression and numerous therapeutic strategies targeting the removal of Aβ have been unsuccessful. The majority (90-95%) of the AD cases are sporadic, yet much of the current research utilizes familial AD mouse models arising from amyloid precursor protein (APP) and presenilin gene mutations that represent 1-2% of AD cases (Jankowsky and Zheng, 2017). Aberrant neuronal cell cycle re-entry is an alternative pathogenic mechanism in AD that has gained substantial support in the literature. We have demonstrated that ectopic neuronal cell cycle re-entry (NCCR) in wildtype mice generates many of the late-stage AD-related pathologies (Park et al., 2007; Park and Barrett, 2020). We recently combined our NCCR mice with App^{NLF} KI FAD mice, which possess humanized Aβ domain and FAD-linked Swedish and Iberian mutations (Saito et al., 2014), to generate NCCR-App^{NLF} mice. These newly generated NCCR-App^{NLF} mice demonstrate that neuronal cell cycle re-entry can induce and enhance many AD-related pathological features such as hyperploidy, neuroinflammation, brain leukocyte infiltration, PHF-1 phospho-tau lesions, neurodegeneration, and cortical atrophy compared to App^{NLF} mice (Barrett et al., 2021). As a follow-up study, we evaluated the effect of neuronal cell cycle re-entry in App^{NL} KI mice. App^{NL} mice possess humanized Aβ domain and FAD-linked Swedish mutation. However these mice predominantly produce $Aβ_{40}$, and do not deposit Aβ plaques or show neuroinflammation (Saito et al., 2014; Salas et al., 2018). Here we present gene expression profiling data for evaluating the late-onset AD (LOAD) relevance of neuronal cell cycle re-entry mice. NanoString nCounter Mouse AD panel has been developed to

correlate human disease processes and pathways with mouse brain transcripts as a means for evaluating the LOAD relevance of mouse models (Preuss et al., 2020). Our neuropathological and NanoString nCounter AD panel gene expression profile data from NCCR-*App*^{NL} mice provide additional evidence for the LOAD relevance of the NCCR mice.

Title: Tmem106b increases with physiological ageing in the human hippocampus

Authors: *J. LEE[1], D. J. HARNEY[2], M. LARANCE[2], A. S. DON[1,3];
[1]Centenary Institute, The Univ. of Sydney, Camperdown, Australia; [2]Charles Perkins Centre, Sch. of Life and Envrn. Sciences, Univ. of Sydney, Camperdown, Australia; [3]NHMRC Clin. Trials Centre, The Univ. of Sydney, Camperdown, Australia

Abstract: Ageing is the greatest risk factor for major forms of dementia, including Alzheimer's disease (AD), frontotemporal dementia (FTD) and dementia with Lewy bodies (DLB). These diseases are categorised neuropathologically by protein aggregates that develop with ageing and usually precede clinical dementia. As such, brain ageing is hypothesized to form a prodromal state to neurodegenerative dementias. Allelic variants of *APOE,* encoding apolipoprotein E, are the greatest genetic risk factor for AD, while also regulating risk for DLB and age at onset for FTD. This study employed proteomic analysis of human hippocampus samples to investigate how ageing and *APOE* genotype modulate the risk of developing dementia. Post-mortem tissue samples from the hippocampus (CA1 region) of 76 cognitively- and neuropathologically-normal donors, aged 64 to 104, were used for data-independent mass spectrometry to acquire proteomic data. The dataset was inquired for age- and *APOE* genotype-driven changes at the systems level using Weighted Gene Co-expression Network Analysis (WGCNA). Multiple regression models adjusted for post-mortem interval and sex were applied to determine the effects of age and *APOE* genotype on individual proteins of the hippocampus. All p values were adjusted for false discovery rate (FDR) using the Benjamini-Hochberg correction. As typically observed in the ageing brain, networks of co-expressed proteins enriched with proteostatic, mitochondrial, and astrocytic/endothelial cytoskeletal proteins were associated with age. Seven proteins were significantly associated with age: TMEM106B, MAOB, TBCA, ANXA1, ANXA2, CFL1, and METTL7A. Lysosomal transmembrane protein TMEM106B was most significant ($\beta = 3.10$,

FDR = 2.27 x 10^{-3}, R^2 = 0.25). TMEM106B is a key regulator of lysosomal function and myelination, and its genetic variants modulate the risk for AD, FTD, PD, hippocampal sclerosis, and hypomyelinating leukodystrophy. TMEM106B levels were associated with proteins involved in lysosomal acidification and lipid catabolism (ATP6AP1, ASAH1), myelination (QKI), axon guidance (PLXNB1) and lipid metabolism (ERLIN2, DHRS7). Our results provide the first evidence that TMEM106B protein abundance is increased with normal ageing in the human hippocampus. The association of TMEM106B levels with lysosomal proteins and positive association with a protein critical for myelination (QKI) support literature that have implicated TMEM106B in lysosomal transport and myelination. We speculate that the age-driven increase in TMEM106B levels may offer neuroprotection in the human hippocampus by maintaining lysosomal function and myelination.

Title: Limited substrate specificity of PS/g-secretase is supported by novel multiplexed FRET analysis in live cells

Authors: *M. HOUSER, Y. TURCHYNA, F. PERRIN, O. BEREZOVKSA, M. MAESAKO; Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Presenilin (PS)/γ-secretase plays a pivotal role in essential cellular events as well as in numerous diseases via proteolytic processing of transmembrane proteins, including APP and Notch 1. To better understand the spatiotemporal regulation of PS/γ-secretase activity, we have engineered Förster resonance energy transfer (FRET)-based APP C99 YPet-mTurquoise-GL (C99 Y-T) and Notch1 N100 Y-T biosensors that allow for the first-time recording the activity of endogenous PS/γ-secretase activity overtime, on a cell-by-cell basis, in live cells (Maesako et al. 2020). Using these new biosensors, we uncovered that PS/γ-secretase activity is heterogeneously regulated among cells. However, whether PS/γ-secretase preferentially processes its different substrates (e.g., APP vs. Notch1) in live cells is still poorly understood. Recent structural studies of PS/γ-secretase enfolding a fragment of APP or Notch1 showed that these two key substrates engage the protease in broadly similar ways, suggesting the limited substrate specificity of PS/γ-

secretase. Here, we report the development of a new near-infrared (NIR) C99-720-670 biosensor that incorporates an immediate PS/γ-secretase substrate APP C99 with miRFP670 and miRFP720 as the donor and acceptor fluorescent proteins, respectively (Houser et al. 2020). Our validation demonstrates that the C99 720-670 biosensor permits quantitative monitoring of endogenous PS/γ-secretase activity and is spectrally compatible with our previously developed visible range C99 Y-T biosensor. We then utilized this multiplex imaging platform to monitor how PS/γ-secretase processes two different substrates in the same cell. Overall, we found that PS/γ-secretase similarly cleaves Notch1 N100, wild-type APP C99, and familial Alzheimer's disease (FAD)-linked APP C99 mutants in Chinese hamster ovary (CHO) cells (Houser et al. 2021). These findings support limited PS/γ-secretase substrate processing specificity. Our new multiplexed FRET assay could help better understand the consequences of changes in PS/γ-secretase activity and variability in the processing of multiple substrates in normal and disease conditions.

Title: Glutamate transporter GLT-1 and PS1/γ-secretase are cross-regulated in term of function and activity in Alzheimer's disease

Authors: *F. PERRIN[1], L. C. ANDERSON[2], Y. TURCHYNA[1], M. MAESAKO[2], M. C. Q. HOUSER[1], O. BEREZOVSKA[1];
[1]Neurol., [2]Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Rational: Mutations in Presenilin 1 (PS1), the catalytic sub-unit of γ-secretase, cause early-onset familial Alzheimer's disease (fAD) by inducing a "closed" structural conformation in PS1 and production of longer Aβ species. Interestingly, clinical data revealed that patients with presenilin mutation carriers have significantly higher incidence of epileptiform activity, suggesting that fAD PS1 mutations (Aβ-related or not) could contribute to hyperactivity. We have recently discovered an interaction between PS1 and the major CNS glutamate transporter GLT-1. Here we aim to investigate; i) if mutations in PS1 modulate interactions between PS1 and GLT-1, ii) whether PS1 wt or PS1 fAD impact GLT-1 function in term of localization and

activity, iii) does GLT-1 and PS1 binding affect APP processing. **Methods:** To test whether sporadic AD (sAD) effects the PS1/GLT-1 interaction we examined brain tissue from control, sAD, and frontotemporal dementia (FTD) cases. To examine if the PS1/GLT-1 interaction is disrupted by PS1 pathogenic mutations we use fluorescence lifetime imaging microscopy assay (FLIM) in intact cells *in vitro*. Next, we sought to determine if changes in the PS1/GLT-1 interaction caused by fAD PS1 mutations result in functional changes in GLT-1 cell surface expression by flow cytometry and cell surface biotinylation. We also tested in native condition GLT-1 multimerization profile (GLT-1 dimer and trimer) on different cell lines. In addition, we used glutamate uptake assay to measure the PS1 effects on GLT-1 function. Finally, we monitored the production of different Aβ species in cell lines and neurons expressing PS1/GLT-1 with a multiplex assay. **Results:** We showed that the PS1/GLT-1 interaction occurs in the human brain and this interaction is reduced in sporadic AD brains. We found that the presence of PS1 wt increased GLT-1 cell surface expression and GLT-1 multimerization. Importantly, our preliminary data indicate that GLT-1/mediated glutamate uptake was increased in the presence of PS1. In terms of APP processing, GLT-1 impacts PS1/g-secretase cleavage favoring shorter Aβ(38) species production. **Conclusions:** The change in the PS1/GLT-1 interaction induces functional changes in GLT-1 and PS1. These results could explain the strong connection between fAD PS1 mutations and epileptiform activity in fAD.

Title: Glutamate transporter GLT-1 impacts PS/ɣ-secretase activity and conformation

Authors: *Y. TURCHYNA, M. MAESAKO, F. PERRIN, M. C. Q. HOUSER, O. BEREZOVSKA;
Neurol., MassGeneral Inst. for Neurodegenerative Disease, Massachusetts Gen. Hospital/Harvard Med. Sch., Charlestown, MA

Abstract: Recently GLT-1 was identified by our group as a novel PS1-interacting protein, which allowed us to explore the link between two major hallmarks of Alzheimer's disease - abnormal Aβ production/accumulation and hyperexcitability of neuronal networks. Current study

investigates impact of GLT1 on Presenilin/ɣ-secretase to explore functional outcomes of their interaction. First, Aβ42 and 40 concentrations were measured with ELISA in conditioned medium of CHO PS70 cells transiently transfected with GLT-1 DNA or empty vector. Results revealed that extracellular concentration of both Aβ species was significantly decreased in the presence of GLT-1, compared to control. Among other possibilities, it suggests that activity of PS/ɣ-secretase may be altered. Therefore, using genetically encoded FRET-based biosensor C99 YT and confocal microscopy we monitored endogenous PS/ɣ-secretase activity and discovered that it was significantly decreased due to GLT-1 overexpression. Interestingly, when GLT-1 function was inhibited by 1mM DHK, the activity of PS/ɣ-secretase was not significantly different from control level. This suggests that not only GLT-1 expression, but its functional state is important for modulation of the PS/ɣ-secretase function. Abovementioned changes in extracellular Aβ42 and 40 concentrations measured with ELISA might also be a result of abnormal Aβ production. Since it was previously established that changes in Aβ production may be linked to changes in conformation of PS1, we employed FRET-based FLIM assay and GFP-PS1-RFP genetically encoded probe to determine if GLT-1 expression impacts PS1 conformation. We found that PS1 conformation is shifted to more “open” state in cells expressing GLT-1. Together our results suggest that GLT-1 has powerful impact on PS1 functioning and Aβ generation. GLT-1/PS1 interaction as a potential new target for developing drugs aimed at treating Alzheimer`s disease will be discussed.

Title: Depletion of Caveolin-1 in Type 2 Diabetes model induces Alzheimer’s disease pathology

Authors: *A. SHETTI[1], J. BONDS[3], A. RAMAKRISHNAN[1], K. VO[1], R. MINSHALL[2], O. LAZAROV[1];
[1]Anat. and Cell Biol., [2]Univ. of Illinois at Chicago, Chicago, IL; [3]Northwestern Univ., Chicago, IL

Abstract: Type 2 Diabetes is a major risk factor for the development Sporadic Alzheimer Disease. Vascular dysfunction and impaired insulin signaling are thought to be involved in the development of dementia and Alzheimer's disease (AD) in T2DM but a mechanism connecting these pathologies is currently unknown. Here we show that levels of Caveolin-1 (Cav-1), an endothelial cell enriched protein and its downstream signaling component eNOS were reduced in the brains of T2DM patients compared to healthy ageing individuals. The levels of Cav-1 and eNOS were inversely correlated with β-amyloid (Aβ) in these patients. Depletion of Cav-1 was recapitulated in the brains of T2DM mouse models and correlated with upregulated levels of amyloid precursor protein (APP), β-secretase-1 (BACE-1) and hyperphosphorylated tau (p-tau) species. In addition, the T2DM mice exhibited impairment in recognition memory. Importantly, restoration of Cav-1 in the hippocampus of T2DM mice rescued recognition memory and reduced AD pathology i.e. Aβ, APP, BACE-1 and p-tau levels. Together, our results suggest that reduced levels of Cav-1 in the brain in T2DM accelerate the development of AD hallmarks. Restoring Cav-1 levels may attenuate or prevent AD pathology and cognitive decline in T2DM.

Title: The exocyst complex is an insulin-sensitive regulator of amyloid precursor protein (APP) trafficking and beta-amyloid generation in neurons

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by the loss of cognitive function, language, and memory. Despite decades of AD research, there are still no effective therapies and the pathogenic mechanisms are not fully understood. One prominent histopathological hallmark of AD is the accumulation of amyloid beta (Aβ) peptide

plaques. Neuronal generation of the Aβ peptide arises from proteolytic processing of the amyloid precursor protein (APP) by β- and γ-secretases, and although not fully understood, regulation of APP intracellular trafficking plays a key role in the balance of amyloidogenic APP processing. The exocyst is a highly-conserved eight-protein complex that acts as a Rab GTPase effector to guide subsets of intracellular transport vesicles to their destination for vesicle fusion. Assembly and targeting of the exocyst is controlled by a variety of protein kinases and small GTPases through mechanisms that are often cell type-specific. For example, adipocytes and muscle cells use the exocyst for dynamic exocytosis of GLUT4-containing vesicles in response to insulin signaling. We hypothesize that the exocyst plays a key regulatory role in the neuronal intracellular trafficking of APP. We show in human SH-SY5Y neuroblastoma cells differentiated into neurons, and in primary mouse hippocampal neurons, exocyst subunits were co-localized with APP on intracellular vesicles via high-resolution imaging. We confirmed these findings using proximity ligation assays (PLAs), a novel technique to measure protein-protein interactions within the cell, showing that APP and Exoc5 protein co-localized within 40nm. However, after 15 mins of insulin treatment, this APP-Exoc5 interaction was greatly reduced, while the association of Exoc5 with GLUT4 was increased. Using a stable SH-SY5Y cell line that we generated to express APP containing several familial AD mutations and which secretes high levels of Aβ, RNAi silencing of each exocyst subunit led to dramatic decreases in sAPP and Aβ secretion, with intracellular accumulation of full-length APP. In addition, we observed the same results with RNAi silencing of Exoc3L2, an uncharacterized exocyst gene homolog linked to late onset AD through GWAS. Using live-cell TIRF microscopy of fluorescently-labeled APP and exocyst proteins in differentiated SH-SY5Y neurons, we observed highly correlated movement of APP and Exoc4/7, with the Exoc1 protein often marking the site of APP exocytosis. These experiments show for the first time that the exocyst plays a key role in APP trafficking and Aβ secretion in neurons, and this activity is directly regulated by insulin signaling.

Title: A potential crosstalk between YKL-40 and PTEN in amyloid-beta induced signalling and biological effects in Alzheimer’s disease

Authors: *X. ZENG, K. CHEUNG, P.-Y. OR, Z. LI, T. LIU, A. CHAN;
SBS, CUHK, Hong Kong, Hong Kong

Abstract: YKL-40 has been established to be a diagnostic biomarker of Alzheimer's disease (AD), and its increased immunoreactivity has been observed in astrocytes in the frontal cortex of AD patients. However, the functional role of YKL-40 in the process of AD is still not known. In our previous study, we have confirmed a cell-type specific relationship between YKL-40 and PTEN, which has been implicated in long term depression and synaptic plasticity. Here, we found significantly increased YKL-40 expression level in cerebral spinal fluid (CSF) of 5xFAD mice. By confocal imaging, we found an astrocyte-specific expression pattern of YKL-40. Similarly, in primary cultured astrocytes, we observed increased YKL-40 expression in conditioned medium (CM) following amyloid beta (Aβ) treatment. Interestingly, we also observed activated PTEN-related AKT/mTOR and JAK2/STAT3 pathway in Aβ-treated astrocytes. Since YKL-40 is a secreted protein, we exposed primary neuronal cultures with YKL-40 and Aβ simultaneously. Immunofluorescence staining showed reduced synaptic puncta following Aβ and YKL-40 treatment. Also, by microelectrode array (MEA) recording, we observed significant reduction in the amplitude of spontaneous action potential. In particular, Western blotting analysis revealed increased expression of PTEN, YKL-40 and Caspase-3, and decreased expression of PSD-95 and synaptophysin (SYP), as well as activated AKT/mTOR pathway following YKL-40 and Aβ treatment. All these observations implicate YKL-40 in mediating the neurotoxic effects of Aβ in neuronal cells. In conclusion, our study demonstrates that Aβ increased YKL-40 secretion and this activates the AKT/mTOR pathway, leading to impaired synaptic plasticity in primary cortical neurons. Our results provide impetus in developing anti-YKL-40 therapy as a strategy to alleviate neuronal attrition in AD brains.

Title: A Tau-mTORC1-SOD1 pathway couples nutrient availability to mitochondrial DNA synthesis and its disruption by Amyloid-beta oligomers

Authors: *A. NORAMBUENA[1], X. SUN[1], H. WALLRABE[1], R. CAO[1], N. SUN[2], E. PARDO[1], N. SHIVANGE[1], D. BIGLER[1], L. A. POST[1], H. A. FERRIS[1], S. HU[2], A. PERIASAMY[1], G. S. BLOOM[1];

Abstract: Alzheimer's disease (AD) features accumulation of amyloid-β (Aβ), tau phosphorylation, insulin resistance and mitochondrial dysfunction, but molecular mechanisms connecting these phenomena remain unclear. We recently discovered nutrient-induced mitochondrial activity (NiMA), an inter-organelle signaling pathway whereby activation of mechanistic target of rapamycin complex 1 (mTORC1) on lysosomes by insulin or amino acids (herein, nutrients) stimulates mitochondrial oxidative metabolism (OXPHOS) and suppresses mitochondrial DNA (mtDNA) replication in cultured neurons. Aβ oligomers (AβOs), which activate plasma membrane, but not lysosomal, mTORC1 by a tau-dependent mechanism (Norambuena et al, 2017. *Alzheimer's & Dementia* 13: 152-167), were found to counteract the effects of nutrients on both OXPHOS and mtDNA replication (Norambuena, et al. 2018. *EMBO J* 37: e100241). These observations stimulated further investigation of the mechanism by which tau regulates mtDNA replication and how such regulation may be compromised in AD. Using EdU incorporation and two-photon fluorescence lifetime imaging of NAD(P)H in live cultured neurons, and tracking oxygen metabolism in the live mouse brain with multi-parametric photoacoustic microscopy, we found that mTORC1-mediated phosphorylation of superoxide dismutase 1 (SOD1) at threonine 40 regulates mtDNA synthesis through the NiMA pathway. Mechanistically, we found that in neurons tau enables nutrient-induced activation of mTORC1 at lysosomes, which in turn suppresses SOD1 activity and mtDNA synthesis. In contrast, AβO-induced insulin resistance in neurons increases the lysosomal content of the tuberous sclerosis complex (TSC), an inhibitor of mTORC1 kinase activity, and by extension upregulates SOD1 activity and increases mtDNA synthesis. Dysregulated mtDNA synthesis was also observed in fibroblasts from two patients with tuberous sclerosis, a developmental disorder caused by reduced TSC activity and mTORC1 hyperactivity. Finally, SOD1 activity was found to be elevated in human AD brain. Thus, tau and SOD1 are part of a nutrient-sensing machinery that functionally couples nutrient availability to mtDNA replication and function under normal conditions, and mechanistically links mitochondrial dysfunction to AD.

Title: Axonal Generation of Amyloid-beta from Palmitoylated APP (palAPP) is Regulated by Mitochondria-associated Endoplasmic Reticulum Membranes (MAMs)

Authors: *R. BHATTACHARYYA[1], S. E. BLACK[3], M. S. LOTLIKAR[3], R. H. FENN[3], M. B. TARANTINO[3], M. JORFI[3], D. M. KOVACS[4], R. E. TANZI[2];

Abstract: The subcellular localization of amyloid-β (Aβ) generation and its downstream effects on neurons are key events in Alzheimer's disease (AD) neuropathology. At least 40% of total neurotoxic Aβ is generated via processing of β-amyloid precursor protein (APP) in neuronal processes and axons. The cellular and the molecular mechanisms involved in the axonal generation of the AD-associated Aβ remain largely elusive. We have previously reported that palmitoylated APP (*pal*APP) serves as a preferred substrate for β-secretase (BACE1) in lipid rafts leading to Aβ generation. Mitochondria-associated Endoplasmic Reticulum (ER) Membranes (MAMs) are cholesterol rich lipid domains that bear remarkable similarity to lipid rafts. Recent studies have shown that MAMs are upregulated in AD. APP, BACE1 and γ-secretase components are all found in MAMs, prompting detailed study of the role of MAMs in Aβ generation in AD. In addition, other proteins enriched in MAMs, including inositol-1,4,5-trisphosphate receptor subunit 3 (IP3R3), sigma-1 receptor (S1R) and acyl-coenzyme A: cholesterol acyltransferase (ACAT), have emerged as potential drug targets for AD. Here, we have investigated the role of MAMs in the processing and trafficking of *pal*APP and specifically in the axonal generation of Aβ. For this purpose, we primarily employed human neuronal progenitor cells expressing APP with familial AD (FAD) mutations (FAD hNPCs). These cells differentiated into neurons in a three-dimensional (3D) matrix exquisitely recapitulate AD neuropathology. First, we show that *pal*APP is enriched in MAMs, both in FAD hNPCs and in mouse brain. Next, we show that downregulating MAM assembly by either siRNA-mediated silencing or pharmacological modulation of the MAM-resident sigma1 receptor (S1R) leads to attenuated β-secretase cleavage of *pal*APP. Upregulation of MAMs has promoted trafficking of *pal*APP to the cell surface and has increased β-secretase cleavage. We also show that modulation of MAMs via S1R regulates *pal*APP stabilization. Using a novel microfluidic device, we show that modulation of MAM levels regulates Aβ generation specifically in neuronal processes and axons, but not in cell bodies. Confocal imaging studies have indicated that *pal*APP partitions into axonal MAMs, while total or de-palmitoylated APP resides in somal MAMs. These findings provide a better understanding of the cellular and molecular mechanisms underlying Aβ

generation in axons, and carry significant implications for alleviating Aβ pathology by targeting MAM-associated *pal*APP in axons.

Title: Impact of Transglutaminase type 2 transamidating activity on Amyloid beta aggregation and mitochondrial function in Alzheimer disease models

Authors: *J. PANES-FERNANDEZ, J. A. GAVILAN, P. A. GODOY RIVERA, O. RAMIREZ-MOLINA, A. M. MARILEO, C. F. BURGOS, C. MUNOZ-MONTESINO, G. E. YEVENES, G. MORAGA, P. A. CASTRO, L. GUZMAN, J. FUENTEALBA;
Physiol. Department, Univ. de Concepcion, Concepcion, Chile

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by cognitive impairment that increasingly afflicts the elderly population. The main features of AD have been related with cellular and molecular events like neuronal loss, mitochondrial dysfunction, and aberrant aggregation of Amyloid beta peptide (Aβ) in specific areas of the brain; however, the molecular events associated with Aβ pathology are not well understood. The transglutaminase type 2 (TG2) is a ubiquitous enzyme that have as main role the Ca^{2+}-dependent transamidation of proteins. This enzymatic activity has been closely related with several steps of neurotoxicity in AD pathogenesis, including alterations on mitochondrial O_2 consumption, as well as Aβ crosslinking. In this work, we studied the contribution of TG2 in Aβ aggregation process, and its impact on mitochondrial function in neuronal model of Aβ-pathology as well as J20 mice model. First, we studied the toxic effects of Aβ soluble oligomers (AβOs, 0.5 μM, 24 h) on mitochondrial function parameters as well as on key proteins that regulate mitochondrial biogenesis in hippocampal neurons treated with TG2 inhibitor (Z-DON, 30nM). Using fluorescence approaches, we found that mitochondrial membrane potential (ΔΨm) decrease induced by AβOs was partially prevented by a Z-DON (AβOs 56% vs AβOs + Z-DON = 73%). In parallel, TG2 inhibition could prevent the decrease of PGC-1α levels induced by AβOs (AβOs: 66%, AβOs + Z-DON = 75%). Later, we tested if Aβ peptide is a substrate of endogenous TG2 in an *ex vivo* model of hippocampal slices. We observed a concentration-

dependent raise on TG2 transamidating activity treated Aβ peptide (1-5 μM). Furthermore, hippocampal slices from J20 mice, shown a substantial increase on TG2 transamidating activity (330%), compared with control samples. Finally, we performed an in silico analysis to study the potential TG2-Aβ complex (docking score: -138.3, ΔG_{bind}:-13.2 kcal/mol). Thioflavin-T (ThT) fluorescence assays shown that the recombinant human TG2 (rhTG2) was able to potentiate the Aβ aggregation kinetics, promoting the oligomeric or fibrillar-like structures. These findings reinforce our previous works and lead us to raise the comprehension about TG2 transamidating activity at the onset of Aβ pathology and mitochondrial alterations in AD.

Title: Fluoroethylnormemantine (FENM) used in combination with other therapeutic drugs offers new opportunities in Alzheimer's disease

Authors: *A. FREYSSIN[1,2], A. CARLES[1], S. GUEHAIRIA[1], G. RUBINSTENN[2], *T. MAURICE[1];
[1]MMDN, Univ. Montpellier, EPHE, INSERM, Montpellier, France; [2]ReST therapeutics, Montpellier, France

Abstract: Memantine, a non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist, has been approved for use in Alzheimer's disease (AD). Memantine works by blocking NMDA receptors in the brain and may help improve the symptoms of dementia. However, memantine can cause mild or serious side effects include drowsiness, dizziness, headache, or confusion. Fluoroethylnormemantine (FENM) is a memantine derivative, recently shown to be a superior neuroprotectant than its parent molecule, in the $Aß_{25-35}$ mouse model of AD [Couly et al., Int J Neuropsychopharmacol 2020]. FENM is considered as an anti-excitotoxic drug that may be adequately used in combination for a greater therapeutic efficacy. We therefore tested several FENM-based combinations with drugs acting on different targets of interest in AD: a selective sigma-1 receptor agonist, an acetylcholinesterase inhibitor, an antioxidant, an agonist of GABA-

A receptor and a nonsteroidal anti-inflammatory drug. Memory deficits were induced in mice by intracerebroventricular injection of oligomeric $A\beta_{25-35}$ peptide. Two behavioral tests, namely spontaneous alternation in the Y-maze and passive avoidance response, were used in parallel and protective and symptomatic effects were examined. After determination of the minimal active doses for each compound, the combinations were tested, and combination index (CI) were calculated according to the isobologram representation of drug combination. Results confirmed that FENM presents a different neuroprotective profile than its parent molecule memantine and which extend to the way FENM is active when used in combination with combination with other pharmacological agents. Particularly, outstanding results for combination potentially useful in the treatment of AD will be exposed and discussed.

Title: Does Modulation of Tonic Inhibition Control Sharp Wave Ripples and Hippocampal Place Cell Dynamics?

Authors: M. H. RATNER[1], S. S. DOWNING[1], O. GUO[3], K. ODAMAH[1], T. M. STEWART[2], V. KUMARESAN[1], R. ROBITSEK[1], *D. H. FARB[4];

Abstract: Hippocampal hyperactivity is a hallmark of amnestic mild cognitive impairment (aMCI) in aging and memory dysfunction in Alzheimer's disease, leading to the hypothesis that hyperactivity in the hippocampal trisynaptic circuit impairs memory. As a test of this hypothesis, we sought to recapitulate hyperactivity in young adults by attenuating tonic inhibition in the hippocampal trisynaptic circuit. We used chronically implanted arrays of 96 electrodes arranged as tetrodes and 32 channel silicon probes to record place cell activity within and across the CA1 subregion of young adult rats either foraging in familiar and novel environments or resting in a familiar environment (without foraging) while awake but immobile for ripple band recordings. We find that the nootropic drug α5IA, a selective negative modulator of tonically active predominantly extrasynaptic α5 GABA receptors and established enhancer of episodic memory, enhances CA1 place cell firing rates. Yet properties of place cells believed to reflect memory processing such as spatial information content and pattern separation did not reflect nootropic drug action. This conundrum is resolved by the finding that α5IA substantially augments sharp wave ripple (SPW-R) amplitude, which is known to correlate with improved remembering. These observations strongly suggest that the nootropic actions of α5IA may result from induction of CA1 place cell hyperactivity and enhanced CA1 SPW-R amplitude. Surprisingly, spatial mapping characteristics of place cell firing rates with location were unaffected. We used three strains of rats (Long Evans, Fisher 344, and Sprague Dawley) and found that the outcomes were not strain specific. These results suggest that tonic inhibition may be a key control point in modulating SPW-R amplitude during awake immobility, perhaps leading to enhanced consolidation of encoded information. We posit that modulation of ripple dynamics may be controlled via alterations in extrasynaptic tonic inhibition mediated in part by α5 GABA-A receptors.

Abstract: Alzheimer's disease (AD) is a leading cause of mortality, disability, and long-term care burden in the United States. Women are more likely to develop a rapid progression of dementia than men with a greater risk of developing vascular dementia (VaD) compared to males when predictive factors such as obesity, lifespan, and enhanced stroke severity are considered. While AD-related dementia is associated with tau and amyloid beta accumulation, concurrent derangements in cerebral blood flow (hypoperfusion) have been observed alongside these proteinopathies in humans and mice, a phenomenon known as vascular dementia. Restoring or maintaining cerebral blood flow can improve prognosis and slow dementia progression, making vascular dementia a critical point of investigation in aging and neurodegeneration. Few therapies exist to treat vascular dementia, and there is an urgent need for the discovery of novel targets that treat disease progression and improve patient prognosis. As L-arginine is a crucial driver of nitric oxide synthesis, an ideal target would be involved in this process, and may exist in protein arginine methyltransferases (PRMTs). PRMTs are a novel class of enzymes which can exhibit vasoactivity via the nitric oxide synthase signaling pathway by methylating arginine residues, this methylation reduces the availability of the canonic NOS ligand, l-arginine. This makes PRMTs a relevant target as PRMT products can act on NOS upstream of nitric oxide production. We used aged (9-12 month) 3xTg female mice to recapitulate dementia. We measured PRMT4 protein levels using ProteinSimple capillary-phoresis, and our data suggests that 3xTg female mice have increased levels of PRMT4 (180.0% ± .37% in hippocampus, 5.0% ± .13% in cortex). We assessed peroxynitrite levels using an ELISA kit and our findings suggest that peroxynitrite was increased (40.8% ± 14.0% in hippocampus, 126.8% ± 1.0% in cortex). We used laser speckle contrast imaging to measure regional cortical cerebral blood flow; we found that in aged 3xTg female mice, CBF was reduced (26.0% ± 5.0%). Additionally, administration (30mg/kg/day, 1 week, IP) of specific PRMT4 inhibitor TP-064 improved cerebral blood flow by 162.0% ± 40.4% compared to untreated age/sex matched 3xTg mice. To observe differences in learning and memory, we utilized the modified T-maze; we found that female 3xTg mice score lower (51%), compared to C57 age/sex-matched controls. Overall, our data suggests that enhanced levels of PRMT4 in AD brain results in NOS uncoupling which contributes to peroxynitrite accumulation, hypoperfusion, and functional deficits.

Title: Mek1/2 inhibition rescues neurodegeneration by activation of autophagic lysosomal function in alzheimer's disease

Authors: *Y. CHUN[1], M.-Y. KIM[1], S.-Y. LEE[1], M. KIM[1], H. KIM[1], T.-I. KAM[2,3], S. HAN[1]; [1]Genuv Inc., Seoul, Korea, Republic of; [2]Neuroregeneration and Stem Cell Programs, Inst. for Cell Engin., [3]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Alzheimer's Disease (AD) is a progressive neurodegenerative disorder, which is characterized by cognitive deficit due to synaptic loss and neuronal death. Extracellular amyloid β plaques are one of pathological hallmarks of AD. MEK/ERK signaling pathway is activated in the brain of AD patient and AD animal models, and in primary neurons cultured with Aβ oligomers. Here, we showed that inhibition of MEK/ERK signaling using a clinically available MEK1/2 inhibitor, trametinib (GSK1120212, SNR1611) protected neurons in AD-model mice (5XFAD). The 5-month-old 5XFAD mice were administered either vehicle or 0.1 mg/kg of trametinib for 10 weeks by oral gavage once a day. Administration of trametinib recovered impaired neuronal structures, synaptic dysfunction, and cognitive deficits. Trametinib also protected from apoptotic neuronal death. RNA-sequencing analysis of the brain cortex revealed upregulation of autophagic lysosomal genes by trametinib administration. In addition, trametinib elevated autophagic lysosomal activity in 5XFAD cortex and primary cortical neurons cultured with Aβ oligomers. From these observations, we concluded that MEK inhibition provides neuronal protection by increasing autophagic lysosomal activity, and thus MEK inhibition might be effective therapeutic strategy for AD.

Title: 7,8-dihydroxyflavone attenuates cognitive deficit in icv-stz rat model of alzheimer's disease reversing oxidative stress, mitochondrial dysfunction, and insulin resistance

Authors: *A. AKHTAR, S. P. SAH;
Pharmacol., UIPS, Panjab Univ., Chandigarh, India

Abstract: Objectives: Sporadic Alzheimer's disease (SAD) is the most commonly prevalent dementia and progressive neurodegenerative disease. A polyphenolic flavonoid, 7,8-dihydroxyflavone (7,8-DHF) was used to reverse the cognitive deficit in a rat SAD model by reversing oxidative imbalance, mitochondrial enzyme dysfunction, and insulin resistance. **Methods:** For the SAD model, streptozotocin (STZ-3 mg/kg) was injected intracerebroventricularly (ICV) in male Wistar rats to induce cognitive dysfunction. Cognitive functions were evaluated by Morris water maze (MWM) and novel object recognition (NOR) tests, while locomotor activity was determined in actophtometer. 7, 8-DHF was given orally in doses of 5 mg/kg, 10 mg/kg, and 20 mg/kg, and reference standard drug rivastigmine in a dose of 2 mg/kg. Antioxidant enzymes, mitochondrial enzyme complexes were determined biochemically, insulin-degrading enzyme (IDE) and p-tau by ELISA, and histopathology by H&E staining. **Results:** 7,8-DHF attenuated cognitive deficit induced by ICV-STZ in MWM and NOR. Moreover, in the cortex and hippocampus regions of the brain, levels of reduced glutathione, catalase, superoxide dismutase, and mitochondrial complex enzymes and increased lipid peroxidation, protein carbonylation, and nitrite levels were subsequently reversed by 7,8-DHF and rivastigmine. IDE and p-tau protein were found to be altered. Histopathological examination revealed halted neurodegeneration. **Conclusions:** Conclusively, 7,8-DHF was found to be neuroprotective in the ICV-STZ rat model of SAD by ameliorating oxidative stress, mitochondrial dysfunction, and insulin resistance, thereby improving cognitive functions evident with the behavioral results. Hence, these results can further have clinical relevance in human AD.

Abstract: Alzheimer's Disease (AD) is a neurodegenerative disease that first affects the entorhinal cortex and hippocampus regions of the brain. It is characterized by the aggregation of amyloid-beta (Aβ) protein in the form of plaques in the extracellular space and inclusions in the blood vessels, and hyperphosphorylation of the protein tau, in the form of intraneuronal aggregates of neurofibrillary tangles (NFTs). Clinical manifestations of AD include progressive memory loss, psychological and emotional disturbances, attention deficits, and visuospatial deterioration. Currently, no treatment has been shown to effectively modify the disease progression in AD. Most of the current treatments focus on specific aspects of AD and provide, at best, palliative effects on the targeted symptoms. We chose to test progesterone to treat memory dysfunction in the 3xTg mouse model of AD because of its pleiotropic effects. Progesterone is a major gonadal and neurosteroid hormone that has been shown to exert neuroprotective effects in *in vitro* and *in vivo* studies of brain injury and disease, including some rodent models of AD. Progesterone influences neuronal function by modulating gene transcription and cellular activity by binding to intracellular receptors abundant in the central nervous system. The mouse model used in the current study, 3xTg-AD shows both amyloid-beta plaques and neurofibrillary tangles, as well as the synaptic dysfunction that mimics what is observed in AD patients. The 3xTg-AD mice display behavioral impairments such as severe memory loss, as well as the emotionality and psychological changes that are analogous to those seen in AD patients. As the primary goal of this project was to determine if progesterone is an effective treatment for reducing the memory deficits in the 3xTg model of AD, we utilized a spatial reversal task using a water-T-maze. Daily oral-gavage injections of progesterone (5 mg/kg) or equivalent volumes of the vehicle was administered for 40 days. Our results indicated that progesterone-treated C57 wild-type male mice made fewer errors than vehicle-treated control and 3xTg mice, with the progesterone-treated 3xTg male group showing marginal improvement in their performance on the water-T-maze tests. Although further data analysis is required of additional behavioral tests, our results suggest that progesterone may provide benefits in reducing AD-induced cognitive deficits.

Title: The phosphodiesterase inhibitor ibudilast alleviates Alzheimerr's disease pathology and improves cognition in a transgenic rat model

Authors: *G. OLIVEROS[1], L. XIE[2], P. ROCKWELL[1], P. A. SERRANO[3], M. E. FIGUEIREDO-PEREIRA[1];

Abstract: Alzheimer's disease (AD) is a multifactorial disease characterized by the development of amyloid-beta (Aβ) plaques, neurofibrillary tangles, neuroinflammation, neuronal loss in the brain, and cognitive deficits. Therefore, treatment efficacy is likely dependent on a multi-target drug approach. Using a multi-scale predictive modeling framework, we identified Ibudilast (IBU), a phosphodiesterase (PDE) inhibitor and Toll-like receptor 4 (TLR4) antagonist, as a potential drug candidate. We predicted that IBU inhibits the interleukin-1 receptor associated kinase 1 (IRAK1) as an off-target drug effect. The promise IBU has shown in multiple sclerosis (MS) clinical trials and its efficacy in treating asthma and stroke by reducing neuroinflammation, makes IBU a favorable candidate for treating AD. The Fisher transgenic 344-AD rat model, which expresses human mutant "Swedish" amyloid-precursor protein (APPsw) and Δ exon 9 presenilin-1 (PS1ΔE9), was used to test the efficacy of IBU. TgF-344-AD rats exhibit age-dependent Aβplaques, tau paired-helical filaments, neuronal loss, microgliosis, and cognitive deficits, mimicking the progression of AD in humans. IBU-treatment started at 5 month of age. Following a 6 month IBU-treatment, we assessed spatial learning and memory in transgenic (Tg) and wild-type (WT) male and female rats compared to age-matched non-treated controls using the Active Place Avoidance Task (aPAT). At 11 months of age, untreated Tg rats exhibited deficits in acquisition and retention compared to their untreated WT counterparts. IBU-treatment mitigated these spatial learning deficits and improved memory retention in the Tg rats compared to untreated Tg rats. IBU-treatment also reduced hippocampal (hilar region) Aβ plaque and tau paired-helical filament, and reduced microgliosis. RNA sequencing analysis of Tg hippocampal tissue showed that IBU affects the expression of genes involved in the TLR and ubiquitin/proteasome pathways in a sex-dependent manner. With respect to the TLR pathway, IBU increased the expression of IRAK3, a negative regulator of IRAK1 activity, and altered the expression levels of TRAF6 and other TLR-related ubiquitin ligases and conjugases. Our results

support IBU as a promising drug candidate for AD treatment via its multi-target effects on the TLR and ubiquitin/proteasome pathways to alleviate AD symptoms including cognitive deficits.

Title: Neurometabolite 5α-androstane-3α,17β-diol enhances object recognition memory and hippocampal dendritic morphology in 3xtg-ad mice

Authors: *N. KUWAHARA[1], S. BHULLAR[1], K. TANG[1], L. K. ISAACS[1], K. C. NICHOLSON[1], K. JARDINE[2], B. D. WINTERS[2], N. J. MACLUSKY[1];
[1]Biomed. Sci., [2]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Women have an increased risk of developing Alzheimer's disease (AD) and experience worsened cognitive deterioration at the same stage of the disease, compared to men. This may be due, in part, to the sex differences in age-related decline of circulating gonadal steroid hormone levels. In animal studies, testosterone has been shown to exert neuroprotective and neurotrophic effects in the brain, while men with AD tend to have reduced free levels of circulating testosterone. Recent studies have demonstrated that the steroid hormone-mediated neuroprotection may be augmented through the conversion of primary gonadal steroid hormones into metabolites that may have distinct biological properties from those of their parent hormones. Previously, we showed that the 5α-reduced metabolite of testosterone, 5α-androstane-3α,17β-diol (3α-diol), may play a role in protecting neurons against the neurotoxic effects of amyloid beta exposure and hence contribute to the observed sex differences in AD. Inhibiting the synthesis of testosterone-derived neurosteroids impaired object recognition memory (ORM) and exacerbated AD-like neuropathology in 6-month-old male 3xTg-AD mice (expressing mutations associated with human familial AD: APP Swedish, MAPT P301L, and PSEN1 M146V). However, the possible protective effects of increasing 3α-diol levels *in vivo* remains unknown. To determine whether supplementation with 3α-diol might confer protection against the development of AD-like pathology, male and female 3xTg-AD mice were implanted s.c. with Silastic capsules releasing 3α-diol at 3 months of age (n=15-16 per treatment group). After 6

months of treatment, 3α-diol increased hippocampal CA1 dendritic branching and apical dendritic spine density in females compared to males, and improved ORM in 3xTg-AD females, eliminating the ORM deficit normally observed in female 3xTg animals at this age. These findings suggest that long-term treatment with 3α-diol may induce neuroprotective effects, counteracting the preferential loss of cognitive function otherwise observed in females. Ongoing experiments will determine the effects of 3α-diol on cognitive performance and AD-like neuropathology as the disease progresses beyond 9 months of age.

Title: Neuroprotective effects of Fluoroethylnormemantine (FENM) after chronic infusion by Alzet pumps in the Aß$_{25-35}$ mouse model of Alzheimer's disease

Authors: *A. CARLES[1], A. FREYSSIN[1,2], S. GUEHAIRIA[1], G. RUBINSTENN[2], T. MAURICE[1];
[1]MMDN, Univ. Montpellier, EPHE, INSERM, Montpellier, France; [2]ReST Therapeut., Montpellier, France

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disease and available treatments are mainly symptomatic. In particular, memantine (Ebixa) is a non-competitive NMDA receptor antagonist which mechanism of action suggested promising symptomatic and neuroprotective effects. Fluroethylnormemantine (FENM) is a structural analogue of memantine originally synthesized as a positron emission tomography radioligand, with a substitution of the Fluor atom with 18F, to label NMDA receptors in vivo [Salabert et al., Nucl Med Biol 2015, 2018]. Recently, we showed that FENM, administered intraperitoneally, prevented the toxicity, neuroinflammation and learning deficits in Swiss mice intracerebroventricularly injected with oligomerized Aβ$_{25-35}$ peptide. The drug showed a superior efficacy as compared with Memantine and an absence of direct amnesic effect at higher doses [Couly et al., Int J Neuropsychopharmacol 2021]. In the present study, we compared two modes of administrations of FENM and memantine, namely chronic subcutaneous infusion with Alzet pump and bolus

intraperitoneal injections. C57Bl/6 mice were treated intracerebroventricularly with oligomerized $A\beta_{25-35}$ peptide and after different timepoints behavioral, biochemical and physiological parameters were analyzed. Different memory tests were used including spontaneous alternation in the Y-maze and object recognition test. Then, toxicity induced in the mouse hippocampus or cortex was analyzed biochemically or morphologically, using markers of apoptosis, neuroinflammation and oxidative stress. (De)regulations of NMDA receptor subunits were also analyzed in the hippocampus by western blots. Interestingly, data showed that infused FENM is as effective after infusion than observed after bolus administration, with effective doses in the 0.1-0.3 mg/kg/day range. FENM therefore appeared as a potent neuroprotective drug using two administration modes in the pharmacological model of AD. These results open the possibility of using the compound either as a patch or tablets in human therapy.

Title: Percolation Theory Modeling and Biomarker Identification in an Alzheimer's Disease Mouse Model

Authors: *P. KOTLARZ[1], L. DA SILVA[1], K. XHINDI[1], M. HAGSTROM[1], L. SOSA[1], M. FEBO[2], J. NINO[1];
[1]Materials Sci. and Engin., [2]Psychiatry Dept., Univ. of Florida, Gainesville, FL

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disease that can lead to severe neurocognitive deficits. Due to the degenerative nature of AD, percolation theory, which examines how networks respond to damage, can be used as a potential model. Our objective was to utilize connectomic analysis in conjunction with percolation theory to understand network changes in AD to identify connectivity-biomarkers via fMRI. Effects of Aβ and inflammatory interleukin-6 (IL6), alone or in combination, on in vivo functional network connectivity in the

TgCRND8 mouse model for Alzheimer's-type Aβ deposition were examined using high-field functional magnetic resonance imaging (fMRI). Using a single shot echo planar imaging sequence at 11.1 Tesla, we scanned the brains of 8 months of age mice expressing brain-targeted IL6 or enhanced glial fibrillary protein (EGFP controls). Connectivity matrices were obtained via pre-processing the fMRI images. The matrices were averaged as a group, normalized, and thresholded at 10% graph density, or normalized and thresholded individually. Both global and nodal quantifiers were analyzed. Statistical significance of the quantifiers' difference between AD and control mice were evaluated using the Wilcoxon-rank sum test via nonparametrics. Differences between groups were further elucidated using network-based statistics employing t-tests comparing nodes and edges. Finally, networks and their response to targeted attacks based on specific quantifiers were analyzed. Significant differences were found in four global quantifiers (characteristic path length, global efficiency, network diameter, average strength) as well as specific nodal regions, notably the left ventral tier of the thalamus and left mesencephalic reticular formation. Examining network connectivity indicated reduced connectivity in anterior regions of the AD brain compared to control. This disconnected anterior cluster was also modeled utilizing iterative betweenness centrality and collective influence attack schemes. Percolation theory demonstrated an increase in vulnerability in AD brains in response to network attacks both in terms of overall network composition and sub-regions. While these results point toward significant differences in terms of vulnerability and connectivity between AD and control brains, employing percolation theory modeling can potentially identify preclinical AD via fMRI through examining anterior-to-posterior connectivity, vulnerability via slope analysis, and nodal baselines.

Abstract: Neuro-axonal brain damage releases neurofilament light chain (NfL) proteins, which enter the blood. Serum NfL has recently emerged as a promising biomarker for neuro-axonal injury, monitoring treatment responses, and predicting prognosis in neurological diseases. Importantly, serum NfL level also increases with normal aging, so the interpretation of serum NfL levels in neurological diseases is confounded because a reliable model for age-related variation in serum NfL level in healthy subjects is currently lacking. Graph signal processing (GSP) has emerged as a powerful analytical tool to produce measures of relationships of functional dynamics of brain activity with the underlying structural white matter anatomy. Here, we leveraged a set of low and high graph frequency features extracted from the blood oxygen level dependent (BOLD) signals and structural connectome (Desikan-Killiany atlas, 66 cortical brain regions) using tools from GSP to test their association with serum NfL levels collected from healthy subjects with no history of neurological or developmental disorders (n = 20, mean age = 49.38 years). Age was significantly correlated with serum NfL in this cohort (Pearson's correlation = 0.71, p-value = 4.1e-4). A low and a high graph frequency feature were extracted from the BOLD data for each brain region, resulting in 132 total GSP features per subject. The low or high graph frequency features for a brain region were the metrics of increasing or decreasing conformity of its corresponding functional activity with the underlying structural anatomy. Using a linear model based univariate feature selection analysis, we found the low graph frequency features from isthmus cingulate (F-value = 20.175, false discovery rate (FDR) corrected p-value = 3e-4) and parahippocampus (F-value = 9.68, FDR corrected p-value = 6e-3) in the right hemisphere to be the most significantly related to serum NfL. Furthermore, using linear regression analysis, we observed that the low graph frequency feature from the isthmus cingulate explained 52% of the variance in serum NfL in this cohort. Additionally, mediation analysis revealed that the low graph frequency feature from isthmus cingulate had a significant partial mediation effect (p-val = 0.0056) on the association between age and serum NfL. Therefore, our results suggest that, in addition to age, these GSP-based neuroimaging features may be included in models of baseline variance when evaluating NfL as a biomarker in different contexts. Furthermore, our results raise new questions about the causal association between serum NfL levels and GSP features from certain brain regions during aging.

Title: De-differentiation of functional networks in corticobasal syndrome

Authors: C. T. MCMILLAN[1], **S. SIHAG**[1], J. S. PHILLIPS[1], P. A. COOK[2], M. GROSSMAN[1], J. C. GEE[2], D. IRWIN[1], T. SATTERTHWAITE[3], L. M. MASSIMO[4];
[1]Neurol., [2]Radiology, [3]Psychiatry, [4]Nursing, Univ. of Pennsylvania, Philadelphia, PA

Abstract: There is an increasing acceptance that neurodegenerative diseases manifest as network disorders. In particular, we have established that corticobasal syndrome (CBS) is characterized by structural network degeneration involving grey matter and white matter. Moreover, graph-theoretic analyses of diffusion magnetic resonance imaging (dMRI) have related efficiency of intrinsic brain networks to neuropathological features of CBS. However, little is known about the mechanisms of functional network degeneration in CBS. In this study, we draw upon evidence in the developmental literature that intrinsic networks segregate in adolescence to facilitate functional specialization of cognition and hypothesize that these networks become de-differentiated in neurodegeneration. We analyzed resting state functional MRI in clinically diagnosed CBS patients (23 subjects, 13 males, 10 females, mean age = 68.69 y) and Healthy Controls (12 subjects, 8 males, 4 females, mean age = 57.7 y). We focused our analyses on 5 network parcellations from the 200 parcel Schaefer Atlas (somatomotor, salience, limbic, frontoparietal and default mode network) and quantified de-differentiation using participation coefficient (PC) where higher PC corresponds to decreased network segregation, within-module connectivity for 5 modules, and their respective inter-modular connectivity. We additionally used ordinal regression to relate network segregation features to global clinical dementia rating scale (CDR) for CBS. All analyses were adjusted for age, sex, and average root-mean-square of head displacement, and their statistical significance was evaluated after false discovery rate (FDR) correction for multiple comparisons. The comparisons of segregation measures between CBS and healthy controls revealed that the within-module connectivity in somatomotor network was significantly lower in CBS and subsequently, PC in this network was higher in CBS cohort, consistent with de-differentiation of somatomotor network in CBS. Ordinal regression models suggested significant decreasing trends in within-module connectivity of frontoparietal network (β = -23.37, FDR corrected p-value = 0.04) and inter-modular connectivity between limbic and salience subnetworks (β = -37.21, FDR corrected p-value = 0.04) with worsening disease severity on CDR. These results are consistent with the hypothesis that de-differentiation of critical intrinsic networks is a feature of CBS-related neurodegeneration that increases with disease severity.

Abstract: Blood proteins are emerging candidate biomarkers for Alzheimer's disease (AD). A comprehensive investigation of the AD blood proteome will help identify additional biomarkers to delineate the disease's pathways and define specific AD stages. We quantified 1,160 plasma proteins in a Hong Kong Chinese cohort (n = 106 AD patients, n = 74 healthy controls) by high-

throughput proximity extension assay to identify AD-associated plasma proteins. Specifically, we showed that plasma proteins involved in diverse biological processes were dysregulated in AD. A subset of plasma proteins was selected to represent the AD plasma protein profile, which formed the basis of a scoring system that can accurately classify AD and associated endophenotypes. In addition, we showed that certain plasma proteins and biological processes exhibit stage-specific dysregulation in AD, thus adding biological annotations to AD stages. This study comprehensively profiled the AD plasma proteome and serves as a foundation for a high-performance, blood-based test for clinical AD screening and staging.

Title: Identification of potential new biomarkers for the diagnosis of Alzheimer's disease, through bioinformatic analysis.

Authors: *M. SILVA-LUCERO[1], J. RIVERA-OSORIO[2], G. LOPEZ-TOLEDO[3], L. GOMEZ-VIRGILIO[1], M. CARDENAS-AGUAYO[4];
[1]UNAM, Ciudad de México, Mexico; [2]Inst. de Neurobiología, UNAM, Ciudad de México, Mexico; [3]Physiol. Biophysics and Neurosci., CINVESTAV, Mexico City, Mexico; [4]Physiol., UNAM, Med. Sch., Ciudad DE Mexico, Mexico

Abstract: Introduction. Alzheimer's disease (AD) is the most common cause of dementia, where substantial neuronal loss and neuropathological lesions can damage many brain regions, symptoms of the disease begin with mild memory difficulties and evolve towards cognitive impairment. The discovery of biomarkers that confer high confidence AD diagnosis would be a valuable tool to study the etiology of the disease, find risk factors, discover more treatments, and develop new drugs. Bioinformatics have made possible to analyze large amounts of transcriptomics data bases with greater efficiency to identify genes whose relationship with diseases such as AD was previously unknown. **Methods.** We used the total RNA sequencing

databases microarrays of tissue from the medial temporal lobe (MTL) and peripheral blood (PB) of patients with AD, which were processed by TrueSeq RNA-seq. The values were normalized with the Limma package of the statistical programming language. Subsequently, with the data obtained, we performed a computational analysis of the genetic differential expression using t-statistic-Limma. The data were corrected with the Benjamini and Hochberg approach and the genes with p values equal to or less than 0.05 were considered statistically significant. The direction of the change in gene expression was determined by its variation in the "log2-fold change" between controls and patients. A functional enrichment analysis of genetic ontology was performed using goana and topGO-Limma. The results were compared and confirmed with clusterProfilerR, we also applied the Fry-Limma analysis. **Results.** With MTL database we obtained 359 genes down regulated (DR) and 324 genes up regulated (UR), the altered pathways UR were: transcription, mitochondrial function and hydrolase activity, while DR: gene expression and regulation of cell proliferation, nuclear alterations, transmembrane receptor signaling. KEGG Analysis showed that metabolic pathways are altered UR and cytokine pathways and their receptors are altered DR. The analysis of PB samples showed 383 genes DR and 257 genes UR. KEGG analysis showed alterations in the Retinol and metabolism pathways. **Conclusion.** The intersection of the differentially expressed genes in the two databases exhibited 34 genes shared between the brain and blood arrangement: UR: SCG2, CA14, AHSP, HAPLN2, RALY-AS1, PLEKHG4, PRSS35, LINC01116; DR: DBH, NME8, CXCL6, SERPINA7, OR10H3, NYNRIN, MOS, C3, IL10RB-DT, CDKN2A-DT, CCDC60, CPB2, RBPMS6 CRST, T4ENT5D, DGKG. TRIM58 matched in both databases, DR in patients with AD. Search for altered genes in AD brain tissue will allow us to validate them in in blood samples, as a possible diagnostic tool.

Title: Brain cortical differences in functional connectome strength in subjects with subjective memory complaints, mild cognitive impairment, and Alzheimer's disease

Authors: *A. M. PINTO[1], P. KOTLARZ[2], J. C. NINO[3], M. FEBO[1];
[1]Psychiatry and Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL; [2]Biomed. Engin., [3]Materials Sci. and Engin., Univ. of Florida, Gainesville, FL

Abstract: The early behavioral signs of Alzheimer's disease (AD), which include cognitive difficulty and mood changes, begin years-to-decades before the clinical symptoms of mild-to-severe cognitive impairment and dementia. The objective of the present study was to determine how functional connectivity (FC) between nodes located in distributed brain regions is modified at distinct stages of cognitive decline and AD. To gain insight into strength of connectivity and overall network topology, we applied graph theory analysis to graphs generated from functional connectivity data. We investigated functional connectivity between 300 nodes embedded within 17 distinct networks in control elderly participants (n=51), and participants classified as having subjective memory complaints (SMC, n = 18), early mild cognitive impaired (EMCI, n=34), MCI (n=11), late MCI (LMCI, n=13), or AD (n=7). Subjects were part of the ADNI study (ages: 61-96; n=134, 50% female) and the data were from their initial visit. All resting state functional MRI scans were collected on a Siemens Prisma Fit 3-Tesla scanner with the following parameters: EPI with 197 image repetitions, TR=3seconds, TE=30ms, 3.4mm isotropic voxel resolution. Graph theory-based calculations were applied to weighted undirected matrices constructed from 44,550 pairwise correlations between fMRI signals from 300 regions (Yeo parcellation). We identified a cluster of nodes in the somatomotor and dorsal attention networks that showed a gradual decline in node strength from controls to MCI and AD. A separate cluster of nodes located in default/dorsal attention network showed a transient increase in node strength. Pairwise permutation tests between each group vs controls indicated that differences in node strength varied rostral-caudally across the cortex from SMC to MCI and AD. In AD, significant differences in node strength were observed in occipital, temporal lobe, and superior parietal areas. Large-scale regional changes in node strength across pre- and postcentral gyri, superior parietal and occipital lobe appear to track differences from SMC to MCI and AD. Although the link to underlying synaptic function is unclear, the results suggest that the strength of communication across the cortex could vary over the course of progression of cognitive decline. While applying these network analysis techniques to AD is novel, our aim is to give an overview of our technique and the possible future application of connectomics as biomarkers of cognitive decline.

Title: Role of novel microRNAs in neurodegenerative diseases

Authors: *D. K. LAHIRI[1], R. WANG[2], B. MALONEY[2], J. BECK[3], N. CHOPRA[2], K. SAMBAMURTI[4], S. E. COUNTS[3];
[1]Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Psychiatry, Indiana Univ. Sch. of Medicine, Indianapolis, Indianapolis, IN; [3]Translational Neurosci., Michigan State Univ., Grand Rapids, MI; [4]Neurosciences, MUSC, Charleston, SC

Abstract: Neurodegenerative diseases, such as Alzheimer's disease (AD), are incurable and debilitating conditions that result in progressive degeneration and/or death of nerve cells. In particular, AD results from alterations of key biochemical pathways that lead to classic AD pathology of brain extracellular neuritic plaques generated from aggregates of amyloid-β peptide (Aβ), which is cleaved from Aβ precursor protein (APP), and intraneuronal fibrillary tangles of the hyperphosphorylated microtubule-associated protein tau. More importantly, this is accompanied by progressively debilitating dementia. Dysregulation of proteins involved in Aβ production, such as APP and β-secretase (or BACE1), and/or Aβ degradation, such as membrane metallo-endopeptidase (MME or neprilysin), contribute to excess Aβ deposition. Excess Aβ deposition contributes to tau hyperphosphorylation. MicroRNAs (miRNAs) are non-coding small RNAs that typically downregulate mRNA translation via mRNA 3'-untranslated region (UTR) sequences, and, consequently, many cellular processes. Notably, miRNA expression is often dysregulated in sporadic human disorders, including AD. We tested human specific miRNA species regulating human genes involved in AD. We used human cell cultures and brain tissues from control and AD subjects. Notably, we observed regulation of APP by miR-20b, miR-101 and miR-153; BACE1 by miR-9 and miR-339-5p; and MME by miR-181d. These miRNAs regulate protein expression via the respective target's mRNA-3'UTR (see an exception below). Interestingly we observed that overexpression of miR-298 reduces levels of APP, BACE1 and specific tau protein moieties. Further, we found that miR-346 uniquely *upregulates* APP levels via the APP mRNA *5'UTR* in human cultures and that this activity was part of iron (Fe) homeostasis. Here we report a novel human microRNA (miR20b) that alters AD risk probability and neuronal function. A specific polymorphism close to the MIR20B gene alters levels of CSF Aβ and structure of a critical brain region. Further, we have identified specific miRNAs in brain tissues with altered levels in AD patients vs. controls. Together, these multiple unique regulatory interactions may serve as novel therapeutic targets and enable the development of treatment strategies beneficial against human diseases, including AD. Complexity of interaction effects with other miRNAs may shed further light on brain health, AD and other neurodegenerative disorders.

Title: Alteration of a Specific MicroRNA Regulating Membrane Metalloendopeptidase Expression in Alzheimer's Disease

Authors: *R. WANG[1], B. MALONEY[1], S. E. COUNTS[3], *D. K. LAHIRI[1,2];
[1]Departments of Psychiatry, [2]Med. & Mol. Genet., Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Departments of Translational Neurosci. and Family Med., Michigan State Univ., Grand Rapids, MI

Abstract: Alzheimer's disease (AD) is characterized by accumulation of amyloid β (Aβ) plaques and aggregates of hyperphosphorylated tau protein. Aβ biogenesis and degradation play critical roles in Aβ accumulation. Membrane metallo-endopeptidase (MME, neprilysin) is an Aβ-clearing enzyme. microRNA (miRNA), a group of small non-coding RNAs, regulates protein translation from mRNA. Disruption of miRNA regulation of MME could contribute to AD. Bioinformatics predicted miRNA binding sites on the MME mRNA 3'-untranslated region (3'-UTR), including the miR-181-5p family. We tested miR-181 activity with recombinant fusion reporter gene- MME 3'-UTR constructs. All four miR-181-5p (miR-181a, miR-181b, miR-181c, miR-181d) sequences downregulated reporter signal. We quantified miR-181-5p in human brain tissue specimens from non-cognitive impairment (NCI), mild cognitive impairment (MCI), and AD subjects. Of these, only miR-181d-5p significantly associated with disease status. Human neuronally differentiated cells were transfected with miR-181d-5p mimics. miR-181d-5p treatment produced significant reduction of MME mRNA and protein. Dysregulation of MME by (presumably excess) miR-181d could contribute to AD pathogenesis.

L. BOXER[2], F. HUANG[1];
[1]Denali Therapeut., South San Francisco, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Frontotemporal dementia (FTD) is a common cause of early-onset dementia. FTD is highly heritable, and 10-20% of all cases are caused by mutations in three genes: MAPT, GRN, and C9ORF72. As therapeutics are being developed for FTD, it is essential to identify disease-associated biomarkers in clinically accessible biofluids that may be used as pharmacodynamic biomarkers for dose selection and pathway engagement. It is also important to determine the levels of such biomarkers longitudinally along the course of disease progression.
In collaboration with ALLFTD/NCRAD, we took a discovery and validation approach for patient biomarker analysis. We used a pilot set of CSF and plasma samples from FTD patients with or without GRN mutations for biomarker discovery, and a large longitudinal set of samples including GRN, MAPT and C9ORF72 mutations for biomarker confirmation, examination of genotype effect and longitudinal stability. We used a multidisciplinary approach including targeted mass spectrometry analysis for lipids/metabolites, quantitative immunoassays for microglial and neurodegeneration biomarkers, and untargeted and targeted proteomics for synaptic and lysosomal proteins.
We found plasma glucosylsphingosine (GlcSph), a lysosomal biomarker proximal to progranulin, was elevated in GRN-FTD patients compared to non-GRN clinically normal controls, indicating GlcSph could be a useful peripheral pathway biomarker in clinical studies. CSF bis(monoacylglycerol)phosphate (BMP), a lysosomal phospholipid, showed decreases in sporadic FTD and MAPT-FTD. Glial biomarkers, YKL-40 and GFAP, were elevated in all FTD patients for YKL-40, and in sporadic-FTD, GRN-FTD & MAPT-FTD patients for GFAP. Consistent with previously reported findings, neuronal health related biomarkers, including

neurofilament light chain (Nf-L) and UCH-L1, were elevated for all FTD patients. Synaptic biomarkers NPTXR/1/2 were reduced in CSF of all FTD patients. Interestingly, Nf-L and NPTX2 levels were correlated with disease severity (FTLDCDR-SB) in GRN-FTD & MAPT-FTD patients. Nf-L levels were relatively constant during disease progression, positioning it as a disease related biomarker with potential for monitoring treatment effect.
Taken together, we have identified a panel of progranulin pathway and disease related biomarkers in CSF and plasma from FTD patients, which could serve as useful markers for monitoring treatment effects in the clinic.

Section, LNS, Intramural Res. Program, Natl. Inst. On Aging, NIH, Baltimore, MD

Abstract: High serum homocysteine is a risk factor for Alzheimer's Disease (AD). It has been reported to influence the accumulation of its characteristic lesions - senile plaques (SP) and neurofibrillary tangles (NFT) - containing amyloid β protein (Abeta) and microtubule-associated protein Tau (MAPT), respectively. It is also a known risk factor for retinal degeneration and typically increases in the aging population. We hypothesize that metabolic failure with aging might drive conditions that increase homocysteine and favor SP formation. Reduced food or calorie intake or branch chain amino acids are already known to benefit AD model mice. Restriction of Met, an essential aa, contributes to an increase in longevity without calorie restriction. We treated APP/PS1 transgenic mice with a 75% Met restricted (MR) diet and compared it with an isocaloric isonitrogenous complete diet (CD) for up to 12 months. MR diets significantly alter gut microbiota. As expected, the bacteria that metabolize Met and Cys are reduced. Furthermore, several major species of bacteria were reduced significantly, and the overall diversity of microbiota appears to be increased. Our data show that the treatment significantly drops brain soluble Abeta at 3 and 6 months. Abeta levels are very high and presumably saturated in older mice, explaining the lack of statistically significant differences between the different diets. Nevertheless, older mice show substantial improvement in behavior in a novel object recognition task after MR treatment. MR treatment is known to be senolytic, and therefore, we are currently examining related processes, such as preservation of lysosomal capacity, changes in metabolome, mRNA, and miRNA profiles. Senolysis and improvements in AD pathology may also be mediated by reduced inflammation due to the increased diversification of the microbiome. Thus, such diets may play an important role in strategies to prevent AD, retinal degeneration, and other age-associated disorders.

Title: Differential atrophy along the longitudinal hippocampal axis in Alzheimer's disease

Authors: *T. OLIVEIRA[1], R. MORAIS-RIBEIRO[2], A. COELHO[2];

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder that primarily affects the hippocampus. Since hippocampal studies have highlighted a differential subregional regulation along its longitudinal axis, a more detailed analysis addressing subregional changes along the longitudinal hippocampal axis has the potential to provide new relevant biomarkers. This study analysed structural brain MRI data of 600 participants (aged 55-92 years-old) from the Alzheimer’s Disease Neuroimaging Initiative (ADNI). Hippocampi of cognitively normal (CN) subjects (n=200), mild cognitively impaired (MCI) subjects (n=200) and AD patients (n=200) were segmented with Freesurfer v6.0 and sub-segmented along its longitudinal axis in anterior, intermediate and posterior sub-divisions using an in-house algorithm.Total hippocampal volume normalized to intracranial volume (ICV) negatively correlated with age in all groups. Standardized residuals from the linear regression of normalized hippocampal volume by age were then calculated, showing that the mean relative atrophy corrected for the aging effect was higher in CN than in MCI, and lower in AD, with significant differences between all groups. Both anterior, intermediate and posterior hippocampus negatively correlate with age in all groups, with no significant differences between them. However, when normalizing to total hippocampus, only CN subjects show a significant positive correlation between anterior sub-division and age, and only CN and MCI posterior hippocampus negatively correlate with age. The longitudinal ratio of hippocampal atrophy (anterior sub-division divided by the posterior one) shows a significant increase with age in CN and MCI but not in AD.Normal aging affects the hippocampus differently along its longitudinal axis: its posterior aspect shows more atrophy and the anterior one becomes relatively more prominent. In AD, this antero-posterior gradient is disrupted early on, and hippocampal atrophy occurs in a similar manner along its longitudinal axis from late-adulthood to older ages.

Title: Nexinhib-20 and CX546 ameliorates gut-derived extracellular HMGB1 induced BBB dysfunction and neuroinflammation in an experimental model of Gulf War Illness

Authors: *R. K. SETH[1], D. BOSE[1], P. SAHA[1], P. A. JANULEWICZ[2], J. O'CALLAGHAN[3], L. P. REAGAN[4], A. K. SHETTY[5], K. SULLIVAN[2], S. CHATTERJEE[1,6];

Abstract: The persistence of inflammatory bowel disease, chronic fatigue, neuroinflammation, and cognitive impairment, are the common characteristics of Gulf War Illness (GWI). These symptoms predominantly involve the gut and brain and are associated with exposure to pesticides (permethrin, Per), pyridostigmine bromide (PB), multiple vaccinations, stress, etc., in the war theatre. In the current study, we aimed to examine how permethrin and PB exposure induced gut-derived extracellular high mobility group box-1 (HMGB1) led to blood-brain-barrier (BBB) dysfunction and neuroinflammation in a mouse model of GWI. The study also tested extracellular vesicles (EV) biogenesis inhibitor Nexinhib-20 (Rab27 inhibitor) and glutamate activator ampakines (CX546) in attenuating such neurological ailments. While using an established mouse model of GWI, the C57BL/6 mice (n=6 for each group) were exposed to GW agents (PB+Per) along with restraint stress for one week. Other groups of mice were co-exposed with GW agents and Nexinhib-20 or CX546. Results showed that GW agent exposure and stress increased EV biogenesis and HMGB1 expression in the small intestine and concurrently increased circulatory EVs loaded with HMGB1. Data also showed a decreased Zonal Occludin-1 (ZO1) and Claudin-1 mRNA expression and serum albumin accumulation in the frontal cortex, thus suggesting blood-brain barrier (BBB) integrity loss that likely enabled the entry of circulatory HMGB1 in the brain. Increased HMGB1 in both the frontal cortex and hippocampus activated microglia (M1 phenotype), thus inducing an inflammatory response via TLR4 signaling. We observed that HMGB1 induced neuroinflammation suppressed brain-derived neurotropic factor (BDNF) in the hippocampus and thus might modulate neuroplasticity. The GW agents exposed mice co-treated with EV inhibitor (Nexinhib20) or glutamate activator (ampakine, CX546) showed better BBB integrity and neuroplasticity, and reduced neuroinflammation. In summary, our findings suggested that the gut-derived extracellular HMGB1 played a crucial role in GWI pathogenesis, and Nexinhib 20 and CX546 might be promising therapeutics for GWI.

Title: Oral squalamine treatment protects against parkinsonism

Authors: *T. SUBRAMANIAN[1], K. M. LE[2], K. SAUTER[4], K. VENKITESWARAN[3]; [1]Penn State Hershey Med. Ctr. & Col. Med., Hershey, PA; [2]Neurol., [3]Neurol. and NBS, Penn State Col. of Med., Hershey, PA; [4]Neurol., Penn State Univ. Col. of Med., Hershey, PA

Abstract: The aim of the present study was to determine if the novel prokinetic squalamine lactate (SL) would prevent parkinsonism in an environmentally relevant rat model of Parkinson's disease (PD). Exposure to paraquat, has been linked to development of PD in humans. In our previous studies, we demonstrated that oral paraquat plus lectin (P+L) could trigger the formation of misfolded / aggregated α-synuclein (Ser^{129}-P-α-syn) in the gut, which then can travel via the vagus nerve to reach the substantia nigra pars compacta (SNpc) causing degeneration of these neurons accompanied by symmetric parkinsonism that is L-dopa responsive. Bilateral subdiaphragmatic vagotomy prevents parkinsonism in this model and the degenerating dopaminergic neurons demonstrate aggregates of Ser^{129}-P-α-syn that result in Lewy Body-like structures (Anselmi L, et. al., *NPJ Parkinsons Dis.*. 2018;4(1):30). SL is thought to bind to the surface membrane of neurons in the gut and displace cell membrane bound α-syn and thus mitigate misfolding. We tested the hypothesis that oral administration of SL will prevent or mitigate the development of parkinsonism in rats treated with P+L. SL was administered via the water supply to single-housed adult female Sprague Dawley rats (n=7, 300-500 g) immediately following 7 day oral gavage of P+L. A control group (n=6) was not given SL after P+L. The vibrissae evoked forelimb placement test and the stepping task test were performed before and each week after P+L treatments. After 30 days, animals were perfused with 4% PFA and the brains processed for histology. P+L treated animals without SL, exhibited significantly lower vibrissae evoked forelimb placement test scores (*$p<.05$) than animals treated with SL. Preliminary histology showed bilateral TH loss in SNpc of P+L alone treated animals and

protection of TH loss in SL treated animals. Further analysis including assessments of Ser^{129}-P-α-syn in these animals are ongoing. Our data provides first evidence for effectiveness of oral treatments with SL in mitigating the effects of oral gavage P+L induced parkinsonism. Additional studies including male rats and testing of the effects of oral SL administration after symptoms develop 2 weeks after P+L treatment ongoing. These studies suggest that SL may be a very promising new therapeutic agent for the treatment and disease prevention of PD.

Title: Evaluation of Anti-Parkinson's activity of Rajat bhasma on MPTP induced Parkinson's disease in C57BL/6 mice.

Authors: *A. SHANKAR;
Dept. of Pharmacol. & Therapeut., Seth GS Med. Col. & KEM Hosp., Mumbai, India

Abstract: Background and rationale: Parkinson's disease still has no cure or treatment which can halt the progression of disease by preventing neuronal death. It has symptom descriptions in Ayurveda and modern medicine. The study was designed to validate the claims in Ayurveda regarding the efficacy of Ayurvedic drugs in neurodegenerative disorders. It was decided to conduct an efficacy study of a herbomineral drugs (*Rajat bhasma*) on Parkinson's disease induced chemically in C57BL/6 mice. **Methods:** 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine **(**MPTP), 20 mg/kg, twice a day (12 hours in between) for 4 days, i.p. was used as an inducing agent in C57BL/6 mice. The herbomineral drug (*Rajat bhasma*) was used as study drug after carrying out toxicity study in our lab. The mice were fed with the drug for 15 days and MPTP was administered between 7th- 11th day. On the 15th day, the mice were subjected to neurobehavioural tests. Biochemical estimations of Malondialdehyde and reduced Glutathione

was carried out. Neurotransmitter analysis of Dopamine and it's metabolite (HVA and DOPAC) were carried out along with Immunohistochemistry of 5-hydroxy tyrosine. **Results:** The neurobehavioral assays showed an improvement as compared to the disease group. There was a distinct improvement in the inflammatory markers. Neurotransmitter analysis showed a significant improvement in the Dopamine level. Immunohistochemistry showed an distinct reduction in the loss of dopaminergic neurons. **Conclusion:** The drug (*Rajat bhasma*) was found to be effective in reducing the oxidative stress and also slow down the loss of dopaminergic neurons in the striatum.

Title: Analysis of the role of opioid receptors in the anti-dyskinetic effects of sub-anesthetic ketamine

Authors: *M. J. BARTLETT[1], C. J. STOPERA[2], A. ESQUEDA[1], S. J. SHERMAN[1], T. FALK[1];
[1]Dept. of Neurol., The Univ. of Arizona Col. of Med., Tucson, AZ; [2]Neurosci. GIDP, The Univ. of Arizona, Tucson, AZ

Abstract: We have previously demonstrated that treatment with sub-anesthetic ketamine (10-hrs; 5x20 mg/kg; *i.p.*; 2-hrs apart) can reduce levodopa (L-DOPA)-induced dyskinesia (LID) in a rat model of 6-hydroxydopamine (6-OHDA) and is acutely anti-parkinsonian. Ketamine is a multifunctional ligand with similar binding affinity to both *N*-methyl-D-aspartate (NMDA) and opioid receptors. Through NMDA receptor antagonism, ketamine modulates synaptic function, leading to brain-derived neurotrophic factor release onto striatal medium spiny neurons and neuroplasticity. However, the striatum is rich in both μ- and δ-opioid receptors and it is known that long-term L-DOPA therapy changes the levels of opioid peptides. Recent data also indicates that opioid agonism is required for the anti-depressive activity of ketamine. This leads to the hypothesis that ketamine may also activate opioid receptors in the basal ganglia, contributing to either the anti-dyskinetic or the anti-parkinsonian action of the drug, or possibly both. In this study, we used the pan-opioid receptor antagonist naloxone to investigate if opioid receptor activation is necessary for reducing LID. In this study, unilateral 6-OHDA lesioned male

Sprague-Dawley rats were treated with 6mg/kg of L-DOPA for 21 days to establish a model of LID. Once abnormal involuntary movements (AIMs) were stable over three testing days, the rats (n=7/group) were then treated on Day 0 with either vehicle, ketamine (20mg/kg), or ketamine (20mg/kg) + naloxone (3mg/kg) via the same 10-hour treatment protocol. L-DOPA was administered immediately following the protocol and AIMs were assessed. All animals received a 6mg/kg dose of L-DOPA every 3-4 days to maintain the LID and AIMs were scored once per week. Similar to our published data, ketamine significantly reduced AIMs by 36% immediately following the treatment protocol ($p < 0.05$). However, the addition of naloxone did not prevent ketamine's effects (mean AIMs ± SEM; ketamine = 24.1 ± 1.9 vs. ketamine + naloxone = 22.9 ± 4.4). By Day 7, ketamine treated animals had a non-significant 23% reduction in AIMs scores as compared to both the vehicle and ketamine + naloxone treated groups, and again there was no significant difference between the two treatment groups. This pilot study provides early evidence suggesting that opioid receptor activation may not be necessary for ketamine's anti-dyskinetic effects. Next, we will escalate the doses of both ketamine and naloxone. And in a follow-up study we will investigate in unilateral 6-OHDA-lesioned rats if the anti-parkinsonian activity of ketamine is dependent on opioid receptor activation using the forelimb adjusting steps and rotarod tests.

Title: Impulsive behavior induced by Dopamine D3 receptor agonist treatment in Parkinson's disease is mediated by β-arrestin

Authors: *S. DAS, W. XU, S. KORTAGERE;
Microbiology, Drexel Univ., Philadelphia, PA

Abstract: Impulsive behavior induced by Dopamine D3 receptor agonist treatment in Parkinson's disease is mediated by β-arrestin**Sanjay Das**, Wei Xu and Sandhya

KortagereParkinson’s Disease (PD) is a movement disorder characterized by progressive degeneration and loss of mid-brain dopaminergic neurons. Pramipexole (PRX), a Dopamine D3 receptor (D3R) agonist, has emerged as a potent therapeutic to treat motor deficits, but chronic therapy leads to impulse control disorders (ICDs) in PD patients. ICDs comprise a group of complex behavioral disorders characterized by failure to resist an impulse or temptation to perform an act that is harmful to the individual or to others. While the etiology of ICDs is not well understood, several clinical and animal studies have demonstrated that D3R agonist activity directly correlates with the development ICDs. D3Rs are highly expressed in the mesolimbic pathways and mediate motor and reward processes in the brain. D3R agonists can signal through multiple signaling pathways and predominantly through the activation of G-proteins, β-arrestin, or both. We hypothesize that activation of β-arrestin signaling pathway by D3R agonists such as PRX can induce ICDs in PD. To test this hypothesis, PD rats were trained to criteria in a 5-choice serial reaction time task (5CSRTT) and their baseline levels of impulsive responses (measured as premature responses), correct responses and omissions were recorded. Animals were then treated with vehicle or PRX or our G-protein biased D3R agonist SK609 for 3 weeks (1x/day; i.p) and their responses in the 5CSRTT were measured at the end of week-3. Results from the study demonstrated that PRX significantly increased premature responses compared to vehicle or SK609 treatment. SK609 reduced premature responses and increased the correct responses and reduced omissions when compared to both PRX and vehicle treatment. The increase in premature responses by PRX treatment correlated with an increase in anxiety as measured by time spent in the closed arms of the elevated plus maze. Current studies are aimed at understanding the molecular mechanisms of β-arrestin mediated signaling that promote ICDs. Our study will augment the understanding of biased D3R signaling and its role in modulating ICDs in PD. This study’s outcome will be directly translatable to optimizing therapy for PD without the risk of developing ICDs seen with existing therapies.

[3]Dept. of Chem. and Biochem., Univ. of Notre Dame, Notre Dame, IN

Abstract: The selective inhibitors for Heat shock protein 90 beta and tumor necrosis factor type 1 (TRAP1) reduce the lipopolysaccharide (LPS)-induced inflammatory response in BV2 microglial cells Valentin M Kliebe[1], Amanda G Smith[2], Christen Hanna[2], Brian SJ Blagg[3], Wei Lei[21] Department of Biology, College of Art and Science, Presbyterian College, Clinton, SC 29325[2] Department of Pharmaceutical and Administrative Sciences, Presbyterian College School of Pharmacy, Clinton, SC 29325[3] Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556Neuroinflammation contributes to several health conditions related to the central nervous system, such as Alzheimer's Disease and pain. Understanding the regulation of neuroinflammation is essential for discovering approaches to treat inflammation-related diseases. Previous studies demonstrated that the inhibition of Heat shock protein 90 (Hsp90) using 17-N-allylamino-17-demethoxygeldanamycin (17-AAG) could reduce neuroinflammation. However, the contribution of Hsp90 isoforms, including Hsp90α, Hsp90β, glucose-regulated protein 94 (Grp94), and tumor necrosis factor type 1 (TRAP1), to inflammatory signaling remain poorly understood. This study aimed to determine the impact of selective inhibitors for different Hsp90 isoforms on lipopolysaccharide (LPS)-induced inflammatory responses in microglial cells. A murine microglial cell line, BV-2 cells, were pretreated with selective inhibitors for different Hsp90 isoforms for 1 hour, followed by the stimulation of LPS. The production of Nitric Oxide (NO) was measured using Griess Reagents, and qPCR was performed to detect the expression of tumor necrosis factor alpha (TNF-α) and Interleukin-1 beta (IL-1β). The activation of the nuclear factor-κB (NF-κB) and Nrf2 were investigated. We found that treatment with Hsp90β inhibitors strongly inhibited the production of NO, TNF-α, and IL-1β, and the activation of NF-κB, but showed a modest effect on Nrf2 activation. Meanwhile, a TRAP1 inhibitor, T3, also exhibited anti-inflammatory activities via enhancing the Nrf2 activation. However, the inhibitors targeting Hsp90α and Grp94 had very limited or no effect on the LPS-induced inflammatory responses in the microglial cells. These findings demonstrate that Hsp90β and TRAP1 are the isoforms of Hsp90 which play essential roles in the LPS-induced neuroinflammation in microglial cells.

Abstract: Preventing or reversing the pathological misfolding and self-association of alpha-synuclein (aSyn) can rescue a broad spectrum of pathological cellular insults that manifest in Parkinson's disease (PD), dementia with Lewy bodies (DLB), and other alpha-synucleinopathies. Over the past several years, the field's understanding of which forms of aSyn assemblies are most toxic has evolved, shifting away from mature fibrils rich in β-sheets towards structurally heterogeneous oligomers. Many questions remain regarding these oligomers, including what their exact macromolecular constituency is in cells (i.e., what co-mingles with aSyn), whether they possess any well-defined structural motifs—various forms, including a tetramer, have been described in the literature—and how variations in their molecular properties can contribute to toxicity. These unknowns complicate drug discovery, where it remains to be seen whether a unique small-molecule binding site or epitope even exists for oligomers. More generally, it is unclear whether direct binding of an inhibitor to aSyn oligomers, or fibrils for that matter, is more efficient than indirectly targeting the cellular machinery and pathways that can prevent or alter their assembly.
In our recently published study, we demonstrated our aSyn live-cell time-resolved FRET biosensors performance in a high-throughput screening (HTS) campaign with the 1280-compound LOPAC library. Our combination of inter-protomeric and intra-protomeric FRET biosensors provide complementary insight into aSyn oligomerization and conformation. We then tested the efficacy of hit compounds in SH-SY5Y cells overexpressing unlabeled wild-type aSyn, and we report that two small molecules, Demeclocycline HCl (DEM) and Ro 90-7501 (RO), completely protected SH-SY5Y cells from aSyn-induced death. The compounds are active in the low nanomolar range (EC_{50} = 65nM and 78nM respectively) and are an order of magnitude more potent than previously described small molecules.
We have continued to refine our HTS drug discovery pipeline to include novel FLT-FRET

biosensors and functional assays to improve both the scalability of the HTS platform and to dive deeper into the potential mechanisms of action of hit compounds.

Title: Nad^+ biosynthetic pathway enzymes moonlight as molecular chaperones to protect against proteotoxic stress

Authors: *M. PINKERTON[1], A. BARRIENTOS[2];
[2]Neurol., [1]Univ. of Miami, Miami, FL

Abstract: Neurodegenerative proteinopathies involve the misfolding and aggregation of disease-specific proteins in the brain. Searches for neuronal maintenance factors have identified the NAD+ salvage biosynthetic pathway enzyme NMNAT (nicotinamide mononucleotide (NMN) adenylyltransferase) as an effective suppressor of proteotoxicity. Although there has been some controversy regarding whether the neuroprotective effect of NMNAT is mediated by increased NAD+ levels or a non-catalytic chaperone role of NMNAT, it is now accepted that both may contribute. Screens in yeast models of HD and PD in our lab have allowed us to identify not only the NMNAT homologs Nma1/2 but three additional enzymes of the NAD+ salvage pathway that achieve similar protection against extended polyglutamine- and a-synuclein-induced proteotoxic stress: Npt1, Pnc1, and Qns1. Under proteotoxic stress, the four proteins are recruited to promote the clearance of misfolded and oligomerized proteins. We have shown that the suppression mechanism by NAD+ proteins is independent of their catalytic activity. In vitro and in vivo studies have indicated that the four proteins have the ability to act as molecular chaperones. Our data suggest that they perform holdase and foldase chaperone activities to contribute to the reduction of misfolded toxic proteins, while promoting their refolding. The proteotoxicity suppression mechanism requires the presence of the HSP90 chaperones HSP82/HSC82. In the

case of Nma1, structure-function relationship studies have shown that the C-terminus of the protein is essential for its chaperone activity and presumably for interaction with HSP90. Our data illustrates the existence of an evolutionarily conserved strategy of repurposing housekeeping enzymes under stress conditions, such as age-associated neurodegenerative proteotoxicities.

Title: Gdnf mimic supramolecular nanostructure

Authors: *O. CARBALLO-MOLINA, A. EDELBROCK, *Z. ÁLVAREZ, T. PEREZ-ROSELLO, S. CHIN, T. FYRNER, J. SURMEIER, S. STUPP;
Northwestern Univ., Chicago, IL

Abstract: Parkinson´s Disease (PD) is the second most common neurodegenerative disorder. The administration of glial cell line-derived neurotrophic factor (GDNF) has shown to improve the motor dysfunctions in animal models of PD. However, GDNF has not shown the desired results the clinical outcomes, in part due to a short half-life and the uncontrolled diffusion of this trophic factor. To overcome those obstacles, we report here the incorporation of a GDNF-mimetic peptide on the surface of peptide-based nanofibers. Peptide amphiphiles (PAs) are self-assembling molecules that form nanostructures that have shown the ability to retain and control the release of various growth factors. We show that the nanostructure displaying the GDNF mimetic activates the canonical GDNF receptor RET *in vitro*. Using two-dimensional cell cultures, we demonstrate that GDNF mimetic PA enhanced the cell viability of dopaminergic neurons derived from human induced pluripotent stem cells and promotes their maturation by increasing the expression of MAP2, pre and post-synaptic markers, as well as the improvement of morphometric characteristics. In addition, we observed the improvement of the electrophysiological activity. Like native GDNF, this bioactive nanostructure provides a neuroprotective effect against the neurotoxin 6-OHDA. Furthermore, we used three-dimensional cultures and we found that the neurons encapsulated in the GDNF mimetic PA gels showed better maturation, morphometric and neuroprotective effects, compared to control gels. These results indicate that GDNF mimetic PA is a bioactive matrix capable of mimicking the key properties of GDNF. This bioactive nanostructure has the potential to improve cell replacement

therapy in PD by improving the cell viability of grafted neurons, as well as the morphometric and functional maturation.

Title: Discovery of small molecule inducers of autophagy using a phenotypic mutant A53T alpha synuclein autophagy biosensor

Authors: *E. E. LIAO, A. R. BRAUN, J. N. SACHS;
Biomed. Engin., Univ. of Minnesota TC, Minneapolis, MN

Abstract: Dysregulation of the autophagy pathway has been implicated in various neurodegenerative diseases. As progress is made in understanding the pathogenesis of Parkinson's disease (PD), dementia with Lewy bodies (DLB) and other alpha-synucleinopathies, it is clear that basal autophagy may be a key factor in increasing neuron survival and promoting the clearance of toxic protein aggregates. We designed a high throughput autophagy screening platform that is sensitive to mutant A53T alpha synuclein (aSyn) pathology. Our phenotypic biosensor uses a combination of the LC3 probe with internal control designed by Noboru Mizushima and A53T aSyn expression to screen for small molecule inducers of autophagy that can rescue mutant aSyn pathology. Stable HEK cell clones expressing GFP-LC3-RFP(LC3ΔG) were selected under puromycin and confirmed using flow cytometry and PCR. CRC plates were run using Rapamycin, starvation condition and Bafilomycin A1 to determine the optimal range of the mutant aSyn autophagy biosensor. Coefficient of variance (CV) was also determined on control plates to verify a good HTS screen. Basal GFP/RFP levels in A53T aSyn cells were significantly higher than GFP/RFP levels of HEK-LC3 alone and WT aSyn expressing cells, indicating higher levels of autophagy impairment. Further characterization of the phenotypic biosensor was conducted using immunoblots and LC3 turnover assays, which confirmed blockage of autophagy in A53T aSyn biosensor. Using this mutant aSyn autophagy biosensor, a small molecule drug screen was conducted using the Selleck library of 2,863 compounds with Rapamycin and Bafilomycin A1 as positive and negative tool compounds, respectively. Hit compounds that decreased the GFP/RFP ratio (signifying an increase in the autophagy flux) were further evaluated using a LC3 turnover assay to confirm effects on autophagy. Consequent

analyses using TFEB localization and Lysotracker in conjunction with LAMP1 immunofluorescence were used to confirm and validate the hits. We then tested the hits in a differentiated SH-SY5Y model of PD expressing A53T aSyn and evaluated cellular viability and rescue of aSyn pathology. Hits were further vetted using a HEK-LC3 counter screen to determine pathologic aSyn specific effects. Further evaluation of mechanisms of action of the hits will be conducted in future studies.

Title: Development of an in vitro α-synuclein aggregation assay in primary cortical cultures for pharmacological characterization, target discovery and validation

Authors: S. LARDELL[1], C. NODIN[1], A. BACK[1], *P. KARILA[1], S. ILLES[2], **J. PIHL**[1]; [1]Cellectricon AB, -- Select State/Province --, Sweden; [2]Inst. of Neurosci. and Physiology, The Sahlgrenska Acadamy, Univ. of Gothenburg, -- Select State/Province --, Sweden

Abstract: In Parkinson's disease (PD), the formation and propagation of α-synuclein (α-syn) insoluble amyloid structures is a process hypothesized to drive the pathology of disease. As part of this process, impaired protein clearance and protein aggregation within neurons occurs. From a drug discovery perspective, preventing protein aggregation or promoting protein clearance provide interesting opportunities as pharmacological intervention points. However, there is currently a lack of biologically relevant in vitro systems modelling these mechanisms. Such models are much needed for e.g. development of small molecules, or for further increasing the understanding of pathological processes involved in neurodegenerative disease.
With this in mind, we initiated the development and validation of a high-capacity in vitro model based on primary embryonic mouse cortical cultures in the 384-well format, where endogenous α-syn aggregation was induced at 6 or 10 days in vitro (DIV) using recombinant human α-syn pre-formed fibrils. Endogenous α-syn aggregation and cell health was then quantified at 14 or 17 DIV using immunocytochemistry and automated high content imaging and analysis.
Following the development of a robust protocol for induction and quantification of α-syn aggregation, the model was validated using commercially available small molecule modulators of α-syn aggregation, as well as using lentiviral shRNAs for knock-down of a small set of genes (SNCA, LRRK2, GBA and TMEM175) known for their involvement in PD.
The outcome is a robust, sensitive and high-capacity dual assay for assessment of α-syn aggregation, where it is possible to detect both negative and positive modulators of α-syn

aggregation even in single point screening format. While most of the commercially available small molecules tested were only weakly potent regulators of α -syn aggregation, the knock-down of genes relevant for PD did result in the expected effect on α-syn aggregation for all genes tested. We can therefore conclude that the developed model indeed is relevant for characterization of modulators of α-syn aggregation and can be used for screening of small molecule regulators as well as for target discovery and validation applications.

Title: Patient-derived three-dimensional Cortical Neurosphere to model Parkinson's Disease

Authors: *W. RAJA[1], **E. NEVES**[1], C. BURKE[1], X. JIANG[1], P. XU[1], K. RHODES[1,2], V. KHURANA[3], R. SCANNEVIN[1,4], C. CHUNG[1];
[1]Yumanity Therapeut., Boston, MA; [2]Wave Life Sci., Cambridge,, MA; [3]Brigham and Women's Hosp., Boston, MA; [4]Verge Genomics, South San Francisco, CA

Abstract: There are currently no preventive or disease-modifying therapies for Parkinson's Disease (PD). Prevalence is consequently rising, as is the substantial burden on patients, caregivers, and the healthcare system. Failures in clinical trials necessitate a re-evaluation of existing pre-clinical models in order to adopt models that better recapitulate underlying disease mechanisms and better predict clinical outcomes. In recent years, models utilizing patient-derived induced pluripotent stem cells (iPSC) offer an attractive alternative, as they better recapitulate disease-relevant neuropathology *in vitro* without exogenous overexpression of disease-related pathologic proteins. Here, we utilize iPSC derived from a patient either harboring a point mutation (A53T) in the α-synuclein gene or copy number variation in α-synuclein (triplication of α-synuclein locus) associated with a strong early-onset PD and dementia phenotype. We generated a three-dimensional (3D) cortical neurosphere culture model to better mimic the microenvironment of the brain. We extensively characterized the differentiation process using quantitative PCR, Western blot, and immunostaining. Differentiation and aging of the neurospheres revealed alterations in fatty acid profiles and elevated total and pathogenic

phospho-α-synuclein levels in both A53T and the triplication lines compared to their isogenic control lines. Furthermore, treatment of the neurospheres with a small molecule inhibitor of Stearoyl Co-A Desaturase (SCD) attenuated the protein accumulation and aberrant fatty acid profile phenotypes. Our findings suggest that 3D cortical neurosphere model is a useful tool to interrogate targets for PD and amenable to test small molecule therapeutics.

Title: Autophagy regulation pathways in rotenone-induced Parkinson's disease in SH-SY5Y cells treated with neural induced-human adipose-tissue derived stem cells conditioned medium

Authors: M. RAMALINGAM[1], J. HWANG[1], H.-H. CHO[2], B. C. KIM[3], *S. JANG[1], H.-S. JEONG[1];
[1]Physiol., Chonnam Natl. Univ. Med. Sch., Jeollanamdo, Korea, Republic of; [2]Otolaryngology-Head and Neck Surgery, [3]Neurol., Chonnam Natl. Univ. Med. Sch., Gwangju, Korea, Republic of

Abstract: Rotenone (ROT) is a naturally occurring piscicide that inhibit mitochondrial complex I causing aggregated forms of alpha-synuclein was most widely used to induce Parkinson's disease (PD). Autophagy is the major intracellular degradation system involving lysosomal degradation of damaged organelles and abnormal aggregated proteins which is regulated by mechanistic target of rapamycin (mTOR)-dependent and -independent pathways. The phosphorylation of mTOR multiprotein signaling complexes (mTORC1 and mTORC2) controls several cellular functions. AMP-activated protein kinase (AMPK) directly regulates phosphorylation of ULK1 and function of ATG13. mTOR-independent MAPK/ERK have also been implicated in the regulation of autophagy. The autophagic marker, LC3B, binds autophagic related (ATG) proteins such as ATG3, 5, 7, and 12 to formation of autophagosome. These autophagosomes fused with functional lysosomes result in the formation of autolysosome for further degradation in the cytosol. Impaired autophagy contributes to the pathogenesis of neurodegenerative diseases including PD via accumulation of abnormally aggregated alpha-synuclein. In this study, we examined the neurogenic differentiation of human adipose tissue-derived stem cells (NI-hADSC) conditioned medium (NI-hADSC-CM) against ROT-induced toxicity in SH-SY5Y neuroblastoma cells. ROT toxicity significantly decreased the phospho-/total- (p-/t-) mTORC1 and p-/t-mTORC2 along with p-/t-ULK1 and ATG13 by increased p-/t-AMPK. Moreover, p-/t-ERK and beclin-1 were decreased by ROT but not changed the p-/t-Akt. ROT promoted the lipidation of LC3BI to LC3BII by inducing autophagy representing an adaptive cellular response. ATG3, 5, 7, and 12 were decreased and p62 level was not changed by ROT. Lysosomal LAMP1, LAMP2, and TFEB were decreased during ROT toxicity leading to lysosomal dysfunction. However, NI-hADSC-CM treatment increased the phosphorylation of mTORC1 and mTORC2 and decreased the phosphorylation of AMPK along with increased phosphorylation of ULK1 and ATG13. p-/t-ERK, p-/t-Akt, and level of beclin-1 were increased by NI-hADSC-CM treatment against ROT. In addition, NI-hADSC-CM treatment restored the ROT-induced increase in the level of LC3BII. Together with increased p62 levels, Atgs and lysosomal proteins were all normalized to the control levels by NI-hADSC-CM treatment. Taken together, our results show that NI-hADSC-CM treatment on autophagy regulating signaling pathways could facilitate the beneficial effects on Parkinson's disease.

Title: Interaction of Advancing Age with the BDNF Val66Met Polymorphism (rs6265): Impact on Dopamine Neuron Graft Efficacy and Side-Effect Liability in rs6265 Knock-In Rats

Authors: *C. SZAROWICZ[1], J. A. STANCATI[2], M. CAULFIELD[2], C. E. SORTWELL[2], S. A. BOEZWINKLE[3], T. J. COLLIER[2], K. STEECE-COLLIER[2], N. M. MERCADO[2];
[1]Dept. of Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI; [2]Dept of Translational Neuroscience, Col. of Human Med., Michigan State Univ., Grand Rapids, MI; [3]Col. of Literature, Science, and the Arts, Univ. of Michigan, Ann Arbor, MI

Abstract: We previously investigated the effects of the Val66Met (aka: rs6265) single nucleotide polymorphism (SNP) in the gene for brain-derived neurotrophic factor (*BDNF*) in a rat model of neural grafting for Parkinson's disease (PD), demonstrating that young mature rats (grafted at 8 m.o.) carrying the variant Met allele exhibited paradoxical enhanced graft function but also developed aberrant graft-induced dyskinesias (GID) in contrast to wild-type (WT) rats (PMID: 33188920). Since aging is a primary risk factor for PD and known to reduce graft efficacy, we extended our studies to investigate whether aging interacts with this SNP to further alter cell transplantation outcomes. We hypothesized that aging would (1) dampen enhancement of graft function associated with this genetic variant and (2) exacerbate GID in all grafted subjects. To test this, middle-aged WT (Val/Val) and Met/Met SNP rats (grafted at 15m.o.) were rendered unilaterally parkinsonian, primed with levodopa, then transplanted with WT embryonic day 14 ventral mesencephalic dopamine (DA) neurons. Graft function was assessed over 10 weeks. Reductions in levodopa-induced dyskinesia (LID) severity served as the primary measure of graft function; OFF-time sensorimotor dysfunction served as a secondary measure. In this experiment we demonstrate, in contrast to our hypothesis, that behavioral enhancement associated with rs6265 is maintained with advanced age; however, behavioral improvement per grafted cell was significantly greater in the young cohort compared to the middle-aged cohort at the final post-graft time point regardless of genotype (2-way ANOVA $F(1,24) = 16.07$, $p = 0.0005$; Šídák's multiple comparisons test: Val/Val: $t(24) = 2.545$, $p = 0.0352$; Met/Met: $t(24) = 3.161$, $p = 0.0084$). In keeping with our hypothesis, we demonstrate using amphetamine mediated GID that advanced age is permissive to its induction. Specifically, DA grafted rats of both genotypes with widespread striatal reinnervation developed robust GID compared to sham grafted rats. However, in these middle-aged rats, GID scores were higher in Met/Met compared to Val/Val rats (2-way ANOVA $F(1,27) = 5.510$, $p = 0.0265$; Šídák's test: $t(27) = 2.990$, $p = 0.0118$). Data related to graft-host synaptic connectivity, which is increased with aging in Met68Met but not Val/Val rats, its association with LID, and the co-localization of vesicular

glutamate in grafted DA neurons and its significant association with GID will be presented and discussed. Understanding the role of aging and the common rs6265 SNP on DA terminal replacement therapies will aid in development of safe and optimized approaches for remodeling the parkinsonian striatum.

Abstract: Effect of sonic hedgehog on the axonal guidance of human dopaminergic neurons Parkinson's disease (PD) is a neurodegenerative disorder characterized by the premature death ofdopaminergic neurons (nDA), which causes motor and non motor symptoms. Currently, the maintreatments are palliative. Cell replacement therapy consists on restoring loss of nDA and isconsidered a promising therapeutic strategy, however, it is necessary for transplanted neurons toextend their axons to their appropriate target of innervation. Chemoattractant molecules act asguidance cues capable of guiding axonal growth for the establishment of accurate connectionswithin the brain. Interestingly, Sonic Hedgehog (Shh) is a molecule capable of attracting nDA axonsduring rodent embryonic development, however, this effect has not been studied in human nDA. Inthis study, we evaluate the effect of Shh on the axonal guidance of nDA derived from humanembryonic stem cells (hESC). We used modified hESC that

constitutively express the GFP protein(H9-GFP), which allows the direct visualization of nDA axons derived from H9-GFP cells. At day 28 ofdifferentiation, we used molecular markers (tyrosine hydroxylase (TH), FOXA2, β Tubulin) tocharacterize nDA by immunofluorescence. Once the presence of nDA markers was confirmed, weseeded the nDA cells in axonal growth chambers, where they were exposed to a Shh gradient. Themicrochannels occupied by axons were counted daily to evaluate the axonal growth. Although wefound the presence of nDA markers, neurons exposed to Shh did not show a defined attractive orrepulsive growth pattern. Therefore, further experiments will be performed to determine the effectof Shh on the axonal growth of nDA.**Figure 1. Experimental models for axonal guidance assays.** A) Inmunofluorescence for the nDAmarker TH (red) and the neuronal marker β Tubulin (cyan) after 28 days of differentiation. B) Axonsexpressing the GFP protein and entering the microchannels of the axonal growth chambers.

Title: Three-dimensional direct reprogramming approach to model human glia conversion

Authors: *J. GIACOMONI, A. BRUZELIUS, M. HABEKOST, P. STORM, A. FIORENZANO, D. OTTOSSON, M. PARMAR;
Lund Univ., Lund, Sweden

Abstract: Parkinson's disease (PD), one of the most common neurodegenerative disorders, is primarily characterized by progressive loss of dopamine (DA) neurons in the ventral midbrain. The relatively focal degeneration in PD makes it a good candidate for cell replacement therapies, and efforts are on their way to use stem cell derived-DA neurons in clinical trials. An emerging alternative approach to cell transplantation is *in vivo* reprogramming, where resident glia is converted into neurons directly within the brain parenchyma. Proof-of concept that *in vivo* conversion can be a viable future option has been provided in rodent studies. However, the inaccessibility of human brain tissue and the lack of an *in vitro* culture system that recapitulates the complexity of the human brain represent major limitations in the development and pre-clinical validation of such approach.We have established a renewable and reproducible stem cell-based system of human glial progenitor cells for direct neural conversion and identified optimal combinations of fate determinants for the generation of functional DA neurons *in vitro*. We developed a 3D culture model from previous 2D protocol allowing cells to interact more efficiently by recapitulating the complexity of a 3D space and evaluated it as a pre-clinical model of human glia conversion. Our approach increases conversion efficiency and accelerates the reprogramming process to generate mature neuronal phenotypes with electrophysiological function within 3 weeks. Furthermore, reprogramming in 3D allows long term cultures, and is applicable for a variety of neuronal conversion protocols. We are currently investigating region-specific molecular identity of glial cells and induced neurons using single-nucleus RNA sequencing. With this we hope to explore neuron lineage diversity after direct cell conversion and to understand the reprogramming competence of different subtypes of glial progenitors.

Title: Bio-cognitive markers suggest that young veterans with mTBI show premature cognitive decline and may be at-risk for a prodromal onset of Parkinson's disease: A proof-of-concept, matched-control study

Authors: *V. A. NEJTEK[1], R. JAMES[1], M. F. SALVATORE[1], H. ALPHONSO[2], I. SOTO[1], G. BOEHM[3];
[1]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [2]psychiatry, JPS Hlth. Syst., Fort Worth, TX; [3]Texas Christian Univ., Fort Worth, TX

Abstract: Epidemiological reports suggest 56% of veterans with mild traumatic brain injury (mTBI) will eventually develop Parkinson's disease (PD) within ~5 - 7-years post-injury. Cognitive decline is considered a pre-motor prodromal characteristic of PD. However, specific cognitive domains contributing most to an mTBI-related PD onset is unknown. Identifying which cognitive domains will decline first and examining their relationship to neural biomarkers may yield a novel bio-cognitive profile to augment existing hallmark characteristics of prodromal PD that will inform therapeutic strategies. Here, we report the results of a proof-of-concept, match-controlled, cross-sectional study examining age- and IQ-matched veterans with and without mTBI, non-veteran healthy controls, and IQ-matched non-demented early-stage PD. Dependent variables were scores from well-known standardized neuropsychological tests assessing cognitive flexibility, attention, memory, visuospatial ability, and verbal fluency. Serum-based astrocytic biomarkers of central nervous system (CNS) functioning were analyzed in relation to cognitive outcomes. Out of 200 volunteers, 114 provided evaluable data. Groups significantly differed on cognitive tests using multivariate analyses [F (21,299) = 3.09, p<0.0001]. Benjamini and Hochberg False Discovery Rate post-hoc tests showed veterans with mTBI performed significantly worse than matched-control groups on four out of eight cognitive tests (range: p =.009 to .049), and most often performed similarly to decades older subjects with early-stage PD (range: p =.749 to .140). A Spearman correlation showed that out of three astrocytic biomarkers analyzed, glial fibrillary acidic protein (GFAP) significantly and positively correlated with tests of cognitive flexibility and attention (Trail-making A, rs(101) = .29, p = .004; Trail-making B, rs(101) = .28, p = .005). The significant relationship we found between GFAP and Trail-making tests A and B provides preliminary data supporting a bio-cognitive marker of subtle, premature cognitive aging in veterans with mTBI that potentially identifies them as at-risk for continual cognitive decline, the onset of PD, or some other neurodegenerative disease.

Title: Identifying structural and functional brain features in PD with and without dementia

Authors: *C.-J. HUANG[1], A.-C. YANG[1,2,3];
[1]Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [2]Digital Med. Center, Natl. Yang Ming Chiao Tung University, Taipei, Taiwan, Taipei, Taiwan; [3]Dept. of Med. Research, Taipei Veterans Gen. Hospital, Taipei, Taiwan, Taipei, Taiwan

Abstract: Parkinson's disease (PD) is a common neurodegenerative disorder, mainly affecting the motor nervous system. About 35% of patients are combined with dementia in the later stages of the illness, making their brains shrink faster than those without dementia, but no specific structural and functional abnormalities have been found in the brain area that is related to comorbidity of dementia. We hypothesized that brain structural and functional imaging would differ in specific brain regions between PD without dementia (PDnD) and PD with dementia (PDD). Voxel-based morphometry was used to analyze T1 magnetic resonance images. The study cohort included 113 healthy controls and 381 patients with PD, and the latter were further subtyped into 340 cases of PDnD, and 41 cases of PDD. The General Linear Model was used to examine whether there were differences in gray matter volume between groups and after one year of follow-up while controlling for age, sex, education years and Montreal Cognitive Assessment scores, and the voxel cluster was evaluated with family wise error for the correction of multiple comparisons. No study has been conducted to investigate the relationship between PDnD and PDD by combining structural and functional brain images. By identifying structural and functional differences, we expect to identify possible brain regions that are related to progression of dementia at an early stage of the PD and provide early intervention. We found that at baseline, the volume of the caudate nucleus was significantly bigger in PD and PDnD compared to healthy controls, while the volume of cerebellar region was significantly smaller than healthy controls ($P_{FWE} < 0.001$). When comparing PDD to healthy controls, it was found that the volume of insula was significantly smaller than healthy controls ($P_{FWE} < 0.001$). After one year of disease, PD and PDnD showed a significant increase in volume in the cerebellar region compared to baseline volume ($P_{FWE} = 0.001$); the occipital regions showed a significant decrease in volume ($P_{FWE} = 0.015$). While PDD showed no significant increase in volume after one year of disease, but a significant decrease in volume in the insula ($P_{FWE} < 0.001$). Based on structural imaging findings, it was found that the superior temporal gyrus volume was significantly smaller in PDD than in PDnD. Previous studies have shown that localized brain atrophy can also cause dementia. Frontotemporal dementia is a type of dementia caused by

severe temporal lobe atrophy, with symptoms mostly related to verbal expression. Based on structural imaging and previous studies, significant temporal lobe atrophy may be considered a sign of future dementia in PD.

Title: First test of dopamine buffering capacity imaging as a disease severity biomarker in Parkinson disease

Authors: *K. J. BLACK[1], J. M. KOLLER[2], J. S. PERLMUTTER[3];
[1]Psychiatry, Neurology, Radiology, Neurosci., [2]Psychiatry, [3]Neurology, Radiology, Neuroscience, Physical Therapy, Occup. Therapy, Washington Univ. in St. Louis, St. Louis, MO

Abstract: BACKGROUND: We tested whether a novel pharmacological fMRI approach, dopamine buffering capacity imaging, could quantify disease severity in Parkinson disease (PD). This approach measures how quickly the effect of a dose of levodopa (LD) appears and wears off, using not a clinical effect (which can change e.g. with motivation and fatigue), but LD's objective effect on rCBF (regional cerebral blood flow) in the midbrain and pons. This large rCBF response has been demonstrated repeatedly (e.g. 62-74% increase in DOI: 10.7717/peerj.1381/table-2), but previous studies all averaged over participants and averaged over before- *vs.* after-drug time points. The present study relies on a mathematical model that is well grounded in available information (DOI 10.3389/fneur.2020.00370), but requires measuring for the first time rCBF responses to levodopa over numerous brief time intervals and in individual participants.
METHODS: Details appear in the pre-registered study protocol (DOI 10.17605/OSF.IO/G7DFY). After 200 mg carbidopa by mouth, pCASL fMRI measured rCBF repeatedly for over an hour in 16 people with Parkinson disease, before and during an i.v. infusion of levodopa bioequivalent to about 80 mg by mouth. The effect site rate constant k_e was calculated for a pre-specified midbrain-pons region with a large LD-induced increase in rCBF.
RESULTS: On average, the midbrain region showed a plausible time course of response to LD, with mean rCBF beginning to increase near the end of the i.v. LD loading dose and persisting elevated throughout the 15-40 min. time period during which an increase was expected. However, some participants' time-rCBF curves showed little response, including the participant

who appeared to have the best scan session (minimal head movement, no sleep). The hypothesized correlations of midbrain k_e with disease duration and severity (UPDRS III score and tapping speed in an overnight off state) showed the expected sign but none was significant. DISCUSSION: This novel pharmacological fMRI method to quantify PD disease progression did not perform as expected in this sample using these methodological choices. Specifically, the midbrain region did not give in every subject the expected, pharmacologically sensible time course of increased activity after LD administration. We will discuss possible explanations and potential methodological improvements.

Title: Detection of reactive antibodies against mouse cerebral antigens in serum of Parkinson's disease patients

Authors: J. EGIGUREN[1], E. PAREDES-RODRIGUEZ[2], C. DOMÍNGUEZ-FERNÁNDEZ[2,1], R. FERNÁNDEZ[2], E. ASTIGARRAGA[2], C. MIGUELEZ[1], ***G. BARREDA-GÓMEZ**[2]; [1]Pharmacol., Univ. of the Basque Country (UPV/EHU), Leioa, Spain; [2]Res. and Develop., IMG Pharma Biotech, Derio, Spain

Abstract: Detection of reactive antibodies against mouse cerebral antigens in serum of Parkinson's disease patients
June Egiguren, Elena Paredes, Celtia Domínguez, Roberto Fernández, Egoitz Astigarraga, Cristina Miguelez, Gabriel Barreda-Gómez
Parkinson's disease (PD) has become the second most common neurodegenerative disorder, affecting 1% of the individuals older than 60 years. Despite large research efforts, its diagnosis remains a challenge and no ideal biomarkers have been identified to be used in the early phases of the disease. Although the etiology and pathogenesis of PD remains unclear, several evidences

support the autoimmune basis of the disease, highlighting the existence of reactive antibodies against dopaminergic neurons of the *substantia nigra pars compacta*. The complex immunohistochemistry process required to monitor reactive antibodies in tissue sections has limit their potential as PD biomarkers. However, newer techniques as cell membrane microarrays (CMMA) overcome the main limitations regarding reproducibility, handling and quantitation. Thus, the aim of this study was to set up a serological reactive antibody assay using as sensor cell membranes isolated from multiple brain areas of mice and anti-human IgG secondary antibody as fluorescently probe. For this purpose, CMMA were developed using cell membranes isolated from a collection (N = 5) of mouse brain areas (cerebral cortex, frontal cortex, striatum, hippocampus, hypothalamus, thalamus and striatum). A titration was performed incubating the CMMA with increased concentrations of sera from PD patients with autoimmune disease (N = 4) or without (N = 4), together with controls (N = 4) and the reactive anti-neuronal antibodies were quantified in each of the brain areas. The data were calibrated, normalized and standardize before analyzing the panel of selected biomarkers by machine learning algorithms. 63% of the PD patients present a significant change in the reactive antibody profile against the brain regions included in the CMMA. The prevalence in those PD patients suffering also from an autoimmune disease was higher, although further investigation must be performed with a higher cohort of patients, in order to validate the potency of these easily accessible biomarkers. Moreover, the multiplexing capability of the microarray technology provides a novel approach for regular monitoring of patients and, thus, for checking the efficacy of therapies and disease progression, avoiding surgical procedures.

Title: Feasibility of a system for human visual rating of signals from accelerometers on the extremities of people with Parkinson's disease

Authors: *J. R. BRASIC[1], L. ZIEGELMAN[3], K. A. MILLS[2], M. E. HERNANDEZ[4]; [1]Radiology, [2]Neurol., Johns Hopkins Univ., Baltimore, MD; [3]Neurosci., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [4]Kinesiology and Community Hlth., UIUC, Urbana, IL

Abstract: Objective: To assess methodology for trained experts to rate the signals generated by the extremities of people with Parkinson's disease (PD).
Methods: Ten people with PD underwent a low-cost quantitative structured measurement of movements in the extremities with four accelerometers generating a trace of the three location dimensions. Segments of the signals and the fast Fourier and amor continuous wavelet transforms reflecting the structured repetitive movements were expressed as six panels representing the x, y, and z axes for the finger and the wrist (Figure) or the toe and the ankle for each extremity. Raters were instructed as follows:

Interruptions or freezing

1a 1 to 2 interruptions

2a 3 to 5 interruptions

3a 5 or more interruptions or a freeze, a sustained absence of repetitions

4a Worse

Slowing

1b Minimal

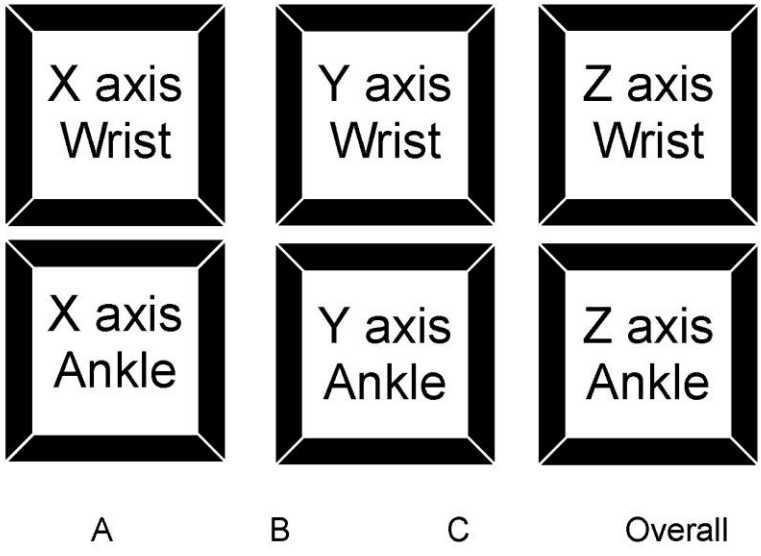
2b Mild

3b Moderate

4b Worse

Amplitude reductions

1c End of sequence



2c Middle of sequence

3c Beginning of sequence

4c Worse

Results: Twenty quizzes representing the output for the (A) signals and fast Fourier transforms and (B) amor continuous wavelet transforms of the left and right assessments of upper and lower extremities were completed and tabulated for 34 trained raters (Ziegelman, *et al.,* 2020).
Discussion:
A methodology for scoring of output of accelerometers on the extremities by an international team of trained raters has generated a valuable dataset (Zieglelman, *et al.,* 2020) for analysis and interpretation. Since this is an inexpensive procedure to quantitatively measure motions in PD and other movement disorders, this will be a valuable resource to colleagues, particularly in underdeveloped regions with limited budgets. The dataset will serve as a template for other investigations to develop novel techniques to facilitate the diagnosis, monitoring, and treatment

of PD, other movement disorders, and other nervous and mental conditions. The procedure will provide the basis to obtain objective quantitative measurements of participants in clinical trials of new agents.

Title: Use of accelerometer signals to improve classification of structured motor assessments of Parkinson's Disease

Authors: *H. HAKIM[1], T. KOSURI[2], L. ZHAO[3], L. ZIEGELMAN[4], K. MILLS[5], A. PANTELYAT[5], J. BANG[5], M. E. HERNANDEZ[6], J. R. BRASIC[7];
[1]Johns Hopkins Univ. Undergraduate Neurosci. Program, Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD; [3]Univ. of Illinois, Urbana, IL; [4]Neurosci., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [5]Johns Hopkins Med., Baltimore, MD; [6]Kinesiology and Community Hlth., UIUC, Urbana, IL; [7]The Russell H. Morgan Dept. of Radiology and Radiological Sci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Motivation/Problem Statement: Routine clinical and research assessments of persons with Parkinson's Disease (PD) by visual observation introduces inaccuracies reflecting inherent human limitations, motivating the need to obtain precise measurements with instrumentation. We sought to develop a protocol to utilize accelerometer signals to rate the severity of movements to obtain optimal classifications of people with PD.
Methods: We expressed accelerometry signals of five repetitive movements for ten participants with PD as panels (Figure) for rating by visual inspection. Trained raters were instructed to check a box for an overall rating of
0 normal
1 minimal
2 mild
3 moderate
4 worse
for individual abnormalities
a interruptions
b slowing
c decreased amplitudes
A higher score indicates greater impairments. The representations of the accelerometry signals of a single extremity without identification of laterality were presented as panels to be scored by trained raters. Each panel contained six images corresponding to the x, y, and z axes of the positions of the accelerometers on the finger and wrist for the upper extremity or the toe and ankle for the lower extremity.
Results: Images were constructed to represent signals corresponding to scores of 0, 1, 2, 3, or 4 (Figure). A protocol was developed to rate signals by interruptions, slowing, and amplitude decrements.
(1) Once started, regular rate and rhythm of movement is observed - this waveform indicates no abnormalities in fluency, speed, or amplitude of movement - trace merits a score of 0.

(2) Single interruption (depicted in red outline) merits a rating of 1a.
(3) Amplitude decrement midway through the trace merits a rating of 2c.
(4) Frequency of trace declines toward end of sequence, warranting a rating of 3b.
Discussion: A methodology for scoring of signals of accelerometers on the extremities by an international team of trained raters has generated a valuable dataset (Ziegelman, *et al.*, 2020) for analysis and interpretation. Abstract: Motivation/Problem Statement: Routine clinical and research assessments of persons with potential Parkinson's Disease (PD) involving the use of visual observation of structured examinations introduces inaccuracies reflecting inherent human limitations, motivating the need to obtain precise measurements with instrumentation. We sought to develop a protocol to utilize amor continuous wavelet transforms (CWTs) to rate the severity of movements to obtain optimal classifications of people with PD.
Methods: We expressed CWTs of five repetitive movements for ten participants with PD as panels (Figure) for rating by visual inspection. Trained raters were instructed to check a box for an overall rating of
0 normal
1 minimal
2 mild
3 moderate
4 worse
For individual abnormalities
a interruptions
b slowing
c decreased amplitudes
The representations of the CWTs of a single extremity without identification of laterality were presented as panels to be scored by trained raters. Each panel contained six images corresponding to the x, y, and z axes of the positions of the accelerometers on the finger and wrist or the toe and ankle.
Results: Raters classified transforms by scoring three particular abnormalities in the CWTs. Interruptions were identified on the CWTs as breaks in continuous horizontal segments of line; slowing was demonstrated by a negative sloping line; amplitude decrements were evident while examining the warmth of color (yellow representing the greatest amplitude). Therefore, lines of diminishing warmth from left to right were deemed to show decreasing amplitude.
i) 0 (no amplitude decrements, slowing, or interruptions seen)
ii) 1 (amplitude decrement seen by decrease in warmth of color)
iii) 2 (3-5 interruptions seen by halts in CWT)
iv) 3 (moderate slowing seen by negative sloping line)
Discussion: A methodology for scoring CWTs of accelerometers on the extremities by trained raters has generated a valuable dataset (Zieglelman, *et al.*, 2020) for analysis and interpretation.

Title: Characterization of motor impairment rating error of transformed IMU data

Authors: *L. ZIEGELMAN[1], T. HARRIGAN[2], J. R. BRASIC[3], M. E. HERNANDEZ[4]; [1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]REDD, Johns Hopkins Univ. Applied Physics Laborator, Laurel, MD; [3]The Russell H. Morgan Dept. of Radiology and Radiological Sci., Johns Hopkins Sch. of Med., Baltimore, MD; [4]Kinesiology and Community Hlth., UIUC, Urbana, IL

Abstract: This study aimed to characterize the relationship between level of movement impairment and rater accuracy of the movement impairment during a clinical task. These terms are operationalized using the Unified Parkinson's Disease Rating Scale (UPDRS) motor subscale to characterize level of impairment and the absolute value of the percent error of the rater's rating of transforms of inertial measurement unit (IMU) data when compared to a clinical gold standard to represent rater accuracy. The rationale for characterizing this relationship is that it allows insight into ways in which transformations of motion data could be compared to a traditional method of diagnosis of movement impairment by a clinician. Additionally, characterizing typical rating error allows for additional necessary information in the creation of machine learning classifiers of UPDRS motor task ratings, which is a meaningful step in the process of creating telemedicine tools for movement disorder specialists. This is done by creating a parent regression model, where the performance of a linear model, cubic model, and exponential decay model are compared, as well as testing the selected exponential decay model for a task effect. The clinical ratings were scored by 35 raters certified to administer the UPDRS on a series of 24 participants diagnosed with Parkinson's Disease (PD) with transformed motion data. The exponential model, which was fit as $Y=-0.00291e^{1.13124}+0.44694$ is shown to have the best fit with all three estimates statistically significant at \alpha=0.05 and finds that UPDRS scores between 0 and 2 are harder to accurately rate as compared to a 3 or 4. This means that mild symptoms of motor impairment are more difficult to separate from no impairment as compared to severe symptoms. This parent exponential decay model is tested for a task effect, which is found to be present. All together, these models indicate that transformed data is not equally easy to evaluate, where the movement impairment and task type impact a rater's ability to rate motion accurately. This is a necessary first step in the evaluation of the feasibility of using IMU data ratings to build telemedicine tools.

Title: Protective effects of NAMPT and MAPK inhibitors on Wallerian degeneration of mammalian axons: mechanisms and synergies

Authors: *A. ALEXANDRIS[1], J. RYU[1], R. HARLAN[2], L. RAJBHANDARI[3], S. AJA[2], D. GRAHAM[2], A. VENKATESAN[3], V. KOLIATSOS[1,3,4];

Hopkins Univ., Saint Petersburg, FL; [3]Neurol., [4]Psychiatry and Behavioral Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Wallerian degeneration (WD) is a highly conserved axon self-destruction program that has been implicated in traumatic axonal injury and other neurological disorders. Several key players have been identified as drivers of WD that are centered on the regulation of the NAD+ metabolome. These include the degradation of nicotinamide mononucleotide adenylyltransferase (NMNAT2), the built up of its substrate NMN, and the activation of the NAD+ degrading Sterile α and TIR motif containing 1 (SARM1) protein, heralding axon fragmentation hours or days after injury. Yet, the time course of these events, their regulation, and their therapeutic targetability are still unclear. Here we utilized an in vitro mouse dorsal root ganglion axotomy model in order to explore pharmacological strategies that modulate NMN and NAD+ metabolism and might protect against WD, namely the inhibition of the NMN-synthesizing enzyme NAMPT and the NMNAT2-degrading MAPK pathway, as well as augmentation of the nicotinic acid riboside salvage pathway. Transected axons were assessed by a complement of techniques including degeneration index analysis, and targeted metabolic and western blot profiling of injury-related signals. We found that the decision point of axon fragmentation occurs within a time window corresponding to 2-4 hours post-injury and is related to reciprocal changes in NMN and NAD+ levels driven in turn by the MAPK-dependent degradation of NMNAT2. NAMPT inhibition was sufficient to partially suppress SARM1 activity, protect axonal NAD+ levels and delay WD in a time-dependent manner whereas its supplementation with nicotinic acid riboside led to further suppression of SARM1 activity and complete repression of axon fragmentation. Metabolite analyses revealed complex and dynamic effects, which however indicated the ratio of NMN/NAD+ as the main driver of SARM1 activity. The existence of a time window of commitment and the successful pharmacological modulation of NMN/NAD+ metabolism, may have translational significance for a wide spectrum of axonopathies.

Title: The potential of astrocyte-derived extracellular vesicles to modulate microglial activation

Authors: *S. L. REED[1], L. SHAPIRO[1], J. C. WONG[1], R. MA[2], G. HU[2], A. ESCAYG[1]; [1]Dept. of Human Genet., Emory Univ., Atlanta, GA; [2]Dept. of Pharmacol. & Exptl. Neurosci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Extracellular vesicles (EVs) are small vesicles released by cells into the extracellular space. EVs play a key role in intercellular communication and are believed to be responsible for mediating at least some of the regenerative benefits of stem-cell based therapies. In fact, the administration of EVs has been shown to elicit neuroprotective and anti-inflammatory effects and reduce neuropathological, cognitive, and behavioral phenotypes in some disease models. Most studies on the therapeutic potential of EVs have utilized stem-cell derived EVs, but there is evidence that EVs from some terminally differentiated cell types, such as astrocyte-derived EVs (astro-EVs), may also have beneficial effects. The contents of astro-EVs include molecules with anti-inflammatory and neuroprotective properties, and astro-EVs have been shown to be efficacious in animal models of stroke and traumatic brain injury. However, the ability of astro-EVs to reduce features common to many neurological disorders, such as gliosis, is not well characterized. Microglia are the resident immune cells of the nervous system. While microglial activation can initiate reparative processes, it is also associated with pathological increases in neuroinflammation and neuronal death. In animal models of neurological injury, such as stroke or status epilepticus (SE), reducing microglial activation can improve recovery and reduce long-term deficits. In this study, we investigated the ability of astro-EVs to modulate the response of microglia in a mouse model of neurological injury. Mouse astrocytic EVs were isolated from conditioned media using ultracentrifugation. Isolated astro-EVs or vehicle were administered to mice following SE. Mice were sacrificed 4-5 days following SE and hippocampi were collected for gene expression analysis. SE was associated with robust increases in the expression of inflammatory genes including pro-inflammatory cytokines and microglial markers. Treatment with astro-EVs significantly attenuated increases in the microglial and macrophage markers CD11b and CD68 in the hippocampus suggesting that astro-EVs can modulate the microglial response to SE. Research is ongoing to determine whether astro-EVs can provide additional therapeutic benefits in this model.

Title: Effects of genetically engineered therapeutic biopolymers on S100B protein mediated demyelination in an organotypic cerebellar slice culture model of multiple sclerosis.

Authors: *P. VIG[1], M. LOPEZ[2], L. KENNEDY[2], J. RYU[2], D. RAUCHER[2], M. WILLIS[2]; [1]Univ. Mississippi Med. Ctr., Jackson, MS; [2]Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: The demyelinating lesions in multiple sclerosis (MS) are often associated with an increased release of calcium binding protein S100B from reactive astrocytes. The excessive amounts of this pro-inflammatory protein impairs oligodendrogenesis, resulting in reduced myelination. It has been demonstrated that administration of S100B protein can induce inflammatory demyelinating disease in animals. Therefore, this study was initiated to assess if blocking S100B with our genetically engineered therapeutic peptide (TP) could suppress demyelination and neurodegeneration in an experimentally induced demyelination ex vivo model. Our TPs were developed with three key elements: An elastin-like polypeptides (ELP) carrier, S100B inhibitory peptide TRTK as TP and Synb1, to penetrate extracellular matrix. The cerebellar slice cultures were prepared from seven to eleven-day-old enhanced green fluorescent protein (GFP) expressing transgenic mice, transgene under the control of Purkinje cell specific-2 promotor. After one week in culture, slices were treated with various concentrations of demyelinating agent lysolecithin (LL) overnight to optimize its neurotoxicity profile as well as demyelination potential. The slices were treated with various concentrations of control Synb1-ELP peptide or Synb1-ELP-TRTK in the presence or absence of optimized concentration of LL overnight followed by incubations with either control peptide or TP in LL-free medium for additional 72 to 96 hours and processed for immunohistochemical and image analysis. We observed reduced dendritic arborization and numerous dendritic swellings of the Purkinje cells (PCs) in LL treated slices. In addition, axonal myelination was markedly reduced in a concentration dependent manner. The control Synb1-ELP peptide did not protect PCs from the effects of LL; however, Synb1-ELP-TRTK treatment showed remarkable suppression. Even the white matter regions were endogenous GFP fluorescence was low showed enhanced levels of immunofluorescence for myelin basic protein immunostaining. These preliminary data demonstrate that our TP could be checked as a candidate to disrupt the S100B-RAGE axis and may further be tested for potential in treating MS lesions.

Abstract: Identification of a putative receptor for the neutrophil-derived growth factor oncomodulin and its role in CNS regenerationLili Xie[1,2], Sheri Peterson[1,2], Yuqin Yin[1,2], Larry Benowitz[1,21]Department of Neurosurgery, Boston Children's Hospital and Harvard Medical School, Boston, MA 02115; [2]F.M. Kirby Neurobiology Center, Boston Children's Hospital, Boston, MA 02115;
AbstractAlthough the optic nerve, like other pathways in the mature mammalian CNS, can not regenerate when injured. This failure can be partially reversed by inducing sterile inflammation. Previous work from our lab showed this phenomenon is mediated in large part by oncomodulin (Ocm), a 12 kDa Ca++-binding protein, secreted by myeloid cells. Ocm also induces outgrowth from dorsal ganglion neurons (DRGs) and may play a role in the conditioning lesion effect, whereby injuring to periphery nerve enhances the ability of DRGs to extend their central axons in the spinal cord. We now report the identification of a potential Ocm receptor (Ocm-R). We identified Ocm-R using biotinylation by antibody recognition (BAR) followed by mass spectrum. Co-immunoprecipitation studies reveal the direct interaction between Ocm and Ocm-R. Knock-down of Ocm-R using CRISPR-Cas9 leads to loss of Ocm binding to retinal ganglion cells (RGCs) and a substantial loss of inflammation-induced regeneration after optic nerve injury without affecting regeneration induced by other means (*pten* delection in RGCs). Conversely, ectopic expression of Ocm-R in cells with low baseline expression results in high Ocm binding. Ongoing studies are investigating the role of Ocm-R in the condition lesion effect and downstream mechanisms by which Ocm binds to Ocm-R contributes to optic nerve regeneration.

Abstract: Severed axons in the CNS do not usually regenerate. Therefore, reversing the damage to CNS axons (for example, spinal cord injury) is currently a major clinical challenge. Recently, studies indicated that AAV delivery of certain genes to neurons could bring out neurons' intrinsic ability to regenerate, providing hope that functional restoration of injured CNS may be possible in the near future. The aim of this study was to develop a gene therapy vector that is effective in promoting CNS axon regeneration and neuroprotection. The roles of brain-derived neurotrophic factor (BDNF)- tropomyosin receptor kinase B (TrkB) signaling in neurite outgrowth and neuroprotection are known; however, whether or not this signaling pathway also plays a role in regeneration of injured CNS axons is unknown. Therefore, we focused on TrkB and generated constitutively active TrkB. For this, we extracted the intracellular domain of TrkB (iTrkB) and attached a farnesyl group (F-iTrkB) for promoting membrane association. Transfection of F-iTrkB to Cos7 cells demonstrated increased levels of pERK and pAkt, which are downstream targets of TrkB signaling. In order to determine the effects of F-iTrkB on axon regeneration and neuroprotection *in vivo*, we used the mouse eye and optic nerve as experimental models. We used AAV serotype 2 (AAV) to deliver F-iTrkB into retinal ganglion cells (RGCs) and examined its effects in an optic nerve crush (ONC) injury model. Intravitreal injection of AAV-F-iTrkB reduced RGC death at 4 weeks after ONC compared with AAV-control, demonstrating its neuroprotective effects on RGCs. Furthermore, we traced RGC axons with intravitreal injection of cholera toxin subunit B and we found that AAV-F-iTrkB treatment promoted robust RGC axon regeneration at 2 and 4 weeks after ONC. We also used an optic tract transection model, in which RGC axons are cut near their projection site, the superior colliculus. We found that RGC death was not observed in this model, indicating that this model allows examination of the effects on axon regeneration without the reduced cell number caused by the

axonal damage. Intravitreal injection of AAV-F-iTrkB promoted robust RGC axon regeneration beyond the transection site in the brain. Excitingly, optokinetic responses were partially recovered in some mice, indicating that AAV-F-iTrkB treatment promoted partial recovery of visual behavior. Taken together, our findings demonstrate that AAV-F-iTrkB promotes CNS axon regeneration and neuroprotection, suggesting that F-iTrkB may be useful for treatment of axonal injuries in the CNS and neurodegenerative diseases.

Title: Role of Netrin-4 in neuronal growth and cornea wound healing

Authors: *C. XIAO, D. LARA, Q. ZHOU, G. DIMAILIG, M. ROSENBLATT, V. H. GUAIQUIL;
Ophthalmology and Visual Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: The cornea is the highest innervated tissue in the human body, receiving axonal projections from the trigeminal ganglia (TG). The cornea acts as a protective barrier against the environment, and its transparency is essential for maintaining normal visual acuity. Injury of the corneal epithelium, its more anterior layer, is clinically relevant, as loss of neuronal innervation may result in the disruption of several modalities of sensation and alterations in vision. Several growth factors, lipids, and microRNAs have been described to play a role in cornea wound healing. Axon guidance proteins can also induce nerve regeneration in the adult cornea. Here, we study the role of Netrin-4 in neuroepithelium regeneration using in vitro and in vivo models. Netrins are a family of secreted proteins that serve as guidance signals during development. Netrin-4 acts through its receptors *deleted in colorectal cancer* (DCC), *uncoordinated family members* (UNC5H1-4), and *neogenin*. Netrin-4 has been shown to prevent inflammation in diabetic retinopathy and promote retinal angiogenesis, but less is known of its role in the cornea. This study aims to determine the expression and localization of Netrin-4 and its receptors, the direct functional effects of Netrin-4 on neuron and epithelium regeneration, and its potential preclinical effects in mice.

We found endogenous expression of Netrin-4, DCC, UNC5H1, and neogenin in the corneal epithelium (mouse and human) and trigeminal ganglia through immunofluorescence staining. After corneal epithelium injury in mice (n=3), the expression of Netrin-4 and its receptors quickly recovered and initially localized to the basal layers of the epithelium. The level of expression increased as the epithelium healed. Our observations were quantitatively corroborated by qRT-PCR on injured mice corneas (n=6). Additionally, we observed neuronal growth induction in isolated TG neurons exposed to recombinant Netrin-4. Our dose-response data shows that 50 ng/ml induced the most potent neuronal growth. We are currently evaluating the direct effects of Netrin-4 on human corneal limbal epithelial cells using scratch assays. Moreover, we initiated studies to determine if the observed neuronal growth induced by Netrin-4 can be seen in vivo. For this, we are using a corneal epithelium debridement model which damages the subbasal nerve plexus in mice that then receive vehicle or recombinant Netrin-4 treatment. Our preliminary data demonstrate that Netrin-4 could play a significant role in cornea wound healing and may be of importance for PNS regeneration.

Title: Optical Gene Delivery for Neuroprotection

Authors: S. BATABYAL[1], S. KIM[1], A. DIBAS[1], B. MAHATO[1], D. NARCISSE[1], H. AL-SAAD[1], M. CARLSON[1], *S. MOHANTY[2];

Abstract: Millions of people in the US suffer from vision loss and blindness due to degeneration of retinal cells (e.g. Glaucoma, diabetic retinopathy: DR, Age-related macular degeneration: AMD). The currently available pharmacological treatments based on anti-VEGF (for exudative AMD), steroid therapies (e.g. Dexamethasone for anti-angiogenesis; and triamcinolone for DR), as well as ongoing clinical trials on complement factors (for dry-AMD) and neurotrophic factors (e.g., Ciliary neurotrophic factor for AMD) for inhibiting neurodegenerations, have significant

limitations with respect to the requirement of multiple injections and related adverse-effects including systemic reactions to medications, and eye infections. We present an optical coherence tomography (OCT)-guided near-infrared laser-based non-viral delivery method for spatially localized delivery of therapeutic genes with two distinct approaches. 1) Ultrafast pulsed laser delivery: optoporation and 2) Low power continuous wave laser in combination to functionalized gold nanorods (fGNRs): Nano-enhanced optical delivery. We used the optical delivery method to deliver engineered the pigment epithelium-derived factor (PEDF) gene (a serpin superfamily neurotrophic factor) to targeted retinal cells for efficient and enhanced long-lasting expression. Our results demonstrated in-vivo OCT-guided laser-based delivery of PEDF genes leads to robust expression in the RGC layer in mice. The efficacy of the neuroprotection was assessed by ERG and VEP, which showed that PEDF expression preserves the electrophysiology in the treated eye as compared to the control eye. Also, the number of RGCs in the acute mice model was found to be high in the optically delivered PEDF treated eyes. We also evaluated the anti-angiogenic effect of PEDF in the choroidal neovascularization mouse model and found that PEDF expression in the targeted retinal region (delivered by OCT guided laser) lead to a significant reduction of CNV as compared to non-treated groups. In addition to PEDF gene delivery and neuroprotection, we also evaluated the successful delivery of other genes such as ceMCO or large ABCA4 genes using Optical delivery platform for the treatment of eye indications such as Retinitis Pigmentosa, Dry-AMD, Stargardt disease. Large animals (NHPs, Pigs) safety, toxicity, and efficacy study associated with optical gene delivery are being conducted. The development of a safe, effective, long-lasting, single-dose, delivery and therapy for the treatment of retinal diseases would be transformative in clinical ophthalmology and would improve the lives of millions of people worldwide.

Title: Neuroprotection by PAF-receptor antagonist plus a lipid mediator against experimental focal cerebral ischemia

Authors: *L. BELAYEV[1], M. M. REID[1], A. OBENAUS[2], P. K. MUKHERJEE[1], L. KHOUTOROVA[1], C. R. ROQUE[3], T. SIMONS[1], B. K. PARK[1], N. A. PETASIS[4], R. B. ORIA[3], N. G. BAZAN[1];

Abstract: Neuroinflammation and oxidative stress play a key role in the pathophysiology of ischemic stroke. We tested the hypothesis that blocking pro-inflammatory platelet-activating factor receptor (PAF-R) plus administering a selected docosanoid after middle cerebral artery occlusion (MCAo) would lead to neurological recovery. Two different types of small bioactive molecules were investigated: LAU-0901 (LAU), PAF-R antagonist that blocks pro-inflammatory signaling, and aspirin-triggered neuroprotectin D1 (AT-NPD1), which activates cell-survival pathways, and their combination that exerts potent anti-inflammatory activity in the brain. This study investigated the dose-response and therapeutic window in a model of focal cerebral ischemia. In each series described below, male Sprague-Dawley rats were subjected to 2h of MCAo. The behavior was evaluated on days 1, 2, 3, and 7, and an *ex vivo* MRI of the brains was conducted using 11.7 T MRI on day 7. In series 1 (Dose-response), rats were treated with LAU (45 and 60 mg/kg, IP, at 3h), AT-NPD1 (111, 222, and 333 µg/kg, IV, at 3.15 h after onset of stroke), LAU+AT-NPD1 (LAU at 3h and AT-NPD1 at 3.15 h) or vehicle (n=5-6 per group). In series 2 (Therapeutic window), vehicle, LAU (60 mg/kg, IP), AT-NPD1 (222 µg/kg, IV), LAU+AT-NPD1 were administered at 3, 4, 5, and 6 h after onset of MCAo. Physiological variables showed no significant differences among groups. Treatments with LAU-0901 (45 and 60 mg/kg) alone improved behavior on days1-7 by 34-36%; AT-NPD1 (222 and 333 µg/kg) by 23-29% compared to vehicle groups. AT-NPD1 in a low dose (111 µg/kg) was not different from the vehicle group. The neuroprotective effect was enhanced using the LAU-0901+AT-NPD1, which resulted in improved behavior up to 32-38% on days 1-7. Total lesion volumes, which were computed using T2WI, were significantly reduced with LAU-0901 (45 and 60 mg/kg) by 73-90% and AT-NPD1 (222 and 333 µg/kg) alone by 83-85% compared to the vehicle group. Ischemic core, penumbra, and total lesion volumes were dramatically reduced with LAU-0901+AT-NPD1 by 94, 92, and 93% compared to the vehicle. Treatment with LAU and AT-NPD1 alone, when administered at 3h, improved behavior on day 7 by 35 and 28%. In contrast, LAU-0901+AT-NPD1 improved behavior by 46% when administered at 3h, by 52% at 4h, 34% at 5h, and 19% at 6h. In conclusion, these data suggest that LAU-0901 and AT-NPD1 alone in moderate doses provide high-grade neuroprotection in the MCAo model. Combination therapy with LAU-0901 and AT-NPD1 is more effective than the single therapy, affording synergistic neuroprotection with improved neurological recovery when administered up to 6 h after focal cerebral ischemia in rats.

Title: Evaluation of a systemically delivered PACAP glycopeptide as a neuroprotective agent in 2 rodent models of Parkinson's Disease

Authors: K. BERNARD[1], A. LUJAN[2], H. MORRISON[3], M. J. BARTLETT[4], C. LIU[5], G. MOLNAR[6], C. APOSTOL[5], L. SZABÒ[5], S. SHERMAN[4], L. MADHAVAN[4], J. STREICHER[6], M. HEIEN[5], R. POLT[5], T. FALK[7];

Abstract: Parkinson’s Disease (PD) is the second most common neurodegenerative disease, yet lacks any disease modifying therapeutics to stop or reverse the ongoing pathology occurring in the brain. Pituitary adenylate cyclase-activating peptide (PACAP) is an endogenous neuropeptide hormone that has been extensively studied as a potential protective therapeutic in a variety of neurodegenerative settings due to its potential for initiating cellular processes that promote survival and inhibit potentially harmful processes such as inflammation. This multi-faceted response to PACAP is due to its interactions with PAC1, as well as VPAC1 and VPAC2 receptors found in both the CNS and periphery. However, despite PACAP’s trophic and anti-inflammatory properties, it has not realized its translational potential due to poor stability and limited blood-brain barrier (BBB) permeability. We have designed and synthesized a glycosylated PACAP analog (2ls98lac) that is able to stimulate cAMP production *in vitro* using individual CHO cell lines expressing PACAP receptors. Glycosylation of a peptide plays two roles in increasing the ability of a peptide to reach the CNS; increasing peptide stability and therefore half-life, and enhancing BBB penetration**.** To test the protective ability of the 2ls98lac, we conducted a study using a progressive unilateral 6-hydroxydopamine (6-OHDA) rat PD model (n=16/group). In the treatment group rats were injected (*i.p.*) with 15 mg/kg of 2ls98lac 6-hrs prior, 48-hrs and 72-hrs post 6-OHDA injection. Analysis of a subset of animals at 4 weeks post-6-OHDA lesion PACAP treated animals exhibited reduced ipsilateral turning behavior in

response to the dopamine agonist amphetamine, consistent with reductions in overall lesion size. Unbiased stereology of dopaminergic neurons in a subset of animals (n=8) revealed an increased number on the lesioned side of 2ls98lac treated animals (10159 in treated, 8020 in vehicle, p=0.0277). Microglial analysis revealed a full restoration of the activated microglia phenotype, that was reduced in the vehicle group, characterized by process length, number of branches per cell and the % area/frame ($p<0.01$ each). Additional motor behavior scoring and stereological analysis is ongoing.We have also begun a pilot in the Thy1-aSyn transgenic mouse model of PD. These mice display early progressive motor deficits and early cognitive impairments. We treated mice every other day for 1 month starting at 2 months of age with 2ls98lac (1 mg/kg, s.c.) or vehicle, and performed motor and cognitive assessments. Brains were harvested for immunohistological analysis of alpha synuclein spread. Data analyses are currently ongoing.

Abstract: CNS Protection by Repetitive Conditioning: Proteomic Analyses of Induced Retinal Phenotypes

Jarrod C. Harman[1,2,3], Emrey Broyles[1], Jessie J. Guidry[2,4], and Jeff M. Gidday [1,2,3,5] *Depts. of Ophthalmology*[1], *Biochemistry & Molecular Biology* [2], *Neuroscience Center*[3], *LSUHSC Proteomics Core Facility*[4], *Physiology*[5], *LSUHSC, New Orleans*

Previous preclinical research from our lab has demonstrated that repetitive hypoxic conditioning (RHC) induces long-lasting neuroprotection in the retina (Zhu Y et al., IOVS 2007; Zhu Y et al., Mol Med 2012) and brain (Stowe et al., Ann Neurol 2011). Herein, we performed quantitative proteomics to elucidate the underlying molecular phenotypes. At 12 wks of age, male and female Swiss-Webster ND4 outbred mice were exposed to 2 wks of RHC; a matched normoxia cohort served as controls. Three days after RHC, retinae were harvested and processed for MS3 analysis on a Fusion Orbitrap Mass Spectrometer using TMTpro labels for quantification, and 1.5 fold-change and <1% FDR thresholds. Subsequent bioinformatic analysis was performed on these differentially expressed proteins using Ingenuity Pathway Analysis (IPA) software. MS3 identified a total of 7,305 proteins, of which 6,253 were quantified. 160 proteins exhibited significant abundance differences in RHC-treated mice, with 31 upregulated and 129 downregulated relative to normoxic controls. 10 of these proteins were differentially expressed in both sexes. The retinal proteome of females was significantly more responsive to RHC than that of males. IPA revealed broad changes in cellular pathways and molecular functions involved in inflammatory responses, including handling of reactive oxygen species. Diverse metabolic functions were also up- and down-regulated, including phase 1 metabolism, protein metabolism, and lipid transport. These epigenetically-mediated changes in the retinal proteome, at both the single protein and pathway/network level, reveal the potential mechanistic underpinnings of neuroprotection, and in turn serve as potential therapeutic targets. Moreover, the unique sex-dependent changes we observed likely contribute to the sexually dimorphic degree of resilience to ischemic injury in RHC-treated mice (Harman et al., IOVS 2020).

Title: Dolutegravir inhibition of matrix metalloproteinases affects mouse neurodevelopment

Authors: *A. N. BADE[1], J. M. MCMILLAN[1], Y. LIU[2], B. J. EDAGWA[1], H. E. GENDELMAN[1];
[1]Dept. of Pharmacol. and Exptl. Neurosci., [2]Dept. of Radiology, Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Dolutegravir (DTG) is a first-line antiretroviral drug (ARV) used in combination therapy for the treatment of human immunodeficiency virus type-1 (HIV-1) infection. The drug is effective, safe, and well tolerated. Nonetheless, concerns have recently emerged for its usage in pregnant women or those of child-bearing age. Notably, DTG-based ARV regimens have been linked to birth defects seen as a consequence of periconceptional usages. To this end, uncovering an underlying mechanism for DTG-associated adverse fetal development outcomes has gained clinical and basic research interest. We now report that DTG inhibits matrix metalloproteinases (MMPs) activities that could affect fetal neurodevelopment. DTG is a broad-spectrum MMP inhibitor and binds to Zn++ at the enzyme's catalytic domain. Studies performed in pregnant mice show that DTG readily reaches the fetal central nervous system during gestation and inhibits MMP activity. Postnatal screenings of brain health in mice pups identified neuroinflammation and neuronal impairment. These abnormalities persist as a consequence of *in utero* DTG exposure. We conclude that DTG inhibition of MMPs activities during gestation has the potential to affect prenatal and postnatal neurodevelopment.

Title: Bictegravir-mediated lysosomal de-acidification inhibits oligodendrocyte maturation and autophagic flux

Authors: *L. FESTA[1], A. E. CLYDE[1], C. C. LONG[1], L. ROTH[2], J. B. GRINSPAN[2], K. L. JORDAN-SCIUTTO[1];
[1]Basic and Translational Sci., Univ. of Pennsylvania Sch. of Dent. Med., Philadelphia, PA;
[2]Dept. of Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Antiretroviral therapy (ART) has led to a reduction in the most severe forms of HIV-associated neurocognitive disorders (HAND); however, cognitive impairment continues to persist in approximately 30-50% of HIV+ patients. As the severity of HAND has shifted with the advent of ART, so has the underlying pathology, though certain deficits continue in the post-ART era. In particular, white matter (WM) alterations persist despite peripheral viral suppression by ART, suggesting that antiretrovirals (ARVs) may directly contribute to WM structural and functional deficits. Work in our laboratory has revealed that ARVs from numerous classes, including integrase strand transfer inhibitors (INSTIs), inhibit oligodendrocyte (OL) differentiation through distinct cellular stress pathways, including oxidative stress and the integrated stress response. We sought to determine whether bictegravir (BIC), a member of the INSTI class, prevents oligodendrocyte maturation. Using our well-established cell culture system of OPC purification and differentiation, we demonstrate that BIC inhibits oligodendrocyte maturation and reduces the expression of mature myelin proteins. In order to determine the potential mechanism underlying this phenomenon, we focused on lysosomal de-acidification since our previous work has revealed that ARVs from other classes can disrupt lysosomal pH, leading to deleterious effects on OPC maturation. BIC de-acidified lysosomes in both OPCs and mature OLs, as well as significantly impaired lysosomal degradative capacity; however, lysosomal membrane integrity was unaffected. De-acidification of lysosomes led to an inhibition of autophagic flux, a process known to be essential for proper OL function. Co-administration of the TRPML1 agonist, ML-SA1, which extrudes Ca^{2+} out of the lysosomal lumen and re-acidifies lysosomes, blocked the ability of BIC to inhibit OL differentiation. Ongoing studies are examining the potential impact of BIC on remyelination following a demyelinating insult. Taken together, our data reveal the critical role of proper lysosome acidification in modulating OL differentiation and maturation. Furthermore, this work has implications for other disorders characterized by WM injury, including multiple sclerosis, where OPC differentiation is impaired and remyelination is insufficient. Thus, our work suggests therapeutic targeting of lysosomal acidification or Ca^{2+} efflux may promote oligodendrocyte differentiation and myelin repair.

Title: Effects of Antiretroviral Bictegravir on Differentiating and Mature Oligodendrocytes

Authors: *A. E. CLYDE[1], L. FESTA[2], L. ROTH[3], K. L. JORDAN-SCIUTTO[2], J. B. GRINSPAN[4];
[1]Col. of Arts and Sci., Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Basic and Translational Sci., Sch. of Dent. Medicine, Univ. of Pennsylvania, Philadelphia, PA; [3]AbbVie Foundational Neurosci. Ctr., Cambridge, MA; [4]Div. of Neurol., Children's Hosp. Philadelphia, Philadelphia, PA

Abstract: HIV-associated neurocognitive disorder (HAND) develops in approximately 50% of HIV (+) people and causes cognitive, motor, and behavioral impairments. Treatment with combined antiretroviral therapy (cART) led to a decrease in the most severe forms of HAND, but manifestations still occur in 30-50% of the HIV (+) population on cART. Despite successful viral suppression in the post-cART era, neuropathologic changes persist including white matter abnormalities and myelin loss. Previous studies from our lab have shown that some antiretroviral (ARV) drugs inhibit the differentiation of oligodendrocytes (OL), the myelin-producing cells in the brain, and could be contributing to the cognitive and white matter deficits seen in HAND. Bictegravir (BIC) is an integrase strand inhibitor (INSTI) front-line ARV drug that was approved in 2018 along with emtricitabine and tenofovir alafenamide in a drug cocktail called Biktarvy for treatment of HIV-1 infection. We hypothesized that bictegravir would decrease oligodendrocyte differentiation and increase cell death in differentiating oligodendrocytes but not in mature oligodendrocytes. To determine the effect of BIC on OL differentiation, oligodendrocyte progenitor cells (OPCs) were placed in differentiation medium (DM) and treated with three different concentrations of BIC for 72 hours. Cells were then immunostained with GalC and propidium iodide to examine immature OLs and cell death, respectively. Cells treated with BIC showed significantly lower numbers of GalC+ cells and lower cell viability compared to vehicle. To determine the effect of BIC on mature OLs, the cells were incubated in DM for 72 hours then treated with the highest dose of BIC for an additional 72 hours. There was no significant decrease in GalC+ cells or viability for BIC treated cells. Interestingly, the mature OLs also showed a smaller decrease in cell viability compared with OPCs when treated with thapsigargin (THAP), an inhibitor of the calcium ATPase on the endoplasmic reticulum, which serves as a positive control for cell death. We found that the mature OLs had significantly higher numbers of GalC+ cells and cell viability when treated with BIC or THAP than the simultaneously treated differentiating OPCs. These data suggest that mature OLs are more resistant to BIC induced changes in viability or differentiation as well as the cell death effects of THAP. Future studies will explore the potential mechanisms underlying the differential effects of BIC on stages of differentiation of the oligodendrocyte lineage.

Title: Pre-exposure prophylaxis (PrEP) inhibits oligodendrocyte differentiation

Authors: *C. C. LONG[1], L. FESTA[3], J. B. GRINSPAN[4], K. L. JORDAN-SCIUTTO[2]; [1]Neurosci. Grad. Group, Univ. of Pennsylvania, PHILADELPHIA, PA; [2]Dept Pathology, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Basic and Translational Sci., Sch. of Dent. Medicine, Univ. of Pennsylvania, Philadelphia, PA; [4]Dept. of Neurol., Children's Hosp Philadelphia, Philadelphia, PA

Abstract: Adolescents comprise one-fourth of individuals diagnosed with HIV in the United States each year. Even with effective peripheral viral suppression by antiretroviral therapy (ART), this population is at risk for significant life-long behavioral, cognitive, and motor impairments as approximately 30-50% of HIV+ individuals develop HIV-associated neurocognitive disorders (HAND). White matter abnormalities are a hallmark of HAND and transcriptome analysis have found a significant decrease in the expression of genes associated with oligodendrocytes (OL), cells that produce myelin, in the white matter of ART treated, HIV+ individuals. Data from our lab has demonstrated that even in the absence of HIV, select antiretroviral drugs of the integrase inhibitor (INSTI) and protease inhibitor (PI) classes inhibit OL differentiation *in vitro*. PrEP, a combination of emtricitabine (FTC) and tenofovir disoproxil fumarate (TDF) two antiretrovirals of the NRTI class, is an effective method to prevent the transmission of HIV in adolescents at substantial risk for acquiring HIV. However, as myelination continues through adolescence and into adulthood, it is important to understand the effect of PrEP on developing white matter, which has not been investigated. Using our well-established cell culture system for purification and differentiation of primary rat OLs, we demonstrated that treatment with FTC and TDF, alone or in combination, inhibited OL differentiation. OL were treated at the time of differentiation with concentrations of FTC or TDF equivalent to that of the plasma C_{max} of patients on PrEP. Treatment with FTC (7uM), TDF (0.6uM), or in combination reduced the number of GalC and PLP positive cells after 3 days of differentiation. Known mechanisms by which ARV drugs affect myelination include ER stress

and lysosome stress, but we focused on lysosome deacidification as FTC and TDF are slightly basic drugs. Treatment with FTC and TDF, alone or in combination, significantly decreased the number of acidic lysosomes and increased the pH of lysosomes in a dose dependent manner. Lysosomes are critical in OLs as they must process and transport large quantities of lipids and proteins necessary for the generation of the myelin membrane and low intralysosomal pH is essential for the function of the lysosomal proteases. These findings suggest that FTC and TDF impair lysosome function and inhibit OL differentiation. Finally, reacidifying lysosomes restores OL differentiation in the context of FTC and TDF treatment. Our findings suggest that PrEP inhibits OL differentiation and the lysosome may be a therapeutic target to mitigate white matter damage in individuals on PrEP.

Title: Occludin provides HIV-1 protection in human brain pericytes by regulating the expression of interferon stimulated genes

Authors: *S. TORICES[1], S. RAMASWAMY[1], T. MORENO[2], L. BERTRAND[1], R. CABRERA[1], A. KLUTTZ[1], O. NARANJO[1], M. TOBOREK[1];

Abstract: HIV-1 associated blood brain barrier (BBB) alteration and neurocognitive disorders are typical clinical manifestations in HIV-1 infected patients. The functional and structural changes of the BBB closely relate with variations in expression of the tight junction protein occludin (ocln). Several studies have shown the capacity of ocln to control HIV-1 infection of human pericytes, ones of the main regulatory cells of the BBB integrity. Our study identified changes in gene expression-related to ocln modifications in human brain pericytes. After ocln

silencing, high-throughput RNA sequencing analyzed possible changes in a total of 14415 genes. We found that after downregulate ocln, there is an alteration in several genes of the INF-stimulated signaling pathway when compared with non-treated cells. This study focused on the genes that compose the ISG15 antiviral mechanism pathway given the capacity of these genes to inhibit infection of different viruses. Using qpcr analysis, we verified that ocln can modulate the expression levels of DDX58, USP18, ISG15, IFIT1, HERC5, MX1 and MX2 genes. Mechanistically, we show that ocln may regulate INF-stimulated genes though JAK/STAT signaling. We show that overexpressing ocln can significantly up-regulate INF-5α, INF-β, IRF3, IRF7 and IRF9 genes. Furthermore, we demonstrated that ocln induces the expression of STAT-1 at RNA and protein levels as well as increase the levels of phosphorylated STAT-1. Additionally, our results show for the first time that DDX58, ISG15, IFIT1, HERC5, and MX2 but not USP18 or MX1 genes regulate HIV-1 infection rate in human brain pericytes. These results potentiate the understanding of the molecular mechanisms for HIV-1 infection in the human brain.

Title: Brain Pericytes and the Formation of HIV-1 reservoirs in the CNS

Authors: *O. NARANJO[1], S. TORICES[1], M. TOBOREK[2];
[1]Miller Sch. of Med., Miami, FL; [2]Biochem. and Mol. Biol., Univ. of Miami Sch. of Med., Miami, FL

Abstract: Successful antiretroviral therapy (ART) has significantly decreased the mortality and morbidity of individuals infected with HIV. Still, low levels of HIV replication persist in viral reservoirs and lead to immune activation and chronic inflammation. The CNS was thought to be

protected from HIV infection. However, experiments on microglia and astrocytes indicated that these cells are all capable of active and latent viral infection. Even on ART, HIV-infected individuals are at a higher risk for non-AIDS related co-morbidities, including cardiovascular and neurological disease. We have pioneered research on HIV-1 infection in brain pericytes and indicated that these cells possess the receptor profile enabling latent and active HIV-1 infection. BBB pericytes have been shown to regulate brain paracellular and transendothelial fluid transport at the BBB, maintain homeostasis of the CNS microenvironment, and maintain BBB integrity. **Due to the position of BBB pericytes in the interplay between HIV and the CNS, we hypothesize that BBB pericytes are a key cell type for CNS viral reservoirs of HIV.** To test this hypothesis, we use a novel HIV reporter, named HIV_{GKO}, that allows for purification of latently infected cells in absence of reactivation. Fluorescence-activated cell sorting was performed to isolate active, latent, and uninfected populations of BBB pericytes. Transcriptome analysis on isolated cell populations indicates key differences in angiogenesis, glycolysis, and several inflammatory, and cell cycle pathways. Combined with in-vivo modeling of the BBB our data will help to understand in the mechanisms that might be triggering pericytes to become latent reservoirs and provide key targets in developing novel protective therapeutics for those suffering from HIV.

Title: Mesenchymal Stromal Cells Protect the Blood-Brain Barrier, Reduce Astrogliosis, and Prevent Cognitive and Behavioral Impairments in Experimental Sepsis

Authors: *M. C. BARBOSA-SILVA[1], A. Y. O. SILVA[1], É. A. AMORIM[1], M. N. LIMA[1], M. G. GRANJA[1], R. CAMPOS[2], C. A. MORAES[1], P. M. FAGUNDES[1], H. A. OLIVEIRA[1], P. R. M. ROCCO[2], H. C. CASTRO-FARIA-NETO[1], T. MARON-GUTIERREZ[1];
[1]Oswaldo Cruz Institute- Fiocruz, Rio de Janeiro, Brazil; [2]Inst. of Biophysics-Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Sepsis is a systemic inflammatory host-response against a pathogen; it is the largest cause of admission to intensive care units (ICUs) in the United States. Sepsis-associated

encephalopathies (SAEs) are neurological complications that occur during or after sepsis events. SAE causes long-term neurological consequences affecting memory, cognition and mood. Currently, there is no prevention or treatment for neurological damage resulting from SAEs. Thus, investigating new therapies is necessary. Both clinical and experimental studies have been show the effects of cell therapy in neurodegenerative diseases. Indeed, the immunomodulatory capacity of mesenchymal stromal cells (MSCs) is well established. The aim of the present study was to evaluate the effects of MSC therapy on blood-brain barrier (BBB) maintenance, astrocyte activation, neuroinflammation and cognitive/ behavioral damage in an experimental model of sepsis. In order to investigate that, we used male adult Swiss mice and cecal ligation and puncture (CLP) surgery for sepsis induction and sham-operated animals were used as control. Six hours after surgery, mice were treated with MSC intravenously (1×10^5 cells in 0.05 mL of saline/mouse) or saline. At day 1 the clinical score and plasma levels of Interleukin (IL) -1β, IL-6, and MCP-1 (assessed by ELISA) were increased in CLP animals. Cell therapy did not affect clinical score or survival rate, but led to a reduction in systemic levels of IL-1β, IL-6, and MCP-1 and also led a reduction in cortical and hippocampal cytokine levels. MSC therapy led a BBB protection (evaluated by Evans Blue Dye Assay) and a reduction in astrogliosis (evaluated by immunofluorescence) at 72h. In cultured astrocytes stimulated with lipopolysaccharide (LPS) conditioned media from MSCs reduced astrogliosis at 24h, suggesting a paracrine mechanism of action. These results might be related with an improvement in spatial memory (Morris Water Maze test), aversive memory (fear-conditioned test) and anxiety-like behavior (Elevated plus maze test). Thus, we can conclude that a single dose- therapy with MSC led to an improvement in cognitive damage, behavioral impairments, protection of the BBB, reduction in local levels of cytokines and astrogliosis and these effects might be associated with a decrease in systemic levels of inflammatory mediators.

Title: Cerebral malaria-related factors heme and Histidine Rich Protein 2 (HRP2)-induced brain organoids damage is Toll Like Receptors 1 and 2-dependent

Authors: *A. HARBUZARIU, J. C. CESPEDES, A. NTI, K. HARP, A. DRISS, J. K. STILES; Morehouse Sch. of Med., Atlanta, GA

Abstract: Rationale: Despite available treatment, *Plasmodium falciparum (Pf)* infection remains a significant global health burden. Over 400,000 deaths mainly due to cerebral malaria (HCM) complications in children under age 5 are reported annually. Previous studies with a 3D *in vitro* model (human brain cortical organoids) indicated that heme and HRP2 released from lysed *Pf*-infected erythrocytes cause brain inflammation (e.g., CXCL10) and loss of neuronal viability and development. Comparative analyses of Human Cerebral Malaria (HCM; *Pf*) and experimental cerebral malaria (ECM; *Plasmodium berghei* ANKA in C57BL/6) revealed that both models activate brain microvascular endothelial cells, cause blood brain barrier (BBB) leakage and perivascular neuronal injury in the late stages. Circulating Neuregulin-1 (NRG1; cytoprotective) declined in HCM, whereas tissue expression of NRG1 and its receptor ErbB4 in damaged brain areas were elevated. Adjunctively administering NRG1 with artesunate (ART) in ECM mice eliminated parasite burden and reduced brain damage and ECM mortality. The molecular pathways mediating heme- and HRP2-induced brain damage are unknown. Transcriptome analysis revealed key roles for toll like receptors 1 and 2 (TLR 1& 2). Hypothesis: heme and HRP2-induced brain inflammation associated with cerebral malaria are TLR (1, 2) dependent. We functionally assessed heme- and HRP2-induced inflammation as well as the neuroprotective effects of NRG1 in brain organoids using IHC, WB and gene microarrays. The involvement of TLR 1 and 2 signaling was also assessed in the brain of Plasmodium berghei ANKA (PbA) infected mice and in post-mortem HCM brain samples by IHC. Results indicate that exposure of human brain organoids to physiologically relevant concentrations of HRP2 (4.2 μg/ml; HCM) and heme (30 μM; HCM) increased TLR 1 and 2 expression in microglia, neurons and astrocytes. Furthermore, heme and HRP2 effects were attenuated by exogenously augmenting NRG1. We conclude that heme and HRP2-induced brain organoids damage is TLR1 and TLR2 dependent and is attenuated by NRG1.

Title: Dendrimer-conjugated N-acetyl cysteine prevents neurobehavioral defects in a pediatric rabbit model of tuberculous meningitis

Authors: *J. KIM[1], C. ERICE[1], L. PIETERSE[1], A. SHARMA[2], S. JAIN[3], R. KANNAN[2], S. KANNAN[1], E. TUCKER[1];
[1]Anesthesiol. and Critical Care Med., [2]Ctr. for Nanomedicine, [3]Dept. of Pediatrics, Johns Hopkins Univ., Baltimore, MD

Abstract: Introduction Tuberculous meningitis (TBM) is the most aggressive form of extrapulmonary TB, particularly among children. Despite standard-of-care treatment with antimicrobials and host-directed therapy (HDT; i.e. corticosteroids), mortality and morbidity are unacceptably high and new therapies are needed urgently. N-acetyl cysteine (NAC) is a promising HDT with antioxidative and anti-inflammatory properties, albeit with poor bioavailability. However, when conjugated to dendrimer (D-NAC) nanoparticles for targeted delivery to activated microglia, it improves behavior deficits and decreases microglia activation in models of neuroinflammation (e.g. cerebral palsy, traumatic brain injury). Our previously established pediatric rabbit model of TBM demonstrated both neurobehavioral defects and increased activated microglia associated with pathophysiology. Here we test the ability of D-NAC to rescue neurobehavioral defects associated with TBM and to determine if behavioral data correlates with decreased neuroinflammation. **Methods** Young New Zealand White rabbits (post-natal day 5) were injected with live *Mycobacterium tuberculosis* H37Rv (infected) or PBS (uninfected control). After 3 weeks, infected rabbits received weekly intravenous D-NAC or PBS for 2 weeks. Neurobehavior testing was done by automated video tracking of open field tests recorded for 2 mins on day 0, 3, 7, 10, and 14 of treatment. A comprehensive score was calculated based on 15 components of motor behaviors from an automated tracking software (Noldus EthoVision XT^{TM}) and manual scoring (by 2 blinded reviewers) of 11 salient neurobehavioral deficits (e.g. limb paresis, head tilt, balance). All scores were normalized to the corresponding day's baseline score established by the control mean score. Neuroinflammation was assessed by ionized calcium binding adaptor molecule 1 (Iba-1) immunostaining of paraffin-embedded brain sections which was semi-quantitively analyzed with the HALO Image Analysis Platform. **Results** Infected rabbits treated with PBS (n=9) showed significantly worse neurobehavioral outcomes at 14 days compared to control (n=8; P=0.0013). However, a decline in behavior was not observed in D-NAC treated rabbits that demonstrated no behavioral deficits compared to control (n=5; P=0.442). Iba-1 staining has been optimized and quantification is underway (n=3 per condition). **Conclusions** D-NAC treatment prevents worsening neurobehavioral outcomes and possibly neuroinflammation in a pediatric rabbit model of TBM. These data suggest D-NAC is a promising HDT candidate and additional studies in combination with antimicrobial regimens would be beneficial.

Title: Evidence of Reactive Oxygen Species in the HIV-1 Transgenic Rat Model of Cardio Pathology

Authors: M. AWOLOWO[1], S. WILLIAMS[1], M. WORTHINGTON[1], H. DAVIS[3], J. BRYANT[3], *F. J. DENARO[2];
[1]Biol., Morgan State Univ., BALTIMORE, MD; [2]Biol. and Imaging Core Director, Morgan State Univ., Baltimore, MD; [3]Animal Model Div., Inst. of Human Virology, BALTIMORE, MD

Abstract: Because of improvements in antiviral medicines, HIV/AIDS has become a chronic disease. The survival rate has been improved markedly. However, HIV is not eliminated from the patient but exists in a restricted population of cells. These reservoir cells continue to produce very low levels of virus and viral proteins (GP-120, Tat, Nef). It has been hypothesized that this low level of HIV or the HIV proteins contribute to the development of noninfectious HIV comorbidities (CM). The longer the patients survive, the greater the probability of development of the CMs. There are a number of organs that are affected. Of particular interest are the heart and brain. There are several theories on how cell death and dysfunction can occur. One is the production of Reactive Oxygen Species (ROS). We have identified the presence of nitrotyrosine in the HIV-1 Transgenic Rat heart (Microscopy and Microanalysis, V26, S2, 2020 pp. 1342-1344) suggesting that free radial damage is occurring. This model produces measurable levels of GP-120. It therefore models chronic viral protein production in treated HIV infection. One mechanism by which ROS can be produced is if the enzyme NOX 2 is activated and up regulated. One way this might happen is if GP-120 binds to CXCR4 positive cells in the heart. Immunocytochemical staining of the HIV-1 rat heart for CXCR4 reveals a positive dendritic cell type. Immunocytochemical staining in the HIV-1 rat heart for NOX2 reveal more positive cells than controls. Also, of a dendritic type. Increased numbers of NOX2 positive cells suggest an inflammatory process. Labels to cell type will reveal if the cells are macrophages (infiltrating) or dendritic cells (resident cells). The production of ROS by these cells may affect the myocytes. Cardiac muscle also presents with an addition mechanism which uses ROS. This is the XROS

system. In this system the microtubules act as a mechanotransducer to activate NOX2. But GP-120 has been reported to bind to tubulin. If this is the case the generation of ROS by the ROS-X system may be compromised. Alteration of XROS signaling could contribute to myopathy in addition to extracellular exposure by macrophages or dendritic cells. Future studies will examine this possibility.

Title: Agent-based modeling of neuronal mitochondrial dynamics and quality control in ischemia/reperfusion injury

Authors: *G. M. FOGO, T. H. SANDERSON;
Univ. of Michigan, Ann Arbor, MI

Abstract: Cerebral ischemia continues to be a leading cause of death and disability. In this injury paradigm, both ischemia and reperfusion induce extensive damage to the brain. A prominent component of ischemia/reperfusion (I/R) injury is mitochondrial dysfunction. While chiefly known as essential generators of cellular energy, mitochondria also act as dynamic agents fusing to form sprawling healthy networks and undergoing fission to separate unhealthy segments. Mitochondrial homeostasis is tightly regulated by the fission and fusion forces of mitochondrial dynamics, as well as mitophagy. Cerebral I/R injury leads to disruptive events of mitochondrial dynamics and mitophagy that exacerbate and drive neurological damage. To better understand the patterns of mitochondrial dysfunction in I/R injury, we aimed to construct a predictive computational model of mitochondrial dynamics and quality control. Utilizing the open-source agent-based modeling platform NetLogo, we have designed a simulation model of single cell mitochondrial dynamics in basal and ischemic conditions. The model simulates several intrinsic factors of individual mitochondria and their influences on dynamic behavior, including: morphology, size, age, connectivity, and local membrane potential. The probabilistic equations that drive the model's behaviors were generated from live cell imaging data of mouse primary cortical neurons. Primary neurons were cultured to DIV14 and exposed to oxygen-

glucose deprivation and reoxygenation (OGD/R) in our live cell imaging setup. In order to correlate intrinsic factors with dynamic events of fusion and fission, we developed an automated machine learning-based methodology for detecting individual fission and fusion events over time during imaging. To extract targeted intrinsic parameters from the mitochondria of these cells, we utilized the genetic reporters MitoTimer and MitoQC, as well as TMRM staining. Our agent-based model closely simulates the dynamic behavior of neuronal mitochondria and is currently in further development to mimic the patterns of mitochondrial dysfunction seen in cerebral I/R injury. Future work will be focused on implementing known proteins of mitochondrial dynamics into the model (i.e., Drp1, Opa1), as well as other intracellular variables including calcium and reactive oxygen species (ROS) signaling. We expect further optimization and utilization of our model will inform the development of potential therapeutic interventions and predict the optimal intervention time to promote cell survival in cerebral I/R injury.

Title: Cd38 activation of the trpm2 ion channel contributes to post-stroke hippocampal dysfunction

Authors: *A. BURCH[1], D. MITCHELL[1], J. ORFILA[2], A. L. DINGMAN[1], N. QUILLINAN[1], P. S. HERSON[2];
[1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [2]Ohio State Univ. Col. of Med., Columbus, OH

Abstract: Emerging clinical data reveals post-stroke cognitive impairment (PSCI) as one of the leading causes of disability in the country. Recently, our lab has identified the TRPM2 ion channel as a potential molecular target for the reversal of cognitive symptoms following global cerebral ischemia, without conferring neuroprotection. These results suggest a potential neurorestorative function of the TRPM2 channel independent of its well-established role in neuronal toxicity and death. Whether TRPM2 channel modulation is of benefit in the context of focal ischemia and PSCI remains an open question. To address this, we perform a 60-minute transient middle cerebral artery occlusion (MCAO) in adult (8-12wk) male mice as a preclinical model for stroke and assess synaptic plasticity in combination with neurobehavior with a focus on the hippocampus, a region known to contribute to PSCI but is not directly supplied by the MCA. To measure hippocampal synaptic plasticity, we employ field electrophysiology and assess long-term potentiation (LTP) in the CA1-Schaffer collateral pathway at delayed (30 day)

timepoints following MCAO. We find that LTP is reduced following MCAO (n=3, 15.0±4.0%) compared to sham (n=6, 47.2±9.2%; $p<0.05$). However, i.v. treatment with tat-M2NX (20mg) on day 29, a potent and specific inhibitor of TRPM2, fully restores LTP on day 30 (n=6, 65.3±8.1%). Consistent with the electrophysiology data, we also observe reduced levels of contextual fear conditioning (a measure of hippocampal-dependent short-term memory), 30 days following MCAO (n=3, 23.6±3.3%), that are reversed following i.v. treatment with 20mg tat-M2NX on day 29 (n=5, 73.4±5.3%). We next investigate potential mechanisms of stroke-induced TRPM2 activation with a focus on CD38, an ectoenzyme and potential source of the TRPM2 ligand, ADP-ribose (ADPr). Using immunohistochemical (IHC) staining, we show CD38 is localized to activated astrocytes in the hippocampus following MCAO. We also find impaired hippocampal LTP on MCAO acute brain slices is restored to sham levels following bath application of apigenin (vehicle n=7, 23.9±7% vs. 10μM apigenin n=7, 65.5±2.5%; $p<0.05$), and 78c (vehicle n=6, 4.0±8.5% vs. 100nM 78c n=6, 78.3±15.8%; $p<0.05$), phenocopying TRPM2 inhibition. Taken together, these data identify the TRPM2 channel as a contributor to stroke-induced hippocampal dysfunction, suggesting a role for TRPM2 beyond neuronal death. Furthermore, we also provide data demonstrating the astrocyte-localized ectoenzyme, CD38, as an ADPr source and potential upstream regulator of TRPM2, uncovering a novel neuroglial pathway underlying PSCI.

Title: High fructose diet-induced obesity worsens post-ischemic brain injury

Authors: *P. PÉREZ CORREDOR[1], G. CARDONA GÓMEZ[1], N. BALCÁZAR MORALES[1], J. GUTIERREZ VARGAS[2];
[1]Univ. of Antioquia, Medellín, Colombia; [2]Corporación Universitaria Remington, Medellín, Colombia

Abstract: Cerebral ischemia is caused by a reduction of the blood flow in a specific area in the brain, triggering cellular cascades in the tissue that result in neuronal death. This process leads to

a neurological decline in patients who suffer cerebral ischemia. The extent of the injury after cerebral ischemia could be related to the comorbidity condition. Therefore, the main aim of this study was to analyze the effect of obesity induced by a high fructose diet (HFD) on the brain after cerebral ischemia in rats. We induced the obesity model in Wistar rats with 20% fructose in water for 11 weeks (n=12). After this time, we performed the cerebral ischemia surgery (2VO) (n=3-4), we also carried out the neurological test at 6-, 24- and 48-hours post-ischemia and we analyzed the histological markers of neurodegeneration (n=3-4). Finally, we treated bend.3 endothelial cell line with 20% of plasm from obese rats and analyzed endothelial damage (n=3-4, 1 replica). Data were analyzed using Shapiro-wilk normality test, T-test and two-way ANOVA. The HFD induced an obese phenotype without insulin resistance. The obese rats exhibited worse neurological performance at 6 hours post-ischemia. Due to the ischemia surgery was global, we observed a different infarct zone in each animal analyzed (caudate-putamen, motor cortex, amygdala, and hippocampus). However, independent of the infarct zone we found the same pattern of neurodegeneration markers related to the damage in the infarct zone; such as higher neuronal loss area and astroglial and microglial hyperreactivity at 48 hours post-ischemia. We also found that the hippocampus was a commonly affected area, where we found loss of neurons, an increase in interleukin 1 â (IL-1B) in the blood vessels of the Dentate gyrus, a remarkable disruption of MAP-2+ dendrites, a loss of BDNF staining, and the presence of PHF-tau. Although, we observed a tendency to increase the IL-1B expression. In the same way, the plasm from obese rats induced more endothelial damage characterized by increased condensed nuclei, and, cPLA2 and phalloidin fluorescence intensity. In conclusion, an HFD induces an obese phenotype, which produces an increase in neuronal loss, inflammation, and plasticity impairment in the hippocampus after cerebral ischemia. Additionally, the endothelial alteration is a possible cellular mechanism of damage in obesity.

Title: Pilot study of calcium imaging in the contralesional hippocampus of aged and young synapsin-Cre/GCaMP6S male mice after stroke

Authors: *T. A. UJAS[1], T. L. ANDERSON[1], M. XIA[1], A. GORNET[1], V. O. TORRES[4], S. MESSMER[1], J. TURCHAN-CHOLEWO[1], M. K. MALONE[1], P. I. ORTINSKI[2], A. M. STOWE[3];
[2]Neurosci., [3]Neurol., [1]Univ. of Kentucky, Lexington, KY; [4]UT Southwestern Med. Ctr., Dallas, TX

Abstract: Background: Stroke injury following a transient middle cerebral artery occlusion (tMCAo) induces a rapid neuroinflammatory response in the injured brain that lasts for weeks. The present study focuses on investigating the effects of neuroinflammation on spatiotemporal synaptic hippocampal activity long-term post-stroke. We sought to establish a protocol using calcium imaging in the contralesional hippocampus to test long-term modulation of adaptive immune responses after stroke. Methods: C57BL/6 synapsin-Cre/GCaMP6S$^{+/-}$ aged mice (12-15 months; n=10) were depleted of B cells (100µg mCD20 or isotype (Iso) control; Genentech) 1 day prior to 60-min tMCAo, with weekly injections to deplete B cell turnover. The second cohort (young, 1.5-3 months; n=10) were split into uninjured and 60-min tMCAo groups. Brains were sectioned into 300µm slices, oxygenated, and kept at 37ºC in aCSF. Wide-field calcium imaging was conducted in 100µM of picrotoxin using a stimulating electrode within the Schaefer collaterals of the stratum radiatum, 5-10µm from the CA1 pyramidal cell layer. Cells were stimulated at increased intensities (0.1-0.5 mA) for 10ms intervals at 100Hz. For each cell, a fluorescence trace was generated by averaging all pixels within ROI outline in each recording frame. The associated background signal was removed from each cell's fluorescence trace. Calcium transients were identified using a wavelet ridgewalking algorithm. Statistical analyses were performed in GraphPad Prism. Results: In the aged cohort, imaging of CA1 pyramidal cells did not occur in the absence of picrotoxin, and few cells were found in the Iso-treated mice (n=2 mice with 13 cells detected) when compared to mCD20-treated mice (n=3 mice with ~100 cells). The amplitude and duration of the fluorescent signal were both significantly affected by stimulus intensity ($p<0.001$) regardless of B cell depletion. The Iso-treated group exhibited a trend for lower amplitude ($F(1,104)=3.2$; $p=0.08$). Young synapsin-Cre/GCaMP6S$^{+/-}$ exhibited low fluorescence expression, with 2/5 uninjured mice having no expressed cells despite a confirmed genotype by PCR. The young cohort is currently being analyzed by the ridgewalking algorithm to determine age-effects after tMCAo. Conclusions: While calcium imaging is useful in determining synaptic activity after stroke, particularly as it may relate to the development of dementia, it has proven challenging using C57BL/6 synapsin-Cre/GCaMP6S mice. This may be secondary to heterozygosity for GCAMP6S, animal age, and injury status. Further optimization is needed to determine the usefulness of this transgenic line in pre-clinical stroke studies.

Title: Protective effects of preconditioning with carbon dioxide inhalation against acute focal cerebral ischemia/reperfusion-induced brain injury in a rat middle cerebral artery occlusion model.

Authors: C. YOON[1], H. LEE[2], I. KWON[2], Y. PARK[1,2,3], Y. SHIM[1,2,3], Y. KIM[1,2], J. HEO[1,2,3], *H. NAM[1,2];

Abstract: Stroke is a major cause of mortality and permanent neurological deficits all over the world. Despite its high incidence and death rate, clinical therapeutic options are still limited. The potential therapeutic target is to keep the ischemic penumbra alive and to prevent destruction of cerebral tissue. Ischemic preconditioning is a promising strategy to save the ischemic penumbra and reduce tissue damage. Carbon dioxide (CO_2) is the most potent vasodilator of cerebral vessels in the earth and CO_2 inhalation dramatically increases cerebral blood flow. However, it is not clear whether preconditioning treatment with CO_2 can effectively reduce cerebral tissue damage and functional deficits. Hence, we evaluated the effects of preconditioning with CO_2 inhalation on focal ischemia-induced brain injury and neurological deficits in a rat ischemic stroke model. Adult male Wistar rats (270-320g, n=8) were inhaled with 20% CO_2 mixed gas (applied in 20% CO_2, 20% oxygen, and 60% nitrogen mixture) with 3 cycles of inhalation for 5 min followed by 10 min recovery (room air) before transient middle cerebral artery occlusion (tMCAO) for 90 min. To evaluate the neurological deficits, behavioral tests were blindly performed with the modified Neurological Severity Scores (mNSS), Longa and Garcia score at 24 h after tMCAO. In order to assess motor coordination and balance after stroke, we also performed the rotarod test and recorded the latency of rats to fall from the accelerating rotarod. We found that the mNSS was 0 in the sham and CO_2 pretreatment sham condition (n=5 per group). The CO_2 inhaled preconditioning tMCAO rats exhibited significantly lower mNSS compared to tMCAO rats (6±2.0 vs. 11±1.3, n=8, $p<0.0001$). Rats in both sham group and CO_2 pretreatment sham group had the latencies in 300 sec. The latency was dramatically increased in CO_2 preconditioning tMCAO rats compared to tMCAO rats (99.5±53.5 sec vs. 27.5±8.7 sec, $p=0.0006$). Furthermore, preconditioning tMCAO rats with CO_2 showed significantly small infarction size compared to tMCAO rats (17.4±4.1% vs. 30.8±3.7%, $p<0.0001$). We demonstrated that CO_2 pretreatment plays an important role in reducing ischemic brain damage. In the sham animals, CO_2 inhalation did not show harmful effects. Taken together, these findings suggest that preconditioning with CO_2 inhalation protects against ischemic-induced brain injury

and improves neurological outcomes without complication after acute ischemic stroke. Therefore, inhaled CO_2 preconditioning treatment may provide a novel therapeutic approach for ischemic stroke.

Title: Poststroke lipid droplet accumulation in residing microglia and its influence on inflammation and phagocytosis

Authors: W. WEI, D. FITZNER, M. BÄHR, ***T. DOEPPNER**;
Univ. of Göttingen Med. Sch., Göttingen, Germany

Abstract: Inflammation is a hallmark of ischemic brain injury, for which resident microglia play a pivotal role. Recent evidence from non-stroke disease conditions suggests microglia to be also involved in abnormal lipid metabolism and lipid droplet (LD) formation. Such processes are highly regulated by lipid-associated proteins like Plin2, a member of the perilipin family. Whereas the role of Plin2 under stroke settings remains elusive, Plin2 has recently been found to promote LD production in Alzheimer's Disease. Using preclinical stroke models in both cell culture and C57BL6 mice, the present work aimed to elucidate the role of LD formation under stroke condtions in general and Plin2 in particular. Indeed, LD formation was significantly increased in microglia exposed to in vitro hypoxia conditions, as was the case in stroke mice. The extent of LD formation correlated with the extent of cell death and brain injury. Likewise, Western blotting against Plin2 revealed increased protein abundance in the aforementioned cells and brain tissue. Using ELISA and RT-PCR techniques, cytokine secretion patterns from microglia displayed increased levels of TNFalpha, IL6, and IL1beta under stroke conditions. The latter was associated with high formation rates of reactive oxygen species. Further analysis of microglia resulted in enhanced M1 phenotypes that displayed high expression rates of the ABCA1 transporter, thus blocking cholesterol efflux into the extracellular matrix. The plethora of observations made herein finally resulted in a stimulation of the proinflammatory NfKb signaling pathway, further increasing cell injury. In conclusion, interfering with lipid metabolism disorders in microglia exposed to stroke rather than to directly exert neuroprotection, may provide a new perspective for the treatment of cerebral ischemia.

Title: Fluorescence lifetime imaging reveals KCC2-dependent chloride microdomains in dendritic blebbing

Authors: *N. L. WEILINGER[1], L. E. WICKI-STORDEUR[1], C. J. GROTEN[1], J. M. LEDUE[2], K. T. KAHLE[3], B. A. MACVICAR[1];
[1]Psychiatry, [2]Ctr. For Brain Hlth. / UBC, Vancouver, BC, Canada; [3]Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: Intracellular chloride ion ($[Cl^-]_i$) homeostasis is critical for neurotransmission and volume regulation. We recently showed that calcium (Ca^{2+})-independent cytotoxic swelling in neuronal somata requires intracellular Cl^- loading through the Cl^- channel SLC26A11. However, our understanding of Cl^--dependent swelling in dendrites (termed “blebbing”), a hallmark of stroke and traumatic brain injury, is poorly understood. Here, we investigated the spatiotemporal $[Cl^-]_i$ dynamics in dendritic subcompartments to elucidate mechanism of synaptic swelling that engenders synaptic lysis. We combined whole-cell patch clamp electrophysiology with simultaneous fluorescence lifetime imaging (FLIM) of the Cl^- dye MQAE to quantitatively map dendritic Cl^- levels in N-methyl-D-aspartate (NMDA) excitotoxicity. We validated FLIM-based $[Cl^-]_i$ readouts from rat and mouse neurons, and found basal $[Cl^-]_i$ measures closely matched expected values from the literature and were corroborated by Rubi-GABA uncaging to measured E_{GABA}. Low baseline $[Cl^-]_i$ in dendrites required Cl^- efflux via the K^+-Cl^- cotransporter KCC2 (*SLC12A5*). To assess the possibility of pathological Cl^- microdomains in dendrites, we applied NMDA which generated spatially heterogeneous and persistent subdomains of high $[Cl^-]_i$ that formed dendritic blebs. Unlike somatic swelling, dendritic $[Cl^-]_i$ dysregulation required local Ca^{2+} influx and Cl^- loading caused by reversed KCC2 transport. Together, our data show that neuronal swelling is mechanistically distinct between somatic and dendritic subcompartments. These data also establish a novel role for KCC2 to generate subcellular $[Cl^-]_i$ microdomains in dendritic blebbing, with relevance for multiple neurological disorders.

Title: Prenatal alcohol exposure elevates stroke severity and increases gut permeability in adult rats

Authors: *S. BAKE[1], S. PANDEY[3], D. HURST[4], M. PINSON[2], R. C. MIRANDA[5], F. SOHRABJI[6];

Abstract: Adverse prenatal experience is linked to poor health outcomes in postnatal life. There is very little information on the developmental origin of adult-onset diseases, particularly prenatal alcohol exposure (PAE) and stroke outcomes. The present study tested the hypothesis that PAE will lead to greater stroke severity and will disrupt the integrity of the gut barrier in adult offspring. Pregnant Sprague Dawley rats were exposed to 10% ethanol vapor for 1 h from GD 8-18 using the rodent alcohol inhalation system. Control animals were exposed to air. The 5 month old adult offspring were subjected to endothelin-1 induced unilateral middle cerebral artery occlusion (MCAo) and outcomes were evaluated after 2 days. Stroke outcomes were assessed from mortality rates, behavioral assays, infarct volume, and gut permeability markers. Interestingly, the PAE males had significantly higher mortality within 48 h of stroke compared to PAE females ($p<0.03$). Behavioral analysis indicates that PAE animals exhibited greater neurological deficits as determined by their higher composite score compared to controls ($p<0.02$). Brain damage assessed by infarct volume was not significantly different from control animals. However, serum LPS was increased in PAE-males ($p<0.03$), and there was also an elevation in serum intestinal fatty acid binding protein (iFABP, $p<0.03$) in PAE-females compared to their control counterparts, suggesting that PAE increased intestinal barrier permeability after stroke. The present findings indicate that PAE contributes to long-lasting adverse effects on adult health as evidenced by greater mortality and poor functional recovery during the acute phase of stroke.

Title: Novel approach to analyzing steady-state intracellular pH and the recovery from NH_4^+-induced acidosis in rat hippocampal neurons and astrocytes during acute hypoxia

Authors: *V. A. RUFFIN[1], W. F. BORON[2];
[1]Natural Sci., Virginia Union Univ., Richmond, VA; [2]Physiol. & Biophysics, Case Western Reserve Univ., Cleveland, OH

Abstract: Regulation of intracellular pH (pHi) in neurons and neuroglial is necessary for optimal brain function, especially in the hippocampus (HC), an area involved in learning and memory. In the absence of CO2/HCO3−, the major family of proteins regulating acid/base balance and pHi are the Na-H exchangers (NHEs). In the present study, we used the pH-sensitive dye BCECF to examine the regulation of steady-state pHi and pHi recovery from NH4+ -induced intracellular acid loads during acute hypoxia in HC neurons and astrocytes, co-cultured from embryonic (E18-20) Sprague Dawley rats, and studied in CO2/HCO3− -free HEPES-buffered ("HEPES") solutions. After at least 14-days in a CO2 incubator, cells were removed, loaded with BCECF, and placed in a recording chamber with flowing HEPES at 37°C. We measured pHi at the beginning of each experiment (checkpoint A), and again after 5 min of stabilization (checkpoint C). The "initial pHi"— the value at checkpoint C, (pHi)C—was 7.423 (N=42) for neurons (astrocytes: 7.184, N=46). We used a twin, unpaired NH4+-pulse protocol (1st pulse in HEPES/21% O2, 2nd pulse in HEPES/1% O2) to examine the acute transition to hypoxia. After each NH4+ removal, pHi recovers (increases) following an ~exponential time course. During pHi recovery from the 1st acid load in HEPES/21% O2, the quasi-single exponential rate constant (kqSExp) averaged 0.0048 s−1. The new average neuronal steady-state pHi, now at checkpoint D, (pHi)D, was 7.293 (astrocytes: 7.154 /0.0096 s−1). After switching to HEPES containing 1% O2, neuron pHi shifts upward to 7.415 (astrocytes: 7.340) at checkpoint E, (pHi)E. We then impose the 2nd NH4+ pulse. During the pHi recovery, kqSExp was 0.0060 s−1;

the new steady-state pHi in 1% O2, now at checkpoint F, (pHi)F, was 7.382 (astrocytes: 7.347/0.0072 s−1). We hypothesize that (pHi)C exceeds (pHi)D because, without HCO3− -dependent acid loaders, cells—after they initially alkalinize as they come out of the CO2 incubator—cannot fully acidify . For each recovery from an acid load, we use a novel analysis in which we plot pHi recovery rate (dpHi/dt) vs pHi. We bin kqSExp values according to (pHi)D, using pHi intervals of 0.2. We find that 1) kqSExp is greater (faster) for astrocytes than neurons; 2) kqSExp tends to be low for cells in the lowest pHi bins, highest in moderate-pHi bins (more dramatically for astrocytes), and low again at the highest-pHi bins; and 3) acute transition from a HEPES solution containing 21% O2 to a solution containing 1% O2 alkaline raises pHi in both neurons and astrocytes. These new analytical approaches may ultimately provide mechanistic insight into cell-to-cell heterogeneity of pHi regulation in the nervous system.

Title: The role of mGluR5 in neurovascular coupling during development and after stroke

Authors: *T. STACKHOUSE[1], Z. LI[4], H. MCCONNELL[1], W. ZHANG[2], A. MISHRA[3,1]; [1]Dept. of Neurology, Jungers Ctr. for Neurosciences Res., [2]Dept. of Anesthesiol. and Peri-operative medicine, [3]Knight Cardiovasc. Inst., Oregon Hlth. & Sci. Univ., Portland, OR; [4]Gen. hospital of Ningxia Med. Univ., Ningxia, China

Abstract: Cerebral blood flow (CBF) is regulated to match local neural activity with high temporal and regional specificity via a process termed neurovascular coupling. In adult humans and rodents, increases in neural activity reliably induces capillary dilations, resulting in an increase in local CBF. However, neurovascular coupling is much more variable in young humans and rodents, suggesting that the underlying mechanisms are different in adults and the developing brain. We studied this developmental change in neurovascular coupling in acute cortical slices using electrical stimulation to evoke neuronal activity. In P6-10 rat slices, stimulation evoked a dilation in 78% and a constriction in 22% of capillaries. The proportion of dilating capillaries increased to 100% by P21. The magnitude of stimulation-evoked capillary dilation also increased with age, from 3.3±2.4% in P6-10 slices to 11.9±3.2% in P11-15 ($p<0.14$) and 15.4±2.0% in >P21 ($p<0.003$). A loss or attenuation of neurovascular coupling is also

reported in many neurological conditions including stroke. Using the middle cerebral artery occlusion (MCAO) model of stroke, we found that activity-dependent capillary response is reduced by ~75%, to 3.3 ± 1.0% dilation, in otherwise healthy ipsilesional cortical regions outside the infarct compared to contralateral hemisphere or naïve brains. Neurovascular coupling at capillaries is mediated by astrocytes in a Ca^{2+}-dependent manner; however the source of this Ca^{2+} is debated, with some findings supporting a role for metabotropic glutamate receptor 5 (mGluR5) while others suggest a role for purinergic P2X1 channels. We investigated whether mGluR5, which is expressed in immature and reactive astrocytes but not healthy adult astrocytes, is responsible for the suppression of neurovascular coupling during early development and after stroke. Inhibiting mGluR5 rescued stimulation-evoked capillary dilation in the stroke hemisphere of MCAO rats, and a similar effect was observed in young (<P21) slices. Importantly, mGluR5 inhibition did not alter neurovascular coupling in healthy adult slices. Our data offer a resolution to the debate surrounding the role of mGluR5 in neurovascular coupling and suggest that an mGluR5-dependent mechanism is responsible for the reduced neurovascular coupling observed in development and after stroke, but not in healthy adulthood. This concept aligns with previously published patterns of mGluR5 expression in astrocytes. Future studies will focus on the specific role of astrocytic mGluR5 in neurovascular regulation and the downstream Ca^{2+}-dependent pathways involved.

Title: Measures of directional and general visuospatial impairments following stroke using a centre-out reaching task

Authors: *K. PARK[1], S. P. DUKELOW[2], S. SCOTT[1];
[1]Queen's Univ., Kingston, ON, Canada; [2]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada

Abstract: Visuospatial neglect is a disorder characterized by an impairment of spatial awareness, most commonly to the contralesional side of space in individuals with stroke. Reaching provides a useful framework to quantify one’s ability to generate motor actions in different spatial directions. Previous studies suggest that individuals with visuospatial neglect

can exhibit delayed reaction times when initiating reaches towards their contralesional side of space. However, no studies have explored the breadth of neglect beyond reaching left or right. In this study, we use an 8 target centre-out visual-guided reaching task on the Kinarm Exoskeleton lab to quantify the ability of individuals with stroke to reach in different spatial directions using their affected and unaffected arms. We assessed 162 left-affected and 103 right-affected individuals following sub-acute stroke and 204 healthy control participants. We developed metrics to quantify reaction time across spatial directions: Asymmetry Score to quantify how reaction time varied across spatial directions, Asymmetry Direction to determine the direction with the slowest reaction time, and a General Score to quantify the fastest response across all directions. Impairments were defined as scores greater than 95th percentile of healthy controls. For the left-affected individuals with stroke, we found 34% were impaired for Asymmetry Score, and 32% were impaired for General Scores for the right unaffected arms. The direction with the slowest reaction time tended to be to the left and slightly away from the body. Interestingly, the direction with the slowest reaction time for the affected left arm tended to be to the left and slightly towards the body, suggesting a general rotation in reaction time impairments between left and right arms. Right affected individuals showed a similar pattern of impairments although the overall number of individuals impaired were slightly lower (left-affected arm: 24% were impaired for Asymmetry Score and 12% were impaired for General Scores). We also found that our metrics correlated with a commonly used measure of visuospatial neglect, the Behavioural Inattention Test (BIT). Most individuals that failed the BIT also were impaired for reaction time measures, whereas some individuals that passed the BIT (>129) were still identified as impaired for reaction time measures.

Title: Sharing of Large-scale Brain Network Between Cognitive Function and Motor Recovery in Stroke Patients

Authors: *J. LEE[1], H. KIM[2], J. KIM[2], W. CHANG[1], Y.-H. KIM[1];
[1]Samsung Med. Center, Sungkyunkwan Univ., Seoul, Korea, Republic of; [2]Sungkyunkwan Univ., Seoul, Korea, Republic of

Abstract: Cognitive and motor functions are known to be linked with each other. The primary motor cortex is activated during motor imagery and movement observation in the absence of any movement, while the corticospinal excitability is altered at an initial intention to motor action. In stroke patients, preserved cognitive function is known to play a role in motor recovery, but there is not enough evidence. In this study, we investigated the relationship between cognitive function and motor recovery in terms of sharing a large-scale brain network. One hundred eight subacute ischemic stroke patients participated. All patients underwent resting-state functional MRI (rs-fMRI) and cognitive/motor function assessments at two weeks after stroke onset using the Fugl-Meyer assessment (FMA) and Korean version mini-mental state examination (K-MMSE). The FMA score was obtained again at three months after stroke onset to assess motor recovery. To construct a large-scale brain network using the rs-fMRI, cortical surface parcellation was performed using Gordon atlas whose parcellation includes 333 regions of interest in twelve resting-state networks. This process included brain extraction, segmentation, generation of white matter and pial surface, inflation of the surfaces to a sphere, and surface-based spherical registration. Within-networks consisting of connections within each resting-state network and between-networks consisting of connections between twelve resting-state networks were extracted in the brain network. These networks related to the initial K-MMSE score (cognitive network) and FMA upper extremity (FMA-UE) recovery score (motor recovery network) was investigated and compared. Strength of within-networks, such as the somato-motor, auditory, cingulo-opercular, salience, cingulo-parietal, and dorsal attention networks, showed a significant correlation with the FMA-UE recovery score. Strength of between-networks, such as somato-motor and fronto-parietal networks, auditory and cingulo-opercular networks, auditory and cingulo-parietal networks, cingulo-opercular and default networks, and dorsal attention and default networks, also demonstrated positive correlation with FMA-UE motor recovery. Interestingly, most of these motor recovery networks were shared by the cognitive network at an early stage of stroke. Particularly, all of the significant within-networks in the motor recovery network were shared by the cognitive network. These results demonstrated that large-scale brain networks shared between cognitive function and motor recovery give some clues of interaction between two functions in the recovery phase of stroke.

Title: Automatic segmentation of stroke lesions on MR images for voxel-based lesion-symptom mapping

Authors: *K. VERMA[1], S. KUMAR[2];
[1]Dept. of Child Neurol., Dell Med. Sch. at Univ. of Texas at Austin, Austin, TX; [2]Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: Over the past century, clinical studies on patients with lesions have provided key insights into the relationship of brain areas to behavior. As a result of this approach, we have gained a better understanding of several functional areas in the brain. However, lesions are often focal and typically follow vascular territories, and involve concomitant brain regions. Due to this, these early studies could not precisely link specific brain regions to behavior. To overcome these limitations, voxel-based lesion-symptom mapping (VLSM) is used to evaluate the role of lesions in cognitive deficits. VLSM is an imaging analysis technique that establishes a relationship between precise lesion location and clinical deficits. It is a major challenge for VLSM to avoid false positives and maintain statistical power (missing true effects). This technique benefits from the directed analysis method by using pre-defined binarized lesions maps. To automate lesion segmentation on MR images, we trained 3D deep convolutional segmentation models with residual learning (3D U-Net). Based on the open-source dataset ATLAS (Anatomical Tracings of Lesions After Stroke), we developed our algorithm using T1-weighted MRIs and manually segmented lesions. A subset of the data (n=229) was standardized, intensity-normalized, and defaced before being used for testing and training the model. The volume of the scans is 197 x 233 x 189 mm^3, and the canonical voxel size is 1 mm^3. Lesion size in the dataset ranges from 10 mm^3 to 2.8×10^5 mm^3. Data was augmented with scaling, brightness adjustments, and elastic deformations to enhance generalization. We used a spatial overlap index - Dice similarity coefficient (DSC) to quantify the segmentation performance. The average DSC across the cross-validated 5-folds was 0.74 (0.61- 0.85; 95% bootstrapped CI). On the ATLAS dataset, our model demonstrated the effectiveness of automated volumetric segmentation of stroke lesions. This approach will be used together with VLSM in future studies to study how precise lesion location relates to clinical deficits caused by stroke lesions on MR images

Title: Corticospinal tract diffusivity is increased within the lesion volume in chronic stroke

Authors: *M. URBIN[1], F. LIU[2], C. MOON[2], J. L. COLLINGER[2];
[1]VA Pittsburgh Healthcare Syst., Pittsburgh, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: White matter anisotropy and diffusivity of the corticospinal tract (CST) exhibit broad change at multiple stages after stroke, but adaptation focal to the portion of the CST falling within the lesion volume (CST_{LV}) is less well understood. Here, we compared CST_{LV} to the entire CST segment originating in primary motor cortex and extending to brainstem ($CST_{M1\text{-}BS}$) inclusive of CST_{LV} on voxel-based (fractional, FA) and population-based (quantified, QA) metrics of anisotropy, and metrics of diffusivity (mean, MD; radial, RD). Stroke survivors (n=11, 64.6±6.1 years, 4 female) with longstanding hand impairment (107.6±73.4 months) underwent MRI using a Siemens Prisma 3T scanner (64-channel coil). T1 and T2 images were acquired for anatomical reference and lesion segmentation using FslTools. A Diffusion Spectrum Imaging scheme acquired a total of 259 diffusion directions (maximum b-value=4000 s/mm^2) via a single-shot, twice-refocused echo planar imaging sequence (~12 min scan time, 2 mm isotropic voxel, repetition/echo time 2490/99.2 ms, multiband factor 3, phase encoding in A>P and P>A, vertex to brainstem coverage). Data were processed using *dsi_studio* software. The CST and lesion were segmented by two raters, and the mean value of each anisotropy and diffusivity metric was computed from CST_{LV} and $CST_{M1\text{-}BS}$. Two-way analysis of variance was used to test for effects of side (contralateral, ipsilateral to the paretic hand) and segment (CST_{LV}, $CST_{M1\text{-}BS}$). FA ($F_{1,10}$=15.9, p=.003, η^2=.61) and QA ($F_{1,10}$=8.8, p=.014, η^2=.47) were reduced in both CST segments on the contralateral side, but there was no difference between segments (p=.43 and .38, respectively) nor a side by segment interaction (p=.06 and .62, respectively). Diffusivity metrics also showed asymmetries with higher MD ($F_{1,10}$=38.8, p=<.001, η^2=.80) and RD ($F_{1,10}$=25.9, p=<.001, η^2=.72) in both segments on the contralateral side. Side by segment interactions were also detected (MD: $F_{1,10}$=32.1, p<.001, η^2=.76; RD: $F_{1,10}$=7.8, p=.019, η^2=.44), indicating an increase restricted to the CST_{LV}. Our preliminary findings demonstrate asymmetries in CST anisotropy and diffusivity at the chronic stage of stroke. However, the portion of the tract falling within the lesion volume exhibits changes in diffusivity, but not anisotropy, relative to the entire CST contralateral to the paretic hand. A complex evolution of pathological processes at the chronic stage might account for less restricted movement of water molecules within the lesion despite maintaining microstructure that is homogenous with the entire CST.

Title: Corticomuscular Coherence and Corticospinal Tract Injury Association During Early Stroke Recovery

Authors: R. GANGWANI[1], J. I. MARK[1], B. ADCOCK[2], R. M. VAUGHN[1], *J. M. CASSIDY[1];
[1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Appalachian State Univ., Boone, NC

Abstract: Introduction Stroke heterogeneity has propelled the development of neuroimaging biomarkers to enhance stroke outcome prediction. Structural neuroimaging biomarkers, such as corticospinal tract (CST) injury, are well-established in the literature. Whereas, biomarkers from functional neuroimaging require additional development. Corticomuscular coherence (CMC) is a functional measure representing synchrony between brain and muscle signals recorded during simultaneous electroencephalography (EEG) and electromyography (EMG) collection. Given the role of CST mediating communication between brain and muscle, this study determined associations between CMC and CST injury in individuals early post-stroke.**Methods** Participants with hemiparetic stroke hospitalized in an inpatient rehabilitation facility (IRF) completed a behavioral battery (Upper Extremity Fugl-Meyer, UEFM; Action Research Arm Test, ARAT), a diffusion MRI, and CMC testing using a 256-lead EEG system at around IRF admission. During CMC testing, muscle activity from bilateral biceps brachii, flexor and extensor digitorum (FD, ED), and first dorsal interossei (FDI) was recorded while participants performed a submaximal isometric grip task with visual feedback provided. CMC measurements involving leads overlying ipsilesional primary motor cortex (iM1) with the above muscles were computed across alpha-mu (11-14 Hz), low beta (13-19Hz), and high beta (20-30Hz) frequency bands. CST injury was determined by computing fractional anisotropy values at ipsi- and contralesional cerebral peduncles and calculating a laterality index.**Results** Eight individuals (3 females, 67±7.2 years, 11.7±4 days post-stroke) with moderate motor deficit (UEFM=47.9±19.8; ARAT=37.1±18.2) resulting from ischemic or hemorrhagic stroke completed all study procedures. Decreased CST injury (higher laterality index values) correlated with greater CMC between leads overlying iM1 and EMG leads over affected biceps in alpha-mu ($r=0.80$, $p=0.05$) and high beta ($r=0.80$, $p=0.006$) frequency bands and also between leads overlying iM1 and EMG leads over affected FDI in the high beta ($r=0.68$, $p=0.03$) frequency band. **Conclusion** Preliminary findings suggest relevant structural and functional connectivity associations, supporting the notion that the CST facilitates communication between central and peripheral nervous systems as captured by CMC. Validation of these findings in a larger sample and determination of longitudinal associations between CMC and CST injury are important next steps.

Title: Preliminary findings regarding a link between atypical corticospinal tract development, as determined with diffusion weighted MRI, and hand impairments in early-onset pediatric hemiplegia

Authors: *A. HRUBY[1,2], D. JOSHI[1,2], J. P. DEWALD[2,1,3], C. INGO[2,4];
[1]Biomed. Engin., [2]Physical Therapy and Human Movement Sci., [3]Physical Med. and Rehabil., [4]Neurol., Northwestern Univ., Chicago, IL

Abstract: Introduction: Early-onset pediatric hemiplegia (PH) is caused by a unilateral brain injury occurring before or during birth. PH severely limits the functional ability of one side of the body, causing reduced strength in the paretic hand (weakness) and involuntary movements in the paretic hand during use of the non-paretic hand (mirror movements). PH often involves atypical corticospinal tract (CST) development due to a combination of damage to the lesioned hemisphere and lack of pruning of atypical ipsilateral projections from the contralesional hemisphere, which we investigated using diffusion tensor MRI (DTI) and tractography analyses of the CST.
Methods: DTI data were collected and processed with steps of brain extraction, denoising, motion and eddy current correction, and tensor fitting to generate maps of diffusivity metrics. Anatomical landmarks were used to guide probabilistic tractography of the CST for analysis in both the lesioned and non-lesioned hemispheres. To quantify grasp weakness and mirroring severity, participants completed a bilateral assessment of grip strength using handheld force measurement devices and custom MATLAB data acquisition software. Spearman correlation analyses were performed between diffusivity metrics and hand impairment measures with age and sex as covariates.
Results: Preliminary results include five participants with early-onset PH (2M, 16±7.8 years) and six controls (2M, 12±3.5 years). For the lesioned hemisphere CST, there were significant positive correlations between grasp weakness severity and mean diffusivity (MD) (ρ=0.66, p=0.038) and between grasp weakness severity and axial diffusivity (AD) (ρ=0.68, p=0.030). For the non-lesioned hemisphere CST, there was a significant positive correlation between mirroring

severity and radial diffusivity (RD) (ρ=0.70, p=0.023). No significant correlations with fractional anisotropy (FA) were found in these preliminary analyses.
Conclusions: For the paretic hand weakness impairment, the increased diffusivity (MD and AD) in the lesioned hemisphere CST may be sensitive to decreased white matter tract density or myelination. For the mirror movement impairment, the increased diffusivity (RD) in the contra-lesioned hemisphere CST may indicate that unpruned, disordered cellular structure is sensitive to the inability for independent hand function. While these relationships between CST diffusivity properties and hand function in PH are preliminary, they provide the first steps to better understand underlying neural mechanisms for motor impairments in early onset PH.

Title: Skull-meninges connections: a new getaway to diagnose and treat neurological diseases

Authors: *Z. KOLABAS[1,2], L. KUMMERLE[1], M. BUTTNER[1], B. FORSTERA[1,2], O. S. CALISKAN[1], M. ALI[1], I. KHALIN[2], Z. RONG[1,2], H. MAI[1,2], M. MOLBAY[1,2], M. STERR[1], R. CAI[2], C. [1]Helmholtz Zentrum München, Munich, Germany; [2]Inst. for Stroke and Dementia, Munich, Germany; [3]Munich Clusters for Systems Neurol. (SyNergy), Munich, Germany

Abstract: Neurological diseases affect about one in six people in the developed countries and can have profound and even debilitating impact. They have become a major socio-economic burden and costing trillion Euros of treatment per year. Given the complexity of the nervous system, understanding of the disease would require rather holistic biological approach and analysis of tissues as whole. Using whole-body vDISCO clearing technique (Cai⋯Ertürk, Nature Neuroscience, 2018), we can reliably image and quantify cellular even subcellular structures in intact mice. Imaging intact mouse heads, we recently discovered short vascular channels connecting the skull's bone marrow to the meningeal surface of the brain. These channels, named skull-meninges connection (SMC), were filled with CSF tracer, unraveling the

accessibility of the skull's bone marrow, which is filled with effective immune cells. A cerebral ischemic stroke in mice, mobilized LysM+ immune cells from skull into SMC and then into meninges. Subsequently, these immune cells invaded the brain parenchyma. These findings suggest that the skull is more than a physical barrier and is a dynamic site that responds to brain injury. The close proximity and accessibility of skull bone marrow's immune cell reservoir to the brain surface suggest that the skull might be involved in diverse brain functions in addition to making it an attractive target site for either diagnostics or therapeutic approaches.

Title: Probabilistic anatomically-constrained tractography enhances correlation between structurofunctional resting-state networks and motor function in chronic stroke

Authors: *R. J. VEGA[1,2], B. D. SCHMIT[2];
[1]Biomed. Engin., Med. Col. of Wisconsin, Milwaukee, WI; [2]Biomed. Engin., Marquette Univ., Milwaukee, WI

Abstract: Post-stroke, crucial anatomical and functional brain networks involved in creating and refining movements may be destroyed or altered. Surviving anatomical connections and functional connectivity (FC) are vital for functional motor and cognitive recovery. Combining diffusion weighted magnetic resonance imaging and functional Magnetic Resonant Imaging (fMRI), presence and strength of brain networks can be extracted. Structural connectivity provides insight into structural integrity of white matter (WM) connections between brain regions. FC alludes to temporal correlations of fluctuations in blood-oxygen-level-dependent (BOLD) signals between voxels or brain regions. Structurofunctional connectivity (SFC) combines the techniques to provide insight of the effects of anatomical reconfigurations and loss of brain network hubs on functional recovery. Ten stroke participants with age matched controls underwent T1-weighted (T1), resting-state fMRI, and high angular resolution diffusion imaging scans. Via Mrtrix3, performing spherical deconvolution on fiber-orientation distributions generated a probabilistic, anatomically-constrained tractography (PACT). Allowing complex modeling of WM tracts—enabling a more accurate SFC from subcortical structures compared to

previous deterministic methods. PACT SFC assigned each voxel a scaled BOLD time series from the sum of its structural connections weighted by the mean fiber length of all connections projected to connected voxels. The voxel's original time series was correlated with the connected time series to derive the structurofunctional coefficient. Voxel-wise application provided a metric of probabilistic intrinsic SFC (piSFC). Also, Probabilistic network SFC (pnSFC) was calculated to identify networks of interest from resting-state FC. piSFC and pnSFC maps were compared between groups via voxel-based Student's T-test with multiple comparisons correction. Linear regression was performed between SFC metrics and clinical measures of lower extremity motor function. Significant decreases ($p<0.01$) in piSFC were found in the stroke group within key functional hubs of sensory and motor areas. pnSFC showed strong connectedness amongst prefrontal regions and cerebellum in controls, and decreases in the stroke group, supporting previous findings indicating a decrease in their FC. pnSFC also showed higher connectedness in the contralesional hemisphere of lower-function stroke participants.The results illustrated changes in piSFC and pnSFC post-stroke correlated with motor function, highlighting importance of anatomical effects on functional recovery within brain networks.

Title: Lesion location and lesion-associated networks predict post-stroke outcomes

Authors: *M. BOWREN, Jr.[1], J. E. BRUSS[1], K. MANZEL[1], D. EDWARDS[2], C. LIU[3], M. CORBETTA[4], D. TRANEL[1], A. D. BOES[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Moss Rehabil. Inst., Elkins Park, PA; [3]USC, Los Angeles, CA; [4]Univ. of Padua, Padova, Italy

Abstract: Being able to make accurate empirical predictions about chronic post-stroke cognitive and motor outcomes could lead to improvements in the healthcare of patients with stroke.

Lesion-behavior mapping (LBM), and structural (sLNM) and functional (fLNM) lesion-network mapping are statistical techniques that link complex functions (e.g., cognitive and motor abilities) to brain regions and networks. Few studies have evaluated the potential of such techniques for predicting stroke outcomes. Here, using data from two large cohorts of individuals with focal brain lesions, we evaluated whether LBM, sLNM, and fLNM can be used to predict cognitive and motor outcomes in a third cohort of patients with stroke, and whether sLNM and fLNM add predictive value beyond LBM. We used data from the Iowa Neurological Patient Registry and the NICHE clinical trial to calculate LBMs for expressive language (n = 437), receptive language (n = 210), verbal memory (n = 477), and motor function (n = 103). We used the local maxima from the LBMs as seed regions-of-interest for sLNM and fLNM analyses based on structural and functional connectivity data from the Human Connectome Project. Using latent growth curve modeling, we evaluated the amount of variance in outcomes and recovery rates predicted by each map in a separate cohort of stroke patients who also completed tests of expressive language (n = 135), receptive language (n = 135), verbal memory (n = 103), and motor function (n = 133). We compared the predictive utility of each map using hierarchical modeling and model fit indices. We found that LBM, sLNM, and fLNM predicted a statistically significant amount of variance in cognitive and motor outcomes. fLNM and sLNM predicted variance in outcomes and/or recovery rates beyond LBM. Though the best predictor varied by domain, the combination of LBM, sLNM, and fLNM consistently performed the best. Our results support the conclusion that LBM, sLNM, and fLNM can be used to predict post-stroke outcomes, and that lesion location, and structural and functional brain networks, capture distinct information. Our work provides some of the largest LBM and LNM analyses of cognitive abilities to date, and represents a step toward the clinical translation of tools from cognitive neuroscience.

Title: Multimodal in vivo imaging reveals differences in post-stroke recovery in Tlr2-deficient mice

Authors: *S. GAJOVIC, P. JOSIć, S. SRAKOčIć, R. ISTER, A. GLASNOVIć, S. ŠKOKIć, M. DOBRIVOJEVIć RADMILOVIć;
Univ. of Zagreb Sch. of Med., Zagreb, Croatia

Abstract: Inflammatory response after ischemic brain injury is mediated by Toll-like receptors (TLR) located on the microglia. Tlr2-deficient mice represent a model of the modified neuroinflammation, which is hypothesized to result in the modified post-stroke recovery. The aim of the current study was to characterize the dynamic of post-stroke events by performing a longitudinal *in vivo* multimodal magnetic resonance imaging and bioluminescence imaging of the ischemic injury in Tlr2-deficient mice. The consequences of the transient middle cerebral artery occlusion (MCAO) were compared between Tlr2-deficient and C57Bl/6 (WT) mice. The animals were imaged at multiple time points by a 7T BioSpec 70/20 USR MRI system and with optical imager Perkin Elmer IVIS Spectrum. Gap43-luc/gfp bioluminescence was imaged to measure neurorepair and caged luciferase VivoGlo (Promega) was imaged to reveal caspase 3 and 7 activity and measure apoptosis. The functional consequences were assessed by behavioral testing and neurological scoring. At day 28 after the ischemia the animals were sacrificed, and the brains were processed for histological analysis. The volume of the ischemic lesion measured by MRI did not differ between Tlr2 and WT animals. However, the functional outcomes were different, and the Tlr2-deficient animals showed higher neurological deficit than the WT mice. Using cumulative linear mixed-modeling (CLMM) as a method of ordinal regression, taking neurological score as a dependent variable, we have managed to explain 59% of variance by including relative stroke volume in the model. Both the stroke size and the experimental group have shown to significantly determine neurological score, with statistically significant differences on both variables. In conclusion, longitudinal multimodal imaging combined with the functional outcome assessment revealed clear differences between Tlr2-deficient and WT animals.

Ctr., Louisville, KY; [6]Dept. of Vet. Sci., Univ. of Wyoming, Laramie, WY; [7]Sch. of Biol. Sci., [8]Georgia Inst. of Technol., Atlanta, GA; [9]Georgia Tech., Atlanta, GA

Abstract: Locomotion requires controlled knee and ankle flexion in early stance as the hindlimb yields with weight acceptance. Yield is controlled by eccentric activity in knee and ankle extensors, ensuring appropriate limb compliance for efficient and stable gait. This eccentric activity is regulated, in part, by Golgi tendon organs (GTOs) and extensive force feedback circuitry. We have shown that after a T9 or 10 lateral hemisection (lHx) in the adult cat, inhibitory force feedback (iFFb) is disrupted, causing exaggerated and biased inhibition of ankle extensors (Niazi et al. 2020). After lHx, animals also have greater ankle flexion at yield (Montgomery et al. 2019) and clinically, changes in yield are observed after spinal cord injury (SCI). If iFFb disruptions lead to deficits in yield then tasks that enhance iFFb, such as downslope walking (Nichols et al. 2014), may facilitate improvements in weight support. We incorporated downslope walking into a rehabilitation program to identify if this task could improve yield after lHx. Changes in iFFb after lHx and training are being investigated by collaborators at Georgia Tech. A companion poster (McMurtry et al. 2021) details changes in iFFb following this training paradigm.

Animals were trained to voluntarily cross an overground (OG) runway and walk bipedally on a treadmill (TM) set to various declines from 0 (level) to -26° (steep). Baseline data was collected for each animal on all tasks. Two weeks following lHx, animals were randomly assigned to one of three groups - non-trained (NT), eccentric trained (ETr), and level trained (LTr). ETr and LTr animals received training 5x a week for 12 weeks. ETr animals trained on TM and OG on various declines, LTr animals trained only on level TM and OG.

Spinally intact animals adapted to steep declines on OG by increasing knee and ankle yield and increasing ankle excursion on -26°. They however, do not show a significant change in yield in response to declines on TM. After lHx, animals displayed exaggerated yield and lost the ability to adapt to declines. Following training, ETr and LTr animals also exhibited greater yield after lHx but in contrast to the NT group, ETr animals retained their ability to adapt to declines.

This study shows that downslope walking allows the nervous system to effectively adapt yield responses to challenging environments. As deficits in yield continue despite current rehabilitative strategies, incorporating downslope walking into rehabilitation programs presents an effective modality to facilitate the recovery of yield.

Title: Evidence for reticular and vestibular regulation of strength and distribution of short latency force feedback

Authors: *A. DE BOEF[1], S. MCMURTRY[1], L. R. MONTGOMERY[2,4], D. R. HOWLAND[2,4], A. TRILL[3], R. VAN SANDT[5], R. NICHOLS[1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Kentucky Spinal Cord Injury Res. Center, Depts of Neurolog. Surgery, Anat, [3]Dept. of Bioengineering, Univ. of Louisville, Louisville, KY; [4]Robley Rex VA Med. Ctr., Louisville, KY, KY; [5]Dept. of Vet. Sci., Laramie, WY, WY

Abstract: Coordinated movement results from feedforward motor signals and sensory feedback. One important source of sensory information is the population of Golgi tendon organs (GTO). GTO's distribute inhibitory force information to muscles that cross different joints and axes of rotation. This system, along with length feedback from muscle spindles, is thought to regulate the mechanical properties of the entire limb. While the strength and distribution of force related inhibition has been observed to vary, the source of its regulation has not been identified. Changes in the organization of these networks and the concomitant behavioral affects have been assessed following selective lesions to the spinal cord to interrupt different supraspinal tracts as part of a collaborative study based out of Georgia Institute of Technology and the University of Louisville.We investigated the intermuscular distribution of force related inhibition in decerebrate animals by recording muscular forces in response to differing stretch combinations. Previous work has shown three main patterns of intermuscular force feedback (Lyle and Nichols(2018) J Neurophysiol 119:668). Following T10 lateral spinal hemisection, in which both dorsal and ventral spinal quadrants on one side are interrupted, only a single pattern of feedback is observed (Niazi et al., 2020, J Neurosci Res, 98: 1646) in which the inhibition onto the ankle extensor muscles is amplified (convergent pattern). This pattern is observed bilaterally.Animals with dorsal quadrant lesions show disruption of the iFFB system primarily on the ipsilesional side, while ventral quadrant lesions lead to bilateral disruption of the iFFB system as is observed following lateral hemisection. The combined results suggest that not only are ventral neural pathways (vestibulospinal and reticulospinal) potential sources for regulation of the distribution

of force feedback. The disruption of interneuronal processing due to the grey matter component of the lesion as well as the medullary aspect of the reticulospinal tract may lead to the convergent pattern of the force feedback network in the case of the dorsal quadrant lesions.

Title: Downslope training induces plasticity in the force feedback system following incomplete spinal cord injury

Authors: *S. MCMURTRY[1], A. DE BOEF[1], L. R. MONTGOMERY[2], D. R. HOWLAND[2,3], T. NICHOLS[1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Kentucky Spinal Cord Injury Res. Center, Dept of Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [3]Robley Rex VA Med. Ctr., Louisville, KY

Abstract: Sensory feedback is imperative for smoothly coordinated movements. Spinal cord injuries (SCI) disrupt motor commands descending from the brain, as well as cause malfunctions in spinal circuitry. One component of sensory feedback, which arises from Golgi Tendon Organs (GTOs), encodes changes in force within the muscles. This feedback creates a network that is widely distributed across the feline hindlimb to regulate whole limb stiffness through inhibitory actions on motoneurons. We evaluate the structure of this network by recording forces from individual muscles in response to combinations of stretches delivered to muscle pairs in decerebrate animals. Spinally intact decerebrate felines may show 1 of 3 patterns of feedback. Following lateral hemisection at the low thoracic level, we have shown loss of the flexibility between patterns and expression of a single, strongly convergent pattern of inhibition focused on the ankle musculature (Niazi et al, 2020; Kajtaz 2019). The loss of flexible patterns and subsequent targeted rehabilitation are being investigated in a cross-collaboration at Georgia Tech as part of a larger study at the University of Louisville looking at the effects of SCI and training on gait, as well as associated structural changes in the spinal cord. A companion poster (Montgomery et al, 2021) addresses concomitant changes under various gait conditions for the

same groups of animals. Based on our previous findings that downslope walking modulates force feedback, we had provided preliminary evidence that training animals with lateral hemisection on downslope walking re-establishes the multiple patterns of force feedback observed in controls (McMurtry et al, 2019). Current work further strengthens this conclusion. Further, animals with lateral hemisections who had undergone training on level ground walking did not show the beneficial effects observed with downslope training. Using our expanded database, we now show that thoracic lateral hemisections produce bilateral effects on the FFB system, which are more pronounced ipsilesionally. Finally, the impact of downslope training initiated at two weeks post-injury is apparent at both 7 and 13 weeks post-SCI, indicating a stable response to this rehabilitation strategy.

Title: Nociception impedes grasping recovery in the spinal cord injured rat.

Authors: *J. WALKER, T. KIM, S. GISZTER, M. R. DETLOFF;
Neurobio. & Anat., Drexel. Univ., Philadelphia, PA

Abstract: Significant deficits in motor control and sensory function diminish an individual's quality of life following spinal cord injury (SCI). A top priority of the injured population is regaining upper limb function. It has been shown that descending motor commands and primary afferent input, such as cutaneous feedback and proprioception, drive plasticity and recovery of function after SCI. Our lab and others have shown that primary nociceptors sprout and facilitate the maladaptive plasticity seen in chronic pain development, but their role in motor control is critically overlooked. The purpose of this experiment was to better understand the role of nociceptive input on recovery of motor function after SCI. Mechanosensitive, non-peptidergic nociceptors were ablated in Sprague-Dawley rats via intraganglionic injections of rIB4 - conjugated saporin or unconjugated (vehicle) saporin into the C7-8 dorsal root ganglia (DRGs). During the same surgery, rats received an ipsilateral C5 hemicontusion and the implantation of a braided multi-electrode probe for recording in the ipsilateral C8 gray matter. The von Frey test

for allodynia and immunohistochemistry, in which cervical DRG and spinal cord sections were stained with antibodies against CGRP and isolectin-B4, were performed to confirm nociceptor ablation. The following battery of food motivated behavioral tests were performed to assess the components of the reach and grasp: single pellet retrieval, isometric pull, paw preference, Montoya staircase, and the cereal manipulation task (IBB). Results indicate that ablation of nociceptors following SCI improved the rats' ability to grasp chocolate food pellets when compared to vehicle controls. Intraspinal recordings of local field potentials in the dorsal horn, intermediate gray, and ventral horn were obtained to measure changes in intraspinal activity in awake behaving rats. Multivariate statistical analyses of the behavioral, anatomical, and electrophysiological outcomes are underway. Increasing our understanding of the role nociceptors play in the spinal plasticity related to motor control following SCI will help guide future research and development of rehabilitative techniques.

Title: Rehabilitation dependent remodeling of intracortical networks during recovery from spinal cord injury

Authors: *H. MOHAMMED, E. R. HOLLIS, II;
Burke Neurolog. Inst., White Plains, NY

Abstract: Motor cortex in rodents undergoes reorganization after spinal cord injury. Spared motor representations expand into the deafferented motor representations depending on the level of spinal lesion. Following C5 dorsal column lesions in mice, the forelimb muscle representations expands into the deafferented hindlimb motor representation. Rehabilitation regains the balance of forelimb flexor and extensor muscle representations previously demonstrated by optogenetic motor mapping. In this study, we focused on the intracortical circuit mechanisms mediating recovery of motor function with rehabilitation. Intracortical hindlimb to forelimb axons show bouton remodeling in CFA in mice receiving rehabilitation in a skilled reach task, demonstrated by in vivo 2 photon imaging. Optogenetically silencing the forelimb circuit and intracortical hindlimb to forelimb projections during recovery reduced the

success rate of skilled reach task in mice. Our results suggests a role for remodeling of intracortical networks in recovery from spinal cord injury with rehabilitation.

Title: Engineering human neural precursors to repair the injured cervical spinal cord

Authors: *L. V. ZHOLUDEVA[1], M. A. LANE[2], T. C. MCDEVITT[1];
[1]Cardiovasc. Dis., Gladstone Inst., San Francisco, CA; [2]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Emerging technologies, such as cell-based repair strategies, offer new promise for some of the most devastating medical conditions that currently lack treatments. However, to harness the full therapeutic potential of stem cells, it will be necessary to understand how to direct their differentiation to appropriate cell phenotypes and ensure that their phenotype and function persist after transplantation into a pathologic environment. Using pre-clinical spinal cord injury (SCI) as a testbed, we tested the therapeutic potential of transplanted human induced pluripotent stem cell (hiPSC)-derived spinal interneurons (SpINs). Neuroanatomical tracing and immunohistochemistry were used to assess transplant integration and connectivity with injured host tissue. Optogenetic activation of hiPSC-SpINs was used to assess development of synaptic connectivity to injured host circuits with time (1-, 2- and 3-months post-transplantation). Bilateral terminal diaphragm electromyography was used to assess functional contribution of transplanted human SpINs to the recovery of phrenic function with time (1-, 2- and 3-months post-transplantation). These studies demonstrated that transplanted human SpINs survived and integrated with injured cervical spinal cord circuits, displayed anatomical (e.g., pre- and post-synaptic proteins) and functional (intratransplant and intraspinal cord recordings) evidence of connectivity. Ongoing work is focused on silencing transplanted hiPSC-SpINs to further elucidate mechanisms by which transplanted cells may contribute to motor recovery post-SCI.

Title: The patterns of axon rewiring of multiple corticospinal tract pathways after stroke in different cortical areas

Authors: *T. SATO, Y. NAKAMURA, M. UENO;
Brain Res. Institute, Niigata Univ., Niigata, Japan

Abstract: Brain injuries such as stroke and trauma often lead to deficits in sensorimotor functions. Previous studies have demonstrated that reorganization of neural network in the spared brain region is one of the key processes to recover functions. The corticospinal tract (CST) that controls voluntary movements is one of the essential neural pathways for functional recovery. We and others previously showed that the CST axons have different trajectories to the spinal cord from multiple cerebral origins such as the motor cortex and the somatosensory cortex, and each has distinct functions during the movements in rodents. However, the patterns of reorganization of those multiple CST pathways are not comprehensively understood across different types of lesion in size and location. In this study, we systematically examined the rewiring patterns of CST pathways of multiple cerebral origins in a mouse stroke model. We first established four different stroke models that vary in size and location in the sensorimotor cortex, and then injected with an anterograde tracer into the ipsi- or contralesional area of the sensorimotor cortex to investigate the projection patterns of remnant CST fibers. We find that the spared contralesional motor and sensory CST axons cross the midline and sprout into the denervated side of cervical cord after stroke with a large cortical region. In contrast, the contralesional CST fibers do not sprout in a small stroke, whereas the ipsilesional axons from the spared motor area grow in the denervated side. Furthermore, we demonstrate that motor and sensory CST axons do not compensate the projections each other when either one is injured. In conclusion, the present study reveals that brain injuries spontaneously induce characteristic patterns of CST rewiring depending on the types of CST, lesion size and location, showing the neural principles in which the rewiring is predominantly induced in functionally homologous and ipsilesional pathways. Our data indicate the importance to target different neural substrates to restore functions among the types of injury.

Title: Overground gait, but not hindlimb stepping on a treadmill, recovers in animals with clasp knife responses following dorsal hemisection

Authors: *R. L. VAN SANDT[1], A. DE BOEF[2], L. R. MONTGOMERY[3], A. N. TRELL[4], S. MCMURTRY[2], T. R. NICHOLS[2], D. R. HOWLAND[3];
[1]Kentucky Spinal Cord Injury Res. Center, Univ. of Louisville, Louisville, KY; [2]Dept. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA; [3]Kentucky Spinal Cord Injury Res. Center, Univ. of Louisville, Robley Rex VA Med. Ctr., Louisville, KY; [4]Robley Rex VA Med. Center, Univ. of Louisville, Louisville, KY

Abstract: A major obstacle in neurorehabilitation is providing training for patients with inadequate lower extremity strength. Understanding control of muscle activation during gait is imperative for rehabilitation program design. This collaborative study used subjects with thoracic dorsal spinal hemisection (dHx) to assess post-injury changes in quadrupedal and bipedal locomotion as well as muscle stretch and force, which play major roles in regulating limb stiffness. Purpose bred animals (n=5) were conditioned to perform gait tasks during level surface walking on an overground (OG) runway and motorized treadmill (TM). Data were captured pre- and post-dHx with a Vicon Motion Analyses system. Independent voluntarily gait was assessed 2- and 6-weeks (wks) post-dHx. Terminal experiments were conducted at 7 wks to investigate intermuscular distribution of force related inhibition. Animals underwent decerebration, were fixed in a standing position, and muscular forces were recorded in response to combinations of stretches of different muscles acting on the knee and ankle. Histological analyses confirmed lesion level and extent. By 2 wks post-dHx, all subjects recovered OG locomotion. Performances were characterized by full weight supported steps with consistent delays in transition from stance to swing relative to pre-dHx data. This delay was the result of an increase in the stance phase duration along with delayed ankle extension and increased late stance hip extension. In contrast, only 1 of 5 subjects could perform bipedal walking on the TM at 2 wks. This did not improve by 6-wks post-dHx. On the TM, 4 of 5 subjects assumed a posture in which both hindlimbs were moderately abducted, extending symmetrically behind the pelvis. These extended limbs full weight supported but did not step at either walking speed (0.5 and 0.8 meters/sec) tested. In these same subjects, muscles stretched during evaluation of force feedback inhibition exhibited clasp-

knife inhibition. Hindlimb sensory input alone was insufficient to promote bipedal stepping in subjects with dHx. Clasp-knife inhibition has a profound inhibitory effect on the muscles in the hindlimb, which likely causes sensory feedback to fail at initiating locomotion on the TM. However, the addition of descending modulation is sufficient to produce voluntary OG walking. Understanding why there are striking differences in muscle activation and limb stiffness between more voluntary (overground) versus more spinally-mediated (TM) walking and standing will be beneficial for the improvement of rehabilitation programs for patients with incomplete spinal cord injury. The abstract does not represent NIH, VHA or NIH views.

Title: The mitochondrial uncoupling agent dinitrophenol decreases nociceptor excitability and inflammatory hyperalgesia

Authors: *D. C. MOLLIVER[1], R. GEGUCHADZE[1], B. M. DAVIS[2], C. STRAUB[3];
[1]Biomed. Sci., Univ. of New England, Biddeford, ME; [2]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [3]Biomed. Sci., Univ. of New England, Col. of Osteo., Biddeford, ME

Abstract: 2,4-dinitrophenol (DNP) is an uncoupler of the mitochondrial proton gradient used in the 1920s as an effective diet drug, with a high incidence of morbidity and mortality. Recently there has been interest in potential neuroprotective effects of DNP at low doses. Given evidence that mitochondrial dynamics impact nociceptor responsiveness, we tested the impact of DNP on nociceptor response properties and behavioral thresholds to noxious stimuli. To examine actions of DNP on acute hyperalgesia, the prostaglandin PGE2 was injected into the hindpaw of mice injected 30 min prior with 5mg/kg DNP or vehicle, i.p. PGE2 induced heat hyperalgesia (Hargreaves assay) that resolved within 3 hours. DNP reduced heat hyperalgesia in male but not female mice, with no change in baseline thresholds. Next, hindpaw injection of 1% carrageenan (CAG) was used as a model of persistent inflammatory hyperalgesia. DNP or vehicle was injected daily (i.p., 5mg/kg) in males, and mice received a hindpaw injection of 1% carrageenan on day 3. Withdrawal thresholds for heat and mechanical (von Frey) stimuli were tested daily. In vehicle-treated mice, CAG caused heat and mechanical hyperalgesia that resolved within 7 days. In contrast, DNP administration reduced both heat and mechanical hypersensitivity. Despite the impact of DNP on hyperalgesia, the dose was not sufficient to reduce body weight. To determine

whether the anti-hyperalgesic effects of DNP could be mediated by a direct action on sensory neurons, DNP was applied to dissociated dorsal root ganglion (DRG) neurons. l00 micromolar DNP caused a dramatic increase in mitochondrial respiration and reduction in mitochondrial ATP production, as measured by oxygen consumption rate (OCR) in the Seahorse mitochondrial stress test, and completely occluded the effect of a maximal dose of the uncoupler FCCP, indicating collapse of the mitochondrial membrane potential (MMP). In contrast, 20 micromolar DNP increased OCR, but cells remained responsive to FCCP, indicating partial depolarization of MMP. Subsequently, patch clamp recordings were performed in isolated neurons using 20 micromolar DNP. DNP (10 min) resulted in hyperpolarization and increased membrane permeability, together reducing excitability and increasing action potential threshold. This effect was observed in a subset of neurons and was not activity dependent. Together, the results indicate that DNP acutely decreases sensory neuron excitability in vitro and exerts anti-hyperalgesic effects in models of acute (PGE2) and persistent (CAG) inflammatory pain. Experiments are underway to identify molecular mechanisms that mediate the effects of DNP on nociceptor excitability.

Title: Single neuron profiling using GeoMx Digital Spatial Profiler platform for transcriptomic analysis of human Dorsal Root Ganglia

Authors: J. BROUGHER[1], L. PAN[2], S. SHIERS[3], D. TAVARES FERREIRA[3], S.-L. J. PHELAN[2], Y. LIANG[2], S. WARREN[2], V. KUMAR[1], ***C. PAIGE**[1], T. J. PRICE[3]; [1]Doloromics, Inc., Foster City, CA; [2]Nanostring, Seattle, WA; [3]Sch. of Behavioral and Brain Sci., Univ. of Texas At Dallas, Richardson, TX

Abstract: Novel drug targets are desperately needed for the treatment of chronic pain, and RNA sequencing provides unparalleled insight into transcriptomic changes underlying the development of chronic pain in patient populations. However, bulk RNA sequencing lacks cell-type specific information, and most methods of single cell sequencing for human DRG rely on cell dissociation and cell sorting, which may distort transcriptomes. Here, we used the Whole Transcriptome Atlas (WTA) on GeoMx® Digital Spatial Profiler (GeoMx DSP) platform to quantify RNA from single human Dorsal Root Ganglia (DRG) neurons. The GeoMx DSP platform uses fluorescence-based region of interest (ROI) imaging to select specific cell-types

and populations for downstream molecular profiling. Fresh frozen preparations of 6 human DRG were sectioned to 8µm, processed with standard antigen retrieval protocols, and incubated with the WTA probes and an anti-peripherin antibody to visualize the neuronal cell bodies. Fifty-nine single cell ROIs that were positive for peripherin immunostaining were selected for transcriptional profiling, and serially exposed to UV light, which releases an indexing oligo from the WTA probes. Oligos were quantitated on an Illumina Novaseq and data was analyzed on GeoMx DSP Control Center. Following initial QC, 42 single cell ROIs were selected for downstream analysis, and the remaining ROIs were excluded due to low RNA content based on the data of over 18,000 genes' expression, We were able to identify neurons from 12 neuronal populations in the human dorsal root ganglia (DRG) previously identified through Visium spatial sequencing. Additionally, differentially expressed neuronal genes were conserved when compared to previously published work. Following this initial quality control analysis, data was analyzed using a previously published interactome algorithm where neuronal and fibroblast ligand-receptor interactions were identified in patients with fibromyalgia. We have validated the use of GeoMx DSP as a platform suitable for sequencing RNA from both single cells and clusters of cells in the human DRG.

Title: Metabolites of Linoleic Acid, A Common Fatty Acid in the Western Diet, as Pain Mediators

Authors: *J. WHEELER[1], A. DOMENICHEILLO[2], G. KEYES[2], K. MAIDEN[2], J. DAVIS[3], C. RAMSDEN[2], S. MISHRA[1];
[1]North Carolina State Univ., Raleigh, NC; [2]Lipid Peroxidation Unit, National Institute on Aging, MD; [3]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Omega-6 (ω-6) metabolites are well established mediators of pain and inflammation. Pain mediators derived from n-6 arachidonic acid are well recognized; however, linoleic acid is the most abundant n-6 fatty acid in modern industrialized diets. Possibly due to this dietary prevalence, several oxidized linoleic acid metabolites (OxLAMs) have been mechanistically linked to pathological conditions ranging from cardiovascular disease to chronic pain. Rodents fed a diet enriched in linoleic acid to mimic the modern western diet had an increased concentration of OxLAMs in tissues associated with idiopathic pain syndromes. In clinical trials, decreasing the amount of dietary ω-6 fatty acids resulted in a decrease in the number of headache days per month. Further, several OxLAMs were found to have decreased concentrations in headache patients with this decreased ω-6 fatty acid diet. Here, we characterize the functional role of one of these mediators, 13-hydroxy-9,10-epoxyoctadecenoate, and its metabolite, 13, 9, 10-trihydroxyoctadecenoate. Using calcium imaging, we first determined that these two compounds are capable of activating sensory neurons. Next, we determined, using the subcutaneous cheek and intraplantar injection, that these OxLAMs induce pain behaviors and thermal hypersensitivity. Additionally, we used these in vitro and in vivo assays to determine the potentially active pharmacophore of these OxLAMs. Taken together, our results suggest a role in pain and hypersensitivy for these OxLAMs.

Title: Single nucleus transcriptomic profiling of hiPSC populations

Authors: *J. BROUGHER[1], V. TRUONG[2], P. WALSH[3], A. HOVLAND[3], C. PAIGE[1], T. J. PRICE[4];

[1]Doloromics, Foster City, CA; [2]Anatomic Inc., Brooklyn Park, MN; [3]Anatomic Inc., Minneapolis, MN; [4]Sch. of Behavioral and Brain Sci., UTD, Richardson, TX

Abstract: Therapeutic development for the treatment of chronic pain requires access to functional screening platforms to ensure target validity. The pain therapeutics field has long relied on animal models, such as rodents, to test upcoming therapeutics; however, recent transcriptomic publications reveal key differences in gene expression between humans and rodents. Further complicating the situation is the difficulty of collecting living human sensory tissue. Here, we address this problem by profiling a scalable RealDRG™ human induced pluripotent stem cell (hiPSC)-derived nociceptor population that can meet the demands of high-throughput screening. Our approach utilized a single nucleus SPLiT-Seq approach to functionally cluster and characterize hiPSC-derived nociceptor populations. Our findings reveal the presence of multiple subpopulations that differentiate from the same hiPSC culture. Within these subpopulations, we have highlighted key genes that are also found within set human nociceptor populations. Together, this data shows that hiPSC-derived nociceptor populations are a transcriptomically similar screening platform to nociceptive populations found within the human dorsal root ganglion.

Title: Transcriptional analysis to study molecular diversity of sensory modality-specific neurons

Authors: *H. M. WEMAN, M. M. CEDER, J. E. T. JAKOBSSON, M. C. LAGERSTRÖM; Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Pain and itch are unpleasant but unquestionably useful sensations, having evolved to induce withdrawal behavior to allow injuries to heal and to scratch off potentially harmful parasites. Unfortunately, both these sensations can develop into chronic conditions, causing the previous protective roles to become maladaptive. Presently, studies have used behavioral and histological approaches targeting specific neuronal populations and signaling pathways in attempts to find targets for novel treatment in different pain and itch models. The present study aims to detect modality-specific sensory neurons in the spinal cord, and will achieve this by identifying neurons activated by certain sensory stimuli using single-cell based and spatial transcriptional profiling. Firstly, mice are microinjected with a virus expressing a reporter gene under the control of the immediate early gene *fos* promotor. This allows detection and isolation of activated neurons (fos-EYFP) in multiple sensory-modality pathways for subsequent single cell mRNA sequencing (scRNA-seq). In the second approach, *in situ* sequencing (ISS), where the expression of multiple genes can be detected spatially in an intact tissue section, is used to study the molecular identity of *fos* expressing neurons. This study will examine which lumbar spinal cord dorsal neurons that are activated by noxious heat and further, how nerve growth factor b (NGFβ)-induced hyperalgesia affects the activity in terms of neuronal recruitment and gene expression. Histological analysis using the viral approach showed that thermally-induced fos-EYFP neurons could be detected ipsilaterally in the medial dorsal laminae of the L5/L6 segments following hind paw stimulation (91.2 ± 2.6 % of fos-EYFP located laminae I-IV and 7 ± 2.1 % in laminae V-X, n animals: 2 females & 1 male, 8 weeks old, n sections: 12) a pattern not visualized in the contralateral dorsal horn ($p < 0.0001$, two-tailed unpaired t-test). The activated cells were overlapping with NeuN (96.8 ± 0.3 %, n animals: 1 female & 1 male, 8 weeks old, n sections: 8) and both inhibitory (37.0 ± 9.3 % overlap with Pax2, n animals: 2 females, 8 weeks old, n sections: 8) and excitatory neurons were identified. The subsequent exploratory analyses will focus on assigning the activated neurons to previously described spinal cord cell types (Häring et al.) and to map these cell types to spinal laminas using ISS. Identifying modality-specific neurons in the spinal cord is a critical and natural next step as scRNA-seq experiments have identified a vast diversity of spinal interneurons.

Title: A molecular approach to elasmobranch nociception

Authors: *R. LACAP, M. TESORO, M. VAN DER PLAS, M. DE BELLARD;
Biol. Dept., California State University, Northridge, Northridge, CA

Abstract: To perceive pain, specialized sensory neurons, specifically nociceptor neurons, must be present to sense noxious stimuli. This process known as nociception is used by animals to avoid injury. In vertebrates, nociceptor neurons projecting from sensory ganglia are either C-fiber or A-δ fiber neurons. However, sharks have been proposed to lack full-scale nociception because of their low numbers of C-fiber neurons and their disregard for serious bodily injury. Sharks belong to a group called elasmobranchs, along with skates and rays. There exists a gap of knowledge regarding elasmobranchs nociception. In the present study, we aim to determine the existence of true nociceptor neurons in elasmobranchs. We conducted RNA sequencing with the trigeminal and dorsal sensory ganglia, followed by RT-PCR and histology. Our results show that elasmobranchs express a larger set of nociceptor genes in their trigeminal ganglia in comparison to their dorsal root ganglia (DRG). Interestingly, we found the presence of the two key transcription factors for nociceptor differentiation (Runx1 and PRDM12) in significant levels in the trigeminal ganglia, while almost no detectable levels in the DRGs.

Title: Macrophage-produced IL-23 Enhances Light and Capsaicin-induced Spontaneous Pain in Female Mice

Authors: ***J. JI**[1], Q. HE[2], X. LUO[3], A. MCGINNIS[2], A. G. NACKLEY[4], R.-R. JI[5];
[1]Duke Univ., Chapel Hill, NC; [2]Duke Univ., Durham, NC; [3]Anesthesiol., Duke Univ., Cary, NC; [4]Dept. of Anesthesiol., Duke Univ., Durham, NC; [5]Pain Res. Division, Anesthesiol., Duke Univ. Med. Ctr., Durham, NC

Abstract: The incidence of chronic pain is especially high in women. However, pain signaling in females remains poorly understood. IL-23 is a pro-inflammatory cytokine, but little is known about its role in pain regulation. Here, we examine the role of interleukin-23 (IL-23) in sex dimorphism in pain, using both behavioral and optogenetic methods. We employed transgenic mice expressing channelrhodopsin-2 (ChR2) in TRPV1-positive nociceptive neurons. Blue light was used to stimulate the hindpaw of the transgenic mice at varying intensities. IL-23 was injected into the hindpaw of mice of both sexes, and the mechanical pain threshold was measured using the von-Frey up-down test. Additionally, we assessed capsaicin-induced spontaneous pain following IL-23 pre-treatment. We also examined the phosphorylation of p38 MAP kinase (p-p38) in dorsal root ganglion (DRG) neurons. We found that blue light stimulation in the transgenic mice induced intensity-dependent spontaneous pain. At the highest intensity, females show more intense spontaneous pain than males. Intraplantar injection of IL-23 induced mechanical allodynia in females only. Furthermore, IL-23 potentiates light-induced spontaneous pain as well as capsaicin-induced spontaneous pain in females but not males. Of note, TRPV1 mRNA expression in a subset of small TRPV1-positive cells (100-200 μm2) was greater in females than males. We observed that IL-23 is expressed by macrophages in mouse DRGs. IL-23 also induced significantly greater p38 phosphorylation in DRG neurons of female mice than male mice. Our findings suggest that IL-23 potentiates spontaneous pain predominantly in females. Given the fact IL-23 is produced by macrophages and can activate p38 in nociceptors, our study may present a new form of cytokine-induced macrophage-nociceptor interaction in a sex-dependent manner.

Title: Deficient AMPK activity in dorsal root ganglion leads to hyper-excitability in nociceptive sensory neurons and hyperalgesia in mice with systemic lupus erythematosus.

Authors: *V. VIATCHENKO-KARPINSKI, L. KONG, H.-R. WENG;
Mercer Univ., Macon, GA

Abstract: Systemic lupus erythematosus (SLE) is an autoimmune disease in which the autoantibodies attacks its own tissues, causing widespread inflammation and tissue damage in the affected organs. Patients with SLE often suffer from chronic pain. We previously reported that overactivation of spinal macrophage colony-stimulating factor-1 receptor causes chronic pain via suppressing glial glutamate transporter in female MRL lupus-prone (MRL/lpr) mice, a SLE mouse model. In this study, we characterized the development of chronic pain and its peripheral mechanisms in a male MRL/lpr mice. We found that male MRL/lpr mice developed thermal hyperalgesia at the age of 10 weeks, which is similar to the time course found in female MRL/lpr mice. Using patch-clamp recording techniques, we compared the membrane properties of nociceptive sensory neurons (membrane capacitance = 23.67 ± 1.82 pF) in L4-5 dorsal root ganglions obtained from MRL/lpr mice with chronic pain and normal controls. We found that in comparison with normal controls, nociceptive sensory neurons from mice with chronic pain had significantly lower rheobase and action potential thresholds, and more positive resting membrane potential (RMP), which indicates an increased excitability in these nociceptive neurons. Our western blot data show that dorsal root ganglions obtained from MRL/lpr mice with chronic pain had significantly lower levels of phosphorylated AMP-activated protein kinase (AMPK). This was concurrently accompanied with increased levels of TNFα and ERK/MAPK activities. More importantly, our patch clamp experiments found that pharmacological suppression of AMPK activity in normal nociceptive neurons by perfusing compound C (10 μM) into the recording bath recapitulates the membrane properties found in mice with chronic pain. Furthermore, subcutaneous injection of compound C (25 μM, 25 μl) in control mice (n=6) induced significantly heat hyperalgesia while activation of AMPK using AICAR (1 mM, 25 μl) significantly attenuated heat hyperalgesia in mice (n=5) with chronic pain. In conclusion, our study reveals that deficiency of AMPK activity in DRG neurons plays a critical role in the increased excitability of nociceptive sensory neurons and chronic pain in male SLE mice.

Title: Signal transduction between keratinocytes and dorsal root ganglion neurons via extracellular ATP

Authors: *K. FUJITA, M. TANAKA, Y. SHINDO, K. HOTTA, K. OKA;
Keio Univ., Yokohama, Kanagawa, Japan

Abstract: The skin is exposed to various external and internal stimulation: heat, several chemicals, oxidative stress, mechanical stimuli, and noxious stimuli including pain. Keratinocytes, which are the main cell type in the epidermis, interact with peripheral sensory neurons and modulate the signal transduction. It has been reported that adenosine triphosphate (ATP) released from keratinocytes contributes to the mechanical sensations (Koizumi *et al*., 2004), however, the detailed mechanisms of ATP-mediated signal transduction is still unknown. To directly visualize and analyze the spatio-temporal dynamics of the ATP and Ca^{2+}, we performed the live imaging of extracellular ATP and intracellular Ca^{2+}. We utilized iATPSnFR (Lobas *et al*., 2019), a genetically encoded ATP sensor localized on the outside of the cell membrane, and Fura Red, fluorescent Ca^{2+} indicator. Mechanical stimulus was applied to the keratinocyte by touching with a fine tip of a glass pipette and the release of ATP from the stimulated keratinocyte was confirmed. In adjacent keratinocytes, we observed transient increase in ATP level on its cell surface and subsequent increase in intracellular Ca^{2+} level. To our knowledge, this is the first report to directly visualize ATP during mechanical sensations. Next, to reveal the signal transduction from keratinocytes to peripheral sensory neurons in vitro, we co-cultured human keratinocytes and rat dorsal root ganglion (DRG) neurons. To visualize the signal transduction from keratinocytes to DRG neurons upon mechanical stimuli, both keratinocytes and DRG neurons were stained with a Ca^{2+} indicator, fluo-4, and mechanical stimulus was applied to a keratinocyte, then the cell types and their contacts were confirmed with immunostaining by anti-keratin14 and anti-βIII-tubulin. The touched keratinocyte showed Ca^{2+} increase followed by large Ca^{2+} increase in DRG neurons contacting with the stimulated keratinocyte and small Ca^{2+} increase in neighboring keratinocytes. To examine the difference between DRG neurons and keratinocytes, the sensitivity of keratinocytes and DRG neurons to ATP was estimated. The half-maximal effective concentration (EC_{50}) was estimated to be 7.3×10^{-7} M for keratinocytes and 4.3×10^{-8} M for DRG neurons, respectively. Our results suggest that the difference of Ca^{2+} response upon mechanical stimuli between keratinocytes and DRG neurons attributes to high sensitivity of DRG neurons to ATP compared to keratinocytes.

Title: A Model for Overshadowing in Conditioned Taste Aversion

Authors: *A. LEPSKY[1], P. MILLER[2];
[1]Brandeis Univ. Undergraduate Neurosci. Program, Waltham, MA; [2]Brandeis Univ., Sudbury, MA

Abstract: Conditioned taste aversion is a psychological phenomenon in which a subject develops a strong negative association with a certain taste because they felt sick or nauseous afterwards. It has been suggested that the formation of these associations in the brain is competitive, since a more recent taste stimulus can reduce the degree of aversion to a prior taste. We investigated whether a model based on competing units, representing distinct populations of neurons, could describe conditioned taste aversion and its key features. Our model was composed of two self-excitatory and cross-inhibitory units in a winner-takes-all circuit and an input stimulus applied equally to both units. We then added a series of intermittent stimuli to represent taste recall and a decay function to represent the decay in synaptic plasticity between the presentation of a taste and the arrival of nausea. Incorporating the decay in synaptic plasticity over time led to a bias in the formation of aversions towards the most recent taste stimulus without fully blocking the aversion to the oldest taste. Overall, the model is able to predict qualitative features of conditioned taste aversion. Further additions to the model will help reproduce experimental results by tuning the time at which each taste was presented to the degree of aversion.

Title: Structural remodeling of peripheral taste neurons

Authors: *Z. WHIDDON, D. ALSTON, *J. MARSHALL, A. MCGEE, R. KRIMM;
Univ. of Louisville, Louisville, KY

Abstract: Taste neurons receive information from taste-transducing cells that undergo continual turnover. Given that taste neurons must connect with new cells, we asked if they undergo structural remodeling over time using intravital imaging. Because the half-life of taste-transducing cells is 10 days, we speculated that half of the arbors (portion of the peripheral taste axon that innervates the taste bud) would remodel within 10 days in order to form connections with new cells. We sampled arbor structure every 12 hours for 10 days. Since synapses occur on distal (terminal) branches of the arbor, we quantified the change in the number of terminal branches over time. We found that all arbors altered their complexity by adding or pruning terminal branches within the first 5 days, and 19 of 31 arbors changed terminal branch number in the first 24 hours. On average 1 terminal branch was gained or lost every 16.0 hours. Given this surprising speed, we imaged arbors at 4 hours for 12 hours. We found that 42.4% of arbors gained or lost a terminal branch more than once in a 12-hour period. and that a terminal branch was gained or lost once every 6.8 hours. This finding indicates terminal branches remodel much faster than would be predicted by taste bud cell turnover. To investigate if terminal arbor size is altered over time, we measured the volume the arbor occupies within the taste bud (convex hull). Minimum hull volume predicts maximum hull volume (R^2=0.937), indicating that arbor size does not change over the full dynamic range in 10 days. Lastly, we examined 26 taste buds every 10 days for 100 days and found that no taste buds added new arbors and only ~5% of arbors were lost from fungiform papillae. Together these data demonstrate that during adulthood arbor structure within the taste bud is plastic, with terminal branches undergoing rapid, continuous remodeling, and that taste neurons can prune whole arbors from taste buds, but this type of refinement is not common.

Title: Obesity alters palatability neurons and decreases lick-spike coherent activity in the rat Lateral Hypothalamus

Authors: *O. X. GUERRERO GUTIERREZ, M. A. VILLAVICENCIO, E. FONSECA, C. I. PEREZ, R. GUTIERREZ;
Pharmacol. Dept., CINVESTAV, CDMX, Mexico

Abstract: The prevalence of overweight and obesity has scaled in the last decades. Despite the consensus that the Lateral Hypothalamic Area (LHA) is important for regulating sleep-wake cycles, feeding, and motivated behaviors, how neural responses in the LHA are altered by a diet-induced obesity (DIO) model remains poorly understood. Mounting evidence indicates that multiple cell types in the LHA are affected by consuming HFD. An equally untouched question is how diet-induced obesity alters LHA neuronal activity in response to sucrose's palatability. To answer this question, we used Wistar rats fed (after weaning) with either a high-fat diet (HFD, 45% fat) to induce DIO or a standard diet (Chow, 8.4% fat) for 12 weeks. We characterized LHA extracellular single-unit activity while DIO and lean rats performed a Brief Access Taste Test (BATT). During training, DIO rats initially exhibited a larger inter-trial-interval (ITI) with a lower trial rate than the lean group, suggesting that initially sucrose motivates less to DIO rats than lean rats. However, after training, the difference disappears, and during recordings, both groups achieved the same level of motivation performing BATT. During recordings, we still found differences in the licking microstructure. Specifically, DIO exhibited a shorter inter-lick interval (ILI), which resulted in a faster fragmentation of licking; that is, DIO rats exhibited a lower lick rate, bout size, and less trial completeness than lean rats, with no changes in the trial rate or total calories consumed. As a neural correlate of the shorter ILIs, a spike-lick coherence analysis revealed that the DIO rats had lower coherence values than the lean rats while maintaining the same proportion of lick-coherent neurons. Therefore, LHA spiking synchronization with rhythmic licking is directly affected in a diet-induced obesity model. Moreover, LHA neuronal population analyses unveiled that in DIO rats, sucrose evoked a different population trajectory dynamic than lean rats, suggesting that LHA neurons processed sucrose concentrations in a fundamentally different manner. We performed a palatability analysis to identify the palatability-related neurons and found that DIO decreased the fraction of negatively correlated palatability neurons but increased those that positively correlated with palatability. These palatability-related neurons were used in a sucrose concentration decoding analysis showing that DIO rats have an earlier decoding onset than lean rats. In sum, we show that DIO alters the licking microstructure, lick-spike coherent activity, and the activity and proportion of the palatability-related neurons in the rat LHA.

Title: Processing of multimodal chemosensory stimuli by the mediodorsal thalamus

Authors: *K. FREDERICKSEN, C. SAMUELSEN;
Univ. of Louisville, Louisville, KY

Abstract: The mediodorsal thalamus (MD) is a higher-order thalamic region important for stimulus-outcome associations and decision-making. Previously, we found that immediate early gene expression in the mediodorsal thalamus differed with experience for an orally consumed odor, taste, or odor-taste mixture. However, how neurons in the mediodorsal thalamus represent odors, tastes, and odor-taste mixtures, as well as its role in consummatory choice for experienced chemosensory stimuli remains unclear. To determine how neurons in the mediodorsal thalamus represent chemosensory signals, rats were given repeated experience with a palatable odor-taste mixture (isoamyl acetate-sucrose), and an unpalatable mixture (benzaldehyde-citric acid). Then, single-unit activity in the mediodorsal thalamus was recorded in behaving rats during the intraoral delivery of individual odors, individual tastes, and odor-taste mixtures. Our preliminary experiments revealed a subpopulation of chemo-responsive neurons in the mediodorsal thalamus (62.9%, 85/135) that are broadly tuned, respond with excitation and suppression, and represent mixtures differently than their odor and taste components. A population decoding analysis revealed that this subpopulation accurately represents the identity of odors, tastes, and odor-taste mixtures, with a quarter of them representing taste palatability (25.8%, 22/85). To determine the role of the mediodorsal thalamus in consummatory choice based on prior chemosensory experience, we used a two-bottle brief-access task to measure preferences for previously experienced odors, tastes, and odor-taste mixtures during the pharmacological inactivation of the mediodorsal thalamus. Pharmacological inactivation (NBQX) of mediodorsal thalamus significantly reduced consumption during both the odor and taste sessions and eliminated the initial odor preference for the saccharin paired odor. Taken together, these preliminary results begin to discern the role of mediodorsal thalamus in processing chemosensory signals to guide consummatory choice.

Title: Neural code of taste processing ethanol in the Orbitofrontal Cortex in mice

Authors: *E. PERRUSQUIA[1,3], K. ZEPEDA REYES[2], R. ANDRADE GONZÁLEZ[1,3], I. PEREZ MARTINEZ[1];
[1]UNAM, Tlalnepantla, Mexico; [2]UNAM, Cuautitlan Izcalli, Mexico; [3]Sip, IPN, Mexico City, Mexico

Abstract: In most people, consuming ethanol for the first time results in an aversive or unpleasant taste experience that requires peripheral and central neuroadaptation processes to increase consumption in subsequent consumption opportunities. This is how constant intake induces neuronal alterations that result in the development of alcohol use disorder (AUD). This is associated with electrophysiological changes in the reward circuit, specifically in prefrontal regions such as the Orbitofrontal Cortex (OFC); which participates in anticipation of both aversive and appetitive stimuli for decisión-making; and is precisely the adaptation to the appetitive and aversive taste qualities of ethanol, which induces the compulsion to ingest it. Before the results presented in this work, it was unknown if the taste code was processed in OFC when ethanol was presented for the first time at the orofacial level, in such a way that it can be determined what the changes that underlie the development of AUD by changes in the gustatory response area. To answer this question, we recorded neuronal OFC activity in C57BL/6 mice under sedation to monitor neuronal modulation without motor elements of ingestión, and we performed extracellular neuronal recordings with a 16-electrode microarray. Different concentrations of ethanol (.6, 1, 2.1, 3.2, 4.3, and 8.6 M) were administered to the togue extensión of the mice and water, quinine, and sucrose as control substances for neutral, bitter, and sweet flavors, respectively. 73 OFC neurons were registered, of which their electrophysiological characteristics were determined for functional classification. Fort the first time, we demonstrate that neuronal modulations or changes in firing rate (Wilcoxon signed rank test, $p<0.001$) encode the neural taste code previously proposed by Katz; a) Early or somatosensory stage, b) middle or identification stage, and c) late or palatability stage. We then observe that OFC neurons form different neuronal assemblies for each type of taste stimulation and low and high ethanol concentrations. Finally, we classify neuronal activity based on changes in the z-score from baseline activity; and we show that the taste coding of ethanol is represented in the activity of neuronal groups that are activated similarly. It makes sense to conclude a robust

sensory integration in OFC of orofacial stimulation with ethanol. Alterations in this processing are fundamental for the initiation, maintenance, and development of addiction to ethanol.

Title: Histological and Functional Characterization of Gastrin-Releasing Peptide-Expressing Neurons in the Gustatory Cortex of Mice

Authors: *L. A. CZARNECKI, O. K. SWANSON, S. SWAMINATHAN, J. F. KOGAN, A. MAFFEI, A. FONTANINI;
Neurobio. and Behavior, SUNY Stony Brook, Stony Brook, NY

Abstract: Gastrin-releasing peptide (GRP) is a peptide expressed both peripherally and centrally. In the periphery, GRP is involved in enteric activities related to digestion and metabolism. GRP has been explored centrally for its role in itch, circadian rhythm, memory, and ingestion. Interestingly, GRP is highly expressed in the gustatory cortex (GC) although its role is unknown. Here, we investigated the anatomical and electrophysiological properties of GC neurons expressing GRP, as well as their taste-evoked responses. First, we show that GRP-expressing neurons constitute an approximate 6% of the total neural population in GC with densest expression in superficial layers, particularly in the dysgranular subdivision. We recorded from GRP-expressing neurons in acute slice preparations of GC and found that all recorded neurons had intrinsic properties consistent with pyramidal cells. To assess taste-evoked responses, we performed two-photon calcium imaging in awake GRP-tdTomato mice. These mice also expressed GCaMP7f under the synapsin promoter which allowed us to visualize calcium-based fluorescent transients in all neurons and to identify GRP-expressing cells. GRP-expressing neurons in GC display characteristic taste-evoked and lick-evoked activity. To assess the connectivity of these neurons, we used anterograde tracing approaches and found the most prominent projections to frontal regions, to contralateral GC, and to the basolateral amygdala (BLA). Since the BLA is involved in taste valence and taste learning, we sought to further investigate the influence of GRP in the BLA. Consistent with previous reports, GRP bath application increased spontaneous inhibitory activity in the BLA. To assess the synaptic properties of GRP+ neurons projecting to BLA, we expressed ChR2 in GRP+ neurons in GC. After 2-3 weeks, we prepared acute slices of BLA and performed whole-cell recordings of excitatory neurons. Optogenetic stimulation revealed that GRP-expressing GC cells make

excitatory synaptic connections with neurons in BLA. Future work will further elucidate the contribution of neurotransmitter versus neuropeptide contributions to synaptic responses as well as evaluate the contribution of the GRP-BLA projection in taste-guided ingestive decisions.

Title: Functionally diverse populations of chemoresponsive neurons in the gustatory cortex identified by photostimulation of fibers from the posterior piriform cortex.

Authors: *S. STOCKE, C. SAMUELSEN;
Univ. of Louisville, Louisville, KY

Abstract: The perception of flavor is a multisensory experience requiring smell and taste. Sampling an odor-taste mixture associates an odor with a taste's quality and hedonic value, resulting in behavioral preferences for odors paired with palatable tastes and avoidance of odors paired with unpalatable tastes. The gustatory cortex (GC) receives convergent gustatory and olfactory signals and is considered a principle site for processing multimodal chemosensory signals. Recent electrophysiological and behavioral studies show that cortico-cortical interactions between the gustatory cortex and posterior piriform cortex (pPC) influence functional and behavioral responses to odors and tastes. However, how neurons in the gustatory cortex represent odor-taste mixtures, when multiple odors are paired with the same taste, as well as the functional connectivity between the posterior piriform cortex and chemoresponsive neurons in the gustatory cortex remains unclear. To test this, we injected the posterior piriform cortex in rats with a virus to drive the expression of channelrhodopsin-2 (ChR2) and implanted a drivable multielectrode optrode into the gustatory cortex. Following surgery, rats were given repeated experience with four odor-taste mixtures: two palatable (isoamyl acetate-sucrose and methyl valerate-sucrose) and two unpalatable (benzaldehyde-citric acid and ethyl butyrate-citric acid). Next, we recorded single-unit activity in the gustatory cortex of alert rats during the intraoral delivery of the individual odors, the individual tastes, and the odor-taste mixtures. Immediately following each chemosensory delivery session, we photo-activated ChR2-expressing posterior piriform fibers in the gustatory cortex to identify the population of neurons likely modulated by input from the posterior piriform cortex. We found that ~40% of chemoresponsive neurons in the gustatory

cortex are modulated by photostimulation of fibers from the posterior piriform cortex. Both the light-responsive and non-responsive populations respond to multiple different odors, tastes, and odor-taste mixtures. Interestingly, a significantly greater proportion of the laser-responsive neurons selectively represent odors and odor-taste mixtures as compared to the non-responsive population. Our preliminary findings support the hypothesis that the gustatory cortex is a key component of the network processing of multimodal chemosensory signals and suggest that cortico-cortical connections with the posterior piriform cortex may underlie the functional diversity of chemoresponsive neurons in the gustatory cortex.

Title: The dynamics of neuronal activity and network connectivity changes that underlie the formation and consolidation of a gustatory associative memory

Authors: E. ARIELI[1], O. RAHAMIM[1], A. ITZKOVITCH[1], ***A. MORAN**[1,2];
[1]Neurobio., Tel Aviv Univ., Tel Aviv, Israel; [2]Sagol Sch. of Neurosci., Tel Aviv, Israel

Abstract: Acquiring new memories is a multi-stage process. Many studies have demonstrated that initially acquired memories are labile, and only stabilized by later consolidation processes. These multiple phases of memory formation are known to involve modification of both cellular excitability and synaptic connectivity, which in turn change neuronal activity at both the single neuron and ensemble levels. However, the specific mapping between the known phases of memory and the observed changes in neuronal activity, as well as the reorganization of the neuronal network remain unknown. We address this unknown in the context of conditioned taste aversion (CTA) learning in which a novel taste is paired with malaise to induce taste avoidance. Following CTA induction, we continuously tracked the activity of gustatory cortex (GC) neurons of rats for 24 hours during which CTA is acquired and consolidated. We found that the progression of neuronal activity changes in the GC depend on the neuronal organizational level. The population response changed continuously; these changes, however, were only reflected in the population mean amplitude during the acquisition and consolidation phases, and in the known quickening of the ensemble state dynamics after the time of consolidation. Preliminary analyses of the activity of hundreds of GC neurons recorded simultaneously using Neuropixels probes showed that network connectivity changes were also time-locked to the memory

acquisition and consolidation phases. Together our results demonstrate how complex dynamics in different representational level of cortical activity underlie the formation and stabilization of memory within the cortex.

Abstract: Categorical perception, the ability to group sounds or images into discrete perceptual categories, enables humans and other animals to rapidly and robustly recognize and respond to stimuli. Categorical representations have been observed for speech and other vocalized sounds along relatively simple time and frequency dimensions. However, the high-order acoustic features and neural computations underlying categorical representations for more general sound categories are not well understood.Here we used a texture synthesis (McDermott & Simoncelli 2011) to synthesize ‘chimeric’ auditory textures. Synthetic chimeric textures are generated by morphing summary statistics of runningwater andcracklingfire sounds. The chimeric sounds were first used in human perception tasks were participants were either required toidentify a chimeric texture as fire or water or alternately required todiscriminate two chimeric textures. For both tasks, the chimeric textures statistics were varied by adjusting the included statistics during the synthesis and the morph ratio (MR) from 0 (water extreme) to 1 (fire extreme). Parallel studies were also carriedout to study the neural representation of chimeric textures in the inferior colliculus (IC) of unanesthetized rabbits. Neural activity was obtained using multi-channel silicon probes inserted along the principal frequency axis during passive listening of the chimeric textures. We demonstrate that shifting high-order summary statistics by changing the morph ratio of fire and water produces a robust shift in human listener’s perception. Participants readily identified water and fire sounds in a categorical-like fashion with increasing morph ratio where the sound correlation structure was the critical statistical cue responsible for the categorical

effect. The categorical-like shift is accompanied by lower discrimination accuracy and larger just noticeable difference limen (JND) for within category as compared to across category discrimination. We then demonstrate how the response statistics of neural ensembles in the IC can be used to decode the sound category. Neural decoders were used to assess how population response metrics can categorize or discriminate the chimeric textures. Shifting the morph ratio produces a similar categorical-like shift in neural decoding performance and similar larger JNDs and lower accuracy trends as for human participants. The findings suggest that high-order statistical sound cues can drive categorical-like perception for textures and that the neural response statistics in IC can contribute towards such phenomenon.

Title: Modulation content of interfering natural background sounds affects neural population synchrony and response power during vocalization processing

Authors: D. PEDRICK[1], X. ZHAI[2], I. STEVENSON[1], ***M. ESCABI**[1];
[2]Electrical & Computer Engin., [1]Univ. of Connecticut, Storrs, CT

Abstract: Selectively listening to a target sound within a noisy environment is a challenge to the auditory system. Studies using simple sounds such as a tone in noise have attempted to understand how sound segregation is accomplished during normal listening. However, in everyday settings natural background sounds confront listeners with far more complex listening conditions. During sound masking, low-order sound structure such as overlapping power spectra can inhibit the strength of neural responses. However, the contribution of higher-order statistics in the modulation content of natural backgrounds to masking at the neural level is less understood. Here we manipulated the spectrum and modulation content of five natural backgrounds (babble, machine noise, water, fire, birds) and white noise to determine their contribution to energetic and modulation masking. To dissociate masking attributed to the spectrum versus modulation content, we generated phase randomized (PR) backgrounds which have the power spectrum of the original sounds but a whitened modulation spectrum. Furthermore, to compare masking effects attributed to the modulation content of different

background sounds, we used spectrum equalized (SE) backgrounds that have a power spectrum identical to pink noise, but retain the original sound modulation content. Electrophysiological recordings were carried out in the inferior colliculus of awake Dutch Belt rabbits. Neural population responses to speech and animal vocalizations were measured in the presence of the natural and perturbed backgrounds.We demonstrate that vocalizations in the presence of PR backgrounds reduce the neural population signal strength and synchrony of the encoded foreground vocalizations, when compared against the unaltered backgrounds. Despite this, and paradoxically, the neural output signal-to-noise ratio of the encoded foreground is higher for the PR conditions. This suggest that PR backgrounds sparse the neural activity, yet they produce a higher fidelity neural representation of the foreground vocalization. In contrast, SE backgrounds have little effect on neural responses when compared to unaltered backgrounds. Masking differences observed across the original background sounds remained for the SE condition suggesting that the background modulation content dominated the observed masking patterns for individual backgrounds.Collectively, these results suggest that modulation statistics in natural background sounds can have varied interfering effects and that the unique modulation content of each of the interfering background sounds can strongly influence the encoding of masked vocalizations.

Title: The role of rate-based and correlation-based neural activity towards the recognition and discrimination of natural sound textures

Authors: *X. ZHAI[1], M. SADEGHI[1], F. HE[2], H. L. READ[3], I. STEVENSON[3], **M. A. ESCABI**[1];
[1]Electrical and Computer Engin., [2]Biomed. Engin., [3]Psychological Sci., Univ. of Connecticut, Storrs, CT

Abstract: Time-averaged summary statistics in sound textures, such as stream and a noisy restaurant, contribute to sound perception and are known to modulate neural activity in auditory midbrain. Yet, the role of different neural codes (rate, timing, and correlation based) towards the neural representation of textures remains largely unknown. Here we recorded neural activity in the inferior colliculus (IC) of unanesthetized rabbits using a linear multi-channel silicon probe

during passive listening to natural sound textures and synthetic variants with perturbed statistics. An analog representation of multi-unit activity (aMUA) and spike-sorted single-unit data were evaluated from the neural recordings and the results were compared to human psychoacoustic tests using the same sounds.We demonstrated that summary statistics strongly influence coordinated firing across the IC neural ensembles and that neural ensemble correlations converged to those measured the original textures as statistics were added to the synthetic variants. By comparison, a rate-based representation of the neural population activity was largely unaffected by adding high-order statistics to the synthetics variants. Single-unit response properties also varied with changing sound summary statistics. Shuffled autocorrelograms exhibited a sharper and stronger peak upon adding higher-order statistics, indicating enhanced temporal coding, higher temporal precision and higher reliability. By comparison, firing rates were relatively constant and unaffected by the summary statistics. Furthermore, correlated firing between single-units showed diverse structures across sounds and increased upon adding statistics to the synthetic stimuli. Next, single-trial neural decoders were used to determine whether the neural correlations and spectrum in IC could allow sound textures to be identified and discriminated. The neural correlation-based classifier performance improved with increasing sound duration and added sound statistics, with an evidence accumulation time scale of ~1 sec, resembling trends observed in human psychoacoustics (Zhai et al 2020). By comparison, neural spectrum-based codes provided a substantially faster neural signal which contributed much more towards texture discrimination, analogous to human participants.The findings suggest that neural response statistics in auditory midbrain are modulated in unique ways by statistical regularities in sounds and that rate-based and correlation-based neural codes may have dissociable roles and time scales for the recognition and discrimination of natural texture sounds. Title: Transformation of population representations of sounds throughout the auditory system

Authors: *S. BAGUR[1], J. BOURG[2], A. KEMPF[3], T. TARPIN[1], E. GOSSELIN[1], S. A. CEBALLO[1], K. BERGAOUI[1], Y. GUO[1], A. MULLER[1], J. BOURIEN[4], J. PUEL[4], B. BATHELLIER[1];

Abstract: Auditory perception relies on robust spectrotemporal pattern separation. Yet the step-by-step computational transformations through which this occurs in the auditory system are still elusive, partly due to the lack of systematic comparison of sound representations at different stages. To address this, we compared population representations based on extensive two-photon calcium imaging and electrophysiology recordings in the auditory cortex, thalamus, inferior colliculus in mice and on a detailed biophysical model of the cochlea. Using a noise-corrected correlation metric, we measured the similarity of activity patterns generated by diverse canonical spectrotemporal motifs (pure tones and chords, amplitude and frequency modulations, broad band noise). This measure evidenced a gradual decorrelation of population responses across sounds, accompanied by a convergence of the information carried by temporal and rate codes in cortex. Rate code representations that were most similar at cochlear level, for example for time symmetric sounds were decorrelated mainly between thalamus and cortex, while many other sound pairs underwent significant decorrelation earlier. Strikingly, representations of different intensities of the same sounds were also decorrelated. While this transformation was related to response sparsenning in the cortex and strong non-linearities, the sound representations remained continuous, preserving local similarity relationships at all stages. Gradual decorrelation of time-independent representations could be reproduced by a deep network trained to detect in parallel basic perceptual attributes of sounds, including estimates of frequency and intensity ranges as well as temporal modulation types. In contrast networks trained on tasks ignoring some perceptual attributes (e.g. intensity) did not decorrelate the related acoustic information. The auditory thalamus was the site of recorrelation of population representations and very dense neural coding, without loss of accuracy in sound encoding. Modifying the architecture of CNN networks to reproduce the anatomical bottleneck of the thalamus resulted in a recorrelation of representations, similar to the data. The contrasting representations of cortex and thalamus, both of which connect to behavioural output regions, suggest complementary roles in the broadcast of auditory information. Together these results establish that the mouse auditory system transforms sound representations to make information about diverse perceptual attributes generically accessible in a rate-based population code.

Title: Relating Mesoscale Local Field Potential and Macroscale Electroencephalography (EEG) Signals in the Rat Primary Auditory Cortex

Authors: *T. JOHNSON, A. GALLAGHER, S. COULSON, L. M. RANGEL;
UCSD, La Jolla, CA

Abstract: Electroencephalography (EEG) signals incorporate summated currents from a range of different sources, making it challenging to precisely identify their local circuit underpinnings. In this study, we acquired skull EEG from the rat primary auditory cortex (A1) while simultaneously recording contralateral local field potential (LFP) activity using silicon probe electrodes that spanned cortical layers. Repetitive auditory stimuli presented at 20, 30, 40, 50, and 80Hz were used to assess the local circuit underpinnings of the Auditory Steady State Response (ASSR) in rats. These stimuli effectively pace networks involved in auditory processing, creating predictable large scale currents at the frequency of the presented stimulus that are reliably detected in electrophysiological measurements in a range of species. In this study, the ASSR manifested prominently in all cortical layers and in the EEG signal of the rat, enabling an assessment of the degree to which features in the LFP (e.g. the magnitude of currents in each layer and the degree of synchrony across layers) related to the EEG signal. Our findings suggest that a resonant response occurs when networks are paced by 40Hz gamma frequency range stimuli, with both current magnitudes and the degree of synchrony across layers contributing to this larger response. By relating signals across these different scales, we provide mechanistic insight into the unique local circuit dynamics underlying distinct EEG signals and auditory processing states in the rat.

Title: Encoding of complex natural sounds in mouse auditory cortex

Authors: *J. SCHWENKGRUB, S. BAGUR, E. GOSSELIN, S. JAMALI, A. RENARD, B. BATHELLIER;
Inst. Pasteur, Inst. de l'Audition, Paris, France

Abstract: The encoding of simple and complex sounds in the large neural ensembles of the mouse auditory cortex (AC) remains a puzzle. Our preliminary data indicate that large clusters of AC neurons respond specifically to complex or natural sounds and not to the simpler sounds (e.g. pure tones) that share the same frequencies. To investigate further how complex sounds are encoded in the AC and which of their features are specifically extracted at this level of auditory pathway, we have exposed animals to the extended set of sounds that not only consists a variety of simple sounds (i.e.: pure tones, intensity ramps, chirps, sine amplitude modulated sounds, chords, and different versions of white noise), but also decomposition of several complex sounds into simpler and yet specific blocks highlighting their features. Mice were also presented with an additional set of natural sounds required for cross-validation of obtained results. Data have been collected throughout all the layers of AC in 14 adult (4-5 months old) awake male mice using large scale multi-plane two-photon calcium imaging that enabled us to record simultaneously neuronal activity in 3 or 4 plans distributed across 200um of vertical extent of AC. Acquired data have been used to test whether our models can predict cortical responses to complex natural sounds.
Our methodology coupled with computational modelling is aimed to establish a better understanding of the contributions of auditory cortex representations to natural sounds perception.

Title: Distinct synaptic plasticity mechanisms determine the diversity of cortical responses during behavior

Authors: M. INSANALLY[1], B. F. ALBANNA[2], **J. M. TOTH**[1], B. DEPASQUALE[3], S. FADAEI[4], T. GUPTA[4], K. RAJAN[5], R. C. FROEMKE[4,6,7];

Abstract: Heterogeneous neuronal responses are found in many cortical areas including visual, auditory, parietal, and frontal cortex. The extent of this heterogeneity is vast. A fraction of cells exhibit trial-averaged responses with obvious task-related features such as pure tone frequency tuning in auditory cortex (classically responsive). However, a substantial number of cells do not appear to fire in a task-related manner and are often neglected from analysis (non-classically responsive). Our recent study used a novel spike-timing-based analysis to show that both classically and non-classically responsive cortical neurons contain significant task information suggesting that non-classically responsive cells may play an underappreciated role in perception and behavior (Insanally et al. 2019). Where do these diverse response profiles come from and what is their contribution to behavior? What are the synaptic inputs that might drive such diverse responses? To address these questions, we trained a novel spiking recurrent neural network model that incorporates spike-timing-dependent plasticity mechanisms and FORCE learning to perform the same task as behaving animals. By leveraging excitatory and inhibitory plasticity, this model reproduces neurons with response profiles consistent with published in vivo data including classically and non-classically responsive neurons which both encode task information in their spike times as seen in vivo. Using simulated perturbation experiments to assess the functional contribution of these subpopulations, we found that classically responsive cells contribute more to behavior via output connections while non-classically responsive cells contribute via recurrent connections by increasing the dimensionality of activity during the choice period. These results provide strong evidence for a double-dissociative function of classically and non-classically responsive neurons. Interestingly, excitatory plasticity played a primary role in establishing the diversity of response profiles observed; however inhibitory plasticity had a strong modulatory effect when excitatory plasticity was active. Local patterns of connectivity predicted single-unit responsiveness and placed constraints on the synaptic patterns required for non-classically responsive activity to emerge making predictions that we compare to in vivo whole-cell recordings taken from the auditory cortex of behaving animals. Our approach recapitulates the heterogeneous neural responses found in behaving animals and provides a powerful lens for exploring large-scale neuronal dynamics and the plasticity rules that shape them.

Title: Reconstruction of natural auditory stimuli from neuronal population activity

Authors: *B. THEILMAN[1], T. S. MCPHERSON[1], M. TURVEY[2], S. RUDRARAJU[2], T. Q. GENTNER[2,1,3,4];
[1]Neurosciences Grad. Program, [2]Psychology, [3]Neurobio. Section, Div. of Biol. Sci., UC San Diego, La Jolla, CA; [4]Kavli Inst. for Brain and Mind, La Jolla, CA

Abstract: The collective activity of neural populations in higher-order sensory brain regions is thought to support the representation of the complex natural stimuli that guide behavior. Encoding properties of single neurons and populations within these higher-order regions of the sensory hierarchy are difficult to characterize, however, because they can respond selectively to multiple, complex stimulus features. In principle, the ability to reconstruct natural stimuli from spiking activity across a neuronal population can provide valuable insight into the nature of natural stimulus representation at the neural population level. Here, we present a method to achieve spectrographic reconstructions of natural birdsong from spiking activity in neural populations in the Caudal Medial Nidopallium (NCM), an auditory region in songbirds analogous secondary auditory cortex. Using the maximum noise entropy method to model linear and non-linear components of NCM neurons' spiking responses, we show that high-fidelity reconstructions can be achieved with out a priori knowledge of the stimulus autocorrelation structure, marking an advance over previous auditory reconstruction efforts. This suggests the presence of an underlying representational "feature space" of lower dimension than the natural birdsongs. To investigate this, we trained a novel autoencoder to yield a nonlinear compression of natural birdsong into a low-dimensional latent-space. We show that these latent spaces capture relevant sensory dimensions for this secondary auditory population enabling high-quality spectrographic stimulus reconstructions. Finally, we relate the geometry of these reconstructions to the combinatorial structure of the spiking activity. Collectively, these results suggest that the information required for reconstruction of any conspecific vocal communication signal in songbirds is intrinsic to spatiotemporal firing patterns in the NCM population.

Abstract: There is mounting evidence that the brain inhibits processing of predictable stimuli and responds more to unpredicted “oddballs”. Neuronal spiking as well as gamma-band frequency (40-100 Hz) power in the local field potential (LFP) are reduced to predictable stimuli, while alpha/beta frequency band (8-30 Hz) LFP power is enhanced to predicted stimuli. In sensory cortex, these modulations occur in a stimulus-specific manner. It has been suggested that these mechanisms for prediction are a feature of awake (conscious) processing. If this is the case, these prediction mechanisms should be reduced or eliminated during unconscious states. To test this, we recorded spiking and LFP activity from auditory (area STG) cortex of two macaque monkeys in both awake and unconscious states. We induced unconsciousness using the anesthetic propofol. Monkeys passively listened to pure tone auditory sequences that were either predictable or unpredictable. In the awake state, we reproduced previous findings that unpredictable stimuli evoke more gamma and less alpha/beta than predictable stimuli. In the unconscious state, baseline levels of both gamma and alpha/beta were strongly reduced relative to the awake state. However, when unpredictable stimuli occurred they enhanced LFP power in

both the gamma and alpha/beta bands relative to predictable stimuli. This power enhancement by unpredictable stimuli was even larger in the unconscious compared to the conscious state. Both awake and unconscious states featured sensory responses that were reduced by predictable stimuli in a stimulus-specific manner. Our findings challenge the hypothesis that inhibition of sensory responses by prediction is a key feature of conscious processing.

Title: Pv neurons enhance cortical coding in the cocktail party problem

Authors: *J. NOCON[1,2,3], H. J. GRITTON[4,5], X. HAN[1,2,3], K. K. SEN[1,2,3];
[1]Dept. of Biomed. Engin., [2]Neurophotonics Ctr., [3]Ctr. for Systems Neurosci., Boston Univ., Boston, MA; [4]Dept. of Comparative Biosci., [5]Dept. of Bioengineering, Univ. of Illinois, Urbana, IL

Abstract: The human brain is a powerful computational device, capable of feats yet to be matched by machines. An impressive example is its ability to solve the cocktail party problem. For example, at a crowded cocktail party, we can hear what a friend is saying among other speakers and background noise. The integrative multisensory nature of such complex scene analysis suggests that the circuits of the cerebral cortex hold the key to solving this problem. How cortical circuits achieve this solution remains poorly understood. Complex auditory scenes typically contain multiple sound sources at different spatial locations. Here, we report auditory cortical neurons in mouse A1 with spatial response properties that are well suited for segregating competing sounds from different locations. We discovered that these neurons are sensitive to the spatial configuration of “target” and “masker” sound sources from different locations. Specifically, we quantified neural discrimination performance over a spatial grid of all possible combinations of target and masker locations and found that cortical neurons display “hotspots” of high performance at particular grid positions. At most hotspots, both rate modulations and spike timing-based coding contribute towards discrimination performance. Individual sites show diverse spatial grids, which enable the population representation of distinct spatial configurations. Finally, we found that optogenetic silencing of parvalbumin-positive (PV)

interneurons resulted in an expected increase in average firing rate that coincided with a decrease in discrimination performance at hotspots. This decrease in performance is accompanied by a reduction in the lifetime sparseness and reproducibility of responses across trials. We used several spike distance metrics to dissect the neural code and found that the decrease in performance at most hotspots is driven by a decrease in spike timing reproducibility and rapid temporal modulations of firing rate, independent of changes in overall spike count. Our findings indicate that PV neurons improve cortical representation of auditory stimuli in the cocktail party problem by promoting a sparse, temporally modulated, and reproducible code.

Title: Probing semantic violations via the N400 event related potential component: provision of a publicly available auditory stimulus set and twenty high-density electrophysiological datasets.

Authors: *K. TOFFOLO, E. FREEDMAN, J. FOXE;
Univ. of Rochester, Rochester, NY

Abstract: When listening to speech, context is used to predict sentence outcome by limiting subsequent word options. How well a word matches a predicted word is quantified by a measure known as ‘cloze probability’. Neurophysiologically, cloze probability is represented at the level of the brain and can be measured using electroencephalography (EEG). The N400 event-related potential (ERP) derived from EEG data is an established outcome measure for semantic processing and integration which is highly sensitive to semantic congruency. The purpose of this study was to create the first publicly-available stimulus set that evokes the N400 ERP through auditory presentation, in order to aid in the comparability and reproducibility of future research examining semantic comprehension. This stimulus set utilizes the semantic anomaly paradigm, provides the cloze probability for all stimuli, and was developed to be used across a wide set of age ranges. This stimulus set was validated with 20 neurotypical adults and was found to elicit the N400 as well as two additional semantically-related ERPs: the late positivity component (LPC) and the recognition potential (RP). This standardized and validated stimulus set can be used to investigate several populations, and future semantic studies that use this stimulus set may benefit from the increased comparability and reproducibility within this field of research.

Title: A toolkit of modeling approaches for interpreting behavior and its neural correlates in quasi-continuous decision-making paradigms

Authors: M. MCGINLEY[1,2,3], S. CHEN[3], J. DE GEE[1,2];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Duncan Neurolog. Res. Inst., Texas Children's Hosp., Houston, TX; [3]Electrical and Computer Engin., Rice Univ., Houston, TX

Abstract: Decision-making and its neural correlates are typically studied in laboratory tasks with rigid trial-based structures. A major appeal of these designs is existent powerful modeling frameworks like signal detection theory (SDT; Green and Swets, 1966) and drift diffusion modeling (DDM; Ratcliff and McKoon, 2008). However, in the real world, stimuli of interest arrive at unpredictable and sometimes long intervals. It may be that the neural circuit implementation of decision-making, including factors like attention and arousal, may differ substantially between rigid trial-based and natural decisions. Naturalistic tasks and efficient and interpretable modeling frameworks are needed. To fill this gap, we have developed a novel quasi-continuous sensory detection paradigm and a toolkit of modeling approaches based on SDT, DDM, and survival analysis.

In the first approach, which we call real-time signal detection theory (rt-SDT), SDT is applied in a sliding time-window, and then take the limit as the window duration goes to zero. We show, analytically, that the resultant equations for sensitivity (d') and bias (c) are equivalent to those derived by applying SDT at the per-stimulus level while ignoring the alternating stimulus sequencing and varying stimulus durations, and can be interpreted in the usual fashion after accounting for an estimated empirical temporal prior of the animal's decisions, using tools from survival analysis.

In a second approach, we modify the conventional DDM by using a single bound (instead of two) and adding leak to the diffusion process, mirroring a recent approach in human studies (Ossmy et al., 2013). With extensive simulations, we show that rt-SDT and this leaky DDM give consistent results; rt-SDT provides simple interpretations that work on small data sets, while the DDM requires more extensive data but provides a richer and behaviorally mechanistic account of the decision process.

As a final approach, we apply GLM models of choice as a binary variable (DeCarlo, 1998) or of

the hazard function for response using survival analysis. We find that these GLM approaches are intermediate between rt-SDT and leaky DDM in terms of constrainability, can be the most opaque to interpretation, but are powerful at incorporating physiological and behavioral covariates. In ongoing work, we are refining the GLM modeling to improve interpretability, thus establishing a firm foundation for our modeling toolkit.

Title: Behavioral and computational approaches to mouse foraging behavior in physical and virtual patchy environments

Authors: *J. WEBB[1], D. LEE[2], C. KEMERE[3,1], M. J. MCGINLEY[1,3];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Electrical and Computer Engin., Rice Univ., Houston, TX

Abstract: Despite the large body of work in key areas of decision making, the neural circuits governing behavior of animals in natural environments has been relatively understudied. In particular, a rich literature in behavioral ecology has highlighted patch-based foraging, in which animals harvest from geographically clumped areas of finite resources, as a central task for many animal species, and thus one for which the brain presumably has evolved. Moreover, a plethora of studies have linked native animal behavior to mathematical models of patch-based foraging tasks, including the marginal value theorem, which states that the animal should leave the current patch and incur the search cost of traveling to a replenished patch when the incremental reward in the current patch falls below the average reward rate across the environment. The similarity to natural behavior and existence of proven behavioral models imply that foraging represents a robust framework for studying natural decision-making.
Here, we extrapolated these ideas to a probabilistic foraging task in both physical and virtual acoustic environments that use custom systems based in Python and LabVIEW, respectively. Reward ports were located at the endpoints of the physical maze or at evenly-spaced intervals in virtual space. When an animal arrived at a reward location, an auditory stimulus (tone cloud) was continuously played to indicate the “patch” is active. Potential rewards accumulated at intervals

which followed a modified non-homogeneous Poisson process with an exponentially decaying Poisson rate, which we term a “Poisson drip process,” and were given in 2 uL droplets in response to licking. A pure tone played when reward was available, and its frequency indicated the number of available reward droplets. The animal could leave the current reward zone at any point, allowing for a continuous background leaving decision, and move to the next active location. While moving between reward locations, a distinct auditory stimulus (pink noise) was played until the animal arrived in the next “patch”, at which point tone cloud played to indicate a new, replenished patch was active.
To analyze this task, we first developed theoretical deterministic and probabilistic models of foraging behavior. Our analysis underscores the importance of parameter selection for foraging environments and highlights potential strategies animals may employ. Fitting our models to preliminary data suggests that the animal's behavior was consistent with the marginal value theorem for both travel time and reward decay rate manipulations. Further analysis will compare learning and performance between the physical and virtual tasks.

Title: Temporal Correlation between medial olivocochlear reflex and electroencephalographic activity during sleep

Authors: *S. OTSUKA, Y. SUZUKI, S. NAKAGAWA;
Chiba Univ., Chiba, Japan

Abstract: The medial olivocochlear reflex (MOCR) is a feedback response that controls the gain of the outer hair cells. It has been reported that the MOCR becomes weaker in a state of sleep. Given this, it is possible that MOCR strength fluctuates depending on awareness. However, no studies have evaluated awareness level quantitatively and examined the relationship with MOCR. In this study, we evaluated stages from awakening to sleep using electroencephalogram (EEG) and electrooculogram (EOG) and investigated the relationship with MOCR strength. The amplitude of β (13-30 Hz), α (8-13 Hz), θ (4-8 Hz) and δ wave (0.5-4 Hz), which reflects each stage from wakefulness to deep sleep, were monitored during the two-hours measurement session. We measured the contralateral MOCR in terms of the suppression of click-evoked otoacoustic emissions (CEOAEs) induced by noise presented to the contralateral ear. Click trains

were played into the right ear canal to generate CEOAEs from within the cochlea. Each click had a duration of 100 μs. Clicks were presented at a 55-dB peak-equivalent sound pressure level (SPL) and at a rate of 50 times per second. The MOCR was elicited by a noise presented to the left ear, referred to as the MOCR elicitor, during the CEOAE recording. The noise was band-pass filtered between 100 and 10,000 Hz, with a duration of 0.5 s, including a 10-ms raised-cosine ramp. The noise was presented at 60-dB SPL and at intervals of 5 s. The CEOAE waveforms measured from one minute before and one minute after each time point were extracted, and then the waveforms measured in the interval with and without contralateral noise were averaged, respectively.
The amount of OAE suppression (MOCR strength) had a statistically significant positive correlation with the time variation of α waves (appearing mainly from awakening to sleep onset), but not with other EEG components and with the time variation of slow eye movement (appears in the sleep onset period), which was calculated from EOG. This result indicates that MOCR strength becomes weaker at a relatively early stage of sleep onset, which has a large change in awareness level, regardless of the depth of sleep. Further, no correlation was found between the auditory brainstem response and the α waves. This result indicates that activities from the inner ear to brainstem are not affected by awareness level, but the activity of the efferent pathway is affected by awareness level.

Title: Pupil size and prefrontal Theta/Beta power reflect phasic adaptation of arousal during subconscious processing of auditory novelty

Authors: *S. OSORIO[1], M. IRANI[2], J. HERRADA[3], F. ABOITIZ[1];
[1]Lab. for Cognitive and Evolutionary Neuroscience, Fac. of Med., [2]Lab. for Neurodynamics of Cognition, Fac. of Med., Pontificia Univ. Catolica de Chile, Santiago de Chile, Chile; [3]Biomed. Neurosci. Inst. (BNI), Fac. of Med., Univ. de Chile, Santiago, Chile

Abstract: The ability to extract statistical regularities from sensory input and detect sudden changes in incoming sensory patterns mediates both autonomic and goal-directed responses. The

pupil response, considered a proxy of noradrenergic modulation of arousal, is sensitive to the detection of sensory novelty. However, how conscious perception modulates the brain's response to novel sensory stimuli and the subsequent adaptation of arousal remains unclear. In this study, we presented subjects (n = 24, mean age = 25.5, range = 13) sequences of sinusoidal tones and asked them to decide whether the last stimulus was the same or different from the previous standard ones. Target stimuli could be another standard tone or a deviant tone that could either be above or below each participant's threshold for conscious auditory discrimination. We collected behavioral (accuracy and reaction times), pupillometric (pupil size) and neurophysiological (Electroencephalography) data. We found faster reaction times for targets that were consciously detected and correctly reported as different (n = 21, $p < 0.05$, Bonferroni-corrected, two-tailed). While the pupil responded to all targets, increased pupil size was associated to the processing of targets that were not consciously detected as novel and therefore incorrectly reported as standards (300-400ms, n=21, $p < 0.05$, one-tailed). A Mismatch Negativity Response was elicited by both types of targets, but only targets that were consciously perceived as novel were associated to a P3 response (n = 20, $p < 0.05$, Bonferroni-corrected, one-tailed). Time-frequency decomposition analyses from source-reconstructed signals revealed increased power in the Beta (15-30hz) and Theta (4-8Hz) frequency range (n = 20, $p < 0.05$, cluster-corrected, one-tailed) within temporal and prefrontal regions for targets that were not consciously perceived as novel. In turn, increased theta power was observed within cingulate and insular regions for targets that were consciously perceived as novel (n = 20, $p < 0.05$, cluster-corrected, one-tailed). These findings suggest that phasic adaptation of arousal can operate independently of conscious perception. We discuss these results in the context of the adaptive-gain framework, where increased phasic arousal following undetected novel targets presumably reflects top-down modulation of neuronal gain functions to optimize performance and satisfy the demands imposed by the task at hand.

Title: Arousal state dependence of short-and long-term auditory novelty response interactions: An intracranial electrophysiology study

Authors: *K. V. NOURSKI[1], M. STEINSCHNEIDER[2], A. E. RHONE[1], R. N. MUELLER[1], H. KAWASAKI[1], M. I. BANKS[3];
[1]The Univ. of Iowa, Iowa City, IA; [2]Albert Einstein Col. of Med., Bronx, NY; [3]Univ. of Wisconsin - Madison, Madison, WI

Abstract: According to the predictive coding hypothesis, sensory processing occurs through bidirectional information flow. The local/global deviant paradigm engages auditory predictive coding over short ('local deviance'; LD) and long ('global deviance'; GD) time scales. Intracranial electroencephalography (iEEG) allows information flow within the human auditory cortical hierarchy to be examined with high spatiotemporal resolution. LD and GD effects differ in their sites of origin, timing, and sensitivity to general anesthesia. Recent findings indicate that LD and GD effects are not independent; their interactions reflect overlapping processing networks that subserve novelty detection. This study examined local-by-global interactions using iEEG in 7 neurosurgical patients (3 female) who performed a GD target detection task before and during induction of general anesthesia with propofol. Recordings were made from auditory cortex, surrounding auditory-related areas, and prefrontal cortex. High gamma (70-150 Hz) activity was used to measure the interaction between responses to short- and long-term auditory novelty, defined as (LDGD-LSGD)-(LDGS-LSGS) where LS and GS denote local and global standard conditions respectively. In the awake state, subjects detected LSGD targets less accurately than LDGD targets. There were two types of neural interactions. Positive interaction corresponded to a greater response to LDGD than LSGD above and beyond LD effect. Negative interaction corresponded to a greater response to LSGD. Positive interaction was more frequent and robust than negative and was largely confined to temporal cortex. Negative interaction typically occurred in prefrontal and temporo-parietal auditory-related cortex and had longer onset latencies. Sedation and subsequent loss of responsiveness led to a progressive reduction in high gamma interactions. General anesthesia had a greater effect on negative interaction. These results show GD to be more behaviorally salient when paired with LD feedforward error signals, accompanied by a positive neural interaction throughout auditory cortex. The behaviorally more challenging LSGD target condition is associated with a negative neural interaction in prefrontal cortex. Temporo-parietal auditory-related cortex exhibits both types of interaction. Positive interaction is partially preserved during sedation and thus may serve as a biomarker of conscious perception in the evaluation of depth of anesthesia and disorders of consciousness.

Title: Graph theoretic measures indexing arousal state transitions during sleep and anesthesia in human subjects

Authors: *D. CAMPBELL[1], B. M. KRAUSE[3], D. G. BERGER[2], C. K. KOVACH[4], K. V. NOURSKI[5], M. I. BANKS[6];
[2]Dept. of Anesthesiol., [1]Univ. of Wisconsin -- Madison, Madison, WI; [3]Dept. of Anesthesiol., Univ. of Wisconsin-Madison, Madison, WI; [4]Dept. of Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [5]The Univ. of Iowa, Iowa City, IA; [6]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI

Abstract: Introduction: Consciousness is associated with a balance between integration and differentiation in cortical networks, but measurements of changes in these properties during sleep and anesthesia using graph-theoretic analyses have been inconsistent. Increases in network segregation [measured as network modularity or local efficiency (E_L)] have been reported during NREM sleep, while decreases have been reported under anesthesia. Decreased integration (measured as global efficiency, E_G) is reported under anesthesia, but whether this also occurs for sleep is unclear. We investigated these issues using diffusion map embedding (DME) applied to resting-state functional connectivity derived from intracranial electroencephalography (iEEG) in neurosurgical patients. DME provides a geometric framework for understanding changes in network structure. Segregation is reflected in the clustering of nodes in embedding space, quantified by the effective dimensionality (D_E) of the normalized connectivity matrix. Integration is reflected in the volume of the data cloud in embedding space.
Methods: iEEG recordings from adult neurosurgical patients to identify seizure foci were obtained during propofol anesthesia (N=15) and natural sleep (N=13). Three arousal states were compared during anesthesia experiments: pre-drug wake (WA), sedated/responsive (S) and unresponsive (U), and five in sleep: wake (WS), N1, N2, N3, and REM. These 8 arousal states were segregated into conscious {WA, S, WS, N1, REM} and reduced consciousness {U, N2, N3} states. Data were segmented (60 sec) and channel-by-channel adjacency matrices were computed as pairwise gamma (30-70Hz) orthogonalized power envelope correlations. Connectivity matrices were thresholded (top 33%) and normalized, and graph-theoretic metrics [D_E, E_G, E_L (or equivalently clustering coefficient, C)] computed and compared across arousal state.
Results: During U, N2, and N3 compared to conscious states, E_G was slightly elevated, C and E_L were substantially higher, and D_E was reduced. D_E and C best tracked transitions in awareness between conscious and reduced consciousness states. The embedding volumes were lower during the reduced consciousness states, reflecting the decreased network integration associated with unconsciousness.
Conclusions: Consistent changes in graph-theoretic measures of network organization during sleep and anesthesia suggest overlapping mechanisms of arousal state transitions. The geometric framework of DME facilitates comparisons of large cortical networks across arousal states.

Title: Changes in the functional geometry of human cortical networks across arousal states

Authors: *B. M. KRAUSE[1], D. I. CAMPBELL[1], C. K. KOVACH[2], R. N. MUELLER[3], M. E. DYKEN[4], H. KAWASAKI[2], K. V. NOURSKI[5], M. I. BANKS[1];

Abstract: Introduction: Leading theories of consciousness predict that loss of consciousness (LOC) under sleep and anesthesia is precipitated by reorganization of brain networks critical for consciousness. Diffusion map embedding (DME) maps data into a space in which distance represents similarity in connectivity to the rest of the sampled network, and has been used previously to demonstrate the hierarchical structure of cortical networks and to track changes in that structure in response to treatments, disorders, and aging. We investigated changes in cortical networks across arousal state using DME applied to functional connectivity derived from resting state intracranial electroencephalography (iEEG) recordings in neurosurgical patients.
Methods: Resting state intracranial recordings were obtained during induction of propofol anesthesia or during sleep from adult neurosurgical patients implanted with electrodes (propofol: n = 15 total; sleep: n = 13 total) in temporal, parietal, and frontal cortex to identify epileptic foci. Three arousal states were compared during anesthesia [pre-drug wake (WA), sedated/responsive (S) and unresponsive (U)] and five in sleep [wake (WS), N1, N2, N3, and REM]. Channel-by-channel adjacency matrices were computed as pairwise gamma (30-70Hz) orthogonalized power envelope correlations. Adjacency matrices were thresholded (top 33%) and normalized to yield the transition probability matrix **P**, which was analyzed using DME. The eigenvalue spectrum of **P** ($|\lambda_i|$) was used to calculate effective dimensionality (estimated as the quadratic entropy: $(\Sigma \lambda_i)^2/(\Sigma \lambda_i^2)$), a measure of network redundancy, and pairwise distances in the embedding space were calculated and compared across states.
Results: Embeddings in states involving reduced consciousness (U, N2, N3) had lower effective dimensionality than corresponding states (S/WA and N1/WS). REM sleep had similar effective

dimensionality to WS. Most node pairs showed reduced distances in the U, N2, and N3 states compared to S/WA or N1/WS, while there was little difference between WA and S, WS and N1, or WS and R. No individual brain region was responsible for these changes, suggesting a global rather than centralized functional reorganization with LOC. More variation in effective dimensionality was observed in U, N2, and N3.
Conclusions: The effective dimensionality of diffusion map embeddings robustly indexes changes in consciousness, and these changes occur across both sensory and higher-order brain regions. Variability of effective dimensionality may reflect fluctuations in arousal in states of reduced consciousness.

Title: Quantitative measures of task similarity to assess transfer in motor learning

Authors: L. NELSON[1], L. A. MROTEK[1], M. CASADIO[2], R. A. SCHEIDT[1], *R. RANGANATHAN[3];
[1]Marquette Univ., Milwaukee, WI; [2]Univ. of Genova, Genova, Italy; [3]Michigan State Univ., East Lansing, MI

Abstract: It has long been recognized that one of the fundamental aspects that influences transfer of motor skills is the similarity between the two skills. However, task similarity has been difficult to define quantitatively in most motor tasks, especially when they involve coordination of multiple degrees of freedom. The goal of this study was to examine the effect of task similarity on transfer of motor learning. We use a novel experimental approach that allows a clear quantitative measure of similarity between coordination patterns, based on the dimensional overlap of coordination patterns. Participants (N = 36) wore a data glove, and the 19 signals from the glove were linearly mapped onto the 2-D position of a cursor on a display screen. The participants were asked to move their fingers to guide the cursor to specific targets as quickly and accurately as possible. The coordination required to perform this task was critically dependent on the 'map' between the glove signals and the cursor motion. To examine transfer, we used a design where participants initially practiced different versions of the map (i.e., the 'prior' task) depending on group assignment. However, halfway through the experiment, all

participants switched to using a common map (i.e., the 'criterion' task). Participants were split into three groups based on the amount of overlap between the prior and criterion tasks - (i) 0% overlap, (ii) 50% overlap and (iii) 100% overlap. Participants performed a total of 480 trials (240 in the prior task, 240 in the criterion task), and a final block of 60 trials on a set of different targets to examine generalization. Results show that the amount of transfer to the criterion task was influenced by task similarity - i.e., the 0% overlap group showed the highest movement times in the criterion task when compared to the 50% or 100% overlap groups. Moreover, this difference between the 0% and 100% groups was seen until the end of the criterion task and in the generalization block, indicating that the interference from the prior task was prolonged. These results not only highlight the importance of task similarity, but also provide a way to systematically manipulate task similarity to fully understand its role in motor transfer.

Title: Bowing a re-strung violin: a real-world test of motor re-learning

Authors: *R. A. SCHEIDT[1], M. MORO[2,3], G. PILIA[2], E. LUDWIG[1], B. BRASCH[4], L. A. MROTEK[1], M. CASADIO[2], R. RANGANATHAN[5];
[1]Biomed. Engin., Marquette Univ., Milwaukee, WI; [2]Informatics, Bioengineering, Robotics and Syst. Engin., Univ. of Genova, Genova, Italy; [3]Ctr. for Machine Learning Genova (MaLGa), Genova, Italy; [4]Hartt Sch., Univ. of Hartford, West Hartford, CT; [5]Kinesiology and Mechanical Engin., Michigan State Univ., East Lansing, MI

Abstract: • Motor re-learning is central to performing arts, athletics and movement rehabilitation after neuromotor injury. Motor re-learning involves reorganizing movement coordination patterns to find alternate solutions in the presence of a previous solution. We partnered with the Chicago Suzuki Institute to explore how task similarity influences motor re-learning in the context of violin bowing, a skill that requires many hours of practice to learn. We used violins with either a standard string arrangement (CONTROL: G-D-A-E) or with 1 of 2 alternate arrangements (INVERTED: E-A-D-G; SHUFFLED: A-G-E-D) to explore re-learning of a familiar motor task. Whereas INVERTED and SHUFFLED violins are both novel, only the

INVERTED and CONTROL violins share identical neighbor relationships between the strings, making them more similar. The SHUFFLED violins shares no neighbor relationships with either the CONTROL or INVERTED violins.
• 51 participants with prior experience playing the violin repeatedly played a 13-note G-scale arpeggio at 140 beats/minute. The first 10 arpeggio trials were performed with a CONTROL violin ("baseline"). The next 30 "test" trials were performed with either an INVERTED (N=19 participants), SHUFFLED (N=21), or CONTROL violin (N=11). The last 10 "washout" trials were performed with the CONTROL violin. We recorded audio at 10000 samples/s and analyzed 3 performance measures (number of notes played per trial; accuracy and variability of note timing) to test the hypothesis that the rate and extent of motor re-learning depend systematically on the degree of similarity between the prior (CONTROL) and novel (INVERTED or SHUFFLED) tasks.
• The INVERTED and SHUFFLED groups demonstrated motor re-learning for each of the 3 dependent variables. Average performances in the first 5 trials of the test block were more highly degraded in SHUFFLED vs. INVERTED, which were in turn worse than CONTROL. By the end of the test block, SHUFFLED still attempted more notes and played them more unevenly than either INVERTED or CONTROL groups, which did not differ from each other. We conclude that the rate and extent of motor re-learning does indeed depend on the degree of similarity between novel and prior tasks. Interestingly, the INVERTED group increased the mean number of notes across the first 5 test arpeggios whereas performance for the remaining test arpeggios declined back toward baseline values, suggesting that participants likely used a pattern of exploration and exploitation to solve the re-learning problem posed by the manipulated violins.

Title: Lack of beneficial effects of moderate-intensity aerobic exercise on visuomotor adaptation and savings

Authors: *R. JAMES, J. WANG;
Univ. of Wisconsin, Milwaukee, WI

Abstract: Acute exercise performed prior to training is thought to have a positive impact on motor skill acquisition and memory retention. In young adults, exercise is linked with biological and behavioral changes due to increased cortical excitability via long-term potentiation (LTP)-like mechanisms. It has also been shown that a single bout of moderate-intensity aerobic exercise can enhance visuomotor adaptation, though not interlimb transfer (Neva et al. 2019). However, the effects of a single bout of moderate-intensity aerobic exercise on aftereffects and savings (faster when individuals are re-exposed to a previously experienced condition) following visuomotor adaptation are unknown. In this study, thus, 16 neurologically intact right-handed young adults completed two conditions (25 minutes of rest and cycling counterbalanced across subjects) on two separate days with a minimum washout period of 14 days between the two conditions (rest vs. exercise). The exercise or rest condition was followed by an adaptation session with the right hand, in which the visual display was rotated 30° counterclockwise about the start circle; then it was followed immediately by washout and readaptation sessions with the same arm. Results indicated similar patterns of adaptation, aftereffects, and savings between the two conditions. These findings suggest that a single bout of aerobic exercise (cycling) before visuomotor adaptation may not be sufficient to enhance visuomotor adaptation or savings in young adults. Further work is needed to determine the effects of aerobic exercise on visuomotor adaptation.

Title: Bayesian statistical modeling of the relationships between error size, proprioception, and the magnitude of implicit adaptation

Authors: *H. E. KIM[1], J. S. TSAY[2];
[1]Univ. of Delaware, Newark, DE; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Bayesian statistics provides a unified framework for combining prior knowledge with data in order to compute joint probability distributions of different world states (i.e., conjectures). Unlike frequentist statistics, Bayesian methods can readily quantify support for null hypotheses and be combined with graphical models to aid causal inference. Here, we leverage these two advantages of Bayesian statistics to reanalyze, and reinterpret, some of our recent published studies on implicit motor adaptation. We recently reported that implicit motor

adaptation in reaching converged to a common asymptote in response to a wide range of error sizes (1.75° - 15°) (Kim et al 2018). Instead of a dose-dependent response, group-averaged motor aftereffects in response to these errors fell within a surprisingly narrow range of 23°-27°, with no reliable differences detected by a frequentist ANOVA. While originally interpreted as evidence of convergence in asymptotic adaptation, upon re-analyzing these data using a Bayesian linear model with weakly informative priors, only 39-49% of the credible differences in asymptotic adaptation fell within a region of practical equivalence (ROPE) of ±3°. That is, while our Bayesian re-analysis revealed only small expected differences in the asymptotic levels of adaptation (1.2° - 3.4°), due to high uncertainty around these estimates there was slightly more evidence for divergence than convergence in asymptotic adaptation, contrary to our original interpretation. We also recently reported a novel link between measures of proprioception (variability and recalibration) and implicit adaptation (Tsay et al 2021). When re-analyzing these data using directed acyclic graphs and Bayesian regression models, we found strong relationships between both proprioception variables with the asymptotic level of adaptation, with over 99% of credible slope estimates having non-zero values. The results of our analyses bolster our original claim and imply a causal relationship between proprioception and the extent of implicit adaptation. Taken together, our application of Bayesian statistics has sharpened our inferences regarding previously published results and demonstrated the merits of this approach in assessing the credibility of different hypotheses. The clear alignment between research question and inference that Bayesian methods afford motivate moving beyond frequentist null hypothesis testing and p-values.

[3]Pediatrics, Sherbrooke Univ., Sherbrooke, QC, Canada

Abstract: Although overlearning (i.e. extending practice at performance asymptote) has been known to enhance retention (Postman, 1962), most studies have examined its effect on retention (Krueger, 1929; Rohrer et al., 2005) or subsequent learning of a different task (A->B; Shibata et

al., 2017). The latter argues that practice at performance asymptote increases neural inhibitory activity, stabilizing and protecting the newly acquired memory but more importantly, making the system refractory to subsequent learning (i.e. detrimental effect of prior learning on future learning; A->B). Interestingly, recent work from our laboratory (Hamel et al., 2021) reported that, if constrained into a close temporal window, learning twice the same task (A->A) also leads to anterograde interference. This leads to a re-evaluation of the classic finding that exposure to a perturbation necessarily leads to faster re-adaptation the second time (i.e. savings; Krakauer, 2009). The objective of this work was to elucidate if increasing the duration of practice would increase savings and lead to faster re-adaptation, or on the contrary would increase the degree of anterograde interference. In a fully within-subject and counterbalanced design, four conditions were carried out where participants (n = 24) adapted to a gradually introduced 20° visual deviation while the length or type of the performance asymptote were manipulated. The performance asymptote at 20° was either Short (40 trials), Moderate (160 trials), Long (320 trials) or kept on changing around 20° for 160 trials (Jagged). Following a 2 min break, participants adapted to the same visual deviation and practiced at performance asymptote for 40 trials. Immediate retention was assessed through reach aftereffects in the absence of corrective visual feedback. Results revealed that increasing the duration of asymptote enhanced immediate retention. Interestingly, however, increasing the duration of asymptote from Short to Moderate also increased anterograde interference. There was no difference between Moderate and Long, suggesting the presence of a ceiling effect. One interpretation is that the increased anterograde interference is prompted by the accumulation of adenosine due to the energy consuming metaplasticity of sensorimotor adaptation.

Title: Static and dynamic gaze states are separately linked with motor learning of reaching movements

Authors: *N. ABEKAWA, H. GOMI;
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: Learning novel motor actions depends on forming and updating internal models. It has been a critical issue in neuroscience how the brain represents internal models with regard to their

association with spatial frames. We recently used a context-dependent learning paradigm to examine the involvement of gaze-related spatial coding in the learning of reaching movements (Abekawa et al. 2019, SfN Abstract). We focused on two types of eye-hand coordination: reach to a target while looking at the target (Foveal-reach: FOV) and while looking elsewhere (Peripheral-reach: PER). The results revealed that two opposing motor skills (e.g. different visuomotor rotations) can be learned simultaneously, which usually interfered with each other, when each skill was associated with FOV and PER. This suggests that there is a link between static representation about eye-hand coordination and internal models of reaching. Meanwhile, reaching movements are usually accompanied with eye movements in our natural behaviors. Here we investigated whether such dynamic chain of eye-hand movements is engaged in the learning of reaching. In the experiment, participants (n=12) performed reaching movements under three different eye-hand conditions presented randomly across trials. In the first two static conditions, as in our previous study, participants reached to the target while looking at a fixation point (FOV and PER). In the last dynamic condition, the trial started in the same way as in PER, but the fixation jumped to the target location before reaching was initiated. Participants had to make a saccade as quickly as possible, and then perform FOV (Sac-Reach). We applied visuomotor rotation with its direction varied across trials, but was uniquely associated with the static or dynamic condition. For half of the participants, CW rotation was applied in FOV and PER, and CCW rotation was in Sac-Reach (For the other half, CCW was in FOV and PER, and CW was in Sac-Reach). The results showed that in all three conditions, the reaching error decreased throughout the training session (1200 trials), with clear aftereffects in the post-learning session where the rotation removed. The control experiment, in which the fixation jump was given without making saccades, showed no progress in learning, especially for the Sac-Reach condition. These results indicate that saccade before reaching can work as the context for motor learning. Taken together, static and dynamic gaze states that are chained with reaching behavior would activate distinct neural states in the sensorimotor pathway, which can be inherently linked with forming and retrieving internal models of reaching.

Title: Contextual interference in implicit sensorimotor adaptation

Authors: *C. IRVING, R. IVRY, J. S. TSAY;
Univ. of California, Berkeley, Berkeley, CA

Abstract: A widely observed phenomenon in skill acquisition is the contextual interference effect: motor skills are learned slower but show better retention when learning takes place under a random practice schedule compared to a blocked practice schedule. A common account of contextual interference is that random practice engages greater attentiveness and more deliberate top-down control, leading to more elaborate and accessible memories. Whether the principles of contextual interference are relevant for implicit sensorimotor adaptation remains unknown.
To explore this question, we used a method that isolates implicit motor adaptation (clamped feedback task), instructing participants to reach to one of three target locations, each paired with a different sized visual clamp, feedback in which the radial position was aligned with the hand but angular position that was rotated by a constant 30º, 45º, or 60º from the target. Participants were divided into two groups: Random Training in which reaches to the three targets were interleaved in a single block of 270 trials, or Blocked Training where each target was tested in a serial manner across three blocks of 90 trials each. Retention was assessed in a no feedback washout block in which, for both groups, the three targets were interleaved. Consistent with previous studies, participants exhibited an implicit and gradual drift in hand angle in the opposite direction of the visual error. The magnitude of this effect was approximately 20 degrees and near asymptotic value by around 100 trials for the Blocked group and 180 trials for the Random group (per target location). A pronounced contextual interference effect was found: Random Training led to slower changes in hand angle during the training block yet a larger aftereffect in the washout block.
Randomizing the targets in the washout phase introduces a context change for the Blocked group. To assess the relevance of this factor, we conducted a second experiment in which the targets were blocked in the washout block. The magnitude of the aftereffect decreased for the second and third locations probed, presumably due to passive decay. Nonetheless, the retention advantage persisted for the Random training group. In a final experiment, aftereffects were probed after each training block in a Blocked group and compared to the aftereffect probed at the end of a single training block for a Random group. Again, random training led to stronger aftereffects.
These results demonstrate that the principles of contextual interference are not only applicable to the development of motor skills demanding explicit control, but also extend to the way we implicitly recalibrate our movements.

Title: Online control influences visual and proprioceptive contributions to motor adaptation

Authors: *A. HOFFMANN[1,2], F. CREVECOEUR[1,2];
[1]Inst. of Information and Communication Technologies, Electronics and Applied Mathematics, Univ. Catholique De Louvain, Louvain-la-Neuve, Belgium; [2]Inst. of Neurosci., Univ. Catholique de Louvain, Brussels, Belgium

Abstract: To date, little is known about how the brain integrates multisensory signals in dynamic contexts, such as during a movement. Here, we investigated the contribution of visual and proprioceptive error feedback as well as their potential interaction on online control and motor adaptation in two frequently used reaching paradigms. We conducted two experiments (N=14 and N=19) on healthy volunteers aged 20 to 34. Participants performed visually guided reaches with a robotic manipulandum while their arm was hidden from view. We randomly applied clockwise or counterclockwise velocity-dependent force-fields in combination with visual cursor shifts. These perturbation trials were interleaved with baseline trials to measure single-trial adaptation by extracting the amplitude of the after effect in the baseline trials. Importantly, to investigate the influence of online control on adaptation we additionally manipulated the instruction to participants asking them to either correct or not correct their movement when encountering a perturbation. We recorded movement kinematics as well as EMG signals from shoulder and elbow muscles. For our analyses we defined proprioceptive error and adaptation as the maximum limb displacement on perturbation and subsequent baseline trials, respectively. The size of the visual error was quantified as the gain applied to shift the visual cursor relative to the true hand position. We observed a scaling of muscle responses with the size of the visual error resulting in a decrease of proprioceptive error with increasing visual error. Using a linear mixed effect analysis, we further found that adaptation was negatively related to the size of the proprioceptive error but showed no consistent relationship with visual errors across the two experiments. Visual and proprioceptive errors exhibited no interaction in their contribution to adaptation. Importantly, in the second experiment we observed an influence of the task instruction on the relationship between sensory errors and adaptation. Our results demonstrate that the interplay between different sensory errors shapes feedback responses during a movement which in turn influences how errors are mapped into updates for the next trial. Thus, explaining the integration of multisensory signals for motor adaptation requires close attention to how task instructions influence participants' engagement with different sources of sensory feedback. Ultimately, understanding if and how sensory integration rules differ between online control and adaptation will be an important step towards extending models of multisensory integration to dynamic contexts.

Title: The influence of action observation on fast feedback control

Authors: N. MANGOS[1], *C. FORGAARD[1], A. PRUSZYNSKI[2], P. L. GRIBBLE[1];
[1]Brain and Mind Inst., [2]Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: Many sensorimotor areas of the brain are engaged while watching others move. This "action observation network" underlies an important mechanism by which humans often learn motor skills: through the observation of a tutor (Mattar & Gribble 2005). Studies to date have focused on how movement observation influences voluntary (feedforward) movement control. Here we tested whether movement observation also influences feedback-based control. When external forces (mechanical perturbations) are abruptly applied to the arm, short- (SLR; 20-50 ms) and long-latency (LLR; 50-100 ms) feedback responses are elicited in the stretched muscles. While the SLR is generated purely by spinal circuitry, the LLR is produced by a transcortical pathway involving primary sensorimotor cortex (Pruszynski et al. 2011). Due to the cortical contributions, the LLR displays many similarities with feedforward control (Forgaard et al. 2021). The purpose of this study was to test whether action observation can also influence the LLR. Sixteen participants performed reciprocal elbow flexion/extension (30 deg) movements in a horizontal plane with strict timing constraints (0.83–1 Hz) using a KINARM exoskeleton robot. Participants then observed a video of an expert performing the same task. During observation participants maintained their right hand in a home target against small background loads that pre-activated elbow flexor (biceps and brachioradialis) or extensor (triceps) muscles. At two different time points in the expert's movement cycle (peak elbow flexor and peak elbow extensor activity), unpredictable torque perturbations were applied at the elbow joint to evoke feedback responses in participants' elbow muscles. Participants were instructed to not intervene in response to the perturbations and to remain focused on the video. The mechanical perturbations successfully evoked an SLR and an LLR in elbow muscles; however, compared to a control condition in which participants observed the expert sitting still with no movement of their arm, neither the SLR nor the LLR was facilitated by observing the expert moving. We did observe a 12% decrease in the brachioradialis LLR at the time point in the video when the expert's antagonist muscle (triceps) was most active, compared to the static control condition. These preliminary findings thus suggest that action observation has a negligible or a weak inhibitory influence on feedback responses.

Title: Transfer of implicit perceptual-motor sequence knowledge across spatially-unique cue colors and shapes

Authors: *P. SHU, R. CHEN, Y. HAN, C. MCROBERT, P. REBER;
Northwestern Univ., Evanston, IL

Abstract: Implicit learning, which is considered fundamental to skill acquisition, has been demonstrated to be largely inflexible. When knowledge acquired in one context cannot be expressed when perceptual conditions have been altered, we infer that these perceptual elements have become part of the learned, inflexible representation.Here we report studies measuring transfer across changes in cue color and shape within a perceptual-motor sequence learning paradigm, the Serial Interception Sequence Learning (SISL) task. In the SISL task, moving cues scroll down the screen to signal a precisely-timed motor response corresponding to the spatial location of the cue. Participants learned a covertly-embedded 12-item sequence during training before completing a test of sequence knowledge under the same condition and transfer conditions. Transfer conditions only changed perceptual aspects of the moving cue irrelevant to the motor response and the motor sequence was constant across all test conditions. In Experiment 1 (n=30), participants completed four blocks of training with one cue shape (circle or square) for all four locations and then completed tests with the trained cue shape, untrained cue shape, and four novel, unique shapes. Robust transfer to the novel shape conditions was observed , indicating that cue shape was not seemingly part of the sequence representation .In Experiment 2 , participants practiced the repeating sequence with either four different cue colors (n=30) or shapes (n=25), each assigned to a specific spatial location. Transfer of sequence knowledge was tested with four completely novel spatially-unique colors/shapes or with the same trained colors/shapes re-assigned to different locations. Transfer was particularly impaired when the trained colors/shapes were re-assigned, $F(2,106)=10.82$, $p<.001$, indicating significantly less expressed sequence knowledge when the specific association between perceptual elements and spatial locations was disrupted at test. The results of the second experiment indicate that when color or shape are uniquely associated with spatial location, this perceptual information becomes part of the sequence representation and interferers with transfer when the cue location is re-associated with a novel feature during test. In contrast, when the color/shape is consistent across locations during training, sequence knowledge can fully transfer to novel perceptual conditions.

This implies that there is no simple rule for what context features become part of the learned representation but rather that implicit learning is sensitive to whether perceptual information is predictive of cued responses.

Title: Examining the time course of forgetting for implicitly learned auditory perceptual-motor sequence knowledge

Authors: *Y. C. HAN, P. J. REBER;
Northwestern Univ., Evanston, IL

Abstract: Implicit statistical knowledge, which is thought to underlie skill learning, has been demonstrated to be resistant to forgetting over time and may be forgotten more slowly. Compared to the well-studied explicit forgetting curve, which demonstrates a steep exponential decline over time, the rate at which implicit memory decays is hypothesized to follow a similar, though shallower, decay curvature. Implicit knowledge retention has primarily been studied in visually-based implicit learning paradigms. Here, we report a study providing a quantitative measurement of the forgetting curve for an auditory-based implicit learning task, which may provide insight into memory decay associated with domains such as statistical aspects of language. To measure the rate at which auditory implicit knowledge decays, we utilized the auditory Serial Interception Sequence Learning (SISL) task, which produces a robust, quantitative, implicit learning signal that allows for measuring performance across a range of time points after acquisition. Auditory cues signaled precisely-timed motor responses based on cue pitch, with keys D, F, J, and K mapped to distinct starting frequencies. Motor responses were timed to the third onset of a three-cue sequence. During training, participants were not informed that there was a covertly embedded repeating sequence of tones (80% of trials). Knowledge of this sequence was quantitatively assessed during a test (33% sequence; 67% foils) by the increased task accuracy for cues within the repeating sequence over foils (SSPA). After completing a training and test phase, participants were randomly assigned to complete a second test after delay periods of 11 hours (n=20), 24 hours (n=17), or one week (n=21). Group-level retention of sequence-specific knowledge was measured as the percentage of SSPA retained

from first to second test for participants who demonstrated robust learning during the first session. A linear regression indicated log-transformed hours significantly predicted retention amount ($F(1,57)=20.6$, $p<.001$, $R2=.25$) across delay intervals (11h, M=73.5%, SE=17.1%; 24h, M=45.9%, SE=11.6%; 1 week, M=63.9%, SE=11.3%). The regression-estimated log-linear implicit forgetting rate follows a fairly shallower curve (slope = -9.6%), suggesting that implicit knowledge decays at slower rate and would persist potentially for years. The forgetting rate for implicit learning estimated here was considerably shallower than classic studies of explicit forgetting (e.g., Ebbinghaus, 1885, log-linear slope = -12.4%), consistent with our hypothesis that implicitly acquired knowledge decays much more slowly than explicit memory.

Title: Audiomotor adaptation

Authors: *B. MILLER-MILLS[1], K. MCANALLY[2], L. LEOW[3], B. F. KEANE[3], P. GROVE[4], T. J. CARROLL[3];
[1]Sch. of Human Movement and Nutr. Sci., Univ. of Queensland, Brisbane, Australia; [3]Sch. of Human Movement and Nutr. Sci., [4]Sch. of Psychology, [2]The Univ. of Queensland, Brisbane, Australia

Abstract: Sensorimotor adaptation has been extensively studied in the visual domain, but the degree to which altered sensorimotor mappings occur in modalities other than vision remains less well understood. Here we manipulated the modality of stimulus presentation to compare motor updates in response to perturbations of visual and auditory feedback location. We compared a) the extent of learning from perturbed sensory feedback for the visual and auditory sensory modalities and b) the magnitude of reach direction aftereffect when the perturbation was removed. Errors related to violations of expected sensory outcomes (sensory prediction errors), as well as errors related to the successful completion of a clearly defined goal (task errors), have been shown to drive motor adaptation. Thus, in order to isolate the contribution of sensory input during motor adaptation, we held sensory prediction errors and task errors constant via a task-irrelevant clamp of sensory feedback. In this paradigm, visual or auditory feedback of the reach endpoint was systematically displaced, but participants were informed of the perturbation and instructed to ignore it and reach directly toward the target. These experiments involved target

and reach angle feedback presented by loudspeakers (Experiment 1), headphones (incorporating head-related transfer functions) (Experiment 2) and a visual display (Experiment 3). Although we appropriately matched auditory location cues between the loudspeaker and headphone conditions, participants of the loudspeaker condition showed substantially greater reach accuracy than participants of the headphone condition during a familiarization block where reaches were made to seven targets separated by 20 degrees. The headphone condition also showed greater adaptation with respect to baseline than the loudspeaker condition (Exp 1 M = 4.4° ± 9, Exp 2 M = 16° ± 21.6). In Experiment 3, the visual stimuli were presented under conditions similar to those of the auditory experiments; participants saw only a transient visual cursor following a given reach displayed in either the target location or the perturbed location. Consistent with our predictions and previous literature, a significant change in reach direction was observed (Exp 3 M = 3.1° ± 4.8), with an aftereffect that persisted when participants were instructed that the perturbation had been removed. This study provides new evidence that motor adaptation occurs in response to perturbed feedback of reach endpoint across sensory modalities. It remains an open question if these visual and auditory motor adaptations are dependent upon underlying processes that are shared or independent.

Title: Error related potentials in response to erroneous movements generated by Brain Computer Interfaces for hand control

Authors: I. DEMCHENKO, M. BENYAMINI, *M. ZACKSENHOUSE;
Tech. IsraelInstTech, Haifa, Israel

Abstract: Background: In recent years, brain computer interfaces (BCIs) studies and applications, which provide direct communication between the brain and the computer, have grown rapidly. A widely used technique for measuring brain activity is electroencephalogram (EEG). EEG is a relatively inexpensive, easy to use, and provides a high-temporal resolution. BCI for closing\opening the hand are very important for comfortable and intuitive brain-controlled hand prosthesis and may help 3 million upper limb amputees worldwide. Recently it

has been shown that Error related potentials (ErrP), which are evoked as a reaction to erroneous hand movements significantly improve the final decision of a movement.
Methods: Here we investigate ErrPs in response to different erroneous BCI decisions of closing\opening hand.
Experiment design: Participants controlled two virtual hands that appeared on a computer screen by moving their hands (hand control). The posture of the hand was determined by bend-sensitive sensors embedded in the gloves wore by participants. A ball was places in front of each virtual hand and participants were asked to close/open their hands if the color of the ball changed from red to green or from green to red, respectively. Participants were asked to maintain the hand posture if the color did not change. Data collected during hand controlled was used to train a convolutional neural network (CNN) BCI-classifier, which was used to control with virtual hands in the second part of the experiment. The experiment was designed to investigate the response to three types of errors: 1. Virtual hands-maintained posture even though participant changed the posture of one hand. 2. Virtual hand changed posture even though participant-maintained hands' posture. 3. The wrong virtual hand changed posture.
Results: The accuracy of the CNN-based BCI classifier for 3 different options (change the posture of the right or left hand, or maintain posture) was between 50 to 60 % for all participants. The three types of errors evoked ErrPs with different amplitudes, with largest amplitude in response to the second error-type and smallest for the first error-type.
Conclusions: ErrPs can be detected while using EEG-based BCI to control hand closing/ opening. ErrPs evoked in response to different error-types have different latency and amplitudes.

Title: A nonlinear body machine interface for controlling assistive robotic arms

Authors: F. RIZZOGLIO[1,3], M. GIORDANO[2], ***F. A. MUSSA-IVALDI**[3], M. CASADIO[4]; [2]DIBRIS, [1]Universita` di Genova, Genova, Italy; [3]Northwestern University/Shirley Ryan Ability Lab., Chicago, IL; [4]Univ. of Genova, Genova, Italy

Abstract: One of the consequences of spinal cord injury is the loss of the ability to coordinate body motions and perform functional movements. Common activities, such as grooming and object manipulation, could be facilitated through the use of assistive robotic manipulators. However, designing interfaces for controlling such devices can be challenging when dealing with the control of many degrees of freedom (DoFs). Here, we propose an approach based on the framework of body machine interfaces (BoMIs). BoMIs exploit the fact that, even after a severe injury, most individuals retain the ability to perform some movement, especially with their head and shoulders. These residual movements, can be used to control external devices. BoMIs typically rely on Principal Component Analysis (PCA) to extract the lower dimensional control space from information in voluntary movement signals, such as as body kinematics and muscle activity. Despite its widespread use, PCA might not be suited for controlling devices with a large number of DoFs, as the variance explained by successive components drops precipitously after the first. As a consequence most signal information is captured by the first two to three PCs.Here, we propose the use of non-linear autoencoder (AE) networks to overcome these difficulties. Not only non-linear AEs are able to estimate the dimensionality of their input more parsimoniously than PCA, but their structure can also be customized to obtain a variance that is more uniformly distributed across its latent dimensions. The hypothesis of this study is that the customizability offered by AEs makes them an ideal candidate for operating devices with more than two DoFs, such as an assistive robotic arm.To test this hypothesis, we developed a BoMI based on non-linear AEs that mapped kinematic signals recorded from the participants' upper arms into joint angles of a 4D virtual robotic manipulator. First, we performed a validation procedure that aimed at selecting an appropriate AE structure that would allow to distribute the variance uniformly across the dimensions of the control space. Then, we assessed the users' proficiency practicing a 3D reaching task by operating the robot with the validated AE over the course of training across two non-consecutive days.All participants managed to acquire a high level of skill when operating the 4D robot as a consequence of training with the interface. Moreover, they retained the performance they had at the end of the first day while converging towards a more consistent solution over the course of training. We consider these findings as supporting a future implementation of our interface as an assistive tool for people with motor impairments.

Title: An adaptive sequence-based stimulus selection in ERP-based brain-computer interface by thompson sampling in a multi-armed bandit problem

Authors: *T. MA[1], J. E. HUGGINS[2], J. KANG[1];
[1]Biostatistics, [2]Physical Med. & Rehabilitation, Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Background: A P300 speller is a non-invasive communication tool for people with severe neuromuscular diseases. It displays a series of stimuli on the computer screen and searches for the elicited P300 event-related potential (ERP) response. The checkerboard paradigm (CBP) is a common stimulus presentation standard [1].
Although a few past studies have proposed data-driven methods for stimulus selection, they suffer from either the intractable decision rule, large computation complexity, or error propagation in real-time use. In addition, no methods have been applied to CBP directly.
Thompson sampling is a heuristic for sequential decision making that addresses the exploration-exploitation dilemma in the multi-armed bandit (MAB) problem. It chooses the optimal action by maximizing the expected reward function with respect to the posterior distribution of the parameters. This Bayesian-like procedure provides a natural framework for data-driven stimulus selection.
Method: We develop a sequence-based algorithm for adaptive stimulus selection by Thompson sampling in the MAB problem with multiple selections.
First, we use the CBP to specify a candidate set of stimulus groups of size 26, where the keyboard contains 84 keys. During each sequence, the algorithm selects a random subset of stimulus groups with fixed size by the posterior probability, aiming to identify all target stimuli and to improve the spelling speed by reducing non-target stimuli. We compute “clean” stimulus-specific rewards from raw classifier scores via the Bayes rule.
We perform simulation studies to evaluate our method, considering the ideal and the practical scenarios. We generate raw classifier scores from two normal distributions with different means but the same standard deviation and record the number of stimuli needed according to two separate criteria: 1) the probability of selecting all target stimuli exceeds 0.9 and, 2) the probability of the target character exceeds 0.9. We compare the results to the conventional offline design. For the practical scenario, we adapt our method to address the observational delay and the refractory effect in real-time BCI use.
Results: For all scenarios, the subset sizes were 3, 8, 13, and 26. In the ideal scenario, we needed 28, 35, 36, and 39 stimuli, respectively, to meet criterion one and 33, 43, 47 and 54 stimuli, respectively, to meet criterion two. In the practical scenario, we needed 33, 43, 141 and 143 stimuli, respectively, to meet criterion one and 36, 46, 148 and 157 stimuli, respectively, to meet criterion two.

Title: Improvement in motor function with combination therapy of Brain-Computer Interface based Electromagnetic Field Treatment with upper extremity physical therapy in people with chronic cervical spinal cord injury.

Authors: *N. DATTA, D. C. CILIEN, D. CILIEN, K. L. GANT, D. W. DIETRICH;
The Miami Project To Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: In recent years modern, noninvasive brain stimulation (NIBS) techniques have been extensively explored in the arena of motor recovery and neuronal plasticity. However, as a subset of NIBS, electromagnetic field exposure (EMF), and especially extremely low-frequency electromagnetic field (ELF-EMF) exposure is a relatively unprobed field though studies suggest there are beneficial effects of EMF exposure in-vitro, animal models of CNS injuries, and even humans. There are hypotheses purporting regenerative effects of EMF on the spinal cord through modulation of neuroinflammation, stimulation of nerve regeneration, and mesenchymal stem cell proliferation. The aim of this study is to determine the safety and efficacy of a novel brain-computer interface (BCI) based electromagnetic field (EMF) treatment (BrainQ Technologies Ltd., Jerusalem-Israel) in improving function and self-care in persons with chronic SCI. 3 subjects with Chronic (1-year post-injury) Incomplete cervical spinal cord injuries (SCI) received 1 hour treatment sessions of ELF-EMF with BrainQ (thrice a week for 14 weeks) combined with upper extremity physical therapy (PT), after undergoing 4 weeks (12 sessions) of PT alone. Assessments including Graded Redefined Assessment of Strength, Sensibility and Prehension (GRASSP), Modified Ashworth Scale for Spasticity (MAS) and Spinal Cord Independence Measure (SCIM III selfcare) were administered at baseline (week 0), 2nd baseline (after 4 weeks of PT only), and at 4 weeks intervals till end of treatment (week 18 of study). At week 18 of study, analysis showed definite improvement in SCIM III selfcare score in all subjects (3 ± 1.69) with combination therapy as compared to no improvement with PT alone, especially in self-care activities like feeding, grooming and mobility. The change in GRASSP strength sub scores was variable for each subject over the course of the study. There was a gain in quantitative prehension sub scores in all 3 subjects both with PT alone (3± 4.58) and with combination therapy (2.3 ± 1.53) on the dominant side. No change in qualitative prehension or sensibility sub scores were noted either with PT alone or with combination therapy. There was a reduction in spasticity of the wrist in 2 subjects who presented with spasticity at baseline, both at the end of PT alone and after combination therapy. BCI-based EMF treatment in combination with PT is both safe and shows promise regarding improvement in fine motor skills as evidenced

by improvement in SCIM III scores. The ability to perform selfcare with little or no help will significantly improve the quality of life of persons with SCI and warrants further research into ELF-EMF based treatments.

Title: Toward High Gamma (70+ Hz) from Scalp Electroencephalography for Brain-Computer-Interface

Authors: *G. MILSAP, C. SCHOLL, W. COON, M. OGG, E. MCDOWELL, J. WATHEN, P. PERANICH, J. PITTMAN;
Johns Hopkins Univ. Applied Physics Lab., Columbia, MD

Abstract: Brain-computer-interfaces (BCI) that use scalp electroencephalography (EEG) typically operate on signals with <40 Hz bandwidth. This may be due as much to tradition as it is to a number of real limitations, inherent in the physics of EEG signal acquisition, that make higher frequency content less salient. High frequency activation (>70 Hz broadband activity, a.k.a. “high gamma”) was discovered around the turn of the century within electrocorticographic (ECoG) recordings and continues to be one of the most useful neural features in these datasets. While high gamma activity can be easily observed within streaming ECoG data, in some cases without the need for any trial averaging, the signals are very difficult to record at the scalp due to the low signal-to-noise ratio (SNR) of high gamma in traditional EEG recording setups. In a 2008 article, Ball et. al. performed experiments designed to elicit well-characterized and spatiotemporally constrained high gamma activation across many trials recorded in a shielded environment, and demonstrated that high gamma activity is present at the scalp, albeit more spatially distributed and at significantly reduced SNR. The research performed here is an effort to understand the sources of noise that diminish the presence of high gamma at the scalp, and additionally to explore modifications to traditional scalp EEG to optimize detection of high gamma activity at the scalp with less integration time (fewer trials). The ability to distinguish high gamma activity with short integration times may facilitate next-generation BCI technology

based on scalp EEG, which remains one of the least expensive and most extensible non-invasive neural recording modalities. In this research, we characterized the amplitude of task-based high gamma modulation at the scalp, the noise floor present in the recordings, the various sources of noise present in shielded and unshielded environments that contaminate the high gamma frequency range, and iterated our recording technique and post-processing to achieve a modest gain in high gamma SNR at the scalp. We describe our methods and custom recording apparatus, as well as suggest some of the fundamental limitations and alternative approaches to recording high gamma from electrodes on the scalp.

Title: A hybrid approach for ERP and ERDS in motor imagery BCI

Authors: *D. GWON[1], M. AHN[2];
[1]Handong Global Univ., Pohang-Si, Gyeongsangbuk-Do, Republic of, Korea, Republic of;
[2]Computer Sci. and Electrical Engin., Handong Global Univ., Pohang, Korea, Republic of

Abstract: A motor imagery (MI) is an imagination of movement and known as producing power change at certain frequencies (e.g., alpha, beta and gamma) which is called event related (de)synchronization (ERD/S) [1]. Since different body limbs involve with different spatial patterns in the brain, this feature is used in building a Brain-Computer Interface (BCI) that decodes user's intention. Indeed, most algorithms in MI-BCI are designed to focus this feature. However, only a few studies pay attention to the lower frequency which may be related to event-related potential (ERP). In this study, we investigate the existence of ERP in motor imagery data and propose a hybrid approach to use both ERP and ERD/S features in classification of motor imagery types (left and right). ERD/S features from common spatial pattern (CSP) [2] and ERP features from Stepwise regression were combined and fed into a linear discriminant analysis (LDA). The average classification accuracy was obtained by 10x10 fold cross validation technique. For this study, we used an open electroencephalogram (EEG) dataset (64 channels, sampling rate 1000 Hz) recorded from 54 subjects [3]. Each subject conducted two motor imagery sessions. As a result, we found the presence of ERP by motor imagery and further the

different spatial pattern of ERP according to imagery types. ERP is likely to be stronger and faster at C3 channel during left MI. This pattern was also observed at C4 during right MI. Statistical test revealed that this spatial difference is significant (Student's T test, Bonferroni correction $p < 0.05$). In the classification analysis, the proposed hybrid approach shows 79.43/80.13% (session 1 and 2 respectively), which were statistically higher (Student's T test $p < 0.05$) than the conventional methods (CSP+LDA: 73.84/75.49% and ERP+SWLDA: 67.08/68.23%). In conclusion, ERP is also important feature to understand motor imagery process and this feature should be included in building an advanced MI BCI. [1]G. Pfurtscheller and F. H. Title: Target-related alpha attenuation in a brain-computer interface (BCI) rapid serial visual presentation (RSVP) calibration task

Authors: *D. KLEE[1], T. MEMMOTT[2], B. S. OKEN[3];
[1]Neurol., [2]Neurol. & Inst. on Develop. and Disability, Oregon Hlth. & Sci. Univ., Portland, OR; [3]Neurol. & Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Brain-computer interfaces (BCIs) are systems designed to leverage neurophysiological signals to assist users with various tasks, including communication and movement. It is well-established that amplitude of EEG alpha-band activity is sensitive to a variety of cognitive and sensory processes. The objective of this exploratory study was to identify attention-related changes in posterior alpha amplitude following the presentation of target and non-target letter stimuli during a visual attention task as part of an extant BCI for communication (BciPy). EEG data were collected from healthy adult participants as they

completed multiple instances of a standardized rapid serial visual presentation (RSVP) calibration paradigm in BciPy. Recordings during the calibration sequence consisted of 100 randomized sequences of one target stimulus and nine non-target stimuli. Time-frequency analysis using continuous wavelet transformations showed a reduction in alpha amplitude approximately 400 ms following the onset of target stimuli. A paired-samples t-test confirmed a significant decrease in alpha amplitude following targets compared to non-targets ($p < .001$). Expected individual differences were observed in peak alpha frequency and average alpha amplitude. These results suggest that posterior alpha oscillations are good candidate signals for use in attention-based BCIs.

Title: Skilled independent control of individual motor units enabled by a non-invasive neuromuscular-machine interface

Authors: *P. BOTROS, E. FORMENTO, J. CARMENA;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Brain-machine interfaces (BMIs) have the potential to augment human functions and restore independence in people with disabilities, yet a compromise between non-invasiveness and performance limits their relevance. Here, we hypothesized that individual motor units of the same muscle can be independently controlled to an extent enabling high-performance BMI applications. Through a non-invasive neuromuscular-machine interface (NMI) providing real-time neurofeedback of motor unit activity, 8 participants learned to skillfully and independently control three biceps brachii motor units to complete a two-dimensional center-out task, with marked improvements in control over 6 days of training. Concomitantly, dimensionality of the motor unit population increased significantly relative to naturalistic behaviors, largely violating recruitment orders displayed during stereotyped, isometric muscle contractions. Finally, participants demonstrated the potential of such skilled motor unit control to power general applications by navigating a virtual keyboard in a spelling task. These results highlight a largely unexplored level of flexibility of the sensorimotor system and show that an NMI leveraging skilled independent motor unit control has great potential to enable a new class of devices that can both provide translational benefit and augment motor functions.

Title: Neural correlates of kinesthetic motor imagery during brain-machine interface training to control a walking exoskeleton

Authors: *K. NATHAN[1,2], A. KILICARSLAN[1], R. GROSSMAN[2], J. L. CONTRERAS-VIDAL[1,2];
[1]Univ. of Houston, Houston, TX; [2]Houston Methodist Res. Inst., Houston, TX

Abstract: Kinesthetic imagery is a subset of motor imagery that involves the feeling and perception of effort exerted during imagined movement, consequently invoking more motor-specific areas of the brain compared to purely visual imagery. It has been shown to be elicited even in patients with paralysis, thus making it a hypothetical control signal for intuitively controlling brain-machine interfaces (BMIs) for restoration of movement through cognitively-controlled robotic prostheses and orthoses. But we do not fully understand how the typical neural signatures of kinesthetic imagery are affected by long-term BMI training or how their representation may relate to BMI performance. Here we present results from a longitudinal BMI training paradigm with 7 able-bodied subjects to control the Rex lower-limb robotic exoskeleton. The paradigm consisted of nine sessions in which users developed their ability to use kinesthetic motor imagery to initiate the walking and stopping of the Rex's gait as a Go-NoGo task. The BMI consisted of active EEG with dynamic eyeblink and motion artifact removal processed through a Localized Fisher Discriminant Analysis dimensionality reduction and a Gaussian Mixture Model classifier on time-lagged delta band amplitudes. Subjects underwent a final session with simultaneous EEG-fMRI recording while watching video playback of themselves walking in the Rex performing the same motor imagery, allowing for fMRI-constrained source localization of the EEG. While BMI decoding for controlling the gait was variable among subjects, EEG and fMRI analysis revealed neural signatures for the kinesthetic imagery during the course of the training. The fMRI scans showed contrasts in activation between the Walk and Stop conditions localized in sensorimotor (SMA) and visual processing (IOG) areas associated with imagery. Offline EEG analysis identified the expected readiness potential negativity in response to the walk cue prior to movement onset overlying central motor channels, and a separate biphasic ERP response in posterior occipital channels. Localized EEG dipole sources

were found to be clustered within motor, visual processing, and prefrontal areas. Together, these results can be used to retune BMI decoders relying on kinesthetic imagery to better capture these features.

Title: Transcutaneous stimulation of the cervical spinal cord promotes recovery of upper limb muscle strength in tetraplegia

Authors: *S. CHANDRASEKARAN[1], R. RAMDEO[2], A. STEIN[3], D. GRIFFIN[3], S. J. HARKEMA[4], C. BOUTON[5];
[1]Feinstein Inst. for Med. Res., Manhasset, NY; [2]Feinstein Inst. for Med. Res., New York, NY; [3]Northwell Hlth., New York, NY; [4]Dept Neurol Surgery, Univ. Louisville, Frazier Rehab Inst, KSCIRC, Louisville, KY; [5]Ctr. for Bioelectronic Med., The Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: Spinal cord injury (SCI) affects approximately 18,000 individuals every year in the United States, with over half of the cases resulting in upper limb impairment. Most persons with tetraplegia rank regaining hand function as being of utmost importance. However, functional recovery after SCI tends to plateau beyond 12-18 months post-injury. Therefore, bringing about long-lasting recovery of upper limb function is a priority in SCI clinical research. It has been shown that epidural lumbar spinal cord stimulation can help restore lower limb movement in humans. Recently, this has also been shown for the upper limb with epidural spinal cord stimulation at the cervical level in primates. However, persistent stimulation of the spinal cord is typically required to evoke movements of the paralyzed limb. Thus, long-term restoration of volitional control of movement is yet to be achieved. Recently, transcutaneous spinal cord stimulation (tSCS) was used to promote long-term recovery of function of the upper-limb in people with motor-incomplete spinal cord injury. With the aim of promoting such recovery of function, we targeted transcutaneous stimulation to the cervical spinal cord in two participants with C4/C5 motor complete spinal cord injuries. We combined physical activity of muscles with spinal cord stimulation. As a proof of concept, we assessed the progress of strength of a muscle for which the participants retained some residual level of volitional control of movement, namely the triceps. In this study, we delivered constant stimulation to the cervical spinal cord for approximately 1-2 hours per session, one session per week while the participant performed

moderate physical activity targeted to the muscle. In two patients with tetraplegia, we show up to 200% increase in the force generated by upper arm muscles within 3 months of starting stimulation. Interestingly, the participants maintained this gain in strength even when stimulation sessions of stopped for up to 6 weeks. We also observed up to a 2-point increase in the sensibility component of the GRASSP test in most areas of the hand. In future experiments, we intend to pair tSCS with user intent conveyed by gesture control for recovery of function of the hand.

Title: Connectivity and Neuroanatomy of the Orofacial Motor Cortex and the Laryngeal Motor Cortex for Vocal Modulation in Mice

Authors: *R. AGRAVAT[1], C. D. M. VARGAS[1], E. JARVIS[1,2];
[1]The Rockefeller Univ., New York City, NY; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Vocal communication is a complex behavior that can be innate or learned. In humans, learned vocalizations and speech are the basis of our spoken language, and is a rare behavior that has only been described in five groups of mammals (cetaceans, pinnipeds, elephants, bats, humans) and three groups of birds (songbirds, parrots, hummingbirds). All other species have been shown or assumed to be vocal non-learners. Songbirds have been the standard model of vocal learning, but they lack the experimental tractability found in other species. Recent work in mice, which are tractable and more closely related to humans, shows evidence of a rudimentary vocal plasticity system, including deafness induced vocal deterioration and a sparse direct projection from the motor cortex to the brain stem motor neurons controlling the larynx. This direct projection is thought to be fundamental to the ability to learn vocalizations and finely modulate vocal output. This direct projecting cortical region in humans has been termed the Laryngeal Motor Cortex (LMC). Here we found that the stimulation of the mouse rudimentary LMC and a more anterior Orofacial Motor Cortex (OFC) causes laryngeal muscle contractions with latencies indicative of both direct and indirect projections. We used retrograde and

anterograde viral tracers in the LMC and OFC regions and in vocal muscles. We found labeled neurons from the anterograde tracing experiments in areas such as the posterior portion of the primary motor cortex, dorsal and medial striatum, primary somatosensory cortex, ventral nucleus of the thalamus, hypothalamus, and pyramidal nucleus. Labeled neurons from the retrograde tracing experiments were identified in areas such as the secondary motor cortex, hypothalamus, periaqueductal gray, reticular nucleus, and facial nucleus. Results from these tracing experiments indicate that the two regions are distinct, parallel pathways that influence laryngeal and jaw muscles. The two regions may both act to coordinate vocal behavior through distinct but overlapping circuits.

Title: Enhancement of axon regeneration after peripheral nerve injury using the small molecule trkB ligand prodrug, R13.

Authors: *A. W. ENGLISH[1], D. CARRASCO[1], R. ISAACSON[1], D. HOFFMAN[1], X. LIU[2], K. YE[3];
[1]Cell Biol., [2]Pathol & Lab. Med., Emory Univ., Atlanta, GA; [3]Pathol & Lab. Med., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Axon regeneration after peripheral nerve injury is slow and inefficient, leading to generally poor functional recovery. Activity-dependent experimental therapies that increase expression of brain derived neurotrophic factor (BDNF) and its trkB receptor enhance regeneration, suggesting that treatments with BDNF might also be effective. However, recombinant human BDNF, as well as 7,8 dihydroxyflavone (7,8 DHF), a small molecule BDNF mimetic, may have limited treatment applications because of their modest oral bioavailability and a moderate pharmacokinetic profile. R13 is a 7,8 DHF prodrug. Upon oral administration it is converted in the liver to 7,8 DHF. A single oral treatment with R13 (43.6 mg/Kg) to a mouse immediately following sciatic nerve transection and repair produced increased trkB phosphorylation and phosphorylation of its downstream targets, AKT and MAP kinase, at the site of nerve injury. These increases lasted for more than four hours, an improvement in bioavailability over a comparable dose of 7,8 DHF. In thy-1-YFP-H mice treated daily with this

oral dose of R13 for two weeks following transection and repair of the sciatic nerve, regenerating axon profiles were more than three times longer than controls and significantly longer than in mice treated with 7,8 DHF. More than 40% of these axons were longer than the longest regenerating axon found either in controls or 7,8 DHF-treated mice. Direct muscle EMG responses (M waves) were significantly larger in R13 treated mice four weeks after injury than vehicle treated controls. Oral treatments with the pro-drug, R13, could be a potent therapy for stimulating axon regeneration after peripheral nerve injury.

Title: Explanatory Artificial Intelligence Uncovers Specific Response related White Matter Connectivity Surrounding DBS contacts in Parkinson Disease and Essential Tremor

Authors: *J. TORANZO[1], M. USCAMAYTA AYVAR[1], F. ARNEDO[2], G. POBLETE[3], R. SALAS[3], I. ZWIR[4], G. A. DE ERAUSQUIN[1];
[1]Glenn Biggs institute for Alzheimer's & neurodegenerative diseases, Univ. of Texas Hlth. San Antonio, San Antonio, TX; [2]Univ. of Granada, Granada, Spain; [3]Baylor Col. of Med., Houston, TX; [4]Washington Univ. in St. Louis, St. Louis, MO

Abstract: Deep Brain Stimulation (DBS) is a well established therapy for advanced Parkinson Disease (PD) and disabling Essential Tremor (ET), but clinical improvement after optimization of the surgical lead placement remains less than fully predictable and can only be established posthoc. Diffusor Tensor Imaging (DTI) tractography allows identification of white matter tracts surrounding active contacts using simulated models of the volume of tissue activated by the DBS current, but this methodology has not been broadly applied, and knowledge regarding the specific networks responsible for therapeutic response is very limited. Yet, recent work provides rationale for targeting networks rather than individual anatomic structures. We used explanatory Artificial Intelligence (xAI) to characterize white matter connections and recruited networks surrounding each active contact to identify connections resulting in greatest therapeutic response in a series of 40 patients who underwent DBS surgery for PD (20) or ET (20). Preoperative MRI

images were fused to postoperative high definition computerized tomography (CT) using Standard Parametric Mapping (SPM) and Advance Normalization Tools (ANTs). Following corregistration volumes were normalized using SPM12 segment nonlinear and Hybrid SPM and Brainsfit methods, and Brainshift Correction with Coarse Masks were applied. A fully automated method for electrode trajectory and contact reconstruction in deep brain stimulation was applied (PaCER), followed by localization, and volume of activated tissue (VAT) calculations (SimBio toolbox) for each of the 4 different settings of the stimulation parameters. Structural connectivity was calculated with fibertracking/normalization using the Generalized Q Sampling method, overlapped to parcellation schemes following Schaefer 2018 (1000 parcels. 17 networks). The connectivity network was characterized for each contact using outcome independent clustering (many to many relation analysis) of preoperative data. The fiber track files were analyzed using unsupervised machine learning techniques to identify groups of stimulations sharing particular fibers, specifically, a biclustering method based on Non-negative Matrix Factorization (NMF) identified 5 networks of white matter connectivity based on corresponding overlapping fibers in PD, and 3 in ET. The outcome information associated with each stimulation in the groups was later used to calculate the clinical response of each group. Networks uncovered are generally associated with better clinical responses, consistent with the good clinical outcomes with DBS, which were distinct for ET and PD.

Title: Identity of the hindbrain neurons activated by inflammation

Authors: *M. JALIL[1], T. COVERDELL[2], J. CAMPBELL[3];
[1]Univ. of Virgina, Charlottesville, VA; [2]Pharmacol., [3]Biol., Univ. of Virginia, Charlottesville, VA

Abstract: Inflammation in the body activates neurons of the dorsal vagal complex (DVC) in the hindbrain, some of which form a circuit for suppressing inflammation - the vagal anti-inflammatory reflex. This reflex circuit is being investigated as a treatment for diseases such as irritable bowel disease (IBS), rheumatoid arthritis, and acute kidney reperfusion injury. Yet, in spite of its clinical importance, little is known about the identity of the DVC neurons involved in the circuit. To identify these neurons, we analyzed co-localization of the neuronal-activation

marker, c-Fos (gene, Fos), with different neuronal subtype markers (Phox2b, Chat, Atf3) in DVC neurons in mice 90 minutes after acute treatment with a bacterial endotoxin, lipopolysaccharide (LPS; 5mg/kg, i.p.), or vehicle control. We found out that 70% of the c-Fos immunoreactive neurons were also positive for Phox2b when injected with LPS compared to 39% of the c-Fos immunoreactive neurons in the vehicle control. The total number of Phox2b-immunoreactive neurons in the DVC did not change significantly between treatment conditions. Together, these results suggest that LPS induces cFos immunoreactivity preferentially in the Phox2b+ population of DVC neurons. To further characterize the LPS-activated neurons, we then performed mRNA fluorescence insitu hybridization for Fos, Chat (a marker of cholinergic vagal neurons), and Atf3 in the DVC 30 and 90 minutes after LPS treatment. Strikingly, whereas very few Chat+ DVC neurons were Fos+, essentially all Atf3+ DVC neurons were Fos+. Overall, our results provide deeper insight into the identity of hindbrain neurons which are activated by inflammation and may mediate the anti-inflammatory circuit. Future studies identifying the neuronal population which sense and reflexively suppress inflammation will help in targeting this circuit for treating autoimmune and inflammatory diseases.

Title: 松芝靈芝,脈衝電磁場和乾細胞治療肌肉減少症引起的神經元運動系統行為改變的應用.

Authors: *S. CHEN;
Chung Yuan Christine Univ., Taoyuan City, Taiwan

Abstract: <META NAME="author" CONTENT="阿思">**The application of Ganoderma tsugae, pulsed electromagnetic fields, and stem cells to treat the sarcopenia induced behavioral changes of the neuronal motor system.** Szu-Yu Chen[1], Ming-Wei Chao[2], Chia-Yi Tseng[11]Department of Biomedical Engineering, and [2]Department of Bioscience Technology, Chung Yuan Christine University, No. 200, Zhongbei Rd., Zhongli Dist., Taoyuan City 320314, Taiwan
AbstractThe decrease in muscle mass and muscle strength accelerates with age, leading to the emergence of aging-induced sarcopenia. The etiology of aging-induced sarcopenia is due to accumulation of reactive oxidative species and chronic inflammation of muscles or motor

neurons, false communication in the neuromuscular junction, or lesion in the motor cortex, further leading to changes in motor behavior. This study adopted the integrative medical method with *Ganoderma tsuga*e (GT), pulsed electromagnetic field (PEMF), and human umbilical cord blood mesenchymal stem cells to treat the aging-induced sarcopenia. To explore whether this integrative medical method would add to each other's therapeutic effects and improve motor neuronal behavior performance. Sprague Dawley (SD) rats were divided into six groups: (1) control group, (2) stem cell group, (3) PEMF and stem cell group (4) PEMF and GT group (5) GT group and stem cell group (6) stem cell group, GT and PEMF group. Each group induced aging with subcutaneous D-galactose injections (200 mg/kg). Motor behavior analysis, including rotarod test, rearing count, and tight rope, were conducted to observe muscle strength and activity changes to confirm the induction of aging before treatments were applied. The above behavioral tests are repeated each month after treatment to verify the effectiveness of the treatment. Observations are expected to take up to half a year. After two months of treatment, we currently found that the groups with stem cell injection have significant protective effects against aging in behavioral testing, especially in the rotarod test. However, GT and PEMF show no noticeable protection effect. Based on current data, stem cells show a significant effect on preventing changes in the motor behavior induced by aging sarcopenia.

Title: Estrogen signaling is required for treadmill exercise mediated effects on synaptic plasticity around axotomized spinal motoneurons

Authors: *J. C. WILHELM, V. L. KENNEDY, Jr., S. T. WILSON, G. M. BADER;
Col. of Charleston, Charleston, SC

Abstract: After peripheral nerve transection, changes in spinal cord circuitry occur including the withdrawal of synaptic inputs from the somata and proximal dendrites of axotomized spinal motoneurons. Moderate daily treadmill exercise after transection injuries has been shown to

mitigate the reduction in synaptic coverage. The mechanisms that underlie the effect of exercise are not well understood. Estrogen receptor (ER) signaling has been shown to have an important role in the effects of exercise on regeneration of injured motoneuron. Therefore, in this study we tested the hypothesis that ER signaling also is a part of the mechanism by which treadmill exercise mediates its effects on synaptic inputs. Gonadally intact male and female C57BL/6 mice underwent a unilateral sciatic nerve transection. Injured motoneurons were retrogradely labeled using a fluorescent dye immediately after transection. Mice then were divided into groups and treated for two weeks with 1) treadmill exercise, 2) ER antagonist Fulvestrant, or 3) treadmill exercise and Fulvestrant. Lumbar spinal cord tissue was harvested fourteen days after surgical injury. Tissue sections containing injured motoneurons were reacted with antibodies to vesicular glutamate transporter 1 (vGLUT1) and glutamate decarboxylase (GAD67). The average synaptic coverage of glutamatergic and GABAergic inputs onto labeled motoneurons was assessed using Image J. We found no significant reduction in coverage in mice treated with treadmill exercise. Blocking ER signaling during treadmill exercise prevented the sustaining effects of the exercise and resulted in an increased loss of inputs compared to mice not receiving the ER antagonist. Based on these results we suggest that ER signaling is an important part of the machinery required for the exercise-mediated effects on synaptic inputs onto axotomized motoneurons after sciatic nerve transection.

Title: Is too much REST a bad thing? Characterizing a master transcriptional regulator in motor neurons after peripheral nerve injury

Authors: *A. K. YASZEMSKI[1,2], N. MADIGAN[1], A. J. WINDEBANK[1], L. NESTI[2];
[1]Dept. of Neurol., Mayo Clin., Rochester, MN; [2]Dept. of Surgery, Uniformed Services Univ., Bethesda, MD

Abstract: Introduction: Peripheral nerve injuries (PNIs) present complex challenges for repair as they include large areas of neuronal damage with trauma to the surrounding muscle and vasculature. Re-innervation of muscle tissue after injury is necessary for functional recovery, but

motor neurons may not regenerate sufficiently, and permanent loss of function can occur. A persistent decline in support elements such as neurotrophic factors (NTFs) and improper reinnervation of muscle targets from axonal misguidance can limit regenerative capacity, both of which have been observed in parallel with injury-induced expression of the Repressor Element-1 Silencing Transcription Factor (REST), a master transcriptional regulator in neurons. How elevation of REST expression affects motor nerves and subsequent recovery after PNI has yet to be investigated. We are developing a novel approach to peripheral nerve regeneration by targeting the motor neuron nucleus to enhance the natural proximal to distal regeneration pattern by modulating REST. This work characterizes injury-induced expression of REST in peripheral motor neurons and its effects on the regenerative process in a rodent model PNI. **We hypothesize that REST expression is elevated in motor neurons after PNI and that its activation is inhibiting important neurotrophic factors and neuronal genes that affect regenerative potential.** This repressive transcriptional block represents a potential therapeutic target to accelerate recovery from peripheral nerve injury by enhancing neuroregenerative programming.

Methods: Male Sprage-Dawely rats, 8-9 weeks old were grouped into facial nerve transection or sham injury groups at 6-hour and 48-hour timepoints (n=12/group). The facial nerve transection injury involved a complete transection at the nerve trunk, sham surgery received a skin incision with the nerve trunk exposed but left intact. REST protein and gene expression levels were assessed via immunohistochemistry and RT-PCR, respectively. Relevant target gene expression was analyzed by in situ hybridization.

Results: Significant upregulation of REST protein expression exists in injured animals compared to sham and naïve groups at both time points. RT-PCR showed no significant changes in mRNA expression at either timepoints. Data analysis is in process for in situ hybridization.

Discussion: This is the first evidence of REST activation after peripheral nerve injury in motor neurons. The direct regulation of various neurotrophic factors and regenerative-associated genes makes REST a potential therapeutic target for improving functional recovery after peripheral nerve injury.

Title: Motor training improves coordination and anxiety in Mecp2-null mice despite impaired functional connectivity within the motor circuit

Authors: *Y. YUE[1], P. XU[1], Z. LIU[1], X. SUN[1], J. SU[1], H. DU[1], L. CHEN[1], R. ASH[2], S. SMIRNAKIS[3], R. SIMHA[1], L. KUSNER[1], C. ZENG[1], H. LU[1];

Abstract: Mutations in the X-linked gene Methyl-CpG-binding protein 2 (*MECP2*) causes a severe neurodevelopmental disorder, Rett syndrome (RTT). Children with RTT (typically girls) develop normally until about 6-18 months of age when they undergo a period of regression wherein they lose acquired motor, cognitive, and social milestones and do not make further gains. Male *Mecp2*-null mice model more severe forms of RTT and replicate the course of the disease. Since little is known about how motor learning is encoded by L2/3 and L5 ensembles in the motor cortex, we sought insight into this process by comparing wild-type and *Mecp2*-null mice on a very specific motor learning task: running on a computerized wheel whose speed is controlled by the experimenter. Thus, the skill to be learned is to adapt to increasing or decreasing speeds. While head-fixed mice ran on the wheel, we conducted two-photon calcium imaging to record thousands of neurons in L2/3 and L5a and study changes in event rates and functional connectivity over the course of two weeks of training. We found that the mutant motor cortex, despite their reduced cross-layer connectivity, a ~20% overall lower firing rate, and impairment in maintaining functional connectivity more than a couple of days, retains sufficient plasticity to support motor learning. Interestingly, overall functional connectivity of neuronal pairs in both layers decreased after training but the top 5% of neuronal pairs that were most strongly connected actually increased their functional connectivity with training. More surprisingly, a mere two weeks of training on the speed-changing wheel caused the mutant mice to improve their coordination on different motor assays (ladder-walking and rotarod), reduce anxiety (in the open field and elevated plus maze tests), and survive about 20% longer than untrained null mice. We found a correlation, albeit a weak one, between forepaw coordination improvement and extension of survival in the null mice, but not between any other measures and lifespan; this raises the possibility that learning confers benefits beyond those of mere exercise. Our results support a model in which motor skills are learned by judiciously strengthening the functional connectivity of a subgroup of neurons while decreasing connectivity among the rest of the population to maintain flexibility for learning new skills. These results underscore the benefit of motor training, especially given that motor deficits and anxiety are core symptoms of Rett, which is not diagnosed until well after symptom onset.

Title: Retrospective Review of SMN1 Full Gene Sequencing at Mayo Clinic Laboratories Reveals Two Novel Variants and Two Cases of Homozygous Point Mutations

Authors: *S. BELLAMPALLI, S. COOK, N. VIDAL-FOLCH, H. CABRAL, R. ROWSEY, L. HASADSRI, D. OGLESBEE;
Mayo Clin., Rochester, MN

Abstract: Spinal muscular atrophy is caused by homozygous deletions of the *SMN1* gene in 95% of affected patients. The remainder of SMA diagnoses is heterozygous with a *SMN1* deletion in one allele and a small more subtle mutation in the other allele. SMA cases resulting from homozygous point mutations are rare. Mayo Clinic Laboratories offers SMA Del/Dup testing and *SMN1* full-gene sequencing. Our SMA Del/Dup assay uses novel droplet digital PCR technology to accurately quantify *SMN1* and *SMN2* copy numbers between 0 to 5 copies, whereas other methods cannot report higher than 3. Our *SMN1* sequencing assay identifies variants in all exons of *SMN1*, but cannot discriminate between exon 1 *SMN1* or *SMN2* variants. From October 2018 to March 2021, our *SMN1* full gene sequencing tested a total of 50 patients - age ranged from 5 days to 35 years old. We identified seven missense variants: c.43C>T (p.Q15* known pathogenic), c.46delG (p.E16Rfs*24 novel predicted pathogenic), c.278A>C (p.K93T novel VUS), c.683T>A (p.L228* known pathogenic), c.549delC (p.K184Sfs*29 predicted pathogenic), c.597dupC (p.M200Hfs*56 novel predicted pathogenic), and c.735dupA (p.P246Tfs*10 known pathogenic). Interestingly, two variants occurred as homozygous mutations. In one case, a 17 year old boy presented with symptoms consistent with motor neuron disease. Molecular analysis reported 2 copies of *SMN1*, 2 copies of *SMN2*. Importantly, microarray analysis revealed consanguinity. Our *SMN1* full gene analysis revealed a homozygous pathogenic mutation in exon 6 (c.683T>A). In the other case, a 6 month old girl presented with symptoms consistent with SMA. Molecular analysis reported 2 copies of *SMN1* and 2 copies of *SMN2*.The patient's parents are known to be consanguineous. Our *SMN1* full gene analysis revealed a homozygous pathogenic mutation in exon 6 (c.735dupA). Two of seven variants are novel and not previously reported in the literature. Lastly, two of seven variants occurred in exon 1. Our method uses long-range-PCR of *SMN1* exons 2-8, followed by bidirectional Sanger sequence analysis for nucleotide variants in *SMN1*. Exon 1, however, is PCR-amplified and bidirectionally Sanger-sequenced alone using primers which amplify exon 1 of both *SMN1* and *SMN2*. As a result, clinical correlation is needed to render diagnosis. Our

retrospective review of 50 *SMN1* full gene analyses revealed seven incidences in which *SMN1* variants were detected. Two variants occurred as rare homozygous mutations.Two variants are novel. Lastly, two variants are in exon 1. Our test analyzes exon 1 separate from exon 2-8 as variants detected in *SMN1* exon 1 cannot be distinguished from variants in *SMN2* exon 1.

Title: Tracking axonal loss and unique microglia in the corticospinal tract in ALS patients

Authors: J. LIU[1], S. MARTIN[1], K. JOHN[1], J. LEI[1], J. M. RAVITS[2], J. LOEB[1], ***F. SONG**[1]; [1]Univ. of Illinois at Chicago, Chicago, IL; [2]Neurosciences, Univ. of California San Diego Dept. of Neurosciences, La Jolla, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that selectively involves both upper and lower motor neurons. The mechanism that links upper and lower motor neurons is unknown. However, a common pathological finding in the spinal cord is corticospinal tract (CST) degeneration. We found the myelin loss in the CST in patients with upper motor neuron (UMN)-dominant clinical symptoms at disease onset (1). UMN-dominant ALS is defined as predominantly UMN signs but still with minor lower motor neuron (LMN) signs at disease onset. To determine the anatomical relationships of the connection of patients with UMN–dominant vs LMN-dominant clinical signs at the disease onset, we developed quantitative methods to measure different sizes of axons and glial morphology in well-characterized postmortem spinal cord at three levels (cervical, thoracic, and lumbar) from ALS patients. Patients with UMN–dominant showed myelin loss in the lateral CSTs in the spinal cord at three levels. We found an ‘All or None’ effect in that all levels of the CST were equally effected at the time of death in ALS patients with UMN-dominant clinical symptoms at disease. In contrast, LMN-dominant ALS patients had significantly less CST involvement. LMN loss in

the ventral horn showed in both UMN- and LMN-dominant ALS patients with no clear pattern related to the site of disease onset. Quantification of axon density showed severe loss of axons in both small and large diameter axons in the lateral CSTs in UMN-dominant ALS patients. Interestingly, significantly more unique foamy-shaped microglia were associated with myelin and axon loss in the lateral CST in UMN-dominant ALS patients. This 'All or None' effect of myelin loss in the lateral CST's associated with the increased unique microglia suggests the possibility of aberrant axon-glial interactions contributing to pathogenesis and axonal degeneration in ALS patients with prominent UMN signs at disease onset.

Title: Effects of sedentary aging and exercise on structural plasticity of motor neurons and NMJ structures.

Authors: *A. CINTRÓN-COLÓN, J. FANIZZA, J. M. SPITSBERGEN;
Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: Neuromuscular weakness has been associated with age progression. A possible reason is a disconnection between muscle and neuron, causing components from both the central and peripheral nervous systems to deteriorate. Exercise, however, has beneficial effects for both muscle and nervous tissue, inducing neuroprotection. This study aims to evaluate changes in structural plasticity of motor neurons in the lumbar spinal cord and NMJ structures in the skeletal muscle with sedentary aging and exercise. We hypothesize that motor neuron area size and possibly subgroups decrease with sedentary aging, but in exercised age-matched animals, the area size will increase, and subgroup diversity will remain stable. At the site of the skeletal muscle, we hypothesize that NMJ structures get degraded with sedentary aging, but exercise can maintain those structures even in advanced age. Spinal tissues were taken from sedentary and

exercised Sprague-Dawley rats between 4 weeks and 24 months of age. Sedentary groups consisted of the following: 4-week-old, 14-week-old, 12-month-old, 18-month-old, and 24-month-old rats, while exercised groups consisted of 14-week-old rats that had access to running wheels for ten weeks; and 12-, 18-, and 24-month-old rats that had access to running wheels for 24 weeks. Lumbar spinal tissue and hindlimb skeletal muscle (soleus and plantaris) was used for immunohistochemical analysis. In the spinal tissue, antibodies against choline acetyltransferase (ChAT), neuronal nuclei (NeuN), and the fluorescent dye DAPI were used to identify neurons in the ventral horn of the spinal cord. In skeletal muscle, α-bungarotoxin was used to identify motor end plates and acetylcholine receptors. Results suggest a decrease in stained area size of neurons in the ventral horn in adulthood. Exercised animals, however, had a larger area size when compared to their respective sedentary age-matched group. Histogram analysis suggests that larger neurons tend to be less numerous in adulthood, suggesting a possible loss of motor neuron subgroups. The area size of motor endplates in skeletal muscle from exercised rats was more prominent than their respective sedentary age-matched counterpart. Our results aid in understanding the structural changes that can occur with aging in the neuromuscular system in a mammalian model of aging. Furthermore, this work adds to the pool of knowledge of how exercise can impact at different points in the lifespan of an aging mammalian model and its potential benefits.

Title: Tap to the beat: synchronization between auditory entrainment and motor beta bursts during finger tapping

Authors: *Q. CHEN[1], C. MCALLISTER[1], K. SHAPIRO[1], S. HANSLMAYR[2];
[1]Univ. of Birmingham, Birmingham, United Kingdom; [2]Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Humans can synchronize their movements to an externally presented rhythm, but little is known about the underlying neural mechanisms allowing for such rhythmic behaviour. On the

one hand, it has been shown that the auditory cortex can be entrained to a rhythmic signal. On the other hand, transient bursts of beta oscillations in the motor cortex have been shown to play a critical role in predictive rhythmic action. Arguably, the two processes must interact to allow for movements to be synchronized to an auditorily presented beat, but little is known about this interaction. To shed light on this issue, we recruited 15 young healthy participants to perform a finger-tapping task following rhythmic tones at 1 Hz and 2Hz in an EEG study. Transient motor beta bursts were identified according to established detection algorithms (Staresina et al., 2015) at both scalp and source levels. Preliminary results at the scalp level show that motor beta bursts are significantly more closely related to motor output (i.e., taps) than auditory entrainment (i.e., tones). Surprisingly, behavioural results indicate that the process of adaptation to rhythmic auditory stimuli evolves very quickly, in only 3 consequent tones. In a further analysis, we are planning to investigate the relation between auditory entrained EEG activity and motor beta burst at the source level. Motor beta burst timing is predicted to be modulated by the phase of auditory entrained activity and the degree of modulation is expected to correlate with the performance precision. Overall, our study explores the dynamic configuration of the sensorimotor network in the maintenance of rhythmic motion and timing prediction.

Title: A novel time-based surface EMG measure for quantifying hypertonia in hemiparetic arm muscles during daily activities after stroke

Authors: *M. SOHN[1], J. DEOL[1], J. P. A. DEWALD[1,2];
[1]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL; [2]Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: After stroke, paretic arm muscles are constantly exposed to abnormal neural drive from the injured brain. As such, hypertonia, broadly defined as an increase in muscle tone, is prevalent especially in distal muscles, which impairs daily function or in long-term leads to a deformed resting posture. However, there currently is no quantitative measure that can reliably track how hypertonia is expressed on daily basis. In this study, we propose a novel time-based

surface electromyography (sEMG) measure that can overcome the limitations of the coarse clinical scales often measured in functionally irrelevant context and the magnitude-based sEMG measures that suffer from signal non-stationarity. We postulated that the key to robust quantification of hypertonia is to capture the "true" baseline in sEMG for each measurement session, by which we can define the relative duration of activity over a short time segment continuously tracked in a sliding window fashion. Preliminary results demonstrated that the proposed approach can well characterize the clinically observed differences in hypertonia expressed across different muscles and impairment levels. Specifically, we recorded sEMG from 6 distal wrist/finger and 2 proximal elbow muscles while individuals with stroke (n=3; FMA-UE score: 13-25-38) were nominally 'awake', completely 'relaxed', and executing a 'ambulatory' motor task. We quantified active duration of sEMG within a time segment (5s sliding window), defined as the percent of time signal is above a threshold $\mu+3\sigma$ (μ: minimum segment mean across all recordings; σ: standard deviation in that segment). We found that hypertonia was more prevalent (i.e., greater active duration) in distal than proximal muscles during 'awake' ($t_{254}=5.45$, $p<0.001$) and 'ambulatory' states ($t_{282}=3.54$, $p<0.001$). There was no difference across muscles ($t_{254}=0.99$, $p=0.32$) or participants during the 'relaxed' state, indicating that our measures robustly quantify the "true" baseline (i.e., absent hyperactivity) that is comparable across muscles and participants. Finally, the amount of reduction in active duration from 'awake' to 'relaxed' state increased with impairment level, more so in distal muscles ($t_{254}=-3.51$, $p<0.001$), indicating that individuals with more severe impairment would experience a longer period of continuous involuntary activity, especially in the distal muscles, even during the ordinary awake hours. The proposed measure can be used for continuous and quantitative monitoring of hypertonia while at home, which will allow for the study of practical effect of pharmacological and/or physical interventions that try to combat its presence.

Title: Diurnal rhythm of dendritic spine density and per1 expression in the infralimbic and prelimbic areas: a potential role for glucocorticoid regulation

Authors: *A. M. MILLER, J. A. SHENG, R. M. DANIELS, R. J. HANDA;
Biomed. Sci., Colorado State Univ., Fort Collins, CO

Abstract: Title: Diurnal rhythm of dendritic spine density and per1 expression in the infralimbic and prelimbic areas: a potential role for glucocorticoid regulation. Circadian disruption caused

by shift work is associated with a myriad of poor health outcomes ranging from cardiovascular disease susceptibility to depression. The ventromedial prefrontal cortex (vmPFC) is a critical regulator of the stress response, autonomic function, and mood. Additionally, vmPFC dendrites are remodeled by adrenal glucocorticoid (GCs), which are critical for stress signaling and the entrainment of circadian rhythms. Due to vmPFC functional overlap with pathologies presented in circadian disruption, we assessed whether the mouse vmPFC displays rhythmicity in cortical dendrite morphology across 24-hour periods. Additionally, we assessed whether core clock genes are regulated by GC signaling in the vmPFC. To measure vmPFC rhythmicity, the present study assessed layer V pyramidal neuron dendritic spine density and core clock gene *Per1* mRNA expression in two key vmPFC subregions, the infralimbic (IL) and prelimbic (PL) areas, across the light:dark cycle. All mice (n=4-6/group) were sacrificed at ZT3 (early light phase), ZT12 (dark phase onset), and ZT16 (middle dark phase). For spine studies, Thy1-eGFP transgenic mice were used to visualize eGFP-labeled pyramidal dendritic arbors in IL and PL. A robust spine rhythm was detected in the IL, showing baseline spine density at ZT3, an increase at ZT12 ($p<.001$ vs ZT3), and peak spine density at ZT16 ($p<.0001$ vs ZT3, $p<.05$ vs ZT12). The PL showed a slight, but significant, upregulation in spine density at ZT16 ($p<.05$), but not at ZT12 or ZT3. In SHAM mice, IL *Per1* mRNA measured by droplet digital (dd)PCR showed peak expression at ZT12 and baseline expression at ZT3 and ZT16. In adrenalectomized (ADX'd) mice, IL *Per1* expression was phase-shifted, displaying peak expression at ZT16 ($p<.05$ vs SHAM ZT16) and baseline expression at ZT3 and ZT12 ($p<.01$ vs SHAM ZT12). SHAM PL *Per1* mRNA showed peak expression at ZT12 and ZT16, and baseline expression at ZT3. ADX'd PL *Per1* expression displayed no rhythmicity, remaining at baseline values at all three timepoints ($p<.0001$ vs SHAM ZT12, $p<.05$ vs SHAM ZT16). These findings demonstrate a daily rhythm of dendritic spine density and core clock gene expression in the vmPFC. Additionally, changes in phase and amplitude of *Per1* expression in ADX conditions implicates a role for diurnal CORT rhythmicity in synchronizing molecular clocks within the vmPFC.

Title: A potential pathway for pain-related disruption of circadian rhythms

Authors: A. E. WARFIELD, P. GUPTA, M. M. RUHMANN, *W. D. TODD;
Zoology and Physiology, Program in Neurosci., Univ. of Wyoming, Laramie, WY

Abstract: Daily rhythms in pain intensity have been observed clinically for years, but only recently have these rhythms and their underlying biology begun to be explored in depth. Additionally, there is some evidence that persistent pain disrupts both central and peripheral circadian rhythms, however this topic has been studied considerably less and the circuit basis for such disruption has never been examined. The signaling pathways for pain heavily utilize the superficial lamina of the spinal dorsal horn and the lateral parabrachial nucleus (LPB), however whether these pathways directly project to the circadian system is less clear. Using retrograde tracing from the subparaventricular zone (SPZ), a heterogenous structure with diverse roles in numerous circadian rhythms at both the behavioral and autonomic level, we have found that there is a considerable innervation coming from the LPB. The LPB cells that send this projection appear to be primarly composed of those expressing FoxP2 as well as dynorphin, a subset of these FoxP2 cells. Importantly, dynorphin LPB cells have been implicated in many aspects of pain including physiological, emotional, and learning responses. We also found that the SPZ shows strong c-fos reactivity at ZT2, ZT6, and ZT14 following formalin injection into the right hind paw, lending credence to the potential for pain-related sigals to disrupt entrained and intrinsic rhythms via this pathway. Indeed, using biotelemetry recordings we find clear evidence of such rhythm disruption following intrplantar injection of a long-lasting inflammatory agent, complete Freund's adjuvant (CFA), in the phase angle of entrainment for locomotor activity (LMA) and body temperature (Tb) for the week following these injections. Phase angle represents a measure of how the circadian system is synchronized to the light-dark cycle, by reflecting the amount of time after light offset that the acrophase occurs. We found that phase angles for both LMA and Tb are consistent across mice before CFA injection but then show profound variation between mice following CFA. Such a change was not seen in saline injected controls, as their phase angles stay consistent before and after injection. Interestingly, we saw a less dramatic change in mean hour-by-hour LMA and Tb, although there was a clear increase in both variables at the dark-to-light transition, again suggesting that pain-related signals may be interfering with the circadian system's ability to properly entrain to the light-dark rhythms as its primary zeitgeber.

Title: Dim light at night post stroke increases infarct volume and alters neuroimmune activation

Authors: *J. A. LIU[1], W. H. WALKER, II[1], J. R. BUMGARNER[1], O. H. MELENDEZ-FERNANDEZ[1], N. ZHANG[1], J. C. WALTON[1], A. C. DEVRIES[2], R. J. NELSON[1];

Abstract: Cerebral ischemia (stroke) results from impaired blood flow to the brain causing neuronal damage and injury resulting in physical disability or death. Stroke patients are exposed to increased light at night due to increased care requirements, especially during the first few days post-injury. Previous studies identified that disrupted circadian rhythms by exposure to dim light at night (dLAN) alters several aspects of the adaptive and innate immune system including neuroinflammation; thus, we hypothesized that exposure to dim light at night post stroke dysregulates gene expression related to neuroimmune activation and increased infarct size. Twelve month old male CFW mice received a right transient intraluminal right middle cerebral artery occlusion (MCAO) for 30 minutes confirmed by laser doppler flowmetry at the end of the inactive period, then, were either returned to normal light dark (LD; 12 h 150 lux, 12 h 0 lux) conditions, or exposed to dLAN (5 lux). 12 h post stroke, mice received a sensorimotor general and focal neurological deficit score using Clark's Test, then whole cerebral hemispheres were separated into ipsilateral and contralateral hemispheres and were collected for RNA sequencing. A second cohort of mice received a right MCAO, then exposed to the corresponding lighting conditions, and brains were collected after 24 h for infarct visualization using 2,3,5-triphenyltetrazolium chloride (TTC). We observed that mice exposed to dLAN post MCAO had significantly greater infarct volumes and displayed increased general and focal neurological deficits compared to LD conditions. DLAN mice post stroke displayed increased spleen masses relative to LD. We also identified differentially expressed genes and found that positive regulation of inflammatory response genes including (*MIF, S100A8, S100A9, MMP8*) were upregulated compared to LD conditions, whereas heat-shock protein genes (*Hspd1, Hsp90aa1, Hspe1*) were significantly reduced. Together, these findings suggest exposure to dim light at night is especially detrimental in stroke outcome and recovery, and that reducing circadian disruption post cerebral injury could decrease infarct progression.

Title: Real-time Clock Gene Waveform Dynamics in the SCN Neural Network Encoding Phase Shifts and Entrainment to Photic Input

Authors: *S. KIM[1], D. G. MCMAHON[2];
[1]Neurosci. Grad. Program, [2]Dept of Biol. Sci., Vanderbilt Univ., Nashville, TN

Abstract: The suprachiasmatic nucleus (SCN) is a central circadian clock that orchestrates mammalian physiology and behavior in tune with daily and seasonal light cycles. It is not fully understood how the SCN neurons actively encode phase shifts and entrainment to light input at the molecular and network levels. Here we present new methods to measure molecular circadian rhythms in the ex vivo SCN while it undergoes phase shifts and entrainment. Our approach combines red optogenetic manipulation of clock neuron electrical activity with real-time bioluminescent recording of the clock gene expression, providing precise timing, duration, and intensity of recurring input stimulation to the isolated SCN, and tracking SCN clock molecular rhythms at high spatiotemporal resolution for 3-5 weeks ex vivo. Optogenetically simulated light input transforms the waveform of the molecular clockworks from sinusoidal in free-running conditions to highly asymmetrical trajectories with accelerated synthetic (rising) and extended degradative (falling) phases marking clock advances and delays at simulated dawn and dusk. Daily waveform changes are sufficient to entrain the isolated SCN to non-24h periods, and to different photoperiods with a minimum tolerable night. SCN imaging further reveals that acute waveform shifts are greatest in the ventrolateral SCN, while period effects are greatest in the dorsomedial SCN. Thus, circadian entrainment is encoded by SCN clock gene waveform changes that arise from spatiotemporally distinct intrinsic responses of the SCN neural network.

Title: Shortened Circadian Period Associated with Enhanced Autophagy in Cereblon-null Mice.

Authors: *J. KIM, J. JUNG, J. KANG, S. LEE, C.-S. PARK, T. KIM;
GIST (Gwangju Inst. of Sci. & Tech.), Gwangju, Korea, Republic of

Abstract: The circadian rhythm plays a crucial role in many biological processes, such as the sleep-wake cycle, hormone secretion, cardiovascular health, glucose homeostasis, and body temperature regulation. Recently, the level of autophagy was suggested as a regulating factor of circadian rhythm by affecting protein trafficking. Cereblon is a major component of the E3 ubiquitin ligase complex, which mediates the ubiquitination and subsequent proteasomal degradation of its substrates. Interestingly, cereblon ubiquitinates beclin 1, a potent autophagy inducer. Accordingly, the changes in cereblon are likely to affect the circadian rhythm. However, how cereblon can regulate circadian rhythm is not understood yet. Therefore, we hypothesized that cereblon might be an important regulator of the circadian rhythm and sought to investigate the relationship. We obtained 3-month-old CRBN gene knockout (KO) and wild type (WT) mice (n=4 and 8, respectively). The mice were housed in the wheel-based activity recording system under the 12:12 light-dark (LD) condition for one week and constant darkness (DD) condition for the subsequent two weeks. Autophagy-related proteins, including beclin1, microtubule-associated protein light chain-3 (LC3), and p63, were measured by the western blot. Activity data were analyzed by ClockLab Analysis 6 (Actimetrics, USA). We found that the period of circadian rhythm decreased (23.7 vs. 23.4 hours), and the circadian amplitude was increased in CRBN KO mice. The latency from the light-off time to initiating activities in the dark period was shorter in CRBN KO mice and in WT mice. Western blotting revealed that beclin1, LC3, and p62 increased in CRBN KO mice, indicating increased autophagy. Our results demonstrated that CRBN knockout mice showed a shorter circadian period and reduced autophagy-related molecules. We interpret that the lack of cereblon resulted in reduced degradation of beclin1 that triggers autophagy. As per Beesley et al. (2020), an autophagy-induced decrease in cytoplasmic congestion facilitates the protein trafficking for the crucial components of the molecular circadian clock. The shorter circadian period in CRBN KO mice was primarily due to the enhanced autophagy, although its implication in general health is unclear. Taken together, we suggest that CRBN is associated with circadian rhythm via controlling autophagy. Further investigations to understand how circadian amplitude was increased and the activity latency during the dark period was shortened are needed.

Title: Rhythmic transcriptome network and its connection with autism spectrum disorder in mouse brain

Authors: *C. LEE[1], J. S. TAKAHASHI[2];
[1]Dept. of Neurosci., The Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Dept. of Neurosci., The Univ. of Texas Southwestern Med. Center, Howard Hughes Med. Inst., Dallas, TX

Abstract: The debilitating effects on behavior and cognition caused by autism spectrum disorder (ASD) have had significant impacts on medical and social care world-wide, where its prevalence is 1 case per 68 children. ASD is known to be influenced by transcriptome changes and is also associated with circadian rhythms, the 24 hour cycles of behavioral and physiological changes controlled by the internal biological clock. However, the connection between ASD and circadian rhythms has not been clearly identified at the transcriptome level. We used RNA-seq from wild type mouse brain to first test the connection at the tissue level. Across eight brain tissues (e.g., Olfactory bulb (OB), frontal cortex (FC), striatum (ST), parietal cortex (PC), hippocampus (HI), temporal cortex (TC), occipital cortex (OC), and cerebellum (CB)), we found gene expression rhythms that shared a common pattern in overall phase distribution. Enrichment studies also showed that their rhythmic transcriptomes are shared across brain tissues and are significantly enriched for ASD-risk genes. However, multidimensional scaling studies identified differences in both phase and amplitude. For phase data, HI and FC were different, with their average phases uniquely within the circadian time (CT)19-1. OB and CB exhibited phase shifted genes that show shifts between day and night, which were found to be fear response genes in neuronal synapses. For amplitude data, the rhythmic transcriptomes in OB and OC exhibited small amplitudes, in contrast to FC that had the largest amplitude. Using the phase and amplitude data, circadian rhythm networks could be identified across the brain tissues. Interestingly, OB and CB showed weak connection with the other brain tissues that had strong interconnections in the circadian rhythm network. Notably, FC is involved in social, language, communication, cognitive functions, which are the most disrupted functions in ASD patients. Therefore, I further studied FC transcriptome at the single-cell level using single nucleus RNA-seq. I identified 47 cell clusters from FC and their cell numbers from high to low in the following the order: neuron, astrocyte, oligodendrocyte, microglia, and endothelium. Among them, neurons drive most of the rhythmic transcriptome in FC tissue. Neuronal transcriptomes showed two clear, major peaks of phase that matched with tissue-level phase, and their amplitudes were smaller than non-neuronal transcriptomes. A gene set enrichment study showed that only neurons showed strong enrichment with ASD-risk genes. In conclusion, genome-wide transcriptome analyses showed a significant connection between the rhythmic transcriptome and ASD in neurons.

Title: Circadian clock and stem cell gene expression in quiescent glioma spheroid cultures

Authors: V. P. SHARMA[1], A. DE[2], ***M. E. GEUSZ**[3];
[1]Bio-Rad Laboratories, Inc., Ann Arbor, MI; [2]Dept. of Neurosurgery, Brain Tumor Ctr., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX; [3]Dept. of Biol. Sci., Bowling Green State Univ., Bowling Green, OH

Abstract: Understanding how cancer cells of the nervous system are regulated by circadian rhythms can indicate daily phases when cancers are most vulnerable to treatments. Cancer stem cells within tumors also need to be further characterized because they resist some cancer treatments by remaining mostly quiescent and then producing tumor recurrence by differentiating into rapidly dividing cancer cells. Glioblastomas contain cells of varying states of differentiation including glioma stem cells (GSCs) according to studies of tumorsphere cultures that serve as models of tumor organization. Tumorspheres made from rat C6 glioma cells express circadian rhythms of core clock gene Per2 that is often suppressed in cancer cells, indicating a tumor cell heterogeneity that depends on the culture microenvironment. Furthermore, C6 tumorspheres maintained in culture media lacking added growth factors remain mostly quiescent and produce large amplitude circadian rhythms. Because arrested cell division is typical of GSCs in many tumors we tested whether tumorspheres from a human glioma could also be maintained in this quiescent state. We found that tumorspheres from U251 human astrocytoma cells survive for weeks under quiescent culture conditions. Stem cell marker proteins SOX2, CD133, and MSI1 were expressed in different tumorsphere regions, and their corresponding genes were moderately expressed in published RNA-Seq data from U251 cell cultures where GSCs are sparse, contrasting with their expression in tumorspheres. High HIF1A expression in tumorspheres indicated a hypoxic microenvironment selective for GSCs. Tumorspheres induced to differentiate into cells expressing astrocyte (GFAP) and neuronal (MAP2) markers validated the multipotency of quiescent tumorsphere GSCs. We used RNA-Seq databases to compare astrocytes with U251 cells, which revealed increased expression of the TGFB1/SMAD3 stem cell pathway and NFkappaB signaling (RELA) in U251 cells. Expression of core circadian clock gene CLOCK and circadian-related gene ARNTL2 (BMAL2) was also elevated along with SERPINE1, a gene target of these two transcription factors that facilitates cancer cell migration and metastasis. Other circadian clock gene expression was lower in U251 cells, and to test functioning of the partially repressed genes we knocked down expression of core clock gene Arntl (BMAL1) in C6 cells. The Arntl antisense oligonucleotide inhibited epithelial-mesenchymal transition into viable quiescent cells suggesting a role for BMAL1 in producing or

maintaining quiescent cancer cells and tumorspheres. These results identified potential target genes for suppressing glioblastomas.

Title: High-throughput measurement of molecular rhythms reveals genetic heritability and quantitative trait loci of circadian phenotypes and their correlation with cocaine addiction in genetically diverse mouse populations.

Authors: *S.-M. KIM[1], V. M. PHILIP[2], L. H. GAGNON[2], P. E. DICKSON[2], S. SCHOENROCK[3], L. M. TARANTINO[3], E. J. CHESLER[2], R. W. LOGAN[1], C. A. MCCLUNG[1];
[1]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [2]The Jackson Lab., Bar Harbor, ME; [3]Genet., Univ. of North Carolina, Chapel Hill, NC

Abstract: Circadian clocks coordinate many brain processes including reward-related pathways, and circadian disruption is commonly observed in nearly all individuals with substance use disorders. Accumulated evidence suggests that substance use alters endogenous clock machineries and circadian disruption leads to increased vulnerability for addiction, but the genetic mechanisms underlying this bidirectional interaction is not fully understood. Diversity Outbred (DO) and Collaborative Cross (CC) mice are powerful animal models for investigating the genetics of complex traits because genetic combinations of their eight founder strains including five common-inbred and three wild-derived strains provide high genetic and phenotypic diversity compared to conventional inbred mouse strains. To understand genetics of circadian rhythms and their relationship with drug addiction, our study performed a high-throughput assay to phenotype circadian rhythms and cocaine addiction-related behaviors using DO, CC and their founder strains. Among the founder strains, we found strong heritability and significant strain by sex effects for period and amplitude in molecular rhythms. Extreme period differences in molecular and behavioral rhythm were observed between the inbred A/J, which have the longest period, and the wild-derived CAST/EiJ, which have the shortest period. Our preliminary correlation analysis in the founders revealed that longer periods were associated with more relapse-like behaviors while reduced amplitude was associated with drug-seeking behaviors in cocaine self-administration (IVSA). In CC strains, CC004/TauUnc displayed

significantly higher addiction-related behaviors in cocaine-sensitization and IVSA relative to CC041/TauUnc. CC004/TauUnc also exhibited a longer circadian period and lower amplitude in molecular and behavioral rhythms relative to CC041/TauUnc mice. Furthermore, we characterized molecular rhythms in 329 DO mice for genetic mapping. They displayed more circadian phenotypic variability than the founders: 80% of founders compared to only 25% of DO mice had periods of ~24 h. Genetic mapping identified several quantitative trait loci for molecular rhythms in period and amplitude. Collectively, our findings demonstrate that genetic diversity contributes to phenotypic variability in circadian rhythms and prove that cell-based high-throughput screening of fibroblast rhythms in DO mice is a tractable system for high-precision genetic mapping.

Title: Mosquito Cryptochrome is a Well-Conserved Key Photoreceptor for Light-Mediated Behaviors in Flies

Authors: *D. D. AU, A. J. FODEN, S. PARK, M. TRAN, O. JAIME, T. C. HOLMES; Univ. of California, Irvine, Irvine, CA

Abstract: Light-evoked excitation of the ventral lateral subset of circadian neurons in Drosophila is mediated by the cell autonomous short-wavelength light-sensitive photoreceptor Cryptochrome (CRY), and to a lesser extent, cell autonomously expressed Rhodopsin 7 and photic inputs from the eyes. CRY also regulates the circadian molecular clock via light-induced degradation of the Timeless (TIM) clock protein, as well as avoidant/attractant behavioral responses to strong UV light. We explored the behavioral and electrophysiological light-responsiveness of CRY1s expressed by day-biting Aedes aegypti (Ae) and night-biting Anopheles gambiae (Ag) transgenically expressed in a cry-null Drosophila background. AeCRY1 and AgCRY1 partially rescue the UV (365 nm, 250 µW/cm2) light-excitatory electrophysiological responses of large lateral ventral arousal neurons (lLNvs). AgCRY1 further phenocopies dCRY's neuronal excitatory light-responses shown by blue (450 nm) and red (630 nm) light-evoked electrophysiological responses in lLNv. Our immunocytochemistry

experiments show under 12:12 LD that the phase of TIM cycling for dCRY, AgCRY1, and AeCRY1 are similar. However, the pattern of locomotor behavior under 12:12 LD in AeCRY1 expressing flies is similar to cry-null, while AgCRY1 expressing flies showed similar LD locomotor behavior compared to dCRY expressing flies. Furthermore, attraction/avoidance behaviors to UV light during the day track the distinct differences between daytime and nighttime active species' CRY; dCRY or day active AeCRY1 expressing flies are attracted to daytime UV light, while night active AgCRY1 expressing flies show strong daytime avoidance of UV light. These findings highlight CRY as a key photoreceptor that mediate light-mediated behaviors in a species specific fashion. This may useful for developing more efficient light-based insect control methods.

Title: The regulation of vasoactive intestinal peptide expression by ventral anterior homeobox 1 results in altered circadian output from the suprachiasmatic nucleus

Authors: *B. DEVRIES[1], J. BREUER[3], A. YAW[1], B. JACKSON[2], D. NGUYEN[1], M. GORMAN[4], L. SEMPERE[2], E. V. HO[5], P. L. MELLON[5], H. M. HOFFMANN[1,5];
[1]Dept. of Animal Sci. and the Reproductive and Developmental Sci. Program, [2]Dept. of Radiology and Precision Hlth. Program, Michigan State Univ., East Lansing, MI; [3]Dept. of Obstetrics, Gynecology, and Reproductive Sci. and Ctr. for Reproductive Sci., Univ. of California, San Diego, CA; [4]Dept Psychol-0109, UCSD, La Jolla, CA; [5]Univ. of California San Diego, La Jolla, CA

Abstract: The suprachiasmatic nucleus (SCN) is a brain structure in the hypothalamus important for circadian timekeeping and relaying environmental day-night information to the body. Ventral anterior homeobox 1 (Vax1) is a homeodomain transcription factor that is required for SCN development and function. Previous studies have shown that balanced expression of vasoactive intestinal polypeptide (VIP) and arginine vasopressin (AVP) is required for correct SCN period.

As VAX1 has an established role as an activator of VIP expression and 100% of postnatal day 2 VIP neurons were found to express Vax1, we hypothesized that Vax1 is required for VIP neuron maturation, which may play a role in SCN circadian function. To understand the role of VAX1 in VIP neurons, we conditionally deleted Vax1 in post-natal VIP neurons, generating Vax1-flox/flox:Vip-Cre+ (VaxVIP) mice. To examine whether VaxVIP mice had impaired SCN output, we evaluated wheel running behaviors in constant darkness, which reveals intrinsic SCN rhythms. VaxVIP male and female mice displayed a shortening of the endogenous free-running period (Tau) of the SCN, showing shortened circadian output from the SCN. This shortened behavioral rhythm was reflected in Per2-luciferase ex vivo tissue recordings. Loss of VIP in the SCN is known to shorten Tau, leading us to examine Vip levels. Indeed, VaxVIP mice had reduced VIP mRNA and protein in the SCN. Interestingly, VaxVIP mice had increased Avp expression, which could contribute to the shortened behavioral period. In addition to regulating SCN period through imbalance of VIP and AVP, our data also identified a direct effect of Vax1 on the expression of the molecular clock genes Bmal1 and Per2. Together, these data show a dual role of Vax1 in VIP neurons, where it is required for VIP expression, and impacts VIP neuronal connections to target neurons, leading to an increase in Avp expression. In addition, VAX1 also regulates molecular clock function through a direct action on the Bmal1 and Per2 promoters. In conclusion, we have identified a novel role for VAX1 in maturing SCN VIP neurons, where it is required for both Vip expression and molecular time keeping function.

Title: Genetic and neuronal substrates of melatonin signaling in zebrafish sleep

Authors: *A. HILL, D. PROBER;
Caltech, Pasadena, CA

Abstract: Sleep appears to be conserved across the animal kingdom, and adequate sleep is essential for human health. However, despite its ubiquity and importance, surprisingly little is known about the genetic, molecular, and neuronal mechanisms that govern sleep. Exogenous

melatonin (MT) is recognized as a somnogen in humans, but endogenous MT, whose synthesis is controlled by the circadian clock, has only recently been shown to be required for normal sleep levels. Using the diurnal vertebrate zebrafish, our lab demonstrated that loss of an enzyme essential for MT synthesis causes a dramatic decrease in sleep at night. We also found that loss of MT has no effect on circadian rhythms but abolishes the circadian regulation of sleep, indicating that MT acts downstream of the clock to promote sleep. We are now investigating the mechanisms by which MT promotes sleep. The human genome encodes two MT-binding receptors, MT1 and MT2, whose effects on sleep are not well-understood. The zebrafish genome encodes six MT receptors: 3 that are orthologous to mammalian MT1, 2 that are orthologous to MT2, and an additional receptor not present in mammals. We created zebrafish lines harboring mutations in each of the six receptors, as well as double and triple mutant combinations. We found that zebrafish larvae lacking all three MT1-type receptor paralogs sleep less at night, similar to MT-deficient animals, and are nearly totally resistant to sleep induced by exogenous MT. Next, using *in situ* hybridization chain reaction (HCR), we found that the MT1 receptors are primarily expressed in the periventricular grey zone of the optic tectum, a structure homologous to the superior colliculus of mammals, and in a discrete cluster of cells in the hindbrain. We are currently optimizing HCR to better ascertain the location of these receptors, which we anticipate will point to critical sleep-regulating parts of the brain. Last, we are using 2-photon selective plane illumination microscopy (2P-SPIM) to image the entire brain of larval zebrafish expressing the calcium sensor GCaMP6f pan-neuronally. We hypothesize that animals treated with MT will exhibit specific changes in neuronal activity, which may represent a subset of neuronal changes observed during normal sleep, and that these MT-induced changes are not observed in larvae lacking the relevant melatonin receptors.

Title: Quantitative EEG during REM sleep in patients with frontal brain tumor

Authors: *L. ORTEGA-LEONARD, Y. DEL RÍO-PORTILLA;
Univ. Nacional Autónoma de México, Mexico city, Mexico

Abstract: The frontal lobes previously have been associated in the regulation of eye movements and with the cognitive changes during the dreams in REM sleep stage. This can be explained by the changes in the electroencephalographic bands and in the temporal coupling of the frontal areas with other brain regions. Likewise, electrophysiological sleep patterns can be modified because of a brain pathology, such as tumors, which allows us to know in depth what happens when these lesions affect a particular area of the brain, such as the frontal lobes, and which are scant studies about it. Whereby, ten patients with frontal brain tumor underwent polysomnographic study. They had a mean age of 43.4 years (SD=11, three women and three in the left hemisphere). Patients were registered in the absence of treatment (surgery, chemotherapy or radiotherapy) and without neurological, psychiatric or autoimmune comorbidity. REM sleep stages were selected, inspected for artifacts and analyzed for the first episode from the second half of the night. For the analyses quantitative EEG (qEEG), Fast Fourier Transformation (FFT) algorithm was used to obtain the power spectral for each participant, channel and the following frequency bands: Delta2 (1-3.5 Hz), Theta (3.5-8 Hz), Alfa (8-12 Hz), Sigma1 (12-14 Hz), Beta1 (16-24 Hz), Beta2 (24-32 Hz) and Gamma (32-48 Hz). According to the results, higher spectral power densities for REM sleep, for all electrodes and for each of the bands; can be observed by patients compared to the normative values (Hertenstein et al., 2018). No significant differences by sex, laterality of the tumor, specific location of the frontal lobe (medial, lateral and orbital) and size of the lesion (volume and edema) in the spectral power. Also, there were significant differences in the spectral power in the delta band ($p = 0.003$) and in the total spectral power ($p = 0.02$) between the anterior and posterior electrodes. The changes observed in the spectral power in patients with frontal brain tumor can be considered as a plasticity effect (compensatory reaction) in the sample recorded in this study. Finally, the presence of this type of pathology, which causes structural and functional changes, allows us to understand the organization of the brain during this state.

Title: Basal forebrain astrocytes promote sustained wakefulness through G_q-protein-coupled pathways

Authors: *A. M. INGIOSI, C. R. HAYWORTH, M. G. FRANK;
Translational Med. and Physiol., Washington State Univ., Spokane, WA

Abstract: Sleep disorders continue to be a prevalent health issue, but the cellular and molecular substrates of sleep regulation are incompletely understood. Understanding how sleep is regulated is necessary to better understand the underlying causes and consequences of abnormal sleep and sleep disorders. Accumulating evidence indicates astrocytes contribute to sleep regulation and behavior via intracellular calcium signaling. We recently showed that astroglial calcium activity 1) changes dynamically across arousal states, 2) increases with sleep need, and 3) plays a role in compensatory responses to sleep loss. We are now determining which astroglial signaling pathways act upstream of calcium activity to influence sleep-wake behavior. The latter are likely to involve neurotransmitters like noradrenaline which signal through G-protein-coupled pathways to increase astroglial calcium activity. To test this hypothesis, we used a chemogenetic approach to activate G_q signaling in astrocytes in the basal forebrain and measured sleep-wake behavior and electroencephalographic (EEG) activity. G_q DREADDs (i.e., Designer Receptors Exclusively Activated by Designer Drugs) were expressed selectively in astrocytes by crossing CAG-LSL-G_q-DREADD mice with Aldh1l1-cre mice. Male and female adult (10 - 14 weeks-old) mutant mice (n = 9) and wildtype littermates (n = 7) were stereotaxically implanted with electrodes for EEG and electromyographic (EMG) determination of sleep-wake behavior as well as bilateral guide cannulae in the basal forebrain for local delivery of DREADD ligands. We used a within subject, counterbalanced design to assess the impact of G_q DREADD activation via the DREADD ligand clozapine N-oxide (CNO) versus vehicle. CNO (or vehicle) was injected at light onset and mice were then allowed to sleep undisturbed for 24 h. We found that CNO activation of G_q DREADDs in basal forebrain astrocytes induced sustained wakefulness that could exceed 6 hours—an effect not observed after vehicle treatment or in control mice. JHU37160, a CNO alternative, also induced sustained wakefulness in G_q DREADD-expressing mice. Ongoing analyses and experiments will determine the impact of this sustained wakefulness on EEG spectra, sex differences, and which neuronal populations are responsive to this astroglial-induced wakefulness. Overall, we present preliminary evidence that basal forebrain astrocytes play a role in mediating sleep and wakefulness through G_q signaling pathways.

Abstract: Sleep is observed universally across various species from nematodes to mammals and the properly maintained sleep is directly linked to the general well-being of the organism. Much advances has been made in the identification of the distinct groups of neuronal population that are involved in the transitions between sleep and wake states. These networks of neurons can drive vigilance stage switches and changes in neuronal activity related to sleep and wakefulness. Despite the growing interest and findings in the maintenance of sleep/wakefulness, the intracellular regulatory mechanism of the response to sleep need changes remains largely unknown.
Our EEG/EMG-based forward genetics approach in mouse sleep/wake behavior has successfully identified several sleep regulatory genes. *Sleepy2* is one of such gene locus with a single nucleotide change in the splice acceptor site that leads to out-of-frame mutation. The heterozygous mutant mice with the resulting splice variants showed increase in both daily non-REM sleep (NREMS) time and slow-wave activity during NREMS. Interestingly, a phospho-deficient mutant type mice showed a complete opposite trend in sleep/wake behavior. These mice showed increase in daily wake time and significant decrease in the slow-wave activity during NREMS. These results suggest canonical signaling of *Sleepy2* gene is involved in the regulation of NREMS.
For further understanding of specific neuronal network where the identified sleep regulators may function, we employed a neuron type-specific manipulation engineered by Cre-loxP recombination. From the comparison of various *Cre* reporter lines, distinct neuronal types were identified to regulate the NREMS time and the slow-wave activity. It is plausible *Sleepy2* signaling modulates the amount and quality of sleep discretely neuronal network in type- and region-specific manner.

Title: Molecular hydrogen alters NREM delta oscillations during the recovery from sleep loss and BMAL1 in skeletal muscle

Authors: *S. VINCENT[1], K. GOLDEN[1], M. MADANI[1], C. JACKSON[1], T. LEBARON[2], A. TARNAVA[3], I. S. NICHOLS[1], K. N. PAUL[1];
[1]Integrative Biol. and Physiol., UCLA, Los Angeles, CA; [2]Dept. of Kinesiology and Outdoor Recreation, Southern Utah Univ., Cedar City, UT; [3]Natural Wellness Now Hlth. Inc., New Westminster, BC, Canada

Abstract: Sleeping species have an intrinsic need for sleep that is distinct from the circadian clock. Sleep need is determined by a system which interprets wake- and sleep-experience and generates sleep pressure to maintain sleep-wake homeostasis. The mechanisms underlying this homeostatic process are enigmatic, but we can measure sleep pressure through electroencephalography (EEG) changes in the delta band (0.5-4.0Hz) during non-rapid eye movement (non-REM) sleep in mammals. Acute sleep loss modulates pro-inflammatory mediators, impairs memory, and decreases insulin sensitivity. Behavioral interventions for improving sleep are often inadequate to resolve environmental- or disorder-driven sleep disturbances. Pharmaceutical hypnotics are typically accompanied by undesirable side-effects and long-term use can lead to dependence. Molecular hydrogen is a promising therapeutic with a wide range of potential benefits, including the regulation of pro-inflammatory mediators, and the modulation of insulin sensitivity. Molecular hydrogen has no known toxicity and is widely accepted to have no deleterious side effects. Here, male and female C57BL/6 mice were implanted with head-mounts for polysomnography containing two electrodes for EEG (frontal and parietal) and two electrodes for electromyography (nuchal). At 12-16 weeks, a 24-hour recording of baseline/spontaneous sleep was collected, immediately followed by 6 hours of total sleep deprivation and an 18-hour recovery period. One week later, baseline, sleep deprivation and recovery were evaluated again following 7 days of ad libitum access to hydrogen-rich water (HRW) at 0.7 -1.4 mM during the active phase. Two-way ANOVA revealed no significant differences in undisturbed or recovery sleep amounts, nor in delta power during spontaneous sleep. Significant differences were found in relative delta power during recovery sleep, suggesting that HRW may be sufficient to alter the response to the challenge of sleep loss. Oral ingestion of HRW does not increase hydrogen in the brain, but it does increase hydrogen in femoral arteries. Brain and Muscle-ARNT-like factor (Bmal1/BMAL1) in skeletal muscle is sufficient to regulate numerous aspects of sleep in mice. Hydrogen increases the phosphorylation of muscle glycogen synthase kinase 3 beta (GSK-3β), which is critical for preparing BMAL1 for degradation. We show here that HRW administration by oral gavage (0.25ml, 1.4mM) 30

minutes prior to tissue collection is sufficient to significantly increase BMAL1 protein levels in gastrocnemius of mice, providing a plausible mechanism through which HRW might influence sleep.

Title: Exploring the function of orexin and neurotensin as NREM and REM sleep modulators by the measurement of neuropeptides in the cerebral spinal fluid of hypersomnolence patients

Authors: S. MIYAZAKI[1,2], K. YOSHIZAWA[3], T. KODAMA[4], H. ISHIDO[1], A. IMANISHI[3], M. KASHIWAGI[1], T. SASAJIMA[5], S. SHIMIZU[6], S. CHIBA[1,7], H. KONDO[1], Y. HAYASHI[1,2,8], T. KANBAYASHI[1,7], *M. KIMURA[1];

Sci., Tokyo, Japan; [5]Akita Prefectural Ctr. for Rehabil. and Psychiatric Med., Akita, Japan; [6]Tokyo Med. Univ., Tokyo, Japan; [7]Ibaraki Prefectural Med. Ctr. of Psychiatry, Kasama, Japan; [8]Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan

Abstract: While recent studies reveal an orexin-mediated wake-promoting system, molecular mechanisms regulating non-rapid eye movement (NREM) and REM sleep are less clear. We uncovered that specific neurons in the brainstem are crucial for the switching between NREM and REM sleep in mice (Hayashi et al., 2015). Further, neurotensin produced by a subset of these neurons appears to contribute to inhibiting REM sleep (Kashiwagi et al., 2020). In contrast to cumulative evidence from animal studies, only a few clinical observations demonstrate the direct relationship between sleep and neuropeptides. Here, we analyzed targeted neuropeptides in the cerebral spinal fluid (CSF) of hypersomnolence patients and compared their levels with reference to patients' sleep phenotypes. In this study, the concentration of orexin, neurotensin, melanin-concentrating hormone (MCH), and corticotropin-releasing hormone was measured with

radioimmunoassay or enzyme-linked immunosorbent assay in the CSF samples from more than 30 patients. CSF collections were conducted according to the protocols approved by the ethics review committee at Akita University and University of Tsukuba. The minimum measurable CSF volume for each neuropeptide was 0.1 mL for orexin, neurotensin, and CRH, or 0.25mL for MCH. Based on the absolute concentration, we found a positive correlation between the levels of orexin and neurotensin, both of which are known to suppress REM sleep in rodents. However, no significant correlation between other neuropeptides was detected from the patients' CSF samples. The results indicate that lowered levels of both orexin and neurotensin might be responsible for frequent occurrences of REM sleep seen in the patients. We further explore the role of these neuropeptides in sleep regulation, analyzing any relationship between the amount of NREM sleep or REM sleep and their concentrations.

Abstract: Sleep problems are highly prevalent in autism spectrum disorders (ASD). Duplications of 15q11.2-13.1 (Dup15q syndrome) are highly penetrant for ASD, intellectual disability, hypotonia and epilepsy. In clinical overnight sleep EEG recordings, children with Dup15q syndrome demonstrate elevated beta band oscillations and abnormal NREM sleep physiology. In this study, we use a maternally inherited 15q duplication mouse model (Takumi model) that recapitulates many of the behavioral phenotypes observed in individuals with this condition, yet sleep phenotypes have not been characterized. Male and female adult Takumi mice (12-20 weeks) and wild-type controls were implanted with EEG/EMG recording electrodes in the frontal (EEG1) and parietal (EEG2) cortex for polysomnographic analysis of sleep and wake states during 24 hour of spontaneous sleep, and again after six hours of total sleep loss. Two-way ANOVA revealed no significant differences in NREM or REM sleep amount between Takumi mutant mice and wild-types during baseline (spontaneous) recording. However,

significant differences were found in relative delta and alpha brain waves in the parietal cortex during NREM sleep with respect to genotype, and a significant interaction of time and genotype in beta waves in the parietal cortex. The frontal cortex did not show any significant effects. These results suggest that NREM sleep features may be altered in this Dup15q mouse model.

Title: Molecular hydrogen decreases spontaneous sleep latency in mice

Authors: *K. GOLDEN[1], S. M. VINCENT[1], M. MADANI[1], C. JACKSON[1], T. LEBARON[3], A. TARNAVA[4], I. S. NICHOLS[2], K. N. PAUL[1];

Abstract: There are numerous consequences of sleep loss, and it is important to find therapies which attune its negative effects- impaired memory, increased stress, and inflammation among others. Molecular hydrogen (H2) has been studied to determine if it acts as a therapy for several disorders. Several reports have demonstrated that H2 suspended in water (hydrogen rich water, HRW) regulates proinflammatory mediators (LeBaron et al. 2019). Additionally, HRW appears to have a neuroprotective effect for dopaminergic cells in a rodent model of Parkinson's disease (Yoshii et al. 2017). We investigated how the administration of HRW changes basic sleep architecture in baseline conditions and in response to sleep loss using a mice model. All mice were implanted with intracranial electroencephalography (EEG) and intra-nuchal electromyography (EMG) electrodes. After surgery and acclimation to a reverse light/dark cycle, a 24-hour baseline recording was taken, and mice were then sleep deprived during the first 6 hours of their inactive phase via gentle handling and were given 18 hours for recovery. After recovery from their untreated baseline, sleep deprivation and recovery periods, mice had ad libitum access to HRW for seven days. Another 24-hour baseline recording was taken, followed by 6 hours of sleep deprivation via gentle handling and another 18-hour recovery period. All files were scored manually by sleep experts utilizing Sirenia Sleep Pro, and each 10 second epoch was scored as wake, NREM, REM or artifact. Paired t-tests revealed no significant difference in NREM or REM sleep amount during baseline or recovery sleep. However, we did observe a

significant decrease in baseline sleep latency following 7 days of HRW, suggesting HRW may be a useful therapeutic for improving sleep onset.

Title: A novel MC4R neurocircuit for integrative control feeding and emotional status

Authors: *Y. XU[1], Z. JIANG[2], J. CAI[3], Q. TONG[4];
[1]Ctr. For Metabolic and Degenerative Diabetes, Houston, TX; [2]Ctr. for Metabolic and Degenerative Dis., The Univ. of Texas Hlth. Sci. Ctr. at H, Houston, TX; [4]Inst. of Mol. Med., [3]Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Maladaptation in form of exaggerated feeding responses to risk indicators causes eating disorders that characterized by severe disturbances in both eating behaviors and emotional changes. Despite the well-recognized association between controlling emotional states and feeding behaviors, the brain neuropathway that underlies the connection between these two behavioral programs is still unclear. Lateral septum (LS) is a subcortical forebrain region known to regulate anxiety and stress. Our recent data found that ventral LS (LSv) receives abundant monosynaptic glutamatergic projections from Sim1-expressing neurons of paraventricular nucleus of hypothalamus (PVH), the brain region known extremely important for homeostatic regulation, including feeding and physiological adaptions for survival. We further revealed that MC4R, a key gene for feeding regulation and most frequent monogenic cause of human obesity, but not other subtypes of PVH Sim1 neurons (i.e. oxytocin, AVP, or CRH neurons) project to the LSv (denoted as PVH^{MC4R}→LSv neurocircuit). Optogenetic activation of the PVH^{MC4R}→LSv neurocircuit resulted in strong negative valences of anxiety-related responses, including increased self-grooming and real time place aversion, and produced significant inhibition to hunger-driven feeding in fasting mice. Of note, when the food was paired with laser stimulation, aversion induced by photostimulating PVH^{MC4R}→LSv projections was able to significantly abolish the food seeking motivation in fasting mice. Strikingly, chronic inhibition of PVH-projected LSv neurons led to robust obesity, but chronic activation of these neurons showed the resistance to high-fat-diet induced body weight gain. Furthermore, we found that specific

disruption of glutamate or MC4R neurotransmission from LSv-projecting PVH neurons resulted in the high susceptibility to obesity development. Altogether, our findings show that LSv is a novel extra-hypothalamic center essential for energy homeostasis, and the PVH^{MC4R}→LSv neurocircuit is a novel shared neural pathway for controlling feeding and anxiety-related emotional states.

Informatics, Houston, TX

Abstract: Obesity has reached epic proportions, however, current therapeutics are limited in efficacy and the underlying mechanisms of obesity are not fully understood. Recently, circadian rhythms have become inextricably connected to obesity. Particularly interesting for its circadian involvement, is the paraventricular nucleus (PVN) of the hypothalamus which functions as both an integrator and regulator of energy homeostasis. We discovered that PVN-specific deletion of the core clock gene, BMAL1 (Brain and Muscle ARNT-Like1), elicits arrhythmic patterns of feeding, metabolism and activity along with obesity and insulin resistance in the *Bmal1*-PVN knockout (KO) mice. We hypothesize molecular mechanisms driven by BMAL1 activity regulates rhythmicity of the PVN to mediate diurnal energy balance. Using bilateral injections of adenovirus-mediated (AAV)-Cre-GFP delivered to the PVN of $Bmal1^{fl/fl}$ mice, we produced *Bmal1*-PVN KO mice. Under infrared sensors to measure locomotion, *Bmal1*-PVN KO mice showed a loss of diurnal rhythms in activity even under entrained conditions. Furthermore, metabolic cage analysis revealed a loss of rhythmicity in energy intake. To test whether arrhythmic energy intake is the primary driver of disrupted circadian activity in these mice, we used an 8-hr time restricted feeding (TRF) paradigm in attempt to restore rhythmicity in the *Bmal1*-PVN KO mice. Two weeks of TRF successfully restored behavioral rhythmicity of the *Bmal1*-PVN KO mice, suggesting that altered energy intake, and not rhythmicity defects in the

master clock known as the suprachiasmatic nucleus (SCN), were the primary drivers of the arrhythmic phenotype. Post-mortem analysis of the tissues from TRF and non-TRF *Bmal1*-PVN KO mice demonstrated a rescue of rhythmic gene expression in mice undergoing TRF, and normal expression of BMAL1 in the SCN of both groups. To understand mechanisms by which BMAL1 activity controls rhythmic PVN function, we conducted chromatin immunoprecipitation sequencing (ChIP-seq) on PVNs harvested from C57/bL6/J mice at the peak of BMAL1 binding for several tissues analyzed to date (i.e. *Zeitgeber* time 8) using an antibody to BMAL1. Interesting targets relevant to synaptic plasticity and neuronal function were validated using ChIP-qPCR. ChIP-seq of PVN BMAL1 targets revealed 832 significant genes involved in several neuronal processes, including synaptogenesis, mitochondrial energetics, and cellular senescence. Our data support BMAL1 in the PVN as essential for diurnal energy balance independent of the SCN. We have identified multiple potential candidate genes which may serve as targets for future obesity treatments and therapeutics.

Title: Role of VTA local neurocircuits in regulating obesity resistance

Authors: *J. CAI[1,2], Y. XU[1], Q. TONG[1,2];
[1]Inst. of Mol. Med., Univ. of Texas Hlth. Sci. Ctr. at Houston, HOUSTON, TX; [2]Neurosci., MD Anderson UTHealth Grad. Sch. of Biomed. Sci., Houston, TX

Abstract: Currently, over 40% of US population have been diagnosed with obesity, which leads to severe metabolic results and poor quality of life. Yet, there is no effective therapy to cure obesity. Thus, identification of potential therapeutic targets is urgent. The Ventral Tegmental Area (VTA) is a brain region known to regulate various cognitive and emotional processes as well as reward consumption. Neuronal signaling in the VTA is implicated in obesity development in humans and manipulating VTA neuronal activities in rodents impacts eating behaviors. VTA GABAergic neurons accounts for 30% VTA neurons and send abundant inhibitory inputs to other local neurons. Whether and how VTA local GABAergic circuits are

involved in body weight regulation is unclear. To understand the function of VTA GABAergic neurons, a mouse model with chronic inhibition of VTA GABAergic neurons has been established by expressing mutant inward-rectifier potassium ion channels (Kir2.1) in those neurons using stereotaxic injections. These mice had lower body weight under chow diet and were resistant to high fat diet (60% fat diet) induced obesity. The decreased body weight was mainly due to increased energy expenditure and increased locomotion as measured by metabolic cages. The immunostaining results showed that putative local glutamatergic neurons were disinhibited. In addition, a model with chronic activation of VTA glutamatergic neurons was established by expressing bacterial sodium channels (NaChBac) in VTA glutamatergic neurons. Chronic activation of VTA glutamatergic neurons led to reduced body weight. Consistent with these results, acute chemogenetic inhibition of VTA GABAergic neurons mediated by designer receptors exclusively activated by designer drugs (DREADD) reduced fasting-refeeding food intake and increased locomotor activity. Meanwhile, chemogenetic activation of VTA glutamatergic neurons increased fasting refeeding food intake. Thus, it appears that chronic inhibition of VTA GABAergic neurons reduces body weight potentially through disinhibiting local glutamatergic neurons. Further experiments are required to verify the anatomical and functions connections. In sum, our current findings support a novel function of VTA GABAergic neurons and local circuits in regulating body weight, especially in regard to resistance to diet-induced obesity. Given the current obesity epidemic, this study will likely have a significant impact on research aiming to identify strategies to reverse obesity development.

Abstract: Recent research has identified somatostatin-expressing neurons within the tuberal nucleus of the hypothalamus (SSTtn) as modulators of food intake in mice. As feeding varies between females and males, we hypothesized that SSTtn neurons exhibit functional differences across sex. To test this hypothesis, we used the Cre-lox system and viral stereotaxic injections to selectively manipulate SSTtn neurons of 8-16-week-old *Sst*-Cre mice. Chemogenetic activation of SSTtn neurons via Gq-coupled DREADDs induced food intake in female and male mice. In contrast, selective ablation of SSTtn neurons via virally delivered Caspase-3 decreased food intake in females only. Ablation also revealed an effect of estrous stage, with food intake only decreasing during the night of proestrus when ovarian hormones like estrogen are rising. Surprisingly, this effect of estrous stage was dependent on body weight. While weight inversely correlated with food intake during the night of proestrus, ablation eliminated the weight-dependency of this effect. This indicates that SSTtn neurons are necessary for the integration of body weight and reproductive cues, promoting feeding in animals with low body weight despite hormonal conditions promoting mate-seeking. Furthermore, fluorescent labeling, flow sorting, and transcriptional profiling of SSTtn neurons revealed many sex differences in gene expression, including the gene for estrogen receptor alpha, *Esr1*. Together, these data point to a mechanism whereby SSTtn neurons sense rising ovarian hormone levels and counteract their anorexigenic effects when energy reserves are low. Thus, sex differential recruitment and/or activation of SSTtn neurons may work to mitigate the effects of sex steroids on behavioral feeding output. This research illustrates how gonadal steroid modulation of neuronal circuits can be context-dependent and gated by other physiological signals.

Abstract: The structure of a mitochodrion is highly compartmentalized and changes in response to the energy demands of its cell. The compartments within the inner membrane (known as cristae) undergo structural changes at the nanometer scale that have been connected to significant differences in ATP production rate. It is therefore beneficial to quantify the characteristics of the cristae on real mitochondria morphologies, especially in the dynamic energetic landscape of a neuron. To this end, the dual membrane structure of nine axonal mitochondria in the mouse cerebellum were digitally rendered in three dimensions, retaining dimensional accuracy from TEM tomography taken to an isotropic voxel size of 1.6 nanometers. Geometric analysis of the the cristae membrane, including its curvature, is employed to quantitatively describe the complex structure of the cristae, providing valuable insights into attributes like lamellarity. Derived from “thin plate” in Latin, the word lamellarity has been used interchangeably with cristae shape factor (the surface area to volume ratio of the cristae compartments). The degree of lamellarity, as determined by shape factor, was found to directly correlate with the percentage of cristae surface area having first principle curvature above a given threshold. This connection between lamellarity and high curvature (associated with supercomplex assembly and ATP synthase function) supports the theory that lamellarity increases energy production. Computational models have shown that high cristae shape factor also induces a high proton motive force. It has been speculated that the tradeoff between the efficiency offered by high cristae shape factor and the high overall capacity for ATP production associated with large surface area explains the different use cases of the mitochondria’s two main energetic states (orthodox and condensed). In these nine crisae geometries, however, the lack of an inverse relationship between surface area and surface area to volume ratio suggests that the variation of cristae architecture prevents a decrease in shape factor as the area increases. This optimization of the cristae structure for ATP production is investigated using geometric analysis, identifying common building blocks across these cristae structures and illuminating the role of lamellarity, surface area, and membrane curvature.

Title: Exercise reverses histone regulation of high-fat diet related gene expression in the hypothalamus

Authors: *K. RAPPS[1,2,3], A. MARCO[4,3], T. KISLIOUK[3], G. STEMP[1], N. MEIRI[3], A. WELLER[5,2];

Abstract: Objective: Obesity affects many physiological systems. Recent research has shown that exercise, even in the absence of diet change, can enhance physiological health and reduce symptoms of metabolic syndrome (MeS) that are associated with overweight. However, the mechanisms by which these improvements occur are not clearly understood. Here, we aim to uncover the beneficial effect of exercise on epigenetic mechanisms and genes expressed in the hypothalamus of obese and lean rats. **Methods**: Adult female Wistar chow- or high fat-fed rats were provided with voluntary running wheels or remained sedentary for 4-weeks in computerized exercise chambers, while maintaining their diet. At the end of treatment, body composition was assessed, and the hypothalamic Arcuate nucleus (ARC) was extracted for molecular analysis. RNA-sequencing was utilized to uncover whole-genome transcriptional alterations between groups. Since changes in gene expression are involved, changes in candidate histone modifiers, revealed by the RNA-seq, were validated by RT-qPCR and their role in gene regulation was tested via chromatin immunoprecipitation (ChIP) assays on the promoter of selected differentially expressed genes (DEGs). **Results**: Active obese animals gained less weight and had lower body fat composition compared to non-active animals. Two unique functional families of genes, one associated with inflammation, and the other governing insulin sensitivity were impaired by obesity. These families of genes were rescued by moderate physical activity, even though rats maintained a high-fat diet. To understand the molecular mechanisms that govern transcriptional recovery, we examined major transcription factors (TFs) and epigenetic modulators and pinpointed two distinct modifications that play a key role in their transcriptional rebound. The decrease in expression of inflammatory related genes (such as *Zap70* and *Cd74*) is moderated by a decrease of H3K4me3 markers. Concurrently, the increase in expression of genes related to insulin sensitivity (such as *Synpr* and *Igf2bp2*) is modulated by reduction of the strong repressor, H3K27me3. **Conclusion**: Physical activity can partially reverse high-fat-diet related elevation in hypothalamic expression of inflammatory and insulin-sensitivity related genes. This process is mediated by specific epigenetic histone modifications, which might improve health status.

Title: High-fat, high-sugar diet down regulates activity of oxytocin neurons in female rats

Authors: S. BLYTHE[1], J. KIM[2], K. ATTAL[2], *N. TOPORIKOVA[2];
[1]Biol., [2]Neurosci. Program, Washington and Lee Univ., Lexington, VA

Abstract: Estradiol potently suppresses food intake. Indeed, female rats eat less during the pre-ovulatory phase of the estrous cycle, and ovariectomy (OVX) produces hyperphagia and weight gain. The neurohormone oxytocin (OT) has also been shown to inhibit food intake and consumption of palatable sucrose solutions. Interestingly, chronic sugar consumption reduces activity of OT neurons in the hypothalamic paraventricular nucleus (PVN). Recently, sex differences and estrous cycle influences on oxytocin-stimulated food intake have been reported. However, the relationship between estrogen level and OT activity have not been explored in obese animals. The objective of this study is to compare OT neuron number and activation in cycling, OVX, and OVX + estradiol rats fed either a control diet or high-fat, high-sugar (HFHS) diet.
Our study utilized female Sprague-Dawley rats fed either a HFHS diet or control chow for 15 weeks from weaning. The HFHS animals received food containing 60% fat and a 32% liquid sucrose solution. To assess the central effect of diet on OT neuronal activity, we utilized following three groups (i) cycling females on Diestrus (ii) ovariectomized (OVX) females and (iii) ovariectomized females with slow-release estrogen pellet (OVXE). Two weeks following OVX surgeries, animals were sacrificed. Upon termination, HFHS animals weighed significantly more than their control counterparts and exhibited greater fat pad mass. Similarly, OVX animals weighed significantly more than OVXE animals. We used immunocytochemistry to double stain brain sections with OT and cFOS antibodies. Analysis revealed that OVX reduced number of OT neurons in PVN. In addition, we found that the fraction of cFOS-positive OT cells in PVN was smaller in HFHS group. These observations indicate HFHS diet reduces activity of OT neurons in estradiol-dependent manner. Given the fact that OT has been suggested as a treatment for obesity, these findings are clinically relevant.

Title: Lateral Hypothalamic Leptin Receptor Neurons Encode Motivation for Food Approach

Authors: K. KIM, Y. LEE, Y. KIM, H. SONG, M. JANG, D. HA, J. PARK, S. JUNG, J. LEE, S. KIM, H. CHOI;
Seoul Natl. Univ., seoul, Korea, Republic of

Abstract: <META NAME="author" CONTENT="김규식">Motivation elicited from physiological need drives adaptive behavior for homeostasis. The lateral hypothalamus (LH) in the brain has been known as a motivation center. Past studies have shown that stimulation of the LH region have effect on reinforcing motivation for feeding. Recently, in vivo calcium recordings of individual GABA neurons using miniature microscope in mice have shown diversity in neuronal population during feeding behavior. However, which neural subpopulation compute motivation during multi phasic feeding behavior remains a mystery. Here, we examined neural populations in the LH that encode motivation for feeding using photometry, optogenetics, chemogenetics, and behavioral quantification. Photometry results show that LH LepR neurons start to activate on food accessibility, increase during food consumption. We also show that LH LepR neurons start to activate before voluntary approach to food. Furthermore, LepR neuronal activity decreased when food inaccessibility was perceived. Optogenetic results show that LH LepR neurons induce food approach. Optogenetic activation of LH LepR neurons did not induce food approach when food could not be targeted. However, when food could be targeted, LH LepR neuronal activation induced food approach. Furthermore, cue approach behavior increased when mice entered food zone. Optogenetic deactivation of LH LepR neurons decreased food consumption in hungry mouse. Chemogenetic activation results also showed similar results, increasing approach behavior to food but not increasing consumption behavior. Overall our results show that LH LepR neurons encode motivation for food approach when food can be targeted by mouse. This shows that LH LepR neurons take role in the approach to food but not consumption during the multi phasic feeding behavior of animals.

Title: Effect of ketogenic diet and beta-hydroxybutyrate on socio-cognitive deficits and seizures in mouse models of GRIN disorder

Authors: *Y. YAN[1], T. LIPINA[2], D. J. STEVENS[2], L. PEPERA[2], A. J. RAMSEY[1];
[1]Pharmacol. and Toxicology, [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: NMDA receptors are encoded by *GRIN* genes *GRIN1*, *GRIN2A-D*, and *GRIN3A-B*. Rare *de novo* mutations in the *GRIN* genes cause GRIN disorder, a neurodevelopmental disorder with symptoms of profound intellectual disability, epilepsy, and visual cortical impairment. GRIN disorder can be modeled with *Grin1*^{KD} mice, which have a 90% reduction in GluN1 expression leading to NMDAR hypofunction. Cognitive deficits, reduced social motivation, impaired sensorimotor gating and seizures has been reported in *Grin1*^{KD} mouse, making it a promising model for GRIN disorder. Bioenergetic deficits in *Grin1*^{KD} mouse have been reported, suggesting deficient glucose uptake to meet high energy demand. We asked whether ketone bodies could serve as an alternative energy source in *Grin1*^{KD} mice, particularly since a ketogenic diet is an effective therapy for childhood-onset epilepsy. An emerging hypothesis suggests that elevation in beta-hydroxybutyrate (BHB) is key to the therapeutic effect of a ketogenic diet. BHB can be consumed as a supplement in water, making it a preferred substitute. We hypothesized that both a ketogenic diet and BHB can improve the behavioural consequences in *Grin1*^{KD} mice. Long-term exposure to BHB-supplemented water (NPN 80085843; Natural Health Product, USA; 6mg/ml; from 3 to 14 weeks of age) improved the hyperlocomotion and sensorimotor gating activity in *Grin1*^{KD} mice. However, deficits of social behaviour and spatial working memory (assessed by Y-maze) in *Grin1*^{KD} mice were not improved by BHB. We also tested the effect of a ketogenic diet (TD.07797, Envigo Canada; from 5 to 14 weeks of age) on behavioural impairments of *Grin1*^{KD} mice. Preliminary data suggested minimal effect of a ketogenic diet on social behaviour and spatial working memory function in *Grin1*^{KD} mice. To better understand GRIN disorder and develop treatment for *GRIN1* patients, our lab has generated mouse lines possessing same variants in *GRIN1* patients, including the p.Tyr647Ser (Y647S) variant (*Grin1*$^{+/Y647S}$ mice). We observed an increased number of spontaneous seizures after handling induced convulsion (HIC) test in *Grin1*$^{+/Y647S}$ mice. BHB treatment reduced the severity of seizures induced by HIC test and delayed the onset of spontaneous seizures after HIC. Our results suggested modest effect of BHB on cognitive function and a protective effect of BHB on seizures in two mouse models of GRIN disorder. Preliminary data suggested that a ketogenic diet is not superior to BHB. In fact, it showed unwanted side effects including inadequate weight gain. Our study supports BHB as a preferred substitute over a ketogenic diet because BHB produces comparable beneficial effects with fewer adverse effects.

Title: Bipolar disorder and redox imbalance: probing the link between metabolism and psychiatric illness

Authors: *K. KRUTH[1], J. MEHR[1], A. J. WILLIAMS[2];
[2]Psychiatry, [1]Univ. of Iowa, Iowa City, IA

Abstract: Bipolar disorder (BD) remains one of the most difficult psychiatric illnesses to treat, and a lack of understanding behind the molecular mechanism of the disorder has hindered efforts to produce effective pharmacotherapies. Several studies have suggested that BD manifests with mitochondrial and metabolic dysfunction such as mitochondrial hyperactivity and elevated markers of oxidative stress. Additionally, SNPs in multiple mitochondrial genes have been identified as risk SNPs for BD, further indicating that mitochondrial dysfunction may play a role in BD etiology. Here, we investigate the role of reduction-oxidation (redox) imbalance in human fibroblasts, induced pluripotent stem cells, and induced neurons derived from bipolar and healthy control subjects to further elucidate the source of these mitochondrial phenotypes. We have measured key redox ratios including NAD^+/NADH, $NADP^+$/NADPH, and GSSG/GSH to determine whether these cell lines display oxidative or reductive stress. Further, we have assessed reactive oxygen species (ROS) production in these lines both under baseline and mitochondrial stress conditions to probe for differences between BD and control cell lines in their ability to cope with reduced mitochondrial efficiency. Our results suggest that manipulation of metabolism through supplementation with metabolic intermediates may prove therapeutic in BD by restoring redox balance, thereby ameliorating the accumulation of damaging ROS that contributes to neuronal dysfunction.

Title: Genetic dissection of a basal forebrain-to-lateral habenula circuit that drives reflexive aversion and modulates feeding behavior

Authors: *J. SWANSON[1], J. ORTIZ-GUZMAN[1], J. M. PATEL[2], E. HANSON[1], P. HUNT[1], S. DOOLING[1], B. R. ARENKIEL[1];
[1]Mol. & Human Genet., [2]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Feeding circuitry in the brain is regulated by much more than energy state. Environmental cues, mood, and reward/aversion all drive non-homeostatic feeding. While the hypothalamus has been extensively studied regarding homeostatic feeding, it remains to be determined the neural circuits driving more complex, non-homeostatic feeding mechanisms. Recently, we identified excitatory, glutamatergic neurons of the basal forebrain (BF) potently drive appetite suppression. Notably, acute activation of these neurons induces aversive behaviors, as well as aversion to food-associated cues. While this behavior is in part due to projections to the lateral hypothalamic area (LHA), acute activation of these projections doesn't fully re-capitulate the BF activation phenotype, indicating additional targets must be responsible for this appetite suppression and aversion. One prominent projection of the glutamatergic BF that we've uncovered is the lateral habenula (LHb). The LHb is a particularly interesting candidate for feeding regulation, as it's a critical node in aversion, reward, and addiction, inhibiting reward centers of the brain. Thus, *we hypothesize that glutamatergic BF projections to the LHb decrease food intake due to aversion.* Using viral tracing and channel-rhodopsin assisted circuit mapping, we have determined that the BF and LHb are anatomically and functionally connected. Optogenetic activation of BF-to-LHb circuitry drives a remarkable aversive phenotype, and this aversion overrides the drive to eat in a fasted state. Interestingly, this aversion cannot become associated with contextual markers, nor does it promote release of stress or fight-or-flight hormones. Thus, we have concluded this is reflex-like aversion, bypassing learning and memory or any stress response, to modulate feeding behavior. These data reveal new insights into the complex neural circuitry governing aversive and appetitive behaviors, which may be at play in conditions such as eating disorders like anorexia nervosa and bulimia, as well as behavioral causes of obesity.

Title: Distinct roles of dopamine receptor type-1 and type-2 medium spiny neurons in the tail of the striatum in avoidance of potential threats in a semi-naturalistic foraging task

Authors: *I. TSUTSUI-KIMURA, N. UCHIDA, M. WATABE-UCHIDA;
Harvard Univ., Cambridge, MA

Abstract: In natural environments, it is critical to properly assess potential threats for appropriate behavioral choices. Although it is important to predict threats without experiencing an outcome such as pain, previous studies have often used painful stimuli to model avoidance. Here we used a semi-naturalistic foraging paradigm to model avoidance of potential threats. In this paradigm, a thirsty mouse freely goes out of a homing area and enters a foraging arena to obtain a water reward. In test sessions, a predator-like big object ("monster") surges toward it while a mouse approaches to a reward. On initial encounters with a big monster, most mice advanced close to the reward location but failed to obtain it, and fled into the homing area. In subsequent trials, mice returned home earlier before obtaining reward even before the monster charged, indicating that mice learned to predict a potential threat even before the monster charges. In contrast, mice did not avoid a big monster which remained stationary, or a smaller monster that charged, indicating that the movement and the size are important factors to make an object threatening. Over days of sessions with a moving big monster, mice gradually succeeded more to acquire reward, suggesting that they learned to overcome the threat (habituation). We have previously shown that dopamine neurons projecting to the tail of the striatum (TS) play an essential role in avoiding a threatening stimulus (e.g. air puff and a novel object) (Menegas et al., 2018). In this study, we found that increasing the extracellular dopamine level in TS with dopamine transporter inhibitor (GBR12909, bilateral) induced avoidance of a small monster, while ablation of TS-projecting dopamine neurons with 6-hydroxidopamine (bilateral) decreased avoidance of a big monster. We next examined whether dopamine receptor type-1 or type-2 expressing medium spiny neurons (D1- or D2-MSNs) in TS are involved in avoidance of a monster. D1- and D2-MSNs were ablated by cre-dependent expression of diphtheria toxin in TS of Tac1-cre and Adora2a-cre mice, respectively. We found that mice with D1-MSNs ablation did not avoid the big monster. In contrast, mice with D2-MSNs ablation avoided the big monster and failed to overcome a big monster in subsequent sessions over days. These results suggest a crucial role of dopamine and D1-MSNs in TS in avoidance and prediction of a potential threat, and a contrasting role of D2-MSNs for threat management (habituation). Together, these results

provide not only the mechanism for threat assessment, but also a basic principle of how D1- and D2-MSNs regulate behaviors under the control of dopamine over the course of learning and habituation.

Title: Basolateral amygdala mediates retrieval of both recent and remote fear memories

Authors: *J. LIU, M. S. TOTTY, L. MALISSARI, S. MAREN;
Texas A&M Univ., College Station, TX

Abstract: Considerable evidence indicates that the basolateral amygdala (BLA) has a critical role in the acquisition and expression of Pavlovian fear conditioning in both rats and humans. For example, BLA lesions made up to one year after fear conditioning in rats prevent the expression of conditioned freezing. However, selective optogenetic silencing of BLA principal neurons disrupts freezing only hours, but not days after conditioning. These data suggest a time-limited role for the BLA in fear memory retrieval. To clarify this issue, we reexamined the role of the BLA in fear memory retrieval using optogenetic, electrophysiological, and calcium imaging methods in rats. Importantly, we used a behavioral design that permitted a comparison of recent and remote retrieval in the same subjects. First, we found that the retrieval of recent (1 day) or remote (2 weeks) fear memories yielded similar levels of c-Fos expression in the BLA. Extracellular recordings of BLA neuronal activity in behaving rats revealed similar numbers of CS-responsive neurons during the retrieval of recent or remote fear memories. Moreover, individual BLA neurons exhibited similar increases in CS-evoked spike firing during both the recent and remote retrieval tests. This outcome was also observed in fiber photometric recordings of BLA principal neuron activity (AAV-CaMKII-GCaMP6f), suggesting an enduring role for BLA principal cells in the expression of long-term fear memory. Consistent with these results, continuous optogenetic inhibition (AAV-CaMKII-Jaws) of BLA principal neurons produced robust impairments in conditioned freezing to recent and remote CSs. Similar outcomes were observed when BLA activity was inhibited only during the CS, though these effects were weaker than with continuous inhibition. Lastly, optogenetic activation of BLA interneurons (AAV-mDlx-ChR2) suppressed conditioned freezing to both the recent and remote CS. Collectively,

these results indicate that BLA neurons are indispensable for both recent and remote fear memory retrieval. We conclude the BLA is a long-term storage site for emotional memories acquired during fear conditioning.

Title: Redefining the Sensory Inputs to the Lateral Amygdala

Authors: *J. OREA[1], L. OSTROFF[2], E. PARRISH[2];
[1]Univ. of Connecticut, Storrs, CT; [2]Physiol. and Neurobio., Univ. of Connecticut, Storrs Mansfield, CT

Abstract: The lateral amygdala (LA) has a central role in processing the emotional content of sensory stimuli, and synaptic plasticity in the LA is a well-established mechanism of memory storage for auditory Pavlovian conditioning. LA neurons receive sensory input from both the cortex and thalamus, but how these inputs are organized is not fully understood. According to the canonical literature, the predominant auditory inputs to the LA are thalamic projections from the medial division of the medial geniculate (MGm) and adjacent posterior interlaminar nucleus (PIN), and cortical projections from association area TE3. A projection from the multimodal agranular posterior insular cortex (AIP) has also been reported. The LA may offer unique insights into how neurons integrate converging sensory information, but the classic neuroanatomy literature lacks fine-scale data on the input regions and targets. To better delineate the input regions and map their convergence in the LA, and to determine whether the circuits defined in males are identical in females, we began with small injections of the retrograde tracer Fluorogold in the dorsolateral LA of Sprague-Dawley rats of both sexes. Retrogradely labeled neurons were found in TE3, PIN and the dorsal division of MG (MGd), as previously reported, but there was no labeling in the insular cortex or in MGm. To visualize the boundaries between MGm, PIN, and ventral MG (MGv), we used parvalbumin immunostaining to reveal the MGm-specific inputs from the cochlear nucleus. It is likely that earlier studies reporting MGm projections to LA used less stringent boundaries between PIN and MGm, accounting for the discrepancy. Previous studies reporting AIP projections used bidirectional, transsynaptic tracers and thus may have included anterograde or polysynaptic connections. MGd labeling has been

observed in previous retrograde tracing studies of LA but the inputs have not been mapped. To explore this projection, we performed small injections of an adenoviral tracer expressing a GFP reporter in MGd, which revealed very heavy projections that were restricted to the caudal extent of the dorsolateral LA and validated retrograde observations. Further anterograde injections confirmed that the MGd and TE3 projections have identical projection patterns to dorsolateral LA, which are denser and more restricted than those of PIN. Overall, our results confirm the traditional model of converging inputs to LA from auditory thalamus and cortex, but revise the predominant source of thalamic inputs from MGm/PIN to MGd and PIN.

Title: Sex differences in the expression of defensive behavior of rats under chasing threat paradigm

Authors: *G. PYEON, J. LEE, J.-S. CHOI;
Korea Univ., Seoul, Korea, Republic of

Abstract: Women are more vulnerable to anxiety- and fear-related disorders. However, most of the relevant basic studies have been conducted in male animals. Here we investigated sex differences in anxiety level in the elevated plus-maze and in the defensive response under chasing threat and in Pavlovian threat conditioning. The current study developed a novel fear paradigm called “chasing threat” in which rats are chased by a fast-moving robot in an inescapable maze, which mimics a predatory threat in nature. In Experiment 1, anxiety levels in naturally cycling female and male rats in the elevated plus-maze were measured. The proestrus female rats entered and spent more time in the open arms compared to the male and diestrus female rats. In Experiment 2, female and male rats were exposed to chasing threat and their threat memory was assessed in a retention test 3 days later. The female rats exhibited an active defensive response known as darting, whereas male rats dominantly displayed freezing response, and the darting response in females was maintained until the retention test. In Experiment 3, a new group of rats was used to investigate sex differences in defensive response during Pavlovian threat conditioning. Similar to the chasing threat, female rats displayed a darting response, whereas male rats showed mostly freezing. However, the darting responses in female rats were not maintained until the retention test. Taken together, differential responses to chasing threat

and to the Pavlovian conditioned stimulus demonstrated sex differences in defensive response in which the male rats exhibited passive freezing responses dominantly whereas the female rats displayed active darting responses. However, the chasing threat with high ecological validity showed the more long-lasting effect of sex differences in active defensive responses compared to the Pavlovian situation.

Title: Prefrontal cortex neuronal ensembles process anxiety and fear behavior

Authors: *J. P. CASANOVA[1], C. POUGET[2], I. AGARWAL[2], G. VETERE[2];
[1]ESPCI, Paris, Paris, France; [2]ESPCI, Paris, France

Abstract: Anxiety and fear are distinct but overlapping emotions that express different levels ofrisk assessment and applied behaviour. In this work we studied the dorsomedial prefrontal cortex (dmPFC) neuronal activity underlying the behavioral expression offear and anxiety-like behavior. The neural calcium dynamics from hundreds of dmPFC cells was visualized using a miniaturized fluorescence microscope. Mice were subjected to 3 behavioral tests, in an increasing anxiety- and fear-inducing potential way. Single dmPFC cell activity is preferentially modulated by either anxiety or fear-like behaviour and by electric footshocks. In behavioural tasks where risk assessment is requested, we observed that the dmPFC population cell activity switch between states. Moreover, population cell activity recorder during anxiety-like behaviour can predict freezing behaviour, but not the opposite. However, in tasks where a threatening stimulus elicit strong fear, dmPFC population cell activity stabilizes to a single state over the entire period. Our results further support that dmPFC activity is engaged during anxiety-like behavior and fear at both, single neuron and population level, and that dmPFC has a key role in assessing the risk in uncertain situations.

Abstract: The habenula is a phylogenetically conserved structure present in all vertebrate animals and it is located in the epithalamus, together with the pineal gland. This structure is anatomically divided into medial habenula and lateral habenula (LHb). LHb presents broader connections towards the limbic system and basal ganglia, as well as several structures that transmit information of the internal state, like the insular cortex. Accordingly, LHb connects with some areas of the brain that are crucial during rewarded learning. In this regard, evidence indicates that LHb plays a critical role in aversion-mediated learning since it responds to signals that predict adverse stimuli with aversive outcomes. On experimental animal models, LHb neurons' pharmacological inactivation produces behaviors of "indifference" to the consequences of outstanding events. For example, rats that received deep brain stimulation in the LHb significantly reduced the levels of sucrose self-administration; in contrast, LHb lesion increased sucrose-seeking behavior, delaying extinction response to the substitution of sucrose for water. Thus recently, this structure has related to taste recognition memory as well as during signaling relevance for appetitive stimuli such as sweet tastes. Thus, indirect evidence suggests the involvement of LHb during conditioned taste aversion (CTA), where animals learn to avoid a novel taste associated with visceral discomfort. Hence, it is important to evaluate the participation of the habenula during CTA of a highly appetitive stimulus such as sugar. Therefore, our objective was to assess the function of the LHb through LHb lesions induced by a high concentration of n-methyl-d- aspartate (NMDA) injected before CTA. Adult male Wistar rats with an initial weight of 250-310 g were liquid deprived and trained to consume liquid in a single daily presentation (20min/day). Thirty minutes before CTA acquisition were bilaterally LHb-injected with NMDA (10 μg/μl). Throughout the acquisition, memory retrieval, and three aversive memory extinction sessions, sugar consumptions (10% solution) were measured. The results show that NMDA injection does not affect sensory, motivational, or motor processes during acquisition, and at the dose used, aversive sugar formation was not affected. Furthermore,

no changes in aversive memory retrieval nor the extinction process were observed. In conclusion, the lesion of NMDA-responsive cells in LHb does not alter conditioned sugar aversion, suggesting that during new aversive learning, LHb has not significant involvement.

Title: Gabaergic and glutamatergic neurons of the medial septal area respond differently to punishment and cues predicting punishment

Authors: *C. CALVA, J. COUDRIET, S. IKEMOTO;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Uncertainty in the environment prompts decision-making through the evaluation of potential risks/rewards. Decision-making is fundamental to an animal's ability to survive in constantly changing environments. Therefore, it is critical to understand the neural mechanisms that underlie uncertainty-driven behaviors. Medial septum (MS) neurons have been shown to play a role in motivated behaviors and respond to salient stimuli and cues related to uncertain rewards and punishments. Prior unit activity studies in primates demonstrated that MS neurons respond to certain and uncertain punishments and cues predicting these punishments. Whether similar neural activities can be found in mice and the specific phenotypic neurons responsible remains unknown. Here we examined whether MS glutamatergic (vGlut2) neurons and GABAergic (vGAT) neurons respond to punishment and cues predicting uncertain and certain punishment. AAV9-syn-FLEX-jGCaMP7f-WPRE was injected and a probe implanted into the MS of vGlut2-cre and vGAT-cre mice. We then performed a Pavlovian conditioning paradigm in which three different tones were paired with a 100%, 50%, or 0% chance of a 0.45mA foot shock, respectively. Behavioral procedures were conducted in tandem with fiber photometry to determine if vGlut2 and vGAT neurons in the MS respond to punishment and cues predicting uncertain and certain punishment. Our preliminary evidence suggests that MS vGlut2 neurons and vGAT neurons display divergent responses. Whereas MS vGlut2 neurons did not respond to the 0% tone, vGlut2 neurons located in the dorsal portion of the MS (n=3) displayed ramping activities upon tones signaling 50% or 100% shock. Moreover, these vGlut2 neurons displayed a response to the foot shock. Interestingly, vGlut2 neurons in the ventral portions of the MS (n=4) responded little to any of the conditioned tones or to the shock. These data suggest that dorsal

MS vGlut2 neurons respond to both the anticipation of punishment and the punishment itself. It is unclear whether MS vGlut2 neurons respond differently between certain and uncertain conditions. By contrast, MS vGAT neurons (n=5) did not clearly respond to the cues predicting shocks but markedly responded to shocks. In general, the presentation of tones had no clear effect on MS vGAT neuron activity. The results suggest that MS vGAT and MS vGlut2 neurons distinctly respond to conditioned stimuli and punishments. MS vGlut2 neurons may respond to both the anticipation of punishment and punishment, whereas MS vGAT neurons may respond to punishment. NIDA-IRP and the Center on Compulsive Behaviors supported this work.

Title: Activation of Ventral Subicular Neurons Decreases Open Field Exploration in Mice

Authors: *J. GEWARGES[1,4], J. STOKES[5], C. JOHNSTON[2], J. SPENCER-SEGAL[3];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Michigan Neurosci. Inst., Univ. of Michigan, Ann Abor, MI; [3]Michigan Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [4]Neurosci. Grad. Program, Ann Arbor, MI; [5]New York Univ., New York, NY

Abstract: Hypervigilance, or decreased risk-taking behavior, is a core feature of anxiety disorders in humans. Previous work identified the ventral hippocampus as a neural structure, in both humans and rodents, that mediates risk-taking behavior, although the directionality of this control is not consistent across studies. However, little is known about the projections emanating from the ventral hippocampus and how their activation drives risk-taking behaviors in response to a perceived threat. One candidate structure downstream of the ventral hippocampus is the ventral subiculum (vSUB), which receives its major input from the ventral hippocampus. Previously, vSUB-lesioned rats showed lower risk-taking behavior, spending less time in the center of a novel open field, and vSUB pyramidal neurons were activated by acute psychological stress. Given this previous work, we hypothesized that vSUB pyramidal cell activity drives risk-taking behavior. Specifically, we expected that chemogenetic activation of vSUB neurons in the vSUB pyramidal cell layer would increase exploration of the center in a large, brightly lit open

field. In 12 male and 12 female 12-15 week-old C57Bl/6 mice, we injected AAV5-hSyn-hM3D(Gq)-mCherry into the vSUB pyramidal cell layer. After allowing adequate time for viral expression (3 weeks), mice were injected with clozapine-N-oxide (to activate the hM3D(Gq)) (N = 12) or Vehicle (N = 12) 20 minutes prior to being placed in a large (72 cm square), brightly-lit open field for 10 minutes. CNO and Vehicle-injected mice showed similar total exploration of the open field (mean distance traveled, CNO: 3194 cm +/- 2139 cm, Veh: 3678 cm +/- 766 cm, $p = 0.4682$), but CNO mice showed less exploration of the center (mean distance traveled in the center, CNO: 162 cm +/- 127 cm, Veh: 352 cm +/- 145 cm, $p = 0.0026$). CNO-injected mice also made fewer entries into the center (CNO: 23 +/- 17, Veh: 42 +/- 12, $p = 0.0054$), but there was no difference in time spent in the center (CNO: 80 s +/- 93 s, Veh: 78 s +/- 33 s, $p = 0.941$). There were no sex differences. These results show that chemogenetic activation of vSUB pyramidal layer neurons decreases exploration of the center of a brightly-lit open field. They suggest that vSUB neuronal activity decreases risk-taking behavior, which is contrary to our hypothesis informed by previous lesion studies. These findings may further our understanding of the neural circuitry behind individual differences in the behavioral response to a perceived threat. Future studies aim to further understand the neural circuitry downstream of the vSUB mediating its role in risk-taking behavior.

Title: Local prefrontal circuits in fear modulation

Authors: *T. W. BAILEY, J. H. SPEIGEL, III, J. MAYER, J. PASTORE, E. KORZUS; Dept. of Psychology and Neurosci. Program, Univ. of California Riverside, Riverside, CA

Abstract: When contextual information is associated with an aversive stimulus, contextual fear memories are created. Post-traumatic stress disorder (PTSD) is characterized by the overgeneralized fear response evoked by trauma reminders that resemble cues from the original traumatic experience. We investigated the hypothesis that fear memory specificity is achieved through an mPFC-dependent mechanism involving the reduction of fear responses to the harmless, overgeneralized context in mice. Fear behavior has been shown to be differentially

modulated by the mPFC subdivisions of prelimbic (PL) and infralimbic (IL) cortex, which enhance fear responses and reduce fear responses, respectively. This differential function of mPFC subdivisions may be due to differential connectivity with the amygdala and its nuclei. cAMP response element binding protein (CREB)- binding protein (CBP) is a coactivator of transcription and histone acetyltransferase, and has been shown to be required for long-term memory consolidation. Using CBP mutants and viral gene-delivery neurogenetic tools, we have developed a system for targeting neuronal hypofunction to specific cortical populations by interfering with long-term memory consolidation. When CBPΔHAT is expressed in IL neurons, severe deficits in contextual fear discrimination learning, but not conditioning, are observed. Also, expression of CBPΔHAT in PL neurons results in profound deficits in fear discrimination learning. While observed deficits in selected prefrontal populations can be rescued by enhanced training protocols, the hypofunction targeted to excitatory neurons throughout the mPFC region resulted in a more severe deficit in differential fear conditioning. In addition, we have identified specific prefrontal projections to amygdala which are not engaged during fear acquisition. These findings provide strong evidence for our hypothesis that mPFC-dependent mechanisms drive modulation of fear responses during discrimination learning. The deficit in fear discrimination learning caused by impaired prefrontal/amygdala circuits is likely to be relevant to understanding and treating neuropsychiatric disorders such as PTSD and anxiety disorders.

Title: A Bottom-up Reward Pathway Mediated by Somatostatin Neurons in Medial Septum Underlying Appetitive Learning

Authors: *L. SHEN[1], G. ZHANG[1], C. TAO[1], M. B. SEO[1], L. I. ZHANG[2], H. TAO[3]; [2]Physiol. & Neurosci., [1]USC, Los Angeles, CA; [3]USC Keck Sch. Med., Los Angeles, CA

Abstract: Valence detection and processing are essential for the survival of animals and their life quality in complex environments. Neural circuits underlying the transformation of external sensory signals into positive valence coding to generate appropriate behavioral responses remain

not well-studied. Here, we report that somatostatin (SOM) subtype of GABAergic neurons in mouse medial septum (MS), but not parvalbumin subtype or glutamatergic neurons, specifically encode reward signals and positive valence. Through an ascending pathway from the nucleus of solitary tract (NST) and then parabrachial nucleus (PBN), MS SOM neurons receive innately rewarding taste signals and suppress the lateral habenula (LHb). They contribute essentially to appetitive associative learning via their projections to LHb: learning enhances their responses to conditioned sensory cues, and suppressing their responses to either conditioned or unconditioned stimulus impairs acquisition of reward learning. Thus, MS serves as a critical hub for transforming bottom-up sensory signals to mediate appetitive behaviors.

Title: Dopaminergic plasticity underlying bonding and loss in monogamous prairie voles

Authors: *A. F. PIERCE[1], E. E. CULTER[2], Z. R. DONALDSON[3];
[1]Psychology and Neurosci., Anne Pierce, Boulder, CO; [2]MCDB, The Univ. of Colorado at Boulder, Boulder, CO; [3]MCBD/Psychology & Neurosci., Univ. of Colorado, Boulder, Boulder, CO

Abstract: While healthy social relationships positively contribute to our health and wellbeing, their loss is detrimental for our mental and physical health. In monogamous prairie voles, dopamine (DA) binding in the nucleus accumbens (NAc) is necessary to induce a preference for a mating partner. After a bond as formed, DA binding is no longer necessary for demonstrating a partner preference but is necessary for displaying aggression towards non-partners, which is accompanied by an increase in DA receptors in the NAc. An increase in DA receptors alone is insufficient to explain the shift in the role of DA from affiliative to aggressive. One hypothesis is that in a long-term bond, interaction with a non-partner induces a larger bolus of DA compared to partner interaction, which may illicit aggression towards non-partners. It remains unknown how rapid temporal DA release dynamics change as bonds mature and can mediate the change in the behavioral function of DA. Additionally, there is no research available investigating how DA release dynamics adapt upon partner separation (loss). To test the hypothesis that bonding and loss results in changes in DA release dynamics, our work leverages $GRAB_{DA}$, a fluorescent DA

sensor with millisecond resolution for measuring extracellular DA levels in the NAc of behaving voles. We combined $GRAB_{DA}$ with fiber photometry to test whether bonding results in alterations in socially-evoked release during unrestrained social interaction with a partner or novel vole. We also examined changes in DA release during appetitive versus consummatory social behaviors using an operant task. Finally, we asked whether bonding and loss can change DA release capacity using optical stimulation. In all paradigms, we used a within-animal approach to assess changes in DA release prior to bonding, at short- and long-term bonding timepoints, and following partner separation. Thus far we found that bond formation decreased optically-evoked DA release compared to an unbonded, naïve state and bond loss decreased DA release relative to a long-term bond. Compellingly, we also found that voles with the greatest change in DA release 30 days after partner separation spent the most time with their partner upon reunion. This suggests that plasticity in DA release dynamics may contribute to individual differences in response to partner loss, which can inform treatments for pathological forms of social attachment and grief.

Title: Rhythmic tactile stroking induces 50-kHz ultrasonic vocalizations in rats via the accumbal dopaminergic system

Authors: *R. SHIMOJU;
Ctr. for Basic Med. Res., Intl. Univ. of Hlth. and Welfare, Otawara, Japan

Abstract: Tactile stimulations, such as rhythmic stroking, elicit 50-kHz ultrasonic vocalizations (USVs) in rats, which are thought to reflect positive affective states. We have previously shown that rhythmic stroking increases dopamine release in the nucleus accumbens (NAc). However, it remains unknown whether the mesolimbic accumbal dopaminergic system is involved in the emission of 50-kHz USVs during rhythmic stroking and whether this system is associated with certain call subtypes and call parameters (such as peak frequency and duration). The present study aimed to investigate the effects of dopamine (DA) antagonism in the NAc on 50-kHz USVs induced by stroking, on call rates, and on subtype profiles. Eight male Wistar/ST rats (8 weeks old) were used in this study. For rhythmic hand stroking procedures, each rat was gently held by the back skin in a vertical position and the whole palm was used to gently stroke the rat

repeatedly in one direction for 30 s. Each rat received one dose of either a vehicle or DA antagonist solution once daily. Stroking stimulation was applied for 30 s at 10 minutes before drug/vehicle injection (control condition) and at 5, 15, and 30 min after injection. USVs were recorded in an UltraSoundGate 116H audio device having a CM16/CMA microphone. For acoustic analyses, recordings were transferred to SASLab Pro. The 50-kHz calls were analyzed manually according to the 14-subtype scheme described by Wright et al. (2010). However, calls with overtones that could not be classified were considered as "predominantly flat calls with harmonics." The influence of drug and time (pre- and post-treatment) on USV parameters was assessed using two-way repeated-measures analysis of variance and post hoc Bonferroni comparisons, as appropriate. Bilateral injection of D1 receptor antagonist SCH 23390 (500 ng/side) plus D2/D3 receptor antagonist raclopride (25 μg/side) significantly reduced the number of "predominantly flat calls with harmonics" during stimulation and the number of frequency-modulated (FM) calls after stimulation. In contrast, no substantial changes were observed in the mean peak frequencies and call durations of total and categorized 50-kHz USVs. These results suggest that the emission of different subtypes of 50-kHz USVs may be differently regulated by dopaminergic transmission. The 50-kHz harmonics and FM USVs induced by rhythmic stroking may be useful behavioral markers for tactile reward in rats.

Title: Somatostatin-expressing neurons from ventral tegmental area have long-range projections.

Authors: *E. NAGAEVA, L. ELSILÄ, A.-M. LINDEN, E. R. KORPI;
Pharmacol., Univ. of Helsinki, Helsinki, Finland

Abstract: Somatostatin-containing (Sst) neurons make up a well-known interneuron subtype within the inhibitory gamma-aminobutyric acid (GABA)-releasing neurons in mammalian forebrain. Interestingly, these neurons can also project far from their original locations, as confirmed in cortex, hippocampus, amygdala and other brain regions (for review, Viollet et al., 2008). Major part of the GABAergic long-range projections in the brain express Sst neuropeptide and might be involved in synchronization of oscillatory activity of distant brain regions. Our recent research (Nagaeva et al., 2020; *eLife*) describes the Sst population in mouse VTA for the

first time. These neurons appear to be very heterogeneous by having three different electrophysiological subtypes and expressing both GABAergic inhibitory and/or glutamatergic excitatory markers, and even dopaminergic (DA) markers. We have also shown that physiologically, several Sst neurons can converge on single VTA dopamine neuron and inhibit it, acting as interneurons. Here we report that the mouse VTA Sst neurons also send their projections far outside the midbrain. We injected anterograde CRE-dependent viral tracer into VTA of Sst-CRE mice and found fluorescent Sst axons to end up in the lateral hypothalamus, particularly in its peduncular part and dorsomedial nucleus (n=4); in the central amygdala (CeA), particularly in its medial part (n=5); bilaterally in the paraventricular thalamic nucleus (PVT), particularly in its central and posterior parts (n=4); in the bed nucleus of stria terminalis (BNST), particularly in its lateral division (n=5). Next, we injected retrograde CRE-dependent viral tracer in each found target region (n=3) and confirmed that VTA Sst projections end up there and are not just passing by. Our results demonstrate that Sst neurons in VTA, as in several other brain regions, can be both interneurons and projection neurons. In addition, this study suggests the VTA Sst neurons are part of the global somatostatinergic system in the brain.

Title: Combining electrophysiology and fluorescent dopamine sensing to assess neuromodulatory effects on nucleus accumbens reward activity

Authors: *C. LONG[1], K. LEE[2], L. YANG[1], T. DAFALIAS[1], S. MASMANIDIS[1];
[1]Neurobio., UCLA, Los Angeles, CA; [2]Brain & Cognitive Sci., Daegu Gyeongbuk Inst. of Sci. and Technol., Daegu Metropolitan City, Korea, Republic of

Abstract: Despite significant progress, we have an imperfect understanding of the rapid modulatory effect of dopamine (DA) neurons on downstream brain activity. Here we focus on one of the main projection sites of midbrain DA neurons: the nucleus accumbens, and a prominent type of signal in this pathway: unexpected rewards. DA neurons, as well as DA

release in the nucleus accumbens, strongly signal unexpected reward events, which are thought to play a critical role in reinforcement learning. Neural firing rates in the nucleus accumbens are also similarly modulated by rewards. The temporal coincidence of reward-evoked DA signals with nucleus accumbens spiking has led to the view that rapid DA signaling is a key driver of reward activity in nucleus accumbens neurons. However, this hypothesis has not been rigorously tested. Thus, it is unknown the degree to which DA release is capable of directly altering neural activity on rapid (subsecond) timescales. Furthermore, it is unclear how varying amounts of DA differentially impact nucleus accumbens firing. To facilitate a systematic study of these questions, here we present an approach combining electrophysiology, photometry, and optogenetics. We use a 256 electrode silicon microprobe to record spiking activity from dozens of neurons, and an integrated optical fiber to concurrently monitor local DA signaling with the fluorescent sensor dLight1.2. In parallel, we perform optogenetic manipulations of VTA DA neurons in DAT-Cre male and female mice, to transiently raise or reduce DA levels in the nucleus accumbens. We present data comparing spiking activity during DA release triggered by either caloric rewards or optogenetic stimulation. We find that optogenetically evoked DA release is sufficient to alter the firing rate of a subset of neurons; however, this effect is only evident when the level of DA release exceeds the level corresponding to reward delivery. Taken together, this combined approach enables rigorous evaluation of the neuromodulatory effects of DA in the nucleus accumbens under both physiological and supraphysiological DA regimes.

Title: Stimulation of the rat medial forebrain bundles enhances gamma oscillations in the primary motor cortex.

Authors: *A. YOSHIMOTO, Y. SHIBATA, M. KUDARA, N. MATSUMOTO, Y. IKEGAYA;
Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Stimulation of the medial forebrain bundle (MFB), which includes axonal fibers of dopaminergic neurons of the ventral tegmental area projecting to the nucleus accumbens, is used as a neural reward for operant conditioning of animals. Rewarding brain stimulation is a powerful motivator, and animals rapidly learn to perform a variety of operant tasks to obtain the reward. Although stimulation of the MFB modulates integration of reward and pleasure, it remains unknown how central and peripheral functions are affected by MFB stimulation. To address this question, we simultaneously recorded electrocorticograms (ECoGs) of the cerebral cortices (primary somatosensory cortices (S1) and primary motor cortices (M1)) and the olfactory bulbs in behaving rats while the MFB was stimulated. We first implanted multiple screw electrodes into the cerebral cortices and the olfactory bulbs as well as a stimulating electrode into the MFB or its nearby region. After recovery, we trained each rat to reproducibly perform a nose-poke test, in which poking its nose into a hole was associated with MFB stimulation. Using the nose-poke test, we optimized the current pulse frequency and amplitude for each rat to demonstrate consistent and sustainable self-stimulation. After the three-day nose-poke test, we observed a significant increase in spontaneous locomotion when stimulating the MFB compared to the neighboring region, suggesting the reward-seeking behavior. We also found that MFB stimulation at short intervals increased sniffing rates, monitored by olfactory bulb ECoGs. Moreover, the MFB stimulation at shorter intervals more increased the power of gamma components of M1 ECoGs. Our simultaneous recordings of central and peripheral activity from awake animals with MFB stimulation have demonstrated that the respiration and neural activity is affected by the changes in interstimulus intervals.

Title: Synaptic controllability of dopamine as a mechanism for adaptive reward behaviors

Authors: *S. C. V. BURWELL[1], H. YAN[1], B. C. SHIELDS[2], M. R. TADROSS[2,1];
[1]Dept. of Neurobio., [2]Dept. of Biomed. Engin., Duke Univ., Durham, NC

Abstract: Dopamine neurons in the ventral tegmental area (VTA_{DA} neurons) associate sensory cues with outcomes in a manner consistent with Reward Prediction Error (RPE) theory. Namely,

unexpected reward causes a *phasic burst* in VTA_{DA} neurons, whereas unexpected omission of reward produces a *phasic pause* in these cells. Though RPE is an accepted description of VTA_{DA} dynamics, it remains unresolved whether bursts and pauses are necessary 'teaching signals' for adaptive learning behaviors. Optogenetics has established that exogenous bursts and pauses are sufficient to drive behavioral conditioning and extinction, respectively. However, endogenous bursts and pauses are more heterogeneous than those produced by optical methods, leaving unresolved whether naturally occurring VTA_{DA} dynamics have a causal role in adaptive behaviors. Here, we propose a "synaptic controllability" conceptual framework, reasoning that modifying the strength of synapses that control VTA_{DA} activity would enable causal interrogation of burst and pause dynamics along physiologically meaningful dimensions. Exploration of this question is enabled by an emerging technology, DART (drugs acutely restricted by tethering), which delivers clinical drugs to genetically defined cells. We combine this approach with a custom multiplexed behavioral task to quantify the rate of conditioning (associating a sensory cue with reward) and extinction (learning that a cue is no longer rewarded) simultaneously within a single mouse. Our key finding is that acute $GABA_A$ antagonism of VTA_{DA} neurons with gabazine-DART accelerates extinction with no impact on conditioning. This confirms the hypothesis that $GABA_A$ receptors are critical for negative RPE teaching signals. However, the direction of the effect is surprising, being opposite to the canonical prediction that an antagonist of VTA_{DA} inhibition should prevent phasic pauses and thus block extinction. We are examining this behavioral result with *in vivo* neural recordings, and performing a converse experiment using diazepam-DART, which is a positive allosteric modulator of $GABA_A$. This framework is a starting point for examining how the synaptic controllability of dopamine by the rest of the brain impacts reward prediction error coding in conditioning and extinction behaviors, with fundamental relevance to our understanding of reward circuitry in adaptive and maladaptive behaviors.

Title: Changes in nucleus accumbens dopamine signals accompanying reward-based learning of a goal-directed sensorimotor transformation

Authors: *J. HUANG[1], C. SANDI[2], C. C. PETERSEN[3];
[1]Brain Mind Institute, École Polytechnique Fédérale De Lausan, Lausanne, Switzerland; [2]Brain

Mind Institute, EPFL, Lausanne, Switzerland; [3]École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: Dopamine signals are thought to be important for reward-based learning and appear to play important roles in regulating synaptic plasticity in the nucleus accumbens and the striatum. However, the precise neuronal circuit mechanisms underlying the learning of even the simplest goal-directed sensorimotor transformations remain to be precisely defined. Here, we measured dopamine signals with fiber photometry using dLight expressed in the nucleus accumbens of head-restrained mice across reward-based sensorimotor task learning. Thirsty mice were first trained in a free-licking task, during which the mouse learned to lick a spout, for which they were sometimes rewarded with water delivery. In free licking sessions, reward triggered a positive dopamine signal, consistent with previous findings, while unrewarded licks evoked a negative dopamine signal. The amplitude of the reward-triggered dopamine response decreased across most individual sessions, likely reflecting the gradual reduction in thirst across each session with accumulated reward. Subsequently, the same mice were trained over days in a whisker-detection task, in which mice learned to lick the reward spout in response to a single brief whisker deflection. Reward delivery appeared to evoke a consistent dLight response across learning days. Whisker detection task learning was accompanied by an increase in a fast sensory-evoked dopamine signal, consistent with a large body of literature indicating dopaminergic reward prediction error signals. These dopamine reward-related signals could causally contribute to task-learning, for example through regulating synaptic plasticity at corticostriatal synapses. Interestingly, dopamine signal dynamics in individual mice during the free-licking task appeared to be predictive of performance on the first day of learning of the whisker detection task. Our results are thus consistent with a role of dopaminergic signalling in reward-based learning and further suggest that inter-individual differences in dopamine dynamics may be an early predictor of future learning performance. As a next step, it will be important to carry out pharmacological and optogenetic manipulations to test these hypotheses in further detail.

Title: Binge-like eating promotes behaviors reminiscent of ‘food addiction’ in obese female rats: Role for the orexin/hypocretin system

Authors: *K. FERNANDOPULLE[1,2], S. LIU[1,2], J. B. MEHR[1,2], S. L. O'CONNOR[1,2], A. ARMANIOUS[1,2], M. H. JAMES[1];

Abstract: Introduction: Significant recent attention has been given to the notion that compulsive overeating, often seen in binge eating disorder and obesity, reflects 'addictive' properties of foods, notably those high in sugar and fat content. Rats with a history of overconsuming palatable food exhibit several addiction-relevant behaviors, including compulsive-like food seeking and enhanced food motivation. The orexin/hypocretin neuropeptide system has been demonstrated to mediate various drug behaviors, however its role in 'food addiction' outcomes has not been examined. Here we examined addiction-relevant behaviors in obese female rats with a history of binge-like eating, and tested whether the orexin system is important for their development and expression. **Methods**: Female Long Evans rats (n=18) were maintained on a high fat diet (45% fat, ad libitum) for 8w before being given intermittent access (30 min, twice/week, 4w) to sweetened fat (vegetable shortening/10% sucrose) in a distinct environmental context ('binge' group). A control ('no binge') group was treated identically but were given an empty food tray during 'binge' sessions. Rats were then trained to lever press for sucrose pellets before being tested for several addiction-relevant behaviors, including food seeking during signaled non-availability periods, 'compulsive' (punished) food seeking, food motivation, and food demand intensity/elasticity. In a second group (n=12), we studied the recruitment of orexin cells after exposure to the binge environment. In a third group (n=16), we tested the effects of a selective orexin-1 receptor antagonist (SB334867; SB) and a dual orexin receptor antagonist (suvorexant) on addiction-relevant behaviors. **Results:** Across all behavioral tests, binge rats showed stronger addiction-like behaviors compared to no-binge controls. Exposure to the binge context was associated with robust recruitment of orexin neurons; orexin receptor antagonism reduced the expression of addiction-like behaviors. **Conclusions**: These data indicate that orexin signaling contributes to the expression of 'food addiction-like' behaviors in obese rats with past binge experience, thus highlighting the orexin system as a potential therapeutic target for compulsive overeating.

Title: Hunger drives perseveration by dampening a nucleus accumbens circuit

Authors: *N. K. SMITH[1], J. M. PLOTKIN[1], B. A. GRUETER[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Obesity and eating disorders are characterized by rigid food seeking behaviors that are resistant to change. Food seeking behaviors are directed by higher-order motivated behaviors that rely on circuits centered on the nucleus accumbens (NAc). Synaptic alterations within these circuits underlie the powerful changes in behavior across different motivational states. Here we show that hunger enhances food-seeking perseveration by dampening excitatory transmission in a NAc to lateral hypothalamus (LH) circuit. NAc GPR171 receptor signaling allows hunger to enhance perseveration, but not persistence, of food-seeking behavior by suppressing presynaptic release probability of glutamate on to a select population of NAc neurons that project to the LH. This presynaptic depression proceeds through a circuit driven mechanism involving acetylcholine signaling. We find that chemogenetic upregulation of the NAc to LH circuit is able to reduce perseveration in food deprived animals. These results describe how hunger-driven neuromodulation targets a distinct dimension of motivated behavior by shaping information flow through anatomically defined circuit elements, and provide a novel target for the rigid food seeking behaviors seen in obesity and eating disorders.

Title: Prenatal THC exposure promotes transcriptional network changes in the ventral tegmental area and promotes reward seeking and phasic dopamine terminal release in the adult rat offspring

Authors: *M. A. LUJAN[1], C. CALARCO[1], B. MAHASWETA[1], S. ARONI[2], S. AMENT[1], G. KUMAR[1], M. MELIS[2], M. K. LOBO[1], J. F. CHEER[1];
[1]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Univ. of Cagliari, Monserrato, Italy

Abstract: Marijuana is the most common illicit drug used by pregnant women and is associated with offspring's attention and learning deficits from early childhood until later in life. However, the impact of prenatal cannabis exposure (PCE) on maladaptive gene expression changes and its consequences on accumbal dopaminergic encoding of reward-seeking behavior have not been

specifically addressed in the adult progeny. In order to address this, we conducted transcriptomic analyses (RNA-*seq*) in VTA brain samples of PCE adult rats. Weighted Gene Co-expression Network (WGCNA), Differential Gene Expression (DGE) and Gene Ontology (GO) analyses all identified single-gene and network-wide alterations of cytoskeletal, mitochondrial, and synaptic plasticity processes related to PCE. Furthermore, the addition of sex as a co-variate revealed transcriptome-wide homeostatic adaptations in female but not in male rats, which failed to cope with the prenatal THC insult. A separate cohort of PCE rats underwent operant training to obtain palatable sucrose pellets under different reinforcement schedules. Congruent with our transcriptome findings and with our previously published work, adult male PCE rats showed sex-specific alterations in reward-seeking behaviors and exhibited exacerbated mesoaccumbal dopamine release ($GRAB_{DA}$) in response to reward-associated cues. Our results suggest that a series of complex, long-lasting transcriptomic maladaptations to *in utero* THC exposure were accompanied by alterations in dopaminergic encoding of natural rewards and their associated environmental cues.

Title: Ventral pallidum GABA neurons bi-directionally control remifentanil relapse following voluntary or imposed abstinence in rats

Authors: *M. R. FARRELL[1], Q. YE[1], Y. XIE[1], J. S. D. ESTEBAN[1], S. V. MAHLER[2]; [1]Univ. of California Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Opioid-addicted individuals often cease their drug use due to mounting life consequences, only to succumb to temptation when encountering cues and contexts previously associated with drug use. Such self-imposed abstinence, despite its prevalence in the addiction cycle, is rarely modeled in rodent addiction experiments, though prior studies have shown that distinct neural circuits are involved in reinstatement of drug seeking after voluntary versus experimenter-imposed abstinence. We and others have shown that ventral pallidum (VP), and

specifically VP GABAergic (VP^{GABA}) neurons, mediate highly motivated reward seeking, as is characteristic of addiction. Here, we tested the functions of these neurons in a model of relapse to opioid seeking after 1) punishment-induced suppression of drug seeking or 2) extinction-mediated suppression of drug seeking. Male and female GAD1:Cre rats and wildtype littermates were implanted with jugular catheters, and infused bilaterally into VP with Cre-dependent inhibitory Gi-coupled DREADDs (n = 13), excitatory Gq-coupled DREADDs (n = 25), or a control vector (n = 31). Rats were trained to lever press for i.v. infusions of the short-acting opioid agonist remifentanil (1.9 μg/50 μL) and a contingent light/tone cue, daily for 14 days in Context A. Next, rats were moved to a distinct Context B, where presses yielded 1) remifentanil+cues, but also a 50% chance of co-administered footshock, or 2) no reward/cue (i.e. extinction training). After achieving abstinence criteria in Context B, we asked how VP^{GABA} DREADD inhibition or activation affected remifentanil seeking in the following tests: Context A (safe context) *with* or *without* response contingent cues, Punishment Context B *with* or *without* response contingent cues, or Extinction Context B *with* or *without* response contingent cues. We found that relative to vehicle day tests, both chemogenetic inhibition and stimulation with CNO (5mg/kg) bi-directionally affected reinstatement following either self- or experimenter-imposed abstinence, in a manner dependent upon discrete drug-paired cues. These results provide new insights into the roles for VP^{GABA} neurons in opioid relapse-like behavior, and demonstrate that these neurons play a key role in relapse to opioid drug use regardless of the experimental model employed.

Title: Feeding and exercise essential values examined in cannabinoid type-1 (CB_1) receptor mutant mice exposed to closed economy conditions

Authors: *I. HUREL, B. REDON, E. MESGUICH, G. MARSICANO, F. CHAOULOFF; Neurocentre Magendie, INSERM U1215, Univ. of Bordeaux, Bordeaux Cedex, France

Abstract: Body homeostasis is regulated by the balance between feeding and activity. Dysregulations in this balance, as observed in obesity or anorexia nervosa, find their roots at the motivation level. This led us to develop an operant conditioning protocol wherein wheel-running motivation, palatable food motivation and preference for either reward in a choice task can be assessed. The use of this protocol, combined with pharmacological and genetic (i.e. constitutive and conditional mutant mice for cannabinoid type-1 (CB_1) receptors) approaches, has revealed the involvement of CB_1 receptors located on GABAergic neurons in the choice between palatable feeding and wheel-running (Muguruza et al., JCI Insight 2019). Our protocol however suffers two main limitations which are respectively related to the facts that (i) mice were daily exposed to the operant chambers, albeit for a limited time (1h), and (ii) home cages were provided with (unlimited) food but not with a running wheel. Thus, the drives for palatable food and wheel-running might have been respectively underestimated and overestimated. Accordingly, we next investigated the role of CB_1 receptors in a closed-economy choice setting wherein mice living in the operant chambers were able to feed a standard diet and to run, doing so under fixed ratio (FR) reinforcement schedules (FR1, FR3, FR10 and FR30). Demand curves for food and wheel running allowed the calculations of their respective essential values. We found that CB_1 receptors located on GABAergic neurons in adult male/female mice (n=5-7 mice/genotype/sex) positively control the essential value for wheel-running. As opposed to the role exerted by CB_1 receptors on palatable feeding motivation, the full deletion of CB_1 receptors proved inefficient on standard food motivation, even after successive changes in the price of food. Using conditional male/female mice expressing CB_1 receptors exclusively in GABAergic neurons, we next asked if the essential value for running was rescued in this group. Although such a CB_1 receptor re-expression allowed an increase in the essential value for running, its level did not fully reach that measured in wild-type mice. This finding indicates that CB_1 receptors on GABAergic neurons are necessary, but only partly sufficient, for running motivation under closed economy conditions. Overall, this model provides a new framework for studying genetic and environmental causes of obesity and anorexia nervosa.

Title: Dorsal raphe provides a glutamatergic input to lateral hypothalamic GABA neurons that plays a role in reward

Authors: *H.-L. WANG, D. BARKER, S. ZHANG, J. MIRANDA-BARRIENTOS, H. WANG, D. ESTRIN, B. LIU, A. FIGUEROA GONZALEZ, M. MORALES;
IRP/NIDA/NIH, Baltimore, MD

Abstract: The dorsal raphe (DR) nucleus is known for containing serotonin neurons that innervate many brain structures. However, we previously demonstrated that a subset of DR neurons expressing the vesicular glutamate transporter 3 (VGluT3) provides a major glutamatergic input to ventral tegmental area, and also identified the Lateral Hypothalamus (LH) as a major target of DR-VGluT3 neurons. Here, we applied anatomical, electrophysiological and behavioral approaches to characterize these DR-VGluT3 inputs to LH. By LH application of the retrograde tracer fluorogold (FG), followed by *in situ* hybridization, we found that within the total population of FG neurons, as many as 60% expressed only VGluT3 mRNA, 10% percent co-expressed VGluT3 with tryptophan hydroxylase (for synthesis of serotonin), and 3% co-expressed VGluT3 and glutamic acid decarboxylase (for the synthesis of GABA). To determine the extent to which DR-VGluT3 terminals form synapses on LH-GABA (VGAT) or glutamate (VGluT2) neurons, we tagged DR neurons by local injection of AAV-CamKII-ChR2-mCherry and LH neurons by local injections of AAV-DIO-eYFP in VGAT::Cre or VGluT2::Cre mice. Within the LH, we observed axons co-expressing mCherry and VGluT3 intermixed with both VGAT and VGluT2 neurons. By immuno-electron microscopy, we found that within the LH, DR-VGluT3 neurons made asymmetric (putative excitatory) synapses mostly on GABA neurons (≈ 80 %) and to a less extent on glutamate neurons. To further confirm the excitatory synapses established by DR-VGluT3 terminals on LH neurons, we prepared LH slices from VGluT3::Cre mice expressing ChR2-eYFP in fibers from DR-VGluT3 neurons. By *in vitro* recording, we detected AMPA-mediated excitatory postsynaptic currents evoked by photoactivation of LH VGluT3 fibers. Next, by in vivo tests, we found that activation of DR-VGluT3 fibers in the LH induced c-Fos expression in local LH-GABA neurons, reinforced instrumental behavior, and produced a conditioned place preference. Both photoactivation-induced behaviors were diminished by intra LH application of glutamate receptor antagonists, but not by serotonin or GABA receptor antagonists. We also found that LH photoactivation of VGluT3 inputs increases sucrose reinforcement behaviors without changing the latency to eat. In a mouse model of depression, we detected attenuation of the activity of DR-VGluT3 neurons innervating the LH to a sucrose reward, suggesting that these DR-VGluT3 neurons play a role in reward and may mediate behavioral symptoms of anhedonia. In conclusion, we demonstrated that DR-VGluT3 neurons provide an excitatory input to LH-GABA neurons that play a role in reward.

Title: Hierarchical control of mesolimbic dopamine and striatal encoding of reward-paired cues governs behavioral flexibility

Authors: *K. M. FRASER[1], V. COLLINS[2], F. PAT[3], P. H. JANAK[3], B. T. SAUNDERS[2]; [1]Univ. of California, Berkeley, Berkeley, CA; [2]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: The ability to resolve uncertainty surrounding reward-associated cues is essential for the proper organization and generation of reward-seeking. Dopamine neurons are reported to be sensitive to the likelihood of reinforcement yet how dopamine neurons, dopamine release, and the activity of their striatal targets are related to the coding and resolution of uncertainty is unclear. Here we make use of pharmacology, *in vivo* electrophysiology, calcium imaging, and optogenetics to determine the contributions of the mesolimbic dopamine system to the hierarchical organization of reward-seeking. Long-evans rats were trained to discriminate when a conditioned stimulus would be followed by sucrose reward by exploiting the prior and non-overlapping presentation of a separate discrete stimulus, an occasion setter. Only when the occasion setter's presentation preceded the conditioned stimulus did the conditioned stimulus predict sucrose delivery. We found that either reversible inactivation or dopamine antagonism within the nucleus accumbens prevented rats from properly estimating when the conditioned stimulus would be rewarded. We recorded single neurons within the nucleus accumbens (n=295) and observed that the magnitude of conditioned-stimulus evoked inhibitions were greater when the conditioned stimulus would be followed by reward, than when it would not. Moreover, we observed a population of neurons in the nucleus accumbens that dynamically altered their firing to the conditioned stimulus, being excited when this cue was not predictive and inhibited when it would predict reward. We monitored dopamine release in the nucleus accumbens making use of fiber photometry and the fluorescent dopamine sensor dLight 1.3b. Dopamine release tracked the presentation of the occasion setter and dynamically scaled when the conditioned stimulus would or would not predict reward predicated on the prior presence or absence of the occasion setting cue. Finally, we find that optogenetic inhibition of dopamine neurons in the ventral tegmental area disrupts the ability of rats to use occasion setters to flexibly scale their reward-seeking. Together these results reveal a mechanism for dopamine neurons and the effects of dopamine release in the nucleus accumbens to dynamically control striatal encoding of ambiguous reward-predictive cues and appropriately generate reward-seeking.

Abstract: The nucleus accumbens shell (NAcSh) and the ventral pallidum (VP) are critical for reward processing, although the question of how coordinated activity within these nuclei orchestrates reward valuation and consumption remains unclear. Inhibition of NAcSh firing is necessary for reward consumption, but the source of this inhibition remains unknown. Here, we report that a subpopulation of VP neurons, the ventral arkypallidal (vArky) neurons, project back to the NAcSh, where they inhibit NAcSh neurons in vivo in mice. Consistent with this pathway driving reward consumption via inhibition of the NAcSh, calcium activity of vArky neurons scaled with reward palatability (which was dissociable from reward seeking) and predicted the subsequent drinking behavior during a free-access paradigm. Activation of the VP-NAcSh pathway increased ongoing reward consumption while amplifying hedonic reactions to reward. These results establish a pivotal role for vArky neurons in the promotion of reward consumption through modulation of NAcSh firing in a value-dependent manner.

Title: Distinct neuronal dynamics of lateral hypothalamus encode approach and consumption behavior

Authors: *Y. KIM, Y. LEE, H. SONG, K. KIM, M. JANG, J. LEE, D.-S. HA, S. JUNG, J. PARK, S. KIM, H. CHOI;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Lateral hypothalamus (LH) has been known as a prime candidate for the motivation center in feeding. However, recent studies demonstrated that GABAergic neurons in LH are responsible for behaviors outside feeding contexts; gnawing and chewing non-food objects. In addition, LH GABAergic neurons exhibit heterogeneity, while located widely throughout unspecified areas. Thus, we aimed to identify the food-specific role of LH GABAergic neurons and which subpopulation neurons encode the motivation for food. Micro-endoscope results from LH GABAergic neurons showed that there are food-specific and non-specific neurons in these neurons. Especially, food-specific LH GABAergic neurons responded consistently to food-related situations. Followed by these experiments, we conducted photometry experiments and found that neural activity of LH LepR neurons, which are the subpopulation of LH GABAergic neurons, significantly increases during feeding behavior, but did not change when mice contacted non-food or drank water. More interestingly, micro-endoscope results further demonstrated that LH LepR neurons can be divided into two distinct subpopulations: those that activate at the initiation of food-approach behavior, and those that activate at the initiation of food-consummatory behavior. To investigate the upstream regulator of LH LepR neurons, we tested the role of NPY, which is known to be the AGRP neuron neuropeptide driving sustained feeding behavior. Brain slice study results showed that the activity of LH LepR neurons increases significantly after the application of NPY. In conclusion, by using fiber photometry, micro-endoscope, and brain slice study, we suggest that LH LepR neurons activate only in food-specific contexts and can be further classified into two groups based on feeding phases.

Title: Effective connectivity of reward networks in humorous and monetary rewards

Authors: *Y.-C. CHAN[1], Y.-C. CHEN[1], W.-C. HSU[2], J.-Y. YANG[1], C.-C. YEH[1], C.-H. YEH[1]; [1]Natl. Tsing Hua Univ., Hsinchu, Taiwan; [2]Natl. Taiwan Univ. of Sci. and Technol., Taipei, Taiwan

Abstract: Most of this research has focused on brain regions and functional connectivity and less is known about patterns of effective connectivity for humorous and monetary rewards. Thirty right-handed with no history of neurological or psychiatric disorders participated in this study. The fMRI study used the 32 humor stimuli, along with 32 monetary stimuli with an image of coins and 32 non-reward stimuli with a gray scrambled image were used. Each trial started with a central fixation. One of the visual reward cues appeared, followed by an anticipatory delay period. Next, participants responded a numerical judgment task. Participants were then notified of whether or not they had earned a reward on the trial and provided a subjective pleasantness rating. Imaging was performed using a 3 T Siemens Magnetom Prisma scanner using a standard 20-channel head coil. The images were pre-processed and analyzed using Statistical Parametric Mapping (SPM12) implemented in Matlab. DCM with PEB analysis was conducted to evaluate effective connectivity for the different reward. Effective connectivity during the 'liking' or outcome phase was then conducted with the subjective pleasantness ratings included as covariates. The modulatory effects for humor rewards involved stronger connections from the VTA to the amygdala and from the vmPFC to the amygdala. Additionally, the modulatory effect of pleasure from humor showed that NAc activity causes a decrease in the rate of amygdala activity. Pleasure from monetary gains activated a network from the VTA to the NAc and from the amygdala to the NAc. The modulatory effects of pleasure from monetary gains were also associated with stronger connections from the VTA to the vmPFC and the lOFC to theVTA. In sum, the VTA seems to play a crucial role in receiving rewards. Amusement from humor increased the modulation effect from the VTA to the amygdala, while the VTA to NAc connection was found to be active during consumption of monetary rewards.

Abstract: The ability to respond appropriately to stimuli that predict rewards or punishments lies at the core of evolutionary fitness, and is disrupted in a number of neuropsychiatric disease states. The amygdalostriatal transition zone (ASt) is anatomically poised to provide a shortcut between corticolimbic and basal ganglia circuitry, and, in parallel with the amygdala, mediate associative learning and behavioral responses to salient stimuli. Like the amygdala, the ASt receives converging sensory input from the thalamic and cortical pathways. However, the downstream projections of the ASt are distinct from canonical outputs of the amygdala complex, and are integrated with striatal circuits involved in action selection. Despite this intriguing circuit connectivity, the function of the ASt is almost completely unknown. Here, we characterized the transcriptomic profile of the ASt in comparison to neighboring amygdalar or striatal nuclei, and collect cellular resolution recordings of genetically-defined neurons during a valence discrimination task to interrogate the functional role of ASt circuitry. We first used single-nucleus RNA sequencing to generate a comprehensive profile of gene expression in ASt neurons, and find that the ASt is a genetically distinct structure from adjacent GABAergic brain regions

(n=18-25 mice, >15000 cells per brain region, >50k unique molecular identifiers per cell). RNAscope labelling also showed a greater proportion of neurons expressing dopamine receptor 2 (D2+) than dopamine receptor 1 (D1+) in the ASt compared to other regions of the striatum (n=8 mice, >8 sections per group, Chi-square test, p=0.0032). Using in vivo electrophysiology we found that that ASt neuron responses to a shock-predicting cue were significantly greater following fear conditioning in 'paired group' mice compared with 'unpaired group' controls (n=8 mice, 30 neurons Paired, n=5 mice, 27 neurons Unpaired, p=0.028, RM ANOVA). We also identify distinct groups of ASt neurons that encode opposing responses to cues predicting reward and punishment, including sustained responses to negative valence cues (n=9 mice, n=41 neurons). Preliminary calcium imaging data also suggests that D2+ ASt neurons show increased conditioned cue responses following fear conditioning. Finally, we find that optogenetic inhibition of D2+ ASt neurons causes a striking reduction in conditioned fear responses to a shock-predicting cue (43% decreased freezing, p=0.0145, paired t-test, n=8 mice NpHR, n=9 mice eYFP). Consequently, our findings suggest that the ASt may be an overlooked and critical structure of the amygdala complex that contributes to conditioned responding.

Title: Downstream targets of DRN dopamine neurons represent distinct facets of the experience of social isolation

Authors: *C. R. LEE[1,2], G. A. MATTHEWS[2,3], M. E. LEMIEUX[2,3], G. SCHNEIDER[2], E. M. BREWER[3], M. R. BORIO[2,3], R. MIRANDA[2,3], L. KEYES[2], E. PERONI[3], G. S. PEREIRA[3], A. LOPEZ MORAGA[3], A. PALLÉ[3], E. Y. KIMCHI[3], N. PADILLA-COREANO[3,2], R. WICHMANN[3,2], K. M. TYE[4];

Abstract: Affiliative social connections facilitate well-being and survival in numerous species. Engaging in social interactions requires positive and negative motivational drive, elicited through coordinated activity across neural circuits. However, the identity, interconnectivity, and functional encoding of social information within motivational neural circuits remains poorly understood. Here, we focused on the downstream projections of dorsal raphe nucleus (DRN) dopamine neurons using dopamine transporter (DAT)-Cre transgenic male mice (DRN_{DAT}), allowing us to target this subpopulation of cells which we previously implicated in isolation-induced social motivation (Matthews et al., 2016). We wondered whether dopaminergic innervation from the DRN could transmit information about social isolation to be represented in downstream targets. Using optogenetics, anatomical tracing, ex vivo electrophysiology, and in vivo cellular resolution calcium imaging, we explored how DRN_{DAT} innervation affected social motivation and neural dynamics of the different downstream targets. We investigated four prominent DRN_{DAT} downstream targets - the bed nucleus of the stria terminalis (BNST), central amygdala (CeA), posterior basolateral amygdala (BLP) and medial prefrontal cortex (mPFC) to probe how each facet of this ethological behaviors promoted by DRN_{DAT} photostimulation was implemented by each circuit component. Photoactivation of the DRN_{DAT}-CeA projection promoted social behavior (n=21 mice; p=0.027) and photostimulation of the DRN_{DAT} -BNST projection promoted exploratory behavior (n=22 mice; p=0.0298), while the DRN_{DAT} -BLP projection supported place avoidance (n=12 mice; p=0.0455), suggesting a negative affective state. Given that DRN_{DAT}-CeA projections promoted social behavior, we performed calcium imaging using GCaMP7f and miniature microendoscopes during social interaction before and after acute (24 hours) social isolation. While we were able to weakly decode if animals were group housed or isolated prior to social interaction based on CeA activity (p = 0.0054, effect size = 12.32% of mean), we observed more robust decoding of housing status from mPFC activity (p = 0.0035, effect size 31.68% of mean). Our findings support a role for DRN_{DAT} projections in promoting distinct features of the response to novel social stimuli - orchestrating a coordinated, flexible response through recruitment of specific downstream circuits. Uncovering the neural circuit mechanisms which govern sociability and revealing the neural representation of a loneliness-like-state are keys to understanding the fundamental need for social connection.

Abstract: The ability to assign positive or negative valence to environmental cues is paramount for survival. Basolateral amygdala (BLA) circuits have been implicated in associative learning, and BLA projections to the nucleus accumbens (NAc) predominantly mediate positive valence (reward), while BLA projections to the centromedial nucleus (CeM) of the central amygdala (CeA) predominantly mediate negative valence (punishment). However, the neural mechanisms initially directing signals to the appropriate pathway during learning remain mysterious. Here, we demonstrate the neuropeptide neurotensin (NT) plays a critical role in valence assignment during the acquisition of learned associations. BLA-NAc and BLA-CeM neurons express the neurotensin receptor 1 (NTSR1) at different levels (***P=0.0005), and NT dose-dependently altered glutamatergic transmission in an opposing manner for BLA-NAc (facilitation; *P=0.0425) and BLA-CeM (suppression; **P=0.0039) neurons. Among inputs providing NT innervation to the BLA, we identified the paraventricular thalamus (PVT) as a functional source of NT that mediates learning. Photostimulation of the PVT-BLA:NT projection enhanced reward learning (*P=0.018) and impaired punishment learning (*P=0.027). However, we also found that PVT:NT neurons corelease glutamate into the BLA. To selectively isolate the contribution of NT, while leaving glutamate transmission unaffected, we used a CRISPR-Cas9 mediated *Nt* gene conditional knockout (cKO) and found an impairment in reward learning (**P=0.0052), and an enhancement in punishment learning (*P=0.039). By developing, validating, and applying a genetically-encoded fluorescent NT sensor to isolate NT signaling from coreleased glutamate,

we observed that NT concentration in the BLA increased during reward conditioning (*P=0.047) and decreased during punishment conditioning (*P=0.003). Finally, to reveal the impact of PVT-BLA:NT on the ensemble dynamics during valence processing, we recorded the activity of BLA neurons (n=683) during a valence-discrimination task in mice with PVT-BLA:*Nt* CRISPR-cKO relative to scrambled guide controls. We found that *Nt* cKO blunted responses to both reward- and punishment-predictive cues, and that valence-coding properties of BLA-NAc and BLA-CeA were disrupted, even when controlling for behavioral states on a trial-by-trial basis. Taken together, we have identified a neuropeptide that signals valence in the BLA, and show that NT is a critical modulator of valence processing, distinctly gating synaptic transmission and orchestrating ongoing activity of amygdala projection neurons mediating positive and negative valence.

Abstract: How do we know our social rank? Most social species, from insects to humans, self-organize into social dominance hierarchies. The establishment of social ranks serves to decrease aggression, conserve energy, and maximize survival for the entire group. Despite dominance behaviors being critical for successful interactions and ultimately, survival, we have only begun to learn how the brain represents social rank and guides behavior based on this representation. The medial prefrontal cortex (mPFC) has been implicated in the expression of social dominance in rodents, and in social rank learning in humans. Yet precisely how the mPFC encodes relative social rank and which circuits mediate this computation is not known. We developed a trial-based social competition assay in which mice compete for rewards, as well as a computer vision tool to track multiple, unmarked animals. With the development of our open source deep learning computer vision tool (AlphaTracker) and wireless electrophysiology recording devices, we have established a novel platform to facilitate quantitative examination of how the brain gives rise to social behaviors. We describe nine behaviors during social competition that were accurately decoded from mPFC ensemble activity using a hidden Markov model combined with generalized linear models (HMM-GLM) (sign test p=0.004 HMM-GLM to chance model; n=9 behaviors). Population dynamics in the mPFC were predictive of relative and absolute social rank and competitive success (p=0.00018 using Wilcoxon rank sum test on auROC curves when compared to shuffled data, for both decoders; n=10 folds/1410 trials). This population-level rank representation translated into differences in the individual cell responses to task-relevant events across ranks that were not present when the mice were alone (p<0.001 using Fisher's exact test for 3 out of 6 events). Finally, we demonstrate that mPFC cells that project to the lateral hypothalamus promote dominance behavior during the reward competition (p=0.03 using 2-way RM ANOVA ChR2 and eYFP). Thus, we reveal a cortico-hypothalamic circuit by which mPFC exerts top-down modulation of social dominance.

Title: Alphatracker2.0: a platform for behavioral estimation of multiple animals, enabling real-time, closed-loop manipulations

Authors: *A. BAL[1,2], H. LI[2], L. R. KEYES[2], S. MISHRA[2], R. PAMINTUAN[2,3], J. DELAHANTY[2], K. M. TYE[4];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Salk Inst. for Biol. Studies, La Jolla, CA; [3]Univ. of California San Diego, San Diego, CA; [4]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: To understand how neural dynamics give rise to complex, ethological behaviors, neuroscience must move towards a comparable temporal resolution of measuring behavior as exists for measuring neural activity. Recent advances in deep learning have opened the door for automated behavioral scoring. State-of-the-art tools allow users to capture pose estimates of behaving animals and classify them into distinct behavioral patterns, but this approach has limitations. First, labeling both pose and behavior can be time-consuming. Second, users must label body parts that will be important for detecting behaviors, but such selection can be difficult and subjective. Finally, other existing methods directly classify frames of a video into behaviors; however, these approaches are unable to deal with cases of more than one animal or behavior, such as social interaction studies, where multiple animals often perform distinct independent actions in addition to interactions with each other. To provide solutions to these challenges, we present AlphaTracker2.0 (AT2.0) - a supervised, deep learning-based, behavioral extraction method that directly estimates social and non-social behaviors of multiple animals from images. AT2.0 provides the benefits of 1) greatly reducing the effort expended on labeling by requiring only behavioral labels without body parts, 2) fast inference times by using a single, lightweight neural network, making real-time, closed-loop manipulations possible, and 3) allowing investigations of groups of interacting animals performing various actions by detecting the precise location of behaviors in images. To achieve this, we conceptualize behavioral identification as an object detection problem. We utilize “keypoint” labels common to pose estimation methods, but instead use them to directly label behaviors on images, thereby bypassing body part detection and increasing the rapidity of this process. For example, to classify face-to-face interactions in mice, a “keypoint” can be placed at the location of intersection of the noses of the two mice.
We demonstrate AT2.0’s efficacy by classifying 5 behaviors (chasing, face-to-face, flank attack, rearing, and grooming) in up to four interacting mice, and show high accuracy with over 0.9 mean average precision values across all behaviors. Additionally, AT2.0’s one-step approach results in rapid inference speeds (9.24 ± 0.00852 milliseconds per frame), increasing the feasibility of closed-loop experiments. Overall, we show that AT2.0 functions as an accurate behavior detector capable of running in real-time, which can greatly facilitate neuroscientific studies of behaviors.

Title: Divergent circuits of the cortical amygdala mediate innate olfactory valence

Authors: *J. R. HOWE, C. L. CHAN, C. M. ROOT;
Neurobio., UCSD, La Jolla, CA

Abstract: Innate behaviors are observed across the animal kingdom, wherein individuals display stereotyped responses to specific evolutionarily relevant stimuli in the absence of prior learning or experience, suggesting developmental or genetic origins. Our past research has demonstrated that the cortical amygdala (CoA) is a key brain region mediating innate motivational valence to olfactory stimuli. However, little is known about the pathways linking these stimuli to valence, nor the genetic basis for such circuits. Here, we identify and characterize interlinked molecular organization, projection motifs, and subregions underlying the cortical amygdala's control of innate olfactory aversion and attraction. First, we found evidence suggesting divergent contributions of the anterior (aCoA) and posterior cortical amygdala (pCoA) to negative and positive valence behaviors, respectively. Next, we performed single-nucleus RNA sequencing and single nucleus ATAC-seq separately on aCoA and pCoA, revealing correlated multi-omic gradients in gene expression and chromatin accessibility along the anterior-posterior CoA axis with distinct populations of divergent cell types across the two sub-regions. Further, using anterograde and retrograde circuit tracing, we were able to identify two circuits, where the CoA projects to multiple valence-related subcortical structures, but primarily to the medial amygdala (MeA) and to the nucleus accumbens (NAc). When interrogating these circuits separately, we found that the CoA-MeA projection mediates innate olfactory aversion, and the CoA-NAc projection mediates innate olfactory attraction. Together, these results illustrate the previously unknown molecular, circuit, and anatomical mechanisms involved in innate olfactory valence.

Title: Heart rate change of rhesus monkeys in anticipation of appetitive rewards

Authors: *J. HWANG, J. F. REYELTS, E. A. MURRAY;
Section on Neurobio. of Learning and Memory, Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Autonomic response measures are often used to infer internal states of subjects who cannot do self-reporting. Although the autonomic nervous system is mainly involved in homeostasis, it has been shown in many studies that autonomic activity reflects cognitive and affective states in humans and animals. As a step to develop a method to study affect and mood regulation, we measured heart rates of rhesus monkeys while they performed tasks in which different fluid reward amounts were cued. For the convenience of cardiac activity measurement, a pulse oximetry (PO) sensor was used. We first validated the consistency between electrocardiography (ECG) and PO by recording both signals simultaneously and comparing them. In our data, the peaks in the ECG signals preceded those in the PO signals by about 300 ms and the correlation of heart rates calculated from both signals was high ($r = 0.95$, $p < 1.0 \times 10^{-15}$). Next the monkeys were trained on a choice task in which different visual cues signaled different magnitudes of fluid reward. A fixed set of 7 cues was associated with fixed amounts of fluid, ranging from 0.15 ml to 1.05 ml. A trial began when the monkey pressed a central button for 1.5 s. Then two visual cues, pseudo-randomly selected from the set, were presented for 1.5 s, one on each side of the monitor. The monkey could choose the cue on the left or right side of the screen by selecting and pressing either the left or right button, respectively, after which a 1.5-s waiting period ensued. At the end of the waiting period, the fluid reward amount associated with the chosen cue was delivered. The temporal separation of the cue period and reward delivery ensured that any change in heart rate during the cue period could not be attributed to breath holding or other reward consumption activities. We found that the heart rates estimated by PO increased as the reward amount became larger. The changes in the heart rate began to occur approximately 500 ms after the cue onset. The heart rates during the cue period were analyzed with a regression model which included variables such as the location of the larger reward, choice direction, reaction time and the amount of the larger reward. The heart rate during the cue period was significantly related to the amount of the larger reward (t-test; $p < 0.01$), but not to the reaction time ($p > 0.05$). It has been suggested that heart rate may reflect a temporally extended affective state (10-50 seconds) in nonhuman primates, because of its long latency. However, our results show that heart rate can be modulated fast enough to reflect trial-by-trial changes of attention, arousal or motivation.

Abstract: A brief encounter with a potential rival induces aggressive arousal which increases subsequent aggressive behavior, phenomena referred to as social instigation or aggression priming. Previously, we found that the level of glutamate input into the dorsal raphe nucleus (DRN) was increased when animal was engaging instigation-heightened aggression. The DRN receives glutamatergic projections from the lateral habenula (LHb), and c-Fos analysis showed an activation of DRN-projecting LHb neurons (LHb-DRN projection) during social instigation-heightened aggression. Both chemogenetic and optogenetic inhibition of the LHb-DRN projection blocked aggression-heightening effect of social instigation in male mice. Optogenetic activation of the LHb-DRN projection caused an increase of aggressive behavior, indicating that the activation of this pathway is sufficient to induce escalated aggression. We then examined

which DRN neurons are responsible for the aggression-promoting effect of the LHb-DRN glutamatergic input. Although the DRN is a major serotonin (5-HT) nucleus, optogenetic inhibition of DRN 5-HT neurons did not block instigation-heightened aggression. Anatomical analysis identified that LHb glutamate projection innervate non-serotonergic DRN neurons that project to the ventral tegmental area (VTA). Indeed, optogenetic activation of DRN-VTA projection increased aggressive behaviors. Our results indicate that the LHb-DRN-VTA projection is involved in the escalation of aggression induced by social instigation.

Title: Internal state and behavior dependent responses of Central Amygdala PKC-δ+ neurons to food related stimuli

Authors: *M. SCHMIT[1], M. RIVERA[2], K. VO[2], T. HASNEEN[2], G. OZTURK[2], H. CAI[1]; [1]Neurosci., [2]Univ. of Arizona, Tucson, AZ

Abstract: The central amygdala (CeA) has been shown to play a role in a variety of functions including arousal, anxiety, fear responses, and feeding, among other motivated behaviors. How this confluence in the CeA influences our perception and experience of different emotional and motivational states is a key unresolved question. Our lab focuses on a subset of these CeA neurons, marked by the expression of protein kinase C-delta (PKC-δ+). Although optogenetic and chemogenetic studies suggest these neurons play a role in feeding inhibition, it is unknown how the neural activity dynamics line up with their function. Our work fills this gap, employing in-vivo calcium imaging - expressing Cre-dependent GCaMP6s in *prckd-cre* mice - and observing the neural activity through a head mounted miniature microendoscope during various feeding-related behaviors. Our data show that the baseline activity of PKC- δ+ neurons is increased after i.p. injection of CCK, consistent with previous *cfos* studies. However, we also show that PKC-δ+ neurons respond transiently during the approach to food. Unlike baseline activity, food approach response is enhanced in both fasted and sated conditions. Continuous optogenetic PKC-δ+ neuron activation in a fasted state inhibits food intake, but our data suggests

that activity paired with food approach may serve a different purpose or possibly be parsed differently downstream. We suggest that the homeostatic need of the mouse is represented in the baseline activity of PKC-δ+ neurons, while the salience of the food stimulus is reflected in their transient response during approach. Understanding how these two aspects of feeding are represented in the same neurons in the central amygdala may help us understand how multimodal pieces of information are integrated in this structure.

Title: Amygdala-cortical circuit determinants of social isolation-induced alcohol consumption

Authors: *R. PATEL[1], M. PATARINO[1], R. L. MIRANDA[1], K. KIM[1], K. BATRA[1], C. R. LEE[1], K. M. TYE[2];
[1]Systems Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: An individual's standing in a social hierarchy is inversely related to alcohol consumption in rodents and non-human primates as well as problematic drinking in humans, highlighting the conserved impact of subordination on motivation for alcohol. Social rank also influences how individuals respond to challenges such as social isolation, a particularly profound stressor with increasing human relevance. However, the neural circuit mechanisms by which social stress experiences engender aberrant alcohol drinking remain largely unknown. In this study, we found that social rank of adult, male mice correlates with alcohol intake (r^2 = 0.25 by Pearson's correlation; **p = 0.01; n = 26), and social isolation increases alcohol intake (***p < 0.001 by paired t-test; n = 14). Notably, we identified a previously unknown relationship between social rank and social isolation-induced escalated alcohol drinking, where subordinates

display a greater magnitude increase in drinking compared to dominants (**$p < 0.01$ by unpaired t-test; n=3/group). These data suggest behavioral factors, emerging from dominance hierarchies, can predict vulnerability to social isolation-induced escalated alcohol drinking. Using *ex vivo* whole-cell patch-clamp electrophysiology, we found that social isolation increases basolateral amygdala (BLA) excitability (*$p < 0.05$ by two-way ANOVA; n= 13-14 cells), highlighting the vulnerability of the BLA to isolation stress. Unilateral photoactivation of ChR2-expressing BLA terminals in the mPFC increased alcohol (YFP: 138.5 licks and ChR2: 392.5 licks; ***$p < 0.001$ by two-way ANOVA post hoc; n = 6/group), but not sucrose or water, drinking, suggesting that social isolation may escalate alcohol drinking through BLA projections to the mPFC. Indeed, using single-cell calcium imaging, we found that the BLA encodes alcohol (n = 180-109 cells), and the percentage of alcohol-encoding neurons is increased following social isolation (from 9.5% to 18.3%). Using a SVM classifier, we found that population-level BLA activity preceding a drinking bout accurately (>70%) decodes whether alcohol or water was consumed, further supporting a role of the BLA in encoding alcohol. Together, these findings suggest that low social rank may be a potent risk factor for increased alcohol drinking following a social isolation challenge, which may be mediated by amygdala-cortical circuits.

Title: Suvn-2300191, a 5-hydroxytryptamine 1a receptor partial agonist for the treatment of depressive disorders

Authors: *V. BENADE, H. TALAKANTI, R. ABRAHAM, N. MUDDANA, L. GUTTIKONDA, R. SUBRAMANIAN, S. PETLU, N. NATH, V. TELIDEVARAPALLI, P. AMIDALA, A. MOHAMMED, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Depression is a mental condition affecting more than 300 million people globally, and is considered to be a leading cause of disability worldwide. The treatments available for depression are still inadequate because a good proportion of patients (60%) do not respond to existing antidepressants and majority of patients experience relapse. Serotonin (5-hydroxytryptamine, 5-HT) is one of the major neurotransmitter systems implicated in several neuropsychiatric and neurological disorders. Among all the 5-HT receptors, the potential role of serotonin 5-HT_{1A} subtype is implicated in the pathophysiology of depression and in the

mechanism of action of antidepressants. SUVN-2300191 is a potent and selective 5-HT_{1A} receptor partial agonist. It showed good oral bioavailability and excellent brain penetration in rodents. Dose-dependent occupancy was observed in rat brain for 5-HT_{1A} receptors using non-radiolabelled tracer. In the forced swim assay, it showed antidepressant like effects by significantly reducing the immobility in both rats and mice. SUVN-2300191 produced dose-dependent increase in dopamine and norepinephrine levels in prefrontal cortex. SUVN-2300191 is currently being profiled as a new therapeutic option for the treatment of depression.

Title: Aggregation of CRMP1, DISC1 and NPAS3 in the brains of victims of suicide

Authors: *B. SAMARDZIJA[1], M. PALKOVITS[2], N. J. BRADSHAW[1];
[1]Dept. of Biotech., Univ. of Rijeka, Rijeka, Croatia; [2]Human Brain Tissue Bank & Lab., Semmelweis Univ., Budapest, Hungary

Abstract: Chronic mental illnesses (CMIs), such as schizophrenia and major depression, are complex conditions with hereditary and non-genetic components. As a result of overlapping symptoms between neurodegenerative disorders and CMIs, we and others have proposed protein aggregation as a possible mechanism. Several proteins have so far been implicated as aggregating in CMIs, including Collapsin Response Mediator Protein 1 (CRMP1), Disrupted in

Schizophrenia 1 (DISC1), Neuronal PAS domain-containing protein (NPAS3), and TRIO and F-actin-binding protein (TRIOBP-1). Most of these have been detected in multiple CMIs, suggesting aggregation to cross diagnostic boundaries. In this study, we looked at suicide as an alternative, discrete non-subjective measure that also spans diagnoses. Studies were performed on brains samples from 14 victims of suicide and 14 control individuals. 6 samples each from patients with depression and Alzheimer's disease were also included for context. Brains were donated as part of the Hungary-wide Lenhossék Program, after granting of family or a legal permission. Samples of the insular cortex were isolated, and flash-frozen after a post-mortem interval of 4.60±0.28 hours. Ethical approval for each stage of this work was obtained from the ethical committees and boards from the Ministry of Health of Hungary, the Semmelweis University, and/or the University of Rijeka, as appropriate. Brain samples were homogenized, and the insoluble (including aggregating) protein fraction was purified with a series of solubilization buffers and ultracentrifugation. Both the original homogenates and this purified insoluble fraction were analyzed with Western Blot. All procedures were performed under blinded conditions. Strikingly, specific species of NPAS3 (n=4), DISC1 (n=2) and CRMP1 (n=3) were found only in the insoluble fractions of suicide victims, and not in any control samples. Three of these samples showed multiple aggregated proteins present. Additionally, levels of CRMP1 were seen to vary in the whole sample between depression patients and control individuals or victims of suicide (in both cases $p<0.05$ by one-way ANOVA). Neither sex nor age showed any significant effect on the results. TRIOBP-1, previously only seen to aggregate in schizophrenia, was not seen as insoluble in suicide victims or depression patients. Based on this small-scale study, it, therefore, appears that species of CRMP1, DISC1, and NPAS3 may aggregate in the brains of a subset of victims of studies. Replication studies, as well as confirmation in additional brain regions are now required to examine this phenomenon in more detail and understand its pathological relevance.

Title: Determination of the domain structure of DISC1 in mammalian cells identifies a region crucial for its aggregation in mental illness

Authors: *B. ZAHARIJA[1], L. SANCHEZ-PULIDO[2], N. J. BRADSHAW[1];
[1]Dept. of Biotech., Univ. of Rijeka, Rijeka, Croatia; [2]Inst. of Genet. and Mol. Med., Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: To date, the pathophysiology of psychiatric disorders remains poorly understood. While traditionally investigated using genetics, disrupted protein homeostasis has been suggested as a biological basis for these diseases in at least a subset of patients. Several proteins previously implicated by genetic studies have been shown to form insoluble aggregates in such illnesses, including Disrupted in Schizophrenia 1 (DISC1). DISC1 is a multi-functional scaffolding protein of significant importance for neurodevelopment. However, delineation of the domain structure of DISC1 has only recently been attempted, using high-throughput analysis in *E. coli*. This approach identified four distinct stable domains named D, I, S and C. Here, we used this knowledge to confirm and refine the structure of DISC1 in mammalian cells, as well as to identify the region of DISC1 responsible for its aggregation. Firstly, we attempted to refine the borders of DISC1 by combining previously published bioinformatics data on DISC1 domains with the recent empirical data. Constructs encoding variants of domains D, I and C were cloned, with borders modified based on theoretical predictions. These were transfected into HEK293 cells and tested for stability via a proteasome inhibition assay. Results obtained by immunoblotting showed that modified versions of D and C domains show improved stability over their empirical counterparts, with evidence that the I region may not represent a stable folded domain by itself. The D, S and C domains were further shown to be functional in isolation, based on interaction with known protein binding partners. In order to investigate which structural region(s) might be responsible for its aggregation, fragments of DISC1 were expressed in SH-SY5Y neuroblastoma cells and their localization patterns viewed by fluorescent microscopy. Single domains exhibited clear cytoplasmic localization with no aggregate formation. In contrast, the combination of domains D and I showed clear signs of aggregation, with full length DISC1 used as a positive control. Based on this, we hypothesized that the unstructured region between these two domains, D and I, is responsible for DISC1 aggregation propensity, which was verified using further truncation constructs. With this work, we confirmed and refined the domain structure of DISC1, a known risk factor for mental disorders. Additionally, these results provided an insight into its aggregation as an important emerging aspect of DISC1 pathology. Together, our data will aid in generation of high-quality animal models to study the mechanism and behavioral consequences of DISC1 aggregation and its relevance for major mental illness.

Title: Understanding the Therapeutic Potential of Several Muscarinic M4 Selective Activators by Evaluating Their In Vivo Activity Across Different CNS Models

Authors: *P. IREDALE, H. N. NGUYEN, S. CHAKILAM, G. SUIDAN;
Cerevel, Boston, MA

Abstract: The M4 muscarinic acetylcholine receptor is a Gi-coupled G-protein coupled receptor (GPCR) preferentially expressed in the CNS, particularly in the striatum with more modest levels seen in the cortex and hippocampus. M4 receptors are expressed both presynaptically and postsynaptically. Presynaptic M4 receptors have been linked with negative modulation of various neurotransmitters including acetylcholine, glutamate and dopamine. The unique brain expression profile of the M4 receptor makes it a compelling target for addressing the symptoms associated with a number of different psychiatric diseases, specifically, recent clinical data have suggested significant potential in the treatment of psychosis associated with schizophrenia or Alzheimer's disease. The key hypothesis underlying the apparent antipsychotic effects of M4 receptors is a reduction in the striatal dopaminergic hyperactivity believed to drive the positive symptoms observed in both schizophrenia and potentially Alzheimer's disease. However, the current tool compounds have been limited with a lack of M4 selective molecules available. Here, we present in vivo data in several different behavioral and physiological assays comparing selective positive allosteric modulators, full agonists and partial agonists of the M4 receptor. All molecules were active in reducing amphetamine-stimulated hyperlocomor activity. However, only the full agonists showed a robust effect in conditioned avoidance responding. The results suggest that each mechanism of activation may provide a unique profile that could make it better suited to the treatment of the symptoms associated with a particular CNS disorder.

Title: Suvn-4404091, a multi-target compound for the treatment of schizophrenia and psychotic disorders

Authors: *J. THENTU, S. PETLU, V. MEKALA, R. SUBRAMANIAN, R. ABRAHAM, N. MUDDANA, N. GUDURU, A. SHINDE, K. BOJJA, P. ACHANTA, R. NIROGI;
Suven Life Sci. Ltd., Hyderabad, India

Abstract: Schizophrenia is a chronic and severe mental disorder affecting 20 million people worldwide. It is characterized by distortions in thinking, perception, emotions, language, sense of self and behavior. Common experiences include hallucinations (hearing voices or seeing things that are not there) and delusions (fixed false beliefs). Schizophrenia is associated with considerable disability and may affect educational and occupational performance. Currently available treatments are marred with moderate efficacy and side effects. Approximately 20 to 33% of patients do not have a therapeutic response to existing treatments, and others have residual psychotic symptoms. Lack of therapeutic effects is also attributed to poor compliance due to side effects like extrapyramidal symptoms, sedation, weight gain, metabolic disturbances, and hyperprolactinemia. SUVN-4404091 is one of our lead compounds which targets dopaminergic pathways of schizophrenia via the D_2 receptors. Affinity for serotonergic receptors such as 5-HT_{2A} and 5-HT_{1A} were observed as well. SUVN-4404091 was found to be orally bioavailable with adequate brain penetration. SUVN-4404091 showed dose dependent occupancy at 5-HT_{1A}, 5-HT_{2A} and D_2 receptors with ED_{50} values of approximately 1 mg/kg, *p.o*. Dose dependent increase in cortical dopamine levels was observed in rats when tested at the therapeutically active doses. In an open field study, SUVN-4404091 attenuated amphetamine induced hyperlocomotion. No significant effect was observed on QTcF or blood pressure parameters (systolic, diastolic and mean arterial blood pressure) in beagle dogs. Wide separation was observed between the efficacy and extrapyramidal side effects. There were no off-target effects in preliminary toxicity studies in rats. SUVN-4404091 could be a promising treatment for the management of schizophrenia and psychotic disorders.

Title: Upregulation of cyclophilin D contributes to mitochondrial dysfunction and oxidative stress in parvalbumin expressing interneurons in schizophrenia

Authors: *J. T. O'BRIEN[1], A. J. PHENSY[2], S. KROENER[1];
[1]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX; [2]Dept. of Psychiatry, Univ. of California San Francisco, San Francisco, CA

Abstract: The cognitive symptoms of schizophrenia have been linked to functional deficits in parvalbumin expressing interneurons (PVI) in the frontal cortex and hippocampus. PVI are fast spiking GABAergic neurons which modulate large networks of pyramidal cells and serve as crucial regulators of the excitatory/inhibitory balance (E/I) in the prefrontal cortex (PFC). Reductions in parvalbumin (PV) expression represent a core finding in human postmortem studies and PVI impairments have been linked to dysfunctions in the corticolimbic system in schizophrenia. Aberrant PVI activity disrupts the brake on excitatory signaling, shifting the cortical E/I balance in favor on increased basal neural activity, leading to changes in PFC networks required for cognitive control.
While the precise etiology of these changes remains uncertain, redox dysregulation and oxidative stress may be a final common pathway in the pathophysiology of schizophrenia, causing dysfunction of GABAergic interneurons and loss of PV. Mitochondria are the major source of reactive oxygen species (ROS) in neurons, and they are both a pivotal contributor and amplifier of intracellular oxidative stress in pathological states. The mitochondrial matrix protein cyclophilin D (CypD) modulates the formation of the mitochondrial permeability transition pore (mPTP), which causes release of mitochondrial ROS, initiating a feed-forward cycle of ROS generation and release, metabolic changes, and eventual loss of cell function.
To test if CypD is upregulated in schizophrenia and may contribute to the loss of PV expression in the frontal cortex of patients with schizophrenia, we obtained human brain tissue from postmortem schizophrenic patients and healthy subjects via the NIH NeuroBioBank. We used multilabel immunofluorescent microscopy, paired with an unbiased stereological approach to quantify the expression of PV and CypD within PVI across layers 2/3 of Broadman Areas 9/46. Our results show an upregulation of CypD within PVI, suggesting that CypD-mediated oxidative stress contributes to PVI dysfunction in schizophrenia.
Upregulated levels of CypD and mitochondrial redox dysregulation may thus cause a loss of PVI function which contributes to frontal cortical dysfunction in schizophrenia. These results suggest new mechanisms for the pathophysiology of schizophrenia, as well as potential new therapeutic interventions that target CypD.

Title: Efficacy of low doses neuroleptic drugs on aggressive behaviour and corticosterone levels in CD-1 male mice

Authors: *E. SOKOLOWSKA[1], E. STOJEK[2], D. KOZAREVA[2], J. PRENDERVILLE[2]; [1]Transpharmation Poland Sp. z o.o, Olsztyn, Poland; [2]Transpharmation Ireland Ltd., Dublin, Ireland

Abstract: Several psychiatric disorders are associated with increased aggression resulting in impairment in social skills. Current treatments which target aggressive behaviour can induce sedation, affect mobility and induce idleness. Therefore, a better understanding of the behavioural and neurobiological aspects of aggression is necessary. Here we investigate the effects of two low doses of antipsychotic drugs: risperidone and S15535 on aggressive behaviour in the CD-1 male mice. Risperidone is an atypical antipsychotic used to treat schizophrenia acting at several 5-HT (serotonin) receptor subtypes. S15535 is a highly selective 5-HT1A receptor ligand that acts as an agonist and antagonist at the pre- and post-synaptic 5-HT1A receptors, respectively. In addition, we are investigating if either drug affects levels of corticosterone (CORT), a hormone previously associated with aggression. Briefly, 10-13week old CD-1 mice underwent 3 days of aggression screening by introducing 6-7 weeks old C57BL/6J male intruder to their home cage for a maximum of 180s and latency to the first attack was recorded. Following, CD-1 aggression phenotype was evaluated, leading to selecting only the most aggressive subjects. The aggressive CD-1 mice were then treated with vehicle, risperidone (0.05, 0.5 and 3 mg/kg i.p.) or S15535 (0.5 and 2.5 mg/kg s.c.). Thirty minutes post-treatment mice underwent a single aggression screen followed by locomotor assessment in the open field. Corticosterone levels in the trunk blood were analysed in aggressive and non-aggressive mice using ELISA kit (Enzo, USA). In addition, the prefrontal cortex, amygdala and hypothalamus were collected for future molecular analyses. Only the lowest (0.05 mg/kg) dose of risperidone resulted in a significant reduction ($p<0.005$) of aggressive behaviour without affecting locomotion. The high (2.5 mg/kg) dose of S15535 significantly reduced aggression ($p<0.005$) with 50% of CD-1 mice abstaining from attack initiation and engaging in normal locomotor activity. Risperidone, but not S15535 or vehicle significantly decreased corticosterone levels ($p<0.05$) in the plasma of aggressive mice. CD-1 mice exhibiting non-aggressive phenotype presented the highest levels of CORT, suggesting that social interaction with another mouse during the screening paradigm can induce stress. Taken together, this study successfully demonstrates the aggression inhibiting the activity of both drugs, confirming that, modulation of the 5-HT1A receptors may represent a therapeutic target for aggressive behaviour.

Title: Phenotypic subtyping in binge eating and associated neural correlates

Authors: *L. R. BRUCAR[1,5], E. RAWLS[1], G. DROSSEL[2], C. B. PETERSON[1], A. F. HAYNOS[1], T. HENDRICKSON[3], A. ZILVERSTAND[1,4];
[1]Dept. of Psychiatry & Behavioral Sci., [2]Grad. Program in Neurosci., [3]Univ. of Minnesota Informatics Inst., [4]Med. Discovery Team on Addiction, Univ. of Minnesota, Minneapolis, MN; [5]Dept. of Cognitive Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstract: Standard treatments for binge-type eating disorders are only moderately effective. To improve efficacy, a better understanding of the mechanisms contributing to the maintenance of binge eating (BE) is critical. We applied a data-driven dimensionality reduction approach to a community sample to develop an empirical model of BE behaviors, identify phenotypic subtypes and investigate their neural correlates. We hypothesized that three domains would be impaired in BE and revealed in the subtyping: reward-related processing, negative emotionality, and executive function. We applied exploratory factor analysis to extract phenotypic latent factors from the extensive measures in the enhanced NKI-Rockland Sample (N = 644; 66% F). Subjects were categorized into a BE (N=130, 64% F) or non-BE group (N = 423, 67% F) based on frequency of objective binge episodes (OBE, BE: >=1 OBE/28days; non-BE: 0 OBE). Within the BE group, subtypes were determined using latent profile analysis on the latent factors identified in the full sample. We investigated resting-state functional connectivity related to OBE within each subtype (nodal global and local efficiency, betweenness centrality; Brain Connectivity Toolbox; covariates: age, gender, race, BMI). Twelve latent factors were uncovered that grouped into the hypothesized functional domains, with the BE group showing impairments on all three domains. Subtyping within the BE group revealed a: (I) ‘Internalizing’ type (High Internalizing/General Psychiatric/Negative Affect/Risk Perception), (II) ‘Impulsive’ type (High Urgency, Lack of Cognitive Control, Low Risk Perception), and (III) ‘Risk-Averse’ type (High Risk Perception, Low Norm-Breaking, High Cognitive Control). The Internalizing Subtype exhibited abnormal connectivity in the frontoparietal network (mSPL). The Impulsive Subtype displayed abnormal connectivity in the frontoparietal (mSPL), default mode (sPCC), and visual 2 (V7/l-IPS) networks. The Risk-Averse Subtype demonstrated abnormal connectivity in the frontoparietal (dlPFC, FPC, aIPS), cingulo-opercular (dACC), default mode (mPFC), dorsal-attention (pIPS), somatomotor (aSPL), and ventral-attention (aIFS) networks, and the thalamus. All regions were significant at p-FDR < 0.05.These findings provide evidence for a three-domain model of BE and confirm the existence of substantial heterogeneity in the neurobehavioral

impairments underlying binge eating. Subtyping on functional domains will be important for modelling the vast heterogeneity seen in BE and investigating their clinical relevance and utility in developing more effective, targeted treatments.

Anáhuac Querétaro, Querétaro, Querétaro, Mexico

Abstract: Eating disorders (ED) are psychiatric disorders characterized by disturbed eating behavior. They have a complex etiology, where genetic and environmental factors are interacting. Comethylation modules analysis could detect small effects of epigenetic interactions, reflecting environmental factors influences. The objective of this exploratory study was to create comethylation modules from children and teenagers' DNA methylation samples with an ED, and to correlate these modules with clinical features and genetic variability. We used MethylationEPIC microarray to obtain methylation levels from 63 teenagers with eating disorders. Evaluated features were age, gender, BMI zscore, psychiatric comorbidities and eating behaviours. This study followed principles from the Declaration of Helsinki. We created comethylation modules in WGCNA (Weighted Gene Correlation Network Analysis) and correlated them with clinical features in our subjects. Also, we performed enrichment analysis of CpG sites from comethylation modules. We observed two groups of comethylation modules given the methylation level from beta values. Meanwhile, one group had partially methylated values (turquoise, blue and purple); the other group had hypermethylated values (brown, yellow, green, red, black, pink and magenta). Seven clinical features and comorbidities correlated with different comethylation modules. The yellow comethylation module correlated with body mass index (BMI) zscore (R^2 = 0.47, p = 0.0006), conduct disorder (R^2 = -0.41, p = 0.0030), and

psychotic disorder (R^2 = -0.45, p = 0.0010). Meanwhile, purple comethylation module correlated with gender (R^2 = -1, p < 1e-50), suicide behavior (R^2 = 0.41, p = 0.0030), and attention-deficit/hyperactivity disorder (R^2 = -0.59, p = 6e-06); finally, black module correlated with height (R^2 = 0.4, p = 0.0040). We found significant enrichment pathways from the genes annotated on turquoise and blue modules. These modules were enriched for pathways that could be influenced by development status of the sampled individuals. Partial methylation of these modules suggests transcriptional activation of these pathways. Black module was non-significant enriched in morphine addiction synaptic vesicle cycle, apoptosis, and mTOR signaling pathway. Meanwhile, yellow module was non-significant enriched in alpha-Linolenic acid metabolism, VEGF signaling pathway, and hepatitis C. These data suggest that perturbations in DNA methylation could correlate with somatometric measures and comorbidities in individuals with ED.

Title: Is exercise addictive for patients diagnosed with anorexia nervosa: An anatomical exploration of the role of mu opioid receptors in the release of dopamine in nucleus accumbent of mice acclimated to the wheel with and without food restriction

Authors: *I. PAT-OSAGIE[1,2], C. AOKI[3];
[1]Psychology, Hunter Col., New York, NY; [2]Cns, [3]CNS, NEW YORK UNIVERSITY, New york, NY

Abstract: Anorexia nervosa (AN) is one of the deadliest of all mental illnesses, even beating out depression. Characterized by a distorted self-image, food restriction and, in most cases, excessive exercise, these three features are the reasons why AN's morbidity rate, especially among adolescent girls, is so high. But how is it that we are seeing patients compulsively exercise when science and their physicians advise them to curtail exercise? This is the question that drives the current research. Previous research suggests that aspects of AN, like food restriction (FR) and exercise (EX), may be addictive but the studies are incomplete. We asked how the putatively addictive nature of EX and FR might be represented in the brain of individuals diagnosed with

AN. We hypothesized that addiction to EX among AN patient may be due to the activation of mu opioid receptors (MOR), causing inhibition of the GABAergic neurons in the nucleus accumbens (NAcb), a key brain structure affected in addiction. This would enhance the release of dopamine by the process of disinhibition that enhances firing of the dopaminergic cell bodies in the ventral tegmental area. Alternatively, MOR might modulate dopamine release more directly through their expression on dopaminergic axons in NAcb. We have begun to use the mouse model of AN, called activity-based anorexia (ABA), to examine neuroanatomical substrates supporting these modes of action of MOR while also asking whether animals exhibiting greater EX express greater prevalence of MOR and if so, whether this is specific to animals undergoing ABA or might also be a trend observed among mice acclimated to the wheel without ABA induction (EX only). To this end, we have generated four groups of mice: food restricted and exercising (ABA), EX only, FR only, and control (no EX and no FR). Electron microscopic immunocytochemistry (EM-ICC) was employed to detect MOR and tyrosine hydroxylase, the rate-limiting synthetic enzyme present in dopaminergic axons in NAcb. Correlational analyses between the behaviors of EX and FR and the anatomical features MOR expression relative to dopaminergic neurons promise to provide us with an insight about the addictive nature of excessive EX and FR in ABA and pharmacological treatments to ameliorate these putatively addictive behaviors in AN. Preliminary data (N=2, >100 dopaminergic axon terminals) indicate that MOR are rarely expressed on dopaminergic axons in NAcb shell, favoring the alternative mechanism involving MOR's role in disinhibition.

Title: Ethanol behaviors were unaffected by heterozygous deletion of Cdc42bpb in mice

Authors: K. E. KITCHEN, A. T. LIMAYE, T. N. FOREMAN, *J. BOGENPOHL;
Mol. Biol. and Chem., Christopher Newport Univ., Newport News, VA

Abstract: *Cdc42bpb* encodes a kinase (MRCKβ) that regulates cytoskeleton reorganization and cell migration, which functions downstream of the important Rho GTPase, CDC42. In humans, heterozygous loss of function mutations in *Cdc42bpb* result in a neurodevelopmental disorder reminiscent of the CDC42-associated Takenouchi-Kosaki syndrome. Importantly, *Cdc42bpb* was also recently discovered to be involved in the genomic response to chronic ethanol exposure in

the prefrontal cortex of monkeys and mice. As such, we have conducted behavioral experiments in *Cdc42bpb*+/- mice and wildtype littermates, aimed at characterizing the ethanol phenotypes produced by the deletion. Experimental mice underwent three ethanol-related tests, including the loss of righting reflex test, a light-dark box test, and a two-bottle choice drinking study. Results showed that heterozygous deletion of *Cdc42bpb* did not alter ethanol behaviors, as comparted to wildtype littermates. Other phenotypes included mild hyperactivity and an increased incidence of prolapsed penis, in line with genitourinary defects reported in *Cdc42bpb*+/- humans.

Title: A reduced complexity cross between BALB/c substrains identifies Zhx2 is a candidate gene underlying oxycodone metabolite brain concentration and state-dependent learning of opioid reward.

Authors: *J. BEIERLE[1], E. YAO[1], S. GOLDSTEIN[1], J. SCOTELLARO[1], O. AVERIN[3], D. MOODY[3], A. EMILI[2], G. PELTZ[4], M. FERRIS[5], C. D. BRYANT[1];

Sch. of Med., Stanford, CA; [5]Genet., Univ. of North Carolina, Chapel Hill, NC

Abstract: Understanding the pharmacokinetic profile of an opioid drug is vital to therapeutic success, and mutations in human PK genes can alter therapeutic efficacy as well as addiction liability. Oxycodone is a semisynthetic opioid metabolized into noroxycodone and oxymorphone by CYP450 enzymes. We observed that 30 min post-oxycodone administration (1.25 mg/kg, i.p.) BALB/cJ mice, in particular females, showed higher whole brain concentrations of oxycodone, noroxycodone, and oxymorphone compared to BALB/cByJ that could explain increased oxycodone state-dependent conditioned place preference in BALB/cJ mice. To potentially link behavioral differences with PK differences, we conducted quantitative trait locus (**QTL**) mapping of whole brain oxycodone and metabolite concentrations in a reduced complexity cross

(**RCC**). Because BALB/cJ and BALB/cByJ substrains differ by ~10,000 SNPs/indels, large genetic loci identified in an F2 cross are offset by dramatic reduction in potentially causal variants. QTL mapping in 133 BALB/cJ x BALB/cByJ F2 mice (68F, 65M) revealed a single QTL on chromosome 15 associated with brain [oxymorphone]. Oxymorphone is a full agonist at the mu opioid receptor, with 8x the potency of oxycodone, and likely contributes to oxycodone's addictive properties. Within our interval, hippocampal and striatal cis-eQTL analysis revealed differential expression of Zhx2, a transcriptional inhibitor known to harbor a private BALB/cJ retroviral insertion that dramatically reduces protein expression and subsequent sex specific dysregulation of CYP450 genes within the liver. Whole brain proteomics in parental strain mice corroborated these RNA findings. We hypothesize disruption in Zhx2 expression alters CYP450 expression, and therefore alters whole brain oxymorphone and oxycodone-induced behaviors.

Title: Effects of cocaine use on three-dimensional chromatin organization in medium spiny neurons of the mouse nucleus accumbens

Authors: *J. M. CHITAMAN[1,2], R. S. JASROTIA[1,2], V. MALYSHEVA[3], H. XU[1,2], Y. LI[1,2], M. SPIVAKOV[3], P. FRASER[1], J. FENG[1,2];

Abstract: Drugs of abuse alter the epigenetic landscape in the nucleus accumbens (NAc), a key region in the brain reward pathway, which underlies aberrant gene expression associated with maladaptive synaptic plasticity in drug addiction. In the eukaryotic nucleus, two meters of linear DNA require extensive three-dimensional (3D) folding to fit a micrometer-sized nuclear space. This 3D folding of chromosomes is highly organized and provides higher-order layers of epigenetic regulation that bring distal (i.e., up to a megabase away) regulatory elements within close spatial proximity of target genes. However, such 3D chromatin organization and its potential impact on gene expression remain obscure in drug addiction. In this study, we characterize 3D chromatin interactions in D1- and D2-type medium spiny neurons (MSNs),

respectively, of adult male mice after intravenous cocaine self-administration. D1- and D2-MSNs account for ~95% of neurons within the NAc, but are known to play distinct roles in drug addiction. Using next-generation sequencing approaches including genome-wide and promoter capture Hi-C, we identify hierarchical chromatin structures such as active/inactive compartments, topologically associated domains (TADs), subTADs, and DNA loops. We observe dysregulation of chromatin architecture by cocaine use, particularly in the promoter interactome. Furthermore, we find that cocaine-altered 3D interactions predominantly occur at the submegabase level and contain promoter regions of numerous genes that are differentially expressed in cocaine addiction. Therefore, our study elucidates features of 3D chromatin organization at various scales in NAc neuronal subtypes in cocaine addiction. Our research also provides a framework to explore novel molecular mechanisms of cocaine action in the brain that have the potential to serve as improved diagnostic and therapeutic targets in the future.

Title: Brain-specific inhibition of mTORC1 by a dual drug strategy: implications for the treatment of alcohol use disorder

Authors: *Y. EHINGER[1], Z. ZHANG[2], K. PHAMLUONG[1], D. SONEJA[1], K. SHOKAT[2], D. RON[1];
[1]Neurol., [2]Cell. and Mol. Pharmacol., Univ. of California San Francisco, San Francisco, CA

Abstract: Brain-specific inhibition of mTORC1 by a dual drug strategy: mplications for the treatment of alcohol use disorder Yann Ehinger[1], Ziyang Zhang[2], Khanhky Phamluong[1], Drishti Soneja[1], Kevan Shokat[2], Dorit Ron[11]Department of Neurology, [2]Department of Cellular and Molecular Pharmacology, University of California San Francisco
The mechanistic target of rapamycin complex 1 (mTORC1) plays an important role in mechanisms underlying numerous alcohol-dependent adverse phenotypes such as excessive alcohol use, alcohol seeking, habit, and relapse (Ron and Barak, 2016; Morisot et al., 2019). Therefore, mTORC1 represents a promising therapeutic target for the treatment of alcohol use disorder (AUD). mTORC1 inhibitors are used in the clinic to prevent organ rejection after transplantation. However, chronic inhibition of mTORC1 in the periphery results in undesirable

side effects which reduce the potential use of the inhibitors for the treatment of AUD. To overcome these limitations, we developed a novel approach to selectively inhibit mTORC1 in the brain but not in the periphery (Zhang Z. et al., 2020 bioRxiv). Specifically, we developed a small molecule (Rapablock) which protects mTORC1 activity in the periphery when administered together with the mTORC1 inhibitor Rapalink-1. We demonstrate that a combined treatment of Rapalink-1 and Rapablock in mice enables the selective inhibition of mTORC1 in the brain, while protecting mTORC1 activity in the liver. We further show that whereas chronic inhibition of mice with Rapalink-1 produces sides effects such as body weight loss, glucose intolerance and liver toxicity, co-administration of the two drugs attenuated these adverse effects. Furthermore, we report that Rapalink-1 inhibited alcohol-dependent activation of mTORC1 in the nucleus accumbens (NAc) in the presence of Rapablock. Finally, we show that the co-administration of Rapablock and Rapalink-1 moderates
alcohol drinking and seeking in mice. Together, these data put forward a promising new approach for the treatment of AUD.

Title: Strain- and sex-dependent effects of isolation housing relative to environmental enrichment on operant sensation seeking in mice

Authors: *P. E. DICKSON[1], G. MITTLEMAN[2];
[1]Biomed. Sci., Marshall Univ., Huntington, WV; [2]Psychological Sci., Ball State Univ., Muncie, IN

Abstract: Sensation seeking is a multidimensional phenotype that predicts the development of drug addiction in humans and addiction-like drug seeking in rodents. Several lines of evidence suggest that chronic stress increases sensation seeking and addiction-like drug seeking through common genetic mechanisms. Discovery and characterization of these mechanisms would reveal

how chronic stress interacts with the genome to influence sensation seeking and how drugs of abuse hijack these fundamental reward mechanisms to drive addiction. To this end, we tested the hypothesis that chronic isolation housing stress (relative to environmental enrichment) influences operant sensation seeking as a function of strain, sex, or their interaction. To determine if the BXD recombinant inbred panel could be used to identify genetic mechanisms underlying any identified gene-by-environment interactions, we used mice from the two BXD founder strains. Following 10 weeks of differential housing, we assessed operant sensation seeking using several reinforcement schedules. The primary finding from this study was that DBA/2J but not C57BL/6J mice were significantly vulnerable to an isolation-induced increase in sensation seeking during extinction when the sensory reward was no longer available; this effect was significantly more robust in females. These data reveal a previously unknown isolation-induced effect on extinction of operant sensation seeking that is sex-dependent, addiction-relevant, and that can be dissected using the BXD recombinant inbred panel.

Title: Effects of Selection for Ethanol Preference on Gene Co-Splicing Networks across Multiple Brain Regions of Heterogeneous Stock Mice

Authors: A. COLVILLE[1], O. IANCU[1], ***D. LOCKWOOD**[2], P. DARAKJIAN[1], S. MCWEENEY[1], R. SEARLES[1], C. ZHENG[1], R. J. HITZEMANN[3];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Oregon Hlth. Sci. Univ., Portland, OR; [3]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Colville et al (2017) observed that selection for ethanol preference from HS-CC founders had marked effects on alternative splicing in the nucleus accumbens shell (SH); GTPase related genes were especially affected. The current study expands this observation by including larger sample sizes and two additional components of the addiction network, the central nucleus of the amygdala (CeA) and the prelimbic cortex (PL). The data illustrate that from the perspective of CoSplicEx networks (Iancu et al. 2015), preference selection had its greatest effect on the CeA. Across regions, significant effects were detected for genes associated with GTPase activity and synaptic genes. Some of the synaptic genes were hub nodes in the

CoSplicEx network that had been previously identified as associated with chronic ethanol consumption and included *Nbea* and *Sv2a,* genes previously identified in non-human primates.

Title: Epigenome editing of nucleus accumbens cell subtype transcripts regulated by fentanyl abstinence

Authors: *M. TURNER[1,2], E. CHOI[1,2], R. CHANDRA[3,1], S. A. AMENT[4,5], M. E. FOX[1,2], M. LOBO[1,2];
[2]Anat. and Neurobio., [3]Virus Vector Core, [4]Inst. for Genome Sci., [5]Dept. of Psychiatry, [1]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: In recent years, the opioid use epidemic has significantly impacted the financial and societal health burdens around the world, particularly the United States. This is in part is due to the ease at which synthetic opioids like fentanyl are obtained resulting in an increase in opioid overdoses. Many studies indicate that dysfunctionality in the mesocorticolimbic brain areas are central to understanding opioid use, dependence, and addiction. The nucleus accumbens (NAc) is a critical brain hub for altered molecular processes mediating behavioral responses to opioids and other used substances. Therefore, understanding the molecular and transcriptional programs of the neuronal subtypes within the NAc deserve considerable and critical attention. Our lab has performed cell subtype specific translatome profiling in the two NAc projection neuron subtypes- dopamine receptor 1 and 2 expressing medium spiny neurons (D1- and D2-MSNs) after prolonged abstinence from repeated fentanyl exposure. We identified distinct MSN subtype gene expression networks that are altered during fentanyl abstinence including hub genes genes, which are key drivers of gene expression alterations in MSN subtype specific modules. To build on this, we are developing CRISPR epigenome editing tools that will target specific hub genes in MSN subtype modules that are significantly regulated by fentanyl abstinence- 5 days 10 μg/ml fentanyl followed by 10 days of abstinence. Since most genes are down-regulated we use CRISPRa (activation) to upregulate expression of hub genes in MSN subtypes. Using a two vector adenoassociated virus (AAV) system we designed single gRNA or multiplex gRNAs, the latter targeting multiple hub genes within one module. gRNAs targeting hub genes or a lacZ

control gRNA are cloned into an AAV-gRNA-nlsGFP, which allows expression of nuclear GFP. The second vector is an AAV-DIO-dCas9-VP64 containing the nuclease dead Cas9 fused the VP64 transcriptional activation domain. We have transfected these vectors along with Cre into Neuro2A cells and demonstrate upregulation of MSN subtype fentanyl abstinence regulated hub genes. We are currently packaging these vectors into AAVs to target NAc MSN subtypes, using D1-Cre and A2A-Cre mice, during opioid exposure and abstinence to determine if upregulating hub genes can influence MSN subtype/fentanyl abstinence gene expression networks.

Title: Addiction-associated genetic variants implicate brain cell type- and region-specific cis-regulatory elements in addiction neurobiology

Authors: *C. SRINIVASAN[1], B. N. PHAN[1,4], A. J. LAWLER[2], E. RAMAMURTHY[1], M. KLEYMAN[1], A. R. BROWN[1], I. M. KAPLOW[1,3], M. E. WIRTHLIN[1,3], A. R. PFENNING[1,2,3]; [1]Computat. Biol. Dept., [2]Dept. of Biol. Sci., [3]Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA; [4]Med. Scientist Training Program, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Recent large genome-wide association studies (GWAS) have identified multiple confident risk loci linked to addiction-associated behavioral traits. Most genetic variants linked to addiction-associated traits lie in non-coding regions of the genome, likely disrupting cis-regulatory element (CRE) function. CREs tend to be highly cell type-specific and may contribute to the functional development of the neural circuits underlying addiction. Yet, a systematic

approach for predicting the impact of risk variants on the CREs of specific cell populations is lacking. To dissect the cell types and brain regions underlying addiction-associated traits, we applied stratified LD score regression to compare GWAS to genomic regions collected from human and mouse assays for open chromatin, which is associated with CRE activity. We found enrichment of addiction-associated variants in putative CREs marked by open chromatin in neuronal (NeuN+) nuclei collected from multiple prefrontal cortical areas and striatal regions known to play major roles in reward and addiction. To further dissect the cell type-specific basis of addiction-associated traits, we also identified enrichments in human orthologs of open chromatin regions of female and male mouse neuronal subtypes: cortical excitatory, D1, D2, and PV. Lastly, we developed machine learning models to predict mouse cell type-specific open chromatin, enabling us to further categorize human NeuN+ open chromatin regions into cortical excitatory or striatal D1 and D2 neurons and predict the functional impact of addiction-associated genetic variants. Our results suggest that different neuronal subtypes within the reward system play distinct roles in the variety of traits that contribute to addiction.

Title: COMT val^{158}met (rs4680) genotype influences gray matter, caudate, and thalamic volume and affects Addictions Neuroclinical Assessment incentive salience factor scores

Authors: *D. G. SUCICH[1,4], C. A. HODGKINSON[1], Q. YUAN[1], P.-H. SHEN[1], M. KERICH[2], R. MOMENAN[2,3], D. GOLDMAN[1,3];
[1]Lab. of Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [2]Clin. Neuroimaging Res. Core, [3]Office of the Clin. Director, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [4]Biol., Johns Hopkins Univ., Baltimore, MD

Abstract: The addictions are genetically heterogeneous, chronic relapsing disorders. Ignoring the diversity of etiology within DSM diagnoses for addictions has hindered progress determining the full contribution made by genetics to their development. Directly addressing this limitation, the Addictions Neuroclinical Assessment (ANA) utilizes a variety of quantitative measurements that have been constructed into neurofunctional domains believed to underlie the three stages of the addiction cycle—incentive salience (binge intoxication), negative emotionality (withdrawal/negative affect), and executive function (anticipation/preoccupation). The common human COMT Val158Met variant results in altered rates of monoamine catabolism, a risk factor for substance use disorders. In this exploratory study, genotypic effects of the COMT val158met (rs4680) polymorphism were assessed on the quantitative ANA neurofunctional domain factor scores and brain structure using MRI in 233 individuals (male=134, female=99). Only the volumes of the left side of brain regions were investigated in this preliminary study. Given previous evidence of the importance of COMT in cognitional tasks, such as attention and emotional processing, it was surprising to not see genotypic effects on executive function or negative emotionality factor scores. Individuals homozygous for the lower activity Met allele showed higher incentive salience factor scores, indicative of maladapted reward system function [$F(2,230) = 3.336$, $p = 0.0373$]. Met/Met carriers also presented with higher brain volumes of gray matter [$F(2,230) = 5.629$, $p = 0.0041$], left caudate [$F(2,230) = 4.08$, $p = 0.0181$], and left thalamus [$F(2, 230) = 3.739$, $p = 0.0252$]. High innervation from monoaminergic regions to the paraventricular thalamus (PVT), known to mediate attention to salient stimuli, may explain the effect of altered monoaminergic catabolism by the COMT Val158Met genotype on thalamic volume. Further investigation into monoamine catabolism in the thalamus, sex dependent effects, population admixture, as well as interactions with childhood trauma are warranted.

Title: Fine-mapping candidate addiction-associated regulatory variants using cell type-aware comparative genomics across mammalian genomes

Authors: *B. N. PHAN[1,3], A. LAWLER[1,2], J. HE[4], I. M. KAPLOW[1], D. SCHAFFER[1], A. BROWN[1], W. R. STAUFFER[4], A. R. PFENNING[1];
[1]Computat. Biol., [2]Biol., Carnegie Mellon Univ., Pittsburgh, PA; [3]Med. Scientist Training Program, [4]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Hundreds of loci with thousands of genetic variants have been associated with addiction-associated behaviors, which are largely thought to act at distal regulatory elements and in tissue- and cell type-specific contexts. Measures of genome conservation have proven to be invaluable tools to prioritize which candidate causal genetic variants. Although powerful, these measures currently don't account for the highly cell type-specific nature of regulatory elements nor propose how to test causal effects of genetic variants in closely and distantly related model organisms. Here, we leverage large cross-mammalian genome constraint measurements and machine learning predictions of neural cell type-specific regulatory elements activity to improve the prioritization of genetic variants associated with addiction-associated and other neuropsychiatric traits. We matched 8 orthologous cell types in the caudate nucleus across human, rhesus macaque, and mouse with single nucleus or cre-specific Sun1Gfp nuclear-anchored independent labeling (cSNAIL) open chromatin assays. We trained convolutional neural network models on active open chromatin in 3 species. We apply these models, the Cell Type-Activity Conservation Inference Toolkit (CellTACIT), to predict the open chromatin activity of orthologous conserved DNA of 240 mammals. We interpreted a wide set of human genetic variants across 62 genome-wide association studies spanning addiction-associated traits, other neuropsychiatric, and non-brain traits. We show that chromatin regions that can be mapped to increasingly distant mammals (e.g. primates, mouse, bats) and are predicted by CellTACIT to remain active show increasing heritability enrichment, up to 2- and 10-fold above human open chromatin and mammalian conservation, respectively. Furthermore, we fine-mapped loci dense with genetic variants for addiction- and sleep-associated traits to identify candidate causal variants overlapping human orthologs of D1 and D2 medium spiny open chromatin regions measured in macaque and mouse and predicted active across mammalia. Lastly, we report evidence of mammalian trait diveristy (e.g. brain size) that correlate with predicted cell type-specific open chromatin activity in regions with fine-mapped human genetic variants of related traits. Mapping the conserved cell-type regulatory patterns in the human genome refines the list of candidate causal variants in regions associated with addiction-associated traits beyond conservation or human cell type-specific open chromatin alone, illustrating the power of combining epigenomic and evolutionary information in human polygenic trait studies.

Title: Relationship between harm avoidance and problematic smartphone use in children and adolescents: role of stress from the longitudinal perspectives

Authors: *C.-H. CHOI[1], S. CHUNG[2], S.-Y. BHANG[3], J.-W. KIM[4], Y.-S. KWEON[5], J.-S. CHOI[1];

Abstract: The use of smartphones in children and adolescents might increase the level of stress and problematic smartphone use (PSU). In this study, the relationships between harm avoidance (HA) personality trait, stress, and PSU in children and adolescents was investigated from the perspective of longitudinal changes. At baseline, all participants (184 children and adolescents, 46 girls; mean age 13.15 years) completed screening questionnaires on PSU using the smartphone addiction scale-short version (SAS-SV) and the Korean smartphone addiction proneness scale (SAPS). The daily hassles questionnaire (DHQ) and junior temperament and character inventory (JTCI) were also administered to evaluate stress levels and personality traits. SAS-SV, SAPS, and DHQ were reassessed at 3 and 6 months. Pearson correlation analysis was used to examine the relationships between variables. Further, mediation effects were assessed using the PROCESS macro with 5,000 bias-corrected bootstrap samples. Among the temperament dimensions of JTCI, only HA displayed consistent positive correlations with SAS-SV, SAPS, and DHQ at all time points. Mediation effects of baseline stress on the relationship between HA and PSU were observed at baseline, 3, and 6 months ($\beta = 0.08$, $\beta = 0.07$ at baseline, $\beta = 0.06$, $\beta = 0.04$ at 3 months, $\beta = 0.09$, $\beta = 0.08$ at 6 months in SAS-SV and SAPS, respectively). Stress levels at 3 and 6 months also showed mediation effects on the relationship between HA and PSU at each time point. Our results suggest that managing stress may reduce the risk of PSU in children and adolescents with high HA.

Title: Subtypes in Addiction and their Neurobehavioral Impairments in Approach Behavior, Negative Emotionality and Executive Function

Authors: *G. L. DROSSEL[1], L. R. BRUCAR[2], E. L. RAWLS[2], T. HENDRICKSON[3], A. ZILVERSTAND[2,4,5];
[1]Grad. Program in Neurosci., [2]Dept. of Psychiatry & Behavioral Sci., Univ. of Minnesota, Twin Cities, Minneapolis, MN; [3]Univ. of Minnesota Informatics Inst., Minneapolis, MN; [4]Grad. Program in Neurosci., [5]Med. Discovery Team on Addiction, Univ. of Minnesota, Minneapolis, MN

Abstract: Background: We propose that impairments on three independent functional domains are linked to addiction: 1) approach-related behavior, 2) negative emotionality and 3) executive function. While it is generally accepted that these three mechanisms are linked to substance use disorder (SUD), it has not been investigated if they are independent, which would warrant a subtyping and personalized medicine approach. We hypothesized the existence of at least three distinct subtypes: "reward users" with deviant approach-related behavior, "relief users" with high negative emotionality, and "low functioning users" with impaired executive function.
Methods: To describe the complete phenotypic space, we derived latent factors from the psychosocial and behavioral data from the NKI-Rockland Enhanced sample (*N = 644, 66% F; 54% F within SUD*). Subtypes were determined using clustering via latent profile analysis on these latent factors within those with past SUD (*N = 173, 55% F*). Graph theory-based resting-state connectivity analyses (Brain Connectivity Toolbox) were conducted for each subtype in a subsample with complete fMRI and NIDA Quick Screen data (*past SUD N = 104, 58.6% F; controls N = 302, 73.5% F*). Differences in nodal global efficiency, local efficiency, and betweenness were measured for each subtype compared to matched controls using regression analysis.
Results: The latent factor analysis revealed the hypothesized phenotypic domains. Three subtypes existed among those with past SUD: 1) Reward Users (high sensation seeking/social risk taking/norm-breaking), 2) Relief Users (high internalizing/general psychiatric symptoms/negative affect, lack of perseverance), and 3) Lower Functioning Users (low openness/sensitivity, high general psychiatric symptoms/sensation-seeking). Reward users demonstrated decreased connectivity (betweenness) for the supplementary motor network (SCEF) compared to controls, when predicting on lifetime number of drugs used while covarying for past 6-month tobacco use, and comorbidities ($p_{FDR} < 0.05$). Relief users had increased connectivity (betweenness) for the attention network (7P, VIP, MIP, 6a) compared to controls, when predicting on current number of drugs used ($p_{FDR} < 0.05$). This remained significant after covarying for comorbidities.
Conclusion: These empirical findings provide evidence for the three-domain model of addiction

and the existence of at least three distinct “addiction subtypes” with differential neurobehavioral profiles. This warrants future research into the clinical relevance of these subtypes and their utility in developing personalized medicine approaches.

Title: Effect of transcutaneous vagus nerve stimulation on EEG alpha power.

Authors: J. MARTINEZ[1], R. STERN[1], C. BRIGGLER[1], M. S. MENNEMEIER[2], ***R. ROOSEVELT**[1];
[1]Arkansas Tech. Univ., Russellville, AR; [2]Neurobio. and Developmental Sci., Univ. of Arkansas for Med. Sci., Little Rock, AR

Abstract: Invasive vagus nerve stimulation (VNS) is an FDA treatment for refractory epilepsy and depression with potential application for the treatment of a host of CNS disorders including Alzheimer Disease, attention deficit, stroke, traumatic brain injury. However, the usefulness of VNS is limited to its highly invasive nature. More recently, the observation that auricle branch of the vagus may be stimulated transcutanously (TVNS) without invasive procedures has led to increased interest in vagal stimulation with multiple published studies of cognitive effects. Despite enthusiasm for TVNS, the effectiveness of TVNS has not been sufficiently demonstrated, nor have agreed upon measures of effective stimulation been established. The noradrenergic hypothesis of VNS posits that many of the desired effects of VNS are the result of the release of norepinephrine in the terminal fibers of Locus Coeruleus in the cortex. Considerable evidence supports this view including direct measurement of NE increases following VNS in the rat. We have previously reported here that TVNS in humans alters heart rate variability, increases salivary alpha amylase, and alters pupil dilation. Here we report tentative findings that TVNS suppresses alpha power in humans, a finding consistent with increased release of NE. EEG recordings were obtained from **twelve** participants for analysis. A 10 minutes baseline period and 10 minutes of TVNS were recorded. The TVNS block consisted to 14 seconds of stimulation each minute (0.5mA, 30 HZ). EEG for each block was then decomposed into power bands using FFT and percent change scores between baseline and

stimulation computed. RESULTS: We observed decreased alpha power associated with TVNS consistent with increased NE release at the terminal synapses in the cortex. Overall all decrease in alpha across all channels was 10%. 85% of channels displayed decreased alpha and 15% increased alpha. Thus, these findings support the hypothesis that TVNS is sufficient to alter CNS activity and that TVNS may exert effect in accordance with the noradrenergic hypothesis. Importantly, these findings also suggest that alpha power may serve as a biomarker of effective TVNS

Title: Brain network causal interactions underlying task-evoked pupil response: a simultaneous pupillometry, EEG, fMRI study

Authors: *H. HE[1], L. HONG[1], P. SAJDA[1,2,3,4];
[1]Biomed. Engin., [2]Electrical Engin., [3]Radiology, [4]Data Sci. Inst., Columbia Univ., New York, NY

Abstract: Pupil size not only changes in response to lighting conditions, but also can be modulated by cognition and mental processes, such as effort, arousal, attention, fluid intelligence, and cognitive states. Studies have shown that pupil changes are related to the locus coeruleus (LC) norepinephrine (NE) system, but the cortical-subcortical interactions and the interactions between large-scale brain networks underlying the pupil fluctuations are not well studied. In this study, we used simultaneously acquired pupillometry, EEG and fMRI and an auditory oddball task to study the networks' causal interactions underlying task-evoked pupil response (PR). After data preprocessing, we first employed a single-trial EEG analysis and a general linear model EEG-informed fMRI analysis, which reveals the neural cascade underlying the salient stimuli processing. With the identified neural correlates, the peak voxels of the statistically significant clusters were used to define network nodes, and these regions were fed into an EEG-based state-space model to infer the effective connectivity (EC) between them. With the fMRI-based functional connectivity, we observed an intrinsic organization (early,

middle and late time brain networks) of these nodes. Then, we summarized the EC patterns by the sum of all positive connections within or between networks based on this functional organization of the grouped nodes. We observed a significant ($r = 0.6352$; $p < 0.0035$) correlation between oddball-evoked PR and oddball-modulated late-to-early EC strength. This result aligns with the network-reset theory of LC. The LC phasic activity (indexed by PR) seems to be related to a late-to-early feedback signal from the late network to the early target network (subsystem of dorsal attention network, DAN), which reflects the reconfiguration of DAN to disengage from the task and adapt into the new environment after the response. Our results suggest that LC might modulate pupil changes through large-scale brain networks of the cortex, reflecting a NE-dependent brain-wide network reorganization.

Title: The effect of task-irrelevant semantic information during salient attentional capture

Authors: *X. ZHANG, S. S. SHOMSTEIN;
Psychological and Brain Sci., George Washington Univ., Washington, DC

Abstract: Attention is essential for efficient focusing of cognitive resources in order to accomplish tasks at hand. While it has been shown that attention is constrained by task-relevant factors, recently it has been shown that attention is also influenced by a variety of task-irrelevant factors. A previous study shows that semantic relationships, even when task-irrelevant, bias attention during visual search (Malcolm et al., 2016). In order to elucidate the constraints on task-irrelevant semantic contribution to attentional guidance, we asked a question of whether semantic information influences voluntary shifts of attention as well as automatic (capture) shifts of attention. In the current human behavioral experiment adapted from the Posner cueing paradigm, participants viewed four objects presented around a central fixation, two of which formed a semantic pair (e.g., a cucumber and a carrot). After a variable object exposure delay, a bright circle, serving as a salient cue, flashed around one object of the semantic pair for 100 ms. After either a short (100 ms) or long (750 ms) delay, a target (T or L) and three distractors (T/L hybrids) appeared each on the center of the four objects. The task was to discriminate the target

as T or L. The location of the target was coded as Valid (same object as the cued object), SR (different but semantically-related object), and NR (non-related object). We analyzed participants' reaction time (RT) and accuracy. A validity effect was observed for both short and long post-cue delay conditions, with faster RTs to targets that appeared in the validly cued locations. In addition, when the post-cue delay was short, RT on SR trials was shorter than that on NR trials, showing that semantic information biased attention towards the related object. Most interestingly, this semantic bias disappeared when the post-cue delay was long. We propose that this lack of semantic effect during long delay may be a result of inhibition of return. The results indicated that semantic information influences attention allocation together with other attentional factors, contributing to the same spatial priority maps. The fact that sematic effect was sensitive to delay while validity effect did not, indicates that semantic effect and salience effect on attention might have different temporal profiles.

Title: Stimulus Invariant Attentional Responses In The Human Temporal Cortex

Authors: *F. MOLLA[1], A. BOGADHI[2], M. HIMMELBACH[1];
[1]Ctr. for Neurol., Tübingen, Germany; [2]Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany

Abstract: The role of parietal and frontal cortices in the control of visual attention in humans and macaques is well-known. Recent studies in macaques identified a temporal cortical region involved in the control of visual attention independent of the type of visual stimulation. This temporal cortical region is part of a network including the superior colliculus (SC) in the control of visual attention. In humans, a homolog of this attention-related temporal cortical region has not been identified until now. We set out to locate such an attention-related region in the human temporal cortex using visual stimuli that identified the respective region in macaques, i.e., motion (MS) and dynamic white-noise stimuli (WNS).
In 6 participants (median age: 29 std: 8.6, 2 female), we acquired functional MRI at 9.4T (voxel size 1.5mm isotropic, TR = 1s, TE=21ms) while the participants performed a covert attention task with MS and WNS. The MS was a circular patch of dots with motion direction 30° above horizontal, while the WNS was a dynamic white-noise patch. Two stimuli were presented

symmetrically with 4.5° eccentricity relative to a central fixation and 3.5° above horizontal. The covert attention task had three experimental conditions: Attend Left (AL), Attend Right (AR) and Ignore (IG). In AL, the subjects attend to the stimulus in the left visual field and press a button when the attended stimulus changed direction (MS) or a second-order orientation appeared (WNS). In AR, subjects reported on the stimulus in the right visual field. In IG, the subjects ignored the peripheral stimuli and report dimming of the central fixation spot with a button press.
We find a consistent, lateralized activation in MT, MST, FST and PH across motion and non-motion stimuli when contrasting AR vs AL conditions. Posterior-dorsal sub-regions of the TPOJ and medio-dorsal parahippocampal regions also show attentional activation across tasks without lateralization. These findings add to the growing evidence supporting the involvement of sub-regions of the temporal cortex in visual attentional processing. Further analyses will address the interplay between attention-related regions of temporal cortex and subcortical structures.

Title: A neurofeedback game for attention improvement and its evaluation

Authors: *H. KIM[1], K. WON[2], S. JUN[2], M. AHN[1];
[1]Handong Global Univ., Pohang, Korea, Republic of; [2]Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: Recently, there has been an increasing interest in digital healthcare, where technologies are used to manage and improve one's health. Neurofeedback is a training technique that helps a user to self-regulate the brain state. This technology is used for treatment of various disease [1]. In addition, it is reported that neurofeedback is effective in improving cognitive function in healthy people [2]. In this study, we introduce a neurofeedback-based car racing game that measures a player’s attention level which is quantified from the ratio between beta and theta power in electroencephalogram (EEG) and applies the information to control the speed of a car in the game. To evaluate the effectiveness of the game, we conducted online EEG

experiments (acquired by DSI VR300, Wearable Sensing Inc.) with four subjects (approved by Institutional Review Board at Handong Global University). Each subject played five training blocks; each block takes 5-minute car racing. For measuring the performance of different cognitive functions, three behavioral tasks (Color Word Stroop Task (CWST), Psychomotor Vigilance Test (PVT), and 2-back test) were introduced. Thus, each subject completed the tasks and resting state EEG were measured before and after the neurofeedback training, respectively. The game and experiment were implemented in Unity3D and in Python and OpenViBE. As a result, we found that all subjects consistently show beta increase from pre-training (4.53±2.19) to post-training (5.6±1.78) and decreased Reaction time (RT) in 2-back task (post/pre; CWST: 0.02/0.01, PVT: 0.28/0.27, 2-back: 0.65/0.6). But there were no significant results in accuracies of tasks. In conclusion, we introduced a neurofeedback game which is proven to increase beta rhythm in the brain and also shorten the reaction time in 2-back task. In the future, we will further confirm the results with more subjects and compare with placebo group.

Title: Neural decoding of concurrent speech: lessons from selective and divided attention

Authors: *M. KAUFMAN, K. GUEZENTSVEY, E. ZION GOLUMBIC;
Gonda Multidisciplinary Brain Res. Ctr., Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: It is widely assumed that when individuals apply selective attention to a single speaker in a Cocktail Party setting, other so-called “task-irrelevant” speakers are ignored. However, the extent to which task-irrelevant speech is processed and the nature of its neural representation remains a highly debated topic. This ambiguity is further extended when considering how attention might operate under naturalistic conditions, where it might not always be beneficial to fully tune out task-irrelevant speech. Some have suggested that natural listening in multi-speaker

contexts might involve dynamic attention-switching between relevant and irrelevant speakers. However, this hypothesis is extremely difficult to test experimentally, given the limited access to the listener's internal state in selective attention paradigms. To circumvent this methodological challenge, here we explicitly manipulated the task-relevance of concurrently presented speech and examined how this affects its neural encoding in the brain. Specifically, we compared neural speech tracking of two natural speech streams when only one was task-relevant (Selective Attention) vs. when both were task-relevant (Divided Attention). We recorded the magnetoencephalographic (MEG) response from 27 Hebrew native speakers, while they listened to two concurrent speakers telling short narratives. Before each trial, participants were either instructed to attend to one speaker (Selective Attention condition) or to both speakers (Divided Attention condition). After each trial, participants answered comprehension questions either about the pre-designated attended narrative (Selective) or about both narratives (Divided). Subjects performed significantly better on the Selective Attention task (~89%) compared to the Divided Attention task (~72%), indicating that there is a behavioral cost to dividing attention. Speech-tracking analysis of the neural response to the two speakers replicated previous results of Selective Attention, with reduced responses to the task-irrelevant speaker vs. the task-relevant speaker in auditory regions. Interestingly, the neural representation of the two speakers in the Divided Attention condition was comparable to that of the task-irrelevant speaker in the Selective Attention condition. This suggests that the partial encoding of task-irrelevant speech is akin to the encoding applied when attempting to divide attention among two speakers. By contrasting these two opposing attention regimes, our results broaden the ongoing conversation about the system's capacity and limitations for processing two speech streams in ecologically-valid settings.

Title: Does the visual cortex play a causal role in endogenous covert attention?

Authors: *A. FERNANDEZ, M. CARRASCO;
New York Univ., NYC, NY

Abstract: Covert endogenous (voluntary) spatial attention improves performance in many visual tasks and modulates neural activity at different visual and higher-level areas. The frontal-eye fields and intraparietal sulcus are considered necessary for this improvement to occur, but it is unknown whether early visual areas (V1-V2) play a causal role. We used transcranial magnetic stimulation (TMS) to briefly alter ongoing activity around the occipital pole while observers performed an orientation discrimination task and attention was manipulated via central valid, neutral, and invalid cues. On every trial, observers (n=10) received double pulse TMS at an individually predetermined phosphene region (stimulated region) around the occipital pole. Two cortically magnified gratings were presented simultaneously, one in the stimulated region and another in the symmetric (non-stimulated) region in the opposite hemifield. In every trial the same region was stimulated, in half of the trials the stimulus processed by that region was the target and in the remainder trials was the distractor. Grating contrast was varied to measure contrast response functions for all combinations of attention (valid, invalid, neutral) and stimulation (target, distractor) conditions. Attention affected contrast responses similarly regardless of whether the target or distractor were stimulated. These findings indicate that early visual areas are not necessary for endogenous attention to modulate performance. Additionally, we compare the current results to our previous study where TMS extinguished the effect of exogenous (involuntary) attention on performance (Curr Bio, 2020), and provide competing computational models for the effect of TMS on attention, which are extensions of the Reynolds-Heeger (2009) normalization model of attention (NMA): (1) NMATMS: TMS modifies the strength and spatial spread of attention by scaling the attention field; (2) RGTMS (response-gain): TMS modifies the stimulus drive and attention exerts its effects after normalization; (3) tunedTMS: TMS modifies baseline suppression by changing the bandwidth and strength of the suppressive field. The tuned-NMA model best captured both the endogenous and exogenous attention results. In both cases TMS decreased the spatial spread of suppression, but total suppression was weaker with endogenous than exogenous attention. In conclusion, unlike exogenous attention, early visual areas are not necessary for endogenous attention to modulate performance. Additionally, endogenous and exogenous attention results can be captured by assuming that TMS alters both suppression strength and bandwidth.

Title: Attentional modulation of category-selective regions in ventral occipitotemporal cortex

Authors: *M. MCCARTY[1], O. WOOLNOUGH[2], P. ROLLO[3], Z. J. ROCCAFORTE[3], N. TANDON[4];
[1]MD Anderson UT Hlth. Grad. Sch., Houston, TX; [2]Vivian L Smith Dept. of Neurosurg., Univ. of Texas Hlth. Sci. Ctr. At Houston, Houston, TX; [3]UTHSC at Houston, Houston, TX; [4]Neurolog. Surgery, Univ. of Texas Med. Sch. at Houston, Houston, TX

Abstract: The rapid recognition of a face in a crowd or the words on this page involves a dynamic interplay between visual input and the direction of limited attentional resources required for rapid identification of these inputs. Visual categorization of words and other visual stimuli is known to involve category-selective regions of the ventral occipitotemporal cortex (vOTC) as well as interaction with a broader language and attentional network. Previous functional imaging work demonstrates a topographic map of category selectivity in vOTC. Recent evidence suggests that the boundaries of category-selective regions of the vOTC may shift based on selective attention. Given limited temporal resolution of these methods, the dynamics of these interactions with language and attentional networks remain unclear. To probe these dynamics, we utilize the high spatiotemporal resolution of intracranial EEG recordings during a task where visual attention is directly modulated.
To explore the influence of attentional modulation on category-selective regions of vOTC, we performed intracranial recordings in 18 patients (2,000 + electrodes) undergoing electrode implantation for seizure localization in intractable epilepsy. All participants performed a category localizer task in which visual stimuli of different categories (Faces, Words, Scenes, or Animals) were presented. Patients responded based on a color-changing fixation point, repetition of a presented stimuli (i.e., a one-back task), or when target stimuli within a specific category appeared (e.g., respond to fruit words like “apple”). We analyzed broadband high gamma activity (BGA, 70 - 150 Hz) following each visual stimulus onset, contrasting between stimulus category and attentional task conditions.
High BGA and strong category-selectivity was seen across vOTC and inferior frontal gyrus (IFG). There was enhancement of BGA when the stimuli were attended, compared to BGA activation for fixation. We observed early attentional modulation of BGA activation in IFG and vOTC. Additionally, selective attention of individual categories enhanced category selectivity for the attended category. Research into the localization and modulation of cortical regions selective for different categories of visual stimuli will yield insight into the organizational principles and functionality of these regions. Beyond a purely structural analysis, this research explores how attention dynamically modulates intrinsic selectivity of neural populations in category selective vOTC.

Title: Brain state dynamics reflect generalizable cognitive and attentional state dynamics

Authors: *H. SONG[1], W. SHIM[2], M. D. ROSENBERG[1];
[1]Univ. of Chicago, Chicago, IL; [2]Sungkyunkwan Univ., Suwon, Kyunggi-Do, Korea, Republic of

Abstract: Understanding relationships between cognitive and neural state dynamics is a pivotal goal of cognitive neuroscience. Recent work suggests that the dynamics of large-scale brain states—characterized by distinct patterns of activity and functional interactions—represent time-varying cognitive and attentional states (Shine et al. 2019; Vidaurre et al. 2018), for example, capturing behavioral performance in cognitive tasks (Yamashita et al. 2021; Cornblath et al. 2020) or attentional engagement during movie watching (Van der Meer et al. 2020). However, the underlying characteristics of these brain state dynamics, the nature of the cognitive and attentional states that they reflect, and their consequences for behavior have not been studied in diverse controlled and naturalistic contexts. To ask these questions, we collected multi-session fMRI data (N=27) as participants underwent a variety of paradigms—sustained attention tasks, movie watching, and rest—and measured individuals' moment-to-moment attentional states. Hidden Markov model analyses revealed four latent brain states spanning canonical gradient axes of functional brain organization (Margulies et al. 2016), with a brain state situated at the center of the gradient axes acting as a hub in state transitions. Transient de-synchronization in global cortico-cortical and cortico-subcortical connections (Esfahlani et al. 2020) preceded neural state transitions. To elucidate the functional relevance of latent brain states, we related their occurrences to ongoing measures of attention. We found that brain state dynamics were synchronized across participants and time-locked to narrative event boundaries when subjectively engaging movies (sitcom episodes) were viewed. However, in a less engaging movie (an educational documentary), brain state dynamics were less synchronized across people and more similar to dynamics observed during controlled tasks and rest than to dynamics observed during engaging movie watching. Furthermore, we found that brain state dynamics reflected fluctuations in attention task performance and self-reported engagement during movies. Notably, a common brain state indicated suboptimal attention during tasks and movies, whereas different brain states indicated engaged attention in different contexts. Our results not only generalized across fMRI runs but also across data collected from three independent research groups (Chen et al. 2017; Rosenberg et al. 2016; Chang et al. 2021). Together, these results demonstrate the functional significance of large-scale neural state dynamics for ongoing cognition and attention.

Title: Attention operates differently across eccentricities

Abstract: In primates, foveal and peripheral vision have distinct neural architectures and functions. However, it has been debated if selective attention operates via the same or different neural mechanisms across these different eccentric locations. We hypothesized that the discrepancies between past results arose in part from the differences in neural signals used to index attentional modulations and the differences in task difficulty across eccentricities. Here, we measured three EEG indices of visual processing, while male and female human subjects performed a visual attention task, where they either attended to the fixation or to the visual

stimuli presented at different eccentricities. These EEG indices include the amplitudes of the steady-state visually evoked potentials (SSVEPs), the sustained negative deflection (SND), and the alpha band activity. Critically, we equated task difficulty across the different attention conditions and eccentricities. Overall, the amplitudes of these neural markers reduce as a function of eccentricity, reflecting changes in cortical magnification. However, they expressed totally different patterns of attentional modulations across eccentricities. The SSVEP exhibited prominent attentional gain modulations at the peripheral locations, but attentional modulations were significantly reduced at the parafoveal locations. In contrast, the SND showed relatively similar levels of attentional modulations across the parafoveal and the peripheral locations. On the other hand, alpha band activity exhibited significant attentional modulations only at the peripheral locations, which relied primarily on the relative differences between the contralateral and ipsilateral signals. Taken together, these results suggest that sustained visual attention comprises multiple biophysical processes that differentially impact sensory information processing across eccentricities.

Title: A new tripartite landmark in human posterior cingulate cortex

Authors: *E. H. WILLBRAND[1], B. J. PARKER[1], T. HALLOCK[1], W. I. VOORHIES[1], L. APONIK-GREMILLION[2], J. A. MILLER[1], S. A. BUNGE[1], B. L. FOSTER[3], K. S. WEINER[1]; [1]Univ. of California, Berkeley, Berkeley, CA; [2]Baylor Col. of Med., Houston, TX; [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Human neuroimaging shows that the posterior cingulate cortex (PCC) is an anatomically and physiologically unique brain region, being a central network hub of neocortical connectivity and displaying one of the highest cortical metabolic rates. Nevertheless, PCC function remains poorly understood. For example, while the PCC is typically viewed as a key

node of the default mode network (DN), additional human neuroimaging studies suggest a role of PCC in episodic memory retrieval and cognitive control. Central to this confusion is the varied and inconsistent anatomy/nomenclature used to define the PCC. Across human studies, PCC is used interchangeably with precuneus (PrC) and/or retrosplenial cortex (RSC). Therefore, establishing consistent anatomical landmarks and nomenclature is foundational to progress in understanding PCC function. With this goal in mind, we conducted a multimodal investigation of the sulcal morphology of the posteromedial cortex, which includes PCC, RSC and PrC. Manual identification of 4319 sulci across 552 hemispheres, spanning the human and chimpanzee lifespan, revealed the presence of a novel and shallow sulcus, which we termed the inframarginal sulcus (*ifrms*). Subsequent analyses revealed five main findings regarding the *ifrms*. First, the *ifrms* is a macroanatomical and microanatomical landmark: the *ifrms* identifies a focal point of high cortical thickness and light myelination in PCC with the largest thickness/myelination ratio of PCC sulci. Second, the *ifrms* is a functional landmark, co-localizing with, and predicting the location of, a functional sub-region of the cognitive control network (CCN). Third, the *ifrms* is identifiable in juvenile and healthy older adults, as well as in 48% of chimpanzee hemispheres examined. Fourth, the characteristic morphological features of the *ifrms* change across age groups and between species: the *ifrms* is deeper in older adults and juveniles than in young adults across species, as well as is deeper in humans compared to chimpanzees. Fifth, the *ifrms* gray matter thins across age groups in humans and chimpanzees. Altogether, our results reveal that the *ifrms* is a new tripartite landmark in human PCC that is developmentally and evolutionarily relevant. These findings help reconcile prior discrepancies regarding where the DN ends and the CCN begins in PCC, as well as support a classic, yet largely untested theory that tertiary sulci may serve as landmarks in association cortices, laying the groundwork for future investigations of PCC functional neuroanatomy.

Title: Transcriptomic contributions to the cytoarchitectonic parcellation of the human cerebral cortex.

Authors: *L. KING[1], J. GOMEZ[3], Z. ZHEN[4], K. WEINER[2];
[1]Helen Wills Neurosci. Inst., [2]Psychology Dept., Univ. of California, Berkeley, Berkeley, CA;

[3]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [4]Beijing Key Lab. of Applied Exptl. Psychology, Bejing Normal Univ., Beijing, China

Abstract: *Introduction*: Transcriptomic contributions to the functional and anatomical parcellation of the human cerebral cortex has become a major interest in human brain mapping in the last decade. Recent research shows that active transcription of a small set of genes contributes to large-scale gradients and functional hierarchies in the human cerebral cortex. The combination of previous findings has also shown that different sets of genes contribute to the positioning of cortical areas within functional hierarchies and the organization of functional maps within cortical areas. Complementing these previous micro- and meso-scale approaches, here, we implemented a whole brain, macroscale approach to examine transcriptomic contributions to the cytoarchitectonic parcellation of the human cerebral cortex. *Methods*: This investigation makes novel use of three publicly available datasets: the AHBA transcriptomic dataset, the JuBrain cytoarchitectonic atlas, and the von Economo-Koskinas atlas. This is done by overlaying all three datasets in the common MNI-152 space followed by the application of data-driven methods. This includes the use of PCA to determine the genes most differentially expressed across 87 cytoarchitectonic ROIs in which these ROIs were then clustered based on their similarity in gene expression. Furthermore, using variables such as cellular density and cell width, we correlated microanatomical features to the transcriptomic profiles of these cytoarchitectonic ROIs. *Results*: We show that a novel set of genes contribute to the cytoarchitectonic parcellation of the human cerebral cortex beyond those genes previously identified that contribute to either the parcellation of functional hierarchies or maps within cortical areas. Additionally, the clustering of the cortical ROIs via their transcriptomic profile reveals areas that are more similar in function rather than macroanatomical location: areas between networks are often more transcriptomically similar than areas within the same network. *Conclusion*: These results support a novel hypothesis that there is a nested spatial relationship among transcriptomic, anatomical, and functional parcellations of the human cerebral cortex at the level of maps (mm; areal), gradients and hierarchies (cm; within lobes), and networks (several cm; across lobes). We conclude by showing that a microanatomical substrate supporting this hypothesis across spatial scales is cell density.

Title: Anatomical properties of individual-specific areal-level parcellations predict cognition and behaviour

Authors: *E. DHAMALA[1], R. KONG[2], K. M. ANDERSON[3], L. OOI[2], J. CHEN[2], B. T. T. YEO[2], A. J. HOLMES[1];

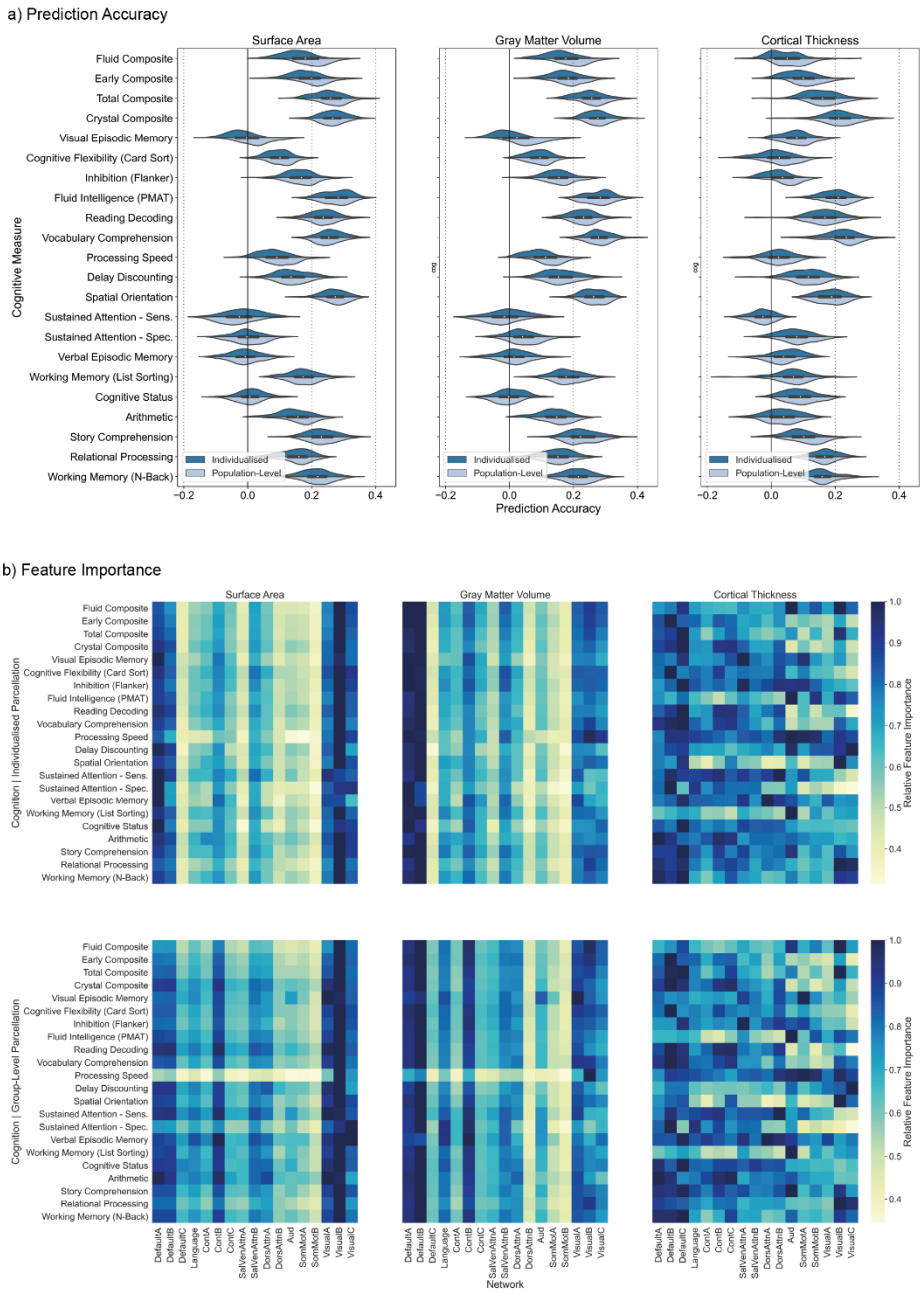

Figure 1: Model Performance for the Prediction of Cognitive Measures.

a) Prediction accuracy (correlation between true and predicted values) violin plots for models using surface area (left), gray matter volume (middle) and cortical thickness (right) computed using individualised (dark blue) and group-level (light blue) Schaeffer parcellations to predict cognitive measures. Average prediction accuracy across all cognitive measures using the individualised parcellations are r = 0.145 ± 0.043 (mean ± standard deviation) for surface area, r = 0.150 ± 0.043 for gray matter volume, and r = 0.097 ± 0.045 for thickness. Average prediction accuracy across all cognitive measures using the individualised parcellations are r = 0.158 ± 0.042 (mean ± standard deviation) for surface area, r = 0.163 ± 0.043 for gray matter volume, and r = 0.112 ± 0.045 for thickness.

b) Network-level mean felative feature importance for models using surface area (left), gray matter volume (middle), and cortical thickness (right) computed using individualised (top) and group-level (bottom) Schaeffer predict cognitive measures. Absolute areal-level feature weights were Haufe-inverted (Haufe et al. 2014), summarised to a network level (Yeo et al. 2011), and averaged over the 100 splits for each model.

Abstract:

Functional and structural properties of the brain underlie cognition. Prior work has shown that individual differences in the spatial topography and size of functional networks predict a wide

range of behaviours (Kong 2018), while variation in regional patterns of cortical thickness and morphometric similarity respectively link with aspects of psychopathology (Parkes 2021) and cognition (Seidlitz 2018). Moreover, functional connectivity measures based on individualised parcellations improve predictions of behaviour (Kong 2021) beyond those achieved with population-level parcellations. Here, we investigate whether areal-level cortical surface area, gray matter volume, and thickness derived from individualised or population-level functional parcellations more accurately capture neural biomarkers underlying cognition. We examined resting-state functional MRI surface data from 967 healthy young adults (ages 22-37; 453 males) from the Human Connectome Project (Van Essen 2013). We used the population-level Schaeffer parcellation (n=400; Schaeffer 2018) and derived individualised parcellations using the gradient-infused multi-session hierarchical Bayesian model (Kong 2021). We then estimated surface area, gray matter volume, and thickness of each parcel, and used those independently to predict cognitive measures with linear ridge regression models with k-fold group-matched cross-validation and 100 distinct train/test (2:1) splits. Prediction accuracy distributions are comparable across individualised and population-level parcellations (Fig 1a). Surface area and gray matter volume in the Default Mode and Visual networks strongly contributed to predictions across cognitive measures, while a diffuse profile of parcels contributed to predictions using thickness (Fig 1b). These results demonstrate that areal-level properties derived using individualised and population-level parcellations comparably capture relationships with cognitive functioning, and these relationships are driven by the Default Mode and Visual networks.

Title: Uncertainty Modulates Visual Maps During Non-Instrumental Information Demand

Authors: *Y. LI[1,2], N. DADDAOUA[1,2], M. HORAN[1], J. GOTTLIEB[1,3,2];
[1]Dept. of Neurosci., [2]Mortimer B. Zuckerman Mind Brain Behavior Inst., [3]Kavli Inst. for Brain Sci., Columbia Univ., New York, NY

Abstract: Humans and animals seek to obtain information that reduces uncertainty even when the information cannot be utilized to increase reward gain. Neurons in the basal ganglia and medial prefrontal cortex encode the motivation to reduce uncertainty, but it is unknown how these global motivational signals are translated into concrete information sampling policies. To examine this question, we investigated the impact of uncertainty on visual representations in the monkey lateral intraparietal area (LIP) that is implicated in attention and eye movement control. Monkeys performed trials with 0%, 50% or 100% reward probabilities, with the 50% condition uniquely inducing reward outcome uncertainty, and had a free viewing period when they could shift gaze to a mask to uncover a cue that predicted the outcome (reward or lack of reward). Importantly, revealing the additional cue was not incentivized and did not alter the trial's reward. Nevertheless, monkeys were intrinsically motivated to reveal the cue, and were more likely to do so at 100% relative to 0% probability (indicating a sensitivity to reward probability) and at 50% relative to 100% probability (indicating a desire to resolve uncertainty). Consistent with this behavioral pattern, LIP neurons showed distinct modulations by reward probability and uncertainty. A time-resolved linear model showed that reward uncertainty signals arose at longer latencies relative to those of reward probability and enhanced firing rates in all epochs of the neurons' response, including anticipatory and visual pre-saccadic responses and post-saccadic responses to the masked or revealed cue. Uncertainty modulations did not encode immediate saccade plans but correlated with behavior on longer time-scales - i.e., predicted variations in the sensitivity to uncertainty in the monkeys' daily revealing behavior. Moreover, in a passive task with no opportunity to sample information, reward modulations were unchanged while uncertainty modulations became negative (suppressing rather than enhancing the visual response). Our results suggest that reward and uncertainty are two independent motivational signals that converge on spatially tuned LIP cells and, by modulating visual priority, affect the likelihood that monkeys will select and process informative visual cues.

Title: Networks underlying the maintenance of endogenous cognitive control

Authors: *M. K. EGAN[1], C. COSTINES[2], M. DESPOSITO[2], S. SADAGHIANI[1];
[1]Psychology, Univ. of Illinois, Urbana-Champaign, Urbana, IL; [2]Psychology, Univ. of California Berkeley, Berkeley, CA

Abstract: Cognitive control comprises a multitude of functions that are difficult to dissociate neurobiologically. These functions are commonly tested in the context of external events that modulate control demands (e.g. cues), informing about externally-driven control but providing no insights into intrinsically maintained cognitive control processes. Here, we designed an fMRI task to investigate the role of internally-driven cognitive control and its relationship with intrinsic functional connectivity networks implicated in cognitive control (dorsal attention network (DAN), fronto-parietal network (FPN), and cingulo-opercular network (CON)). 25 human subjects (13 female) underwent fMRI. Each trial consisted of a pair of sequential stimuli with the subject responding if the stimuli were identical or not. The design had two factors: "Cueing" manipulated the presence of an auditory cue prior to the first stimulus, and "Content" manipulated whether the stimulus category was known (only faces) or unknown (randomly selected from 4 visual and 4 auditory). Factors were analyzed for two time periods, the "Intertrial" period (1.5-10s), and the "Trial" period - the time from cue onset (if present) to response. Interblock intervals (15s) provided implicit baseline. Using a general linear model (GLM), we found that for the contrast of No Cue > Cue significant activations were found in both time periods. During the Intertrial period (endogenous phasic control) activations were found in areas overlapping with DAN. During the Trial period (exogenous phasic control) activations were found in areas overlapping with FPN. To understand how DAN maintains endogenous control during the intertrial period, we investigated the task-related modulation of DAN connectivity using psychophysiological interactions (PPIs). Using the significant voxels within the DAN during the No Cue > Cue contrast as the region of interest (ROI) mask and the same contrast as the context weights, PPI analyses showed significant connectivity changes between the DAN and default mode network (DMN) during the Intertrial period. Finally, we performed an adapted region-by-region PPI analysis using all individual regions of DAN, FP, DAT, and DMN (39 ROIs total). Using network-based statistics we found significant clusters of connections between the DAN and DMN whose connectivity strength increased in the Intertrial period when cues were unavailable. We conclude that the DAN is more engaged during periods of endogenous phasic control, the FPN is more engaged during exogenous phasic control, and there is a significant relationship between the DAN and DMN that is contextually dependent on the presence of a cue.

Title: Dynamic neuronal networks supporting working memory shift with emotion

Authors: *A. CAMPBELL[1], A. S. FERGUSON[2], P. J. MUCHA[3];
[1]Univ. of North Carolina - Chapel Hill, Chapel Hill, NC; [2]Univ. of North Carolina, chapel hill, NC; [3]Dartmouth Col., Hanover, NH

Abstract: Brain activity supporting executive functions is dynamic, adapting and accessing flexible neuronal networks to meet task demands. Theta (4-8Hz) and alpha (8-12Hz) band activity support executive functions, yet their network activity has been less clear. The current study investigated these networks in two affective working memory tasks: one for updating and one for inhibition. Thirty participants completed the affective executive tasks while EEG was recorded with a 64-channel BioSemi Active2 system. In the n-back updating task, participants identified emotional images (from the International Affective Picture System) that were presented 1 or 2 items ago in the series. In the affective go/no-go task participants withheld a pre-potent response to a particular affective image category. For each task and affective category (positive, neutral, or negative) we extracted the evoked power and used the power correlations as the bases for the network. We then assessed network features (centrality, clustering) and dynamic network features using a multilayered network. Within this multilayered network we detected underlying communities. The dynamic network communities clearly aligned with stages of information processing, and a greater number of communities were detected for the tasks with negative information. These results further support the differential nature of negative information and highlight how this information shifts neuronal networks supporting executive functions.

Title: Common brain regions support emotion regulation and cognitive control tasks

Authors: *D. H. SCHULTZ;
CB3, Univ. of Nebraska, Lincoln, Lincoln, NE

Abstract: Cognitive control is the ability to organize behavior in flexible ways in accordance with internal goals. Cognitive control processes can be applied in situations requiring the regulation of emotions. In this case, the cognitive control task demands include monitoring, evaluating, and modulating reactions. The ability to regulate emotion is thought to be critical for maintaining and regaining mental health. Therefore, emotion regulation is related to a variety of mental disorders, such as depression, anxiety, and addiction. Although cognitive control and emotion regulation are conceptually related, the empirical relationship between these processes is largely unknown. Recent data has suggested that the flexible hub properties of the frontoparietal control network (FPN) contribute to cognitive control by being able to update brain network connections in a flexible and rapid manner according to current task demands. I hypothesize the same flexible hub mechanisms that contribute to non-emotional cognitive control tasks extend to emotion regulation. Recent research has suggested that different emotion regulation strategies may be more effective and better associated with outcome measures. The purpose of this study is to examine the relationship between non-emotional cognitive control and emotion regulation, identify a common neural mechanism and assess the efficacy of two different reappraisal strategies (distancing and reinterpretation). I tested these hypotheses in a sample of participants (n=21, 14 females) that completed a non-emotional cognitive control task (n-back) and an emotion regulation task. Participants completed the tasks in the fMRI scanner. Consistent with my hypotheses, the non-emotional cognitive control task and emotion regulation engaged overlapping brain regions. This overlap was apparent in the frontoparietal and cingulo-opercular networks. Both networks have been previously identified as having a role in cognitive control and emotion regulation. Despite a large degree in overlap between cognitive control and emotion regulation activity, vlPFC was preferentially engaged by emotion regulation. This supports the hypothesis that the vlPFC serves an inhibitory function on negative emotion when participants use reappraisal strategies. Finally, we found that activity in the dlPFC was greater when reinterpretation was used relative to distancing-based reappraisal strategies. This is consistent with the hypothesis that reinterpretation may require more effort and resources than distance-based strategies because distance-based approaches are not bound by specific sensory features.

Title: Is brain modularity a biomarker of exercise intervention-related plasticity?

Authors: *S. JAIN[1], M. A. PIPOLY[2], M. SODOMA[1], V. MAGNOTTA[3], G. PIERCE[4], M. VOSS[1];
[1]Dept. of Psychological and Brain Sci., [2]Neurosci., [3]Dept. of Radiology, [4]Dept. of Hlth. and Human Physiol., Univ. of Iowa, Iowa City, IA

Abstract: Research supports promise for physical and cognitive interventions to promote cognitive plasticity. However, there is wide variability in benefits across individuals. Brain modularity, a network-based measure quantifying the extent a brain has non-overlapping subnetworks, has been proposed as a biomarker of individual variability related to training gains including on tasks of working memory. However, no studies have tested whether this relationship would also be seen following a single acute intervention session. We tested the predictive strength of modularity on exercise-induced changes in working memory after an acute and long-term physical exercise intervention. We collected resting state scans and performance data from a face N-Back task (1-Back, 2-Back) from cognitively normal older adults (N = 29, $M_{age} = 67 \pm 4.21$) at the beginning of the study and after both acute and long-term intervention. As part of the acute intervention, each participant performed two physical exercise sessions for 20 mins each on a stationary bike at moderate intensity (increased their heart-rate (HR) to 65% of their HRmax) as well as light intensity (minimal effect on HR). These sessions were performed on different days and their order was counterbalanced. This was followed by a three-month intervention where 62% (N=18) participants trained at moderate intensity and the remaining at primarily light intensity with short moderate intensity intervals. N-back accuracy improved more following moderate compared to light intensity exercise at the acute session; training related behavioral changes after the acute session were predictive of long-term intervention gains for all participants.We tested the predictive ability of a) pre-training modularity and b) modularity after acute interventions on post-training performance. We used weighted undirected functional matrices and the Schaefer 400 parcellation. Modules were defined in a data-driven manner and modularity calculated using the Community Louvain function. Regression analysis showed pre-training modularity did not predict acute or long-term intervention-related accuracy gains. However, modularity calculated after moderate-intensity acute exercise was a significant predictor of working memory accuracy gains after training. Identifying a reliable biomarker of intervention-related cognitive plasticity is not just theoretically important but has wide ranging practical significance. Brain modularity might be a valid biomarker of potential for training-induced plasticity, though our results suggest acute manipulations may enhance sensitivity for predicting exercise-induced benefits on cognition.

Title: The low glutamate diet improves working memory performance and alters functional connectivity within pertinent networks in veterans with Gulf War Illness

Authors: *A. E. KIRKLAND[1], M. T. LANGAN[2], V. C. MUCCIARONE[3], L. C. RICE[3], J. W. VANMETER[4], K. F. HOLTON[3], *A. KIRKLAND[5], *A. KIRKLAND[5];
[1]Med. Univ. of South Carolina, Charleston, SC; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]American Univ., Washington, DC; [4]Georgetown Univ. Med. Ctr., Washington, DC; [5]

Abstract: Gulf War Illness (GWI) is a chronic multi-symptom disorder with severe cognitive impairments thought to be related to glutamatergic excitotoxicity and central nervous system (CNS) dysfunction. The low glutamate diet has been proposed as a comprehensive intervention for GWI because it removes dietary amino acids that can act as excitotoxins in the CNS, which may affect glutamatergic neurotransmission and symptoms of GWI. The objective of this study was to assess the effects of the low glutamate diet on verbal working memory and functional connectivity (FC) in veterans with GWI. Twenty-four participants (age= 53.3 (5.9) yrs, 75% male) completed a fMRI verbal N-back task at baseline and after the one-month low glutamate diet. A data-driven multi-voxel pattern analysis (MVPA) approach was used to identify regions with significant differences in whole-brain FC during the 2-back block of the N-back task (highest cognitive load) before and after the diet. Subsequent seed-to-voxel analyses were used to assess differences in whole-brain task-based FC patterns associated with the MVPA-identified seeds. All analyses were conducted in the CONN toolbox (Version 20b) using a peak level threshold of $p<0.001$ and a cluster defining threshold of $p<0.05$ FDR correction ($k>75$). Accuracy during the working memory 2-back improved after the one-month low glutamate diet (+13%; $p=0.006$). MVPA analysis resulted in 3 clusters with significant differences: part of the frontoparietal network (FPN) was represented in cluster 1 (left anterior and posterior supramarginal gyrus, planum temporale, parietal operculum) and cluster 2 (left inferior and middle frontal gyrus, precentral gyrus), while cluster 3 (right anterior supramarginal gyrus, postcentral gyrus) was part of the ventral attention network (VAN). The seed-to-voxel analysis identified significant FC changes for clusters 1 and 2 after the one-month low glutamate diet. Relative to baseline, cluster 1 and cluster 2 had decreased FC with regions comprising the VAN and somatomotor network. Cluster 2 also had increased FC with regions of the default mode network (DMN; lateral occipital cortex) and the FPN (cerebellum Crus I, II, and VI). Combined, these results suggest that the low glutamate diet reduces potential interference from sensory/attention reorienting networks while strengthening connectivity between the two networks central to working memory (FPN and DMN), which could underlie the working memory improvement. Future studies should replicate these findings in a larger sample of veterans with GWI and explore the effects of the low glutamate diet on performance and functional connectivity within other cognitive domains.

Title: Cognitive Implications of Brain Structural Connectivity Alterations Between Nodes of the Default Mode Network Related to Cannabis Use and HIV Infection

Authors: *P. VIERA PEREZ[1], J. S. FLANNERY[1], R. GONZALEZ, Jr[2], A. R. LAIRD[3], M. T. SUTHERLAND[1];
[1]Cognitive Neurosci., [2]Psychology, [3]Physics, Florida Intl. Univ., Miami, FL

Abstract: To alleviate HIV-related symptoms people living with HIV (PLWH) often report using cannabis (CB). Most PLWH demonstrate neurocognitive impairments showing a need to clarify manifestations of impairments. Emerging evidence suggests that HIV and CB use are both linked with alterations in default mode network (DMN) functional connectivity. Prior studies have demonstrated that resting-state connectivity networks correlate with underlying structural connections between functional nodes. Elucidating the relationship between chronic CB use, HIV, and the structural connectivity of the DMN is important for understanding the possible compounding effects of both CB and HIV on neurocognitive functions. Using diffusion-weighted imaging (DWI) data, we characterized structural connectivity profiles of DMN regions among 100 participants stratified into four groups based on HIV status and CB use history. Structural connectivity profiles across the DMN were established using a deterministic fiber tractography algorithm to track bilateral cingulum tracts (CT), the bilateral superior fronto-occipital fasciculus (FOF), and the genu of the corpus callosum (CC). Participants completed a battery of well-validated tasks to probe behavioral measures of inhibitory control, error processing, and general cognitive control. To explore the influence of HIV infection and CB use on structural connectivity, an ANOVA analysis was conducted on individual white matter tracts. For tracts that showed significant group-level differences, a mixed linear regression was conducted. The ANOVA analysis identified significant group differences in the number of tracts of the right CT between HIV groups, tract volume of the left CT between CB groups, and the average FA of the right superior FOF between CB groups. Posthoc tests revealed that HIV+ groups had more right cingulum tracts, and CB+ groups had higher FA in the right superior FOF and greater tract volume in the left cingulum. The mixed linear regression analyses identified a significant interaction between CB and FA in the left cingulum, such that CB+ groups were associated with more preservative errors than the CB- groups. It was shown that left cingulum

tract volume was positively associated with general processing speed. The left cingulum tract connects areas commonly linked with both memory and emotional regulation. Our results suggest that the left cingulum tract may be more susceptible to CB-related structural connectivity alterations regardless of HIV serostatus. These results suggest alterations to structural connectivity between nodes of the DMN contribute to more preservative errors.

Title: Individual differences in children's neural state segmentation performance are related to intelligence

Authors: *X. XU, S. MA, X. LIU, Y. LI, K. ZHANG, H. WANG, Y. HU, L. LIN, Q. CAI; East China Normal Univ., Shanghai, China

Abstract: To understand the ever-changing world, humans need to maintain a stable representation of the current context, and segregate the contextual information when it is no longer relevant. Such ability is of developmental significance. Using naturalistic materials and fMRI multi-voxel neural state segmentation analyses, studies have found that neural state boundaries co-occur with movie event boundaries, suggesting it might be possible to neurally index state segmentation ability. However, it remains unknown whether neural state segmentation performance might be indicative of individual differences in general cognitive abilities. Here, we collected an fMRI dataset of children (n=61, age: 6-7) watching a customized animation in which cognitive tasks and narrative events were interleaved, resulting in movie state boundaries. We found that neural state boundaries in several cortical networks align with movie state boundaries. To index individual differences in neural state segmentation, we calculated a neural pattern differentiation score to represent how well children's neural patterns differentiate between consecutive movie states. We found that the differentiation scores were reliable across two runs, and higher differentiation scores were associated with higher intelligence scores, with the highest correlation observed in the control network ($r = 0.30$). Further analyses showed that between-consecutive-state neural pattern dissimilarities were more associated with intelligence than within state neural pattern similarities. Moreover, this differentiation score based on neural pattern information outperformed univariate task-related neural response magnitude in predicting

intelligence. Together, these results showed that there are meaningful individual differences in children's neural state segmentation performance, which might be indicative of general cognitive development.

Title: Hemispheric Asymmetries in Individual Differences in Functional Connectivity

Authors: *D. C. PEREZ, A. DWORETSKY, C. GRATTON;
Psychology, Northwestern Univ., Evanston, IL

Abstract: Resting-state functional connectivity (rs-FC) research has produced highly validated group representations of the brain's network architecture. However, cortical network architecture is known to vary across individuals. "Precision" fMRI approaches allow us to examine functional organization at the individual level with high reliability by obtaining extended amounts of fMRI data for each subject. Individualized network maps derived using precision fMRI have revealed the existence of localized regions that exhibit divergent network organization in individuals compared to the group average. These regions have been termed "network variants" because their rs-FC pattern diverges from that of the canonical network associated with its location. Network variants have been shown to be present in all individuals, stable across time, and related to functional variation in tasks. However, the potential differences across hemispheres in the properties of variants have not been examined in detail. Here, we use data from the Human Connectome Project (HCP; n = 384 unrelated individuals) to investigate hemispheric differences in the properties of network variants. For each subject, we identified regions where the pattern of functional connectivity differs strongly from the group average. We found that the left and right hemispheres differ significantly in spatial location of network variants ($p < 0.001$), with more variants in the inferior frontal gyrus, angular gyrus and dorsomedial prefrontal cortex in the right hemisphere and in the supramarginal gyrus and posterior temporal gyrus in the left hemisphere. This result was replicated with an independent sample from the Midnight Scan Club dataset ($n = 9$; $p < 0.001$). Additional analyses using the HCP dataset show hemispheric differences in average variant size, where variants tend to be bigger in right compared to left hemisphere ($p(FDR) < 0.05$). Moreover, the number of variants associated with the frontoparietal and default mode networks was significantly greater in the right hemisphere compared to left hemisphere ($p(FDR) < 0.01$). Interestingly, the opposite

pattern was observed for network variants associated with the language network (p(FDR) < 0.01). Understanding the properties of network variants may help elucidate the relationship of variability in rs-FC to individual differences in behavior.

Title: Unique sampling of cortex-wide neural dynamics underlies individual behavioral phenotypes

Authors: *C. MACDOWELL, K. S. MILLER, M. LENZI, D.-L. FERGUSON, T. J. BUSCHMAN;
Princeton Univ., Princeton, NJ

Abstract: Behavior differs across individuals, lying along a spectrum that can range from typical to atypical phenotypes. Previous work has shown individual differences in behavior are related to differences in neural structure and/or function. Here, we show that individual differences in behavior are related to differences in the sampling of cortex-wide neural dynamics. Using a battery of behavioral tests, we quantified the spectrum of behavioral phenotypes ranging from 'typical' wildtype mice to mice with an induced 'atypical' phenotype. Then, using cortex-wide calcium imaging, we quantified cortical neural activity into a set of 16 'motifs'. These motifs captured repeated spatio-temporal patterns of neural activity that propagated across cortical areas. The same set of motifs were seen in all animals. However, an individual's phenotype was correlated with the likelihood of observing specific motifs. This relationship was seen both when animals were alone, and at rest, and when they were engaged in social interactions. Furthermore, animals' motif activity correlated with traditional measures of zero-lag functional connectivity across cortical areas. Since multiple motifs can engage the same brain areas, this suggests that differences in zero-lag functional connectivity reflects cortical activity dominated by specific spatiotemporal patterns in information flow. Together, our results relate cortical neural dynamics to behavioral phenotypes and suggest that individual differences may be driven by biases in animals' sampling of cortical dynamics.

Title: The impact of clutter on the spatial sensitivity of face selective populations in the macaque brain.

Authors: *J. TAUBERT, S. G. WARDLE, C. T. TARDIFF, A. PATTERSON, C. I. BAKER; The Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Representations of stimuli in the ventral visual pathway are thought to be organized according to two principles: retinotopic space (i.e., where something is) and category (i.e., what something is). Although these principles were originally thought to be reflected in different sectors of the ventral visual pathway, recent fMRI studies have reported that category-selective regions in the human brain are also spatially biased, with some support coming from macaque single unit recordings. Our goal was to investigate the spatial sensitivity of face-selective populations in the macaque when preferred stimuli are presented under more naturalistic circumstances, i.e., in cluttered visual displays. We tested a large sample size of macaques (N=7) using contrast-enhanced, high resolution (4.7T) functional imaging. This whole-brain approach circumvents the sampling limitations associated with electrophysiological studies and facilitates comparisons across species. In an initial experiment, we presented two subjects with three objects at a time (i.e., a face, an object, and a scene), with only one of these objects occupying the central screen location (i.e., at fixation). For example, in the *face* condition, faces were presented behind the central fixation point while objects and scenes were presented in the two peripheral locations to the left and right of the face. Fixation on the central stimulus was reinforced with juice, blocks were removed from the analysis if the subject was not fixating more than 95% of the time. We found that face-selective populations responded selectively to their preferred stimulus category when it was presented in the center of the cluttered stimulus array. However, there was no evidence of this selective response when the preferred stimulus was moved to the more peripheral locations within the stimulus array. Next, in a series of three experiments (n = 5) we interrogated the spatial sensitivity of face-selective populations to faces that were either presented alone or within cluttered displays. We found that face-selective populations are more sensitive to peripheral shifts when the subject is viewing a cluttered stimulus array than when faces are presented in isolation. However, multivariate analyses

revealed that information about the peripheral location of faces within cluttered arrays is encoded by face-selective populations in ventral inferior temporal cortex, raising interesting questions about the time course of these effects. Overall, these findings demonstrate that visual clutter, which more closely simulates the processing demands of natural environments, alters the response profile of face-selective regions.

Title: Visual, Social, Reward, and Eye Movement Activity in Macaque Area F7

Authors: *F. ABOHARB[1], J. SLIWA[2], S. SERENE[1], W. FREIWALD[1];
[1]Rockefeller Univ., New York, NY; [2]The Rockefeller Univ., New York, NY

Abstract: Primate medial prefrontal cortex is assumed to play a central role in social cognition. For example, a recent fMRI study (Sliwa & Freiwald, 2017) found selectivity for social interactions in this region simply during the observation of videos. Other studies demonstrated reward related activity, and classical work on the control of eye movements found saccade selectivity in the nearby supplemental eye fields. Yet, how these very different properties are encoded within the same population of cells has not been investigated before. To this end, we recorded in two awake, behaving macaque monkeys while they viewed clips falling into 8 categories: socially interacting conspecifics engaging in ethologically relevant behaviors, such as chasing, grooming, mounting, and fighting, or controls, which included conspecifics engaging in non-social behaviors, such as idling and goal directed behavior, such as eating, foraging, and manipulating a toy, as well scenes and moving objects. Recordings were performed using linear S-probes and targeted to area F7. Of 1392 recorded multi-unit sites, 978 (70%) show modulation during one of the three visual epochs (pre-video fixation period, stimulus presentation, and reward). Additionally, sites responded to different task elements: one fifth (297, 21%) were modulated by the appearance of the fixation dot and half the sites (696, 50%) were modulated activity in response to reward delivery. Using a sliding-window encoding method, we found 527 (38%) of sites encode the category of stimulus being presented. Unexpectedly, the neural population also carried signatures of more specific visual events, in particular the occurrence of particularly salient events which could drive responses across categories. To examine this effect

quantitatively, we compared firing rates in the periods following labeled events which included head turns, body turns, and eye contact. Across the population, 273 (20%) responded to either a left or right head turn, 84 (6%) responded to body turns, and 72 (5%) responded to eye contact. We found that 292 sites (21%) modulated activity around subject-generated saccades. Analyzing joint tuning, we found that neurons carried multiple of these very different selectivities. Together, these results show that an area in medial prefrontal cortex, F7, encodes visual information at both a fine-grain and a categorical level, motor, and reward information in a mixed format, thought to maximize information representations in neural populations. Thus functionality in F7 goes beyond a simple label like social interaction selectivity.

Title: Cross modal representation of identity in marmoset hippocampus

Authors: *M. METKE[1], T. TYREE[1], C. T. MILLER[2];
[2]Cortical Systems and Behavior Lab., [1]Univ. of California San Diego, La Jolla, CA

Abstract: Human and nonhuman primate communication are dominated by visual and acoustic social signals (i.e. faces and voices). Not only are these communicative signals integrated perceptually (i.e. McGurk), categorical information about the individual of the signaler converge to form highly-selective, cohesive cross-modal representations of identity in human hippocampus (i.e. concept cells). Such schema-based representations of identity are likely crucial for the rapid individual recognition needed to effectively navigate human societies. Although human and nonhuman primates enjoy broad similarities in their social cognitive faculties, whether a similar schema-based representation of individual identity would also be evident in the hippocampus of our simian cousins is not yet clear. Here we sought to test this question by presenting awake marmoset monkeys stimuli with faces and vocalizations of multiple conspecifics while recording the single-unit activity across numerous regions of hippocampal. We presented subjects with these social signals either as unimodal or cross-modal stimulus trials. During the latter cross-modal stimulus trials, the identity of the individual face image and vocalization stimulus was either matched or mismatched. We recorded the activity of ~2500 single neurons in the hippocampus of four adult marmosets in these test conditions. Preliminary

analyses of this population revealed three key results. First, while hippocampal neurons were responsive to faces and voices as unimodal stimuli, a population of neurons also exhibited cross-modal integration for these social signals. Second, neurons in marmoset hippocampus exhibited significant changes in the neural firing rate between identity match and mismatch trials suggesting that this population of neurons was sensitive to the individual identity of multiple conspecifics when integrating between visual and auditory modalities. Third, a population of hippocampal neurons was also highly selective to specific individual animals suggesting a potential analog in marmosets to human concept cells. Ongoing analyses are focused on explicating the relationship between these two parallel cross-modal representations of identity in marmoset hippocampus.

Title: Large scale ECoG recording during social scene watching in awake marmosets

Authors: *H. XU, Y. SU, J. SHARMA, W. MENEGAS, C. TRIMMER, R. LANDMAN, M. SUR, R. SAXE, G. FENG, R. DESIMONE;
MIT, Cambridge, MA

Abstract: Humans can understand social scenes at a glance. Abilities such as these are thought to rely on a network of brain regions often referred to as the social brain. Although people have found cortical patches selective for social content including faces, bodies and social interactions, it is mostly unknown how these domains work collectively dynamically during perception. People with autism spectrum disorders typically have deficits in some aspects of social cognition, but there are disagreements over which brain regions are responsible. Here we “map” the regions of cortex important for social perception and cognition in wild type marmosets which is a new world monkey that is highly social. We showed images and videos with marmoset faces and/or marmosets engaged in several forms of social behavior, together with matched control images and videos. We mapped brain regions responsive to the visual stimuli with micro-electrocorticogram (ECoG) recordings over the posterior and middle temporal cortex and lateral prefrontal cortex in animals seated in a primate chair with head fixed and gaze monitored. Stimulus selectivity was evident in the high gamma band. We localized several face/body/object patches in temporal and frontal lobe, which appear to be in similar locations to areas mapped with fMRI scanning. We also identified patches that appear to be selective for social interactions. Timing data suggests a first posterior to anterior feedforward wave of activation, followed by a

second feedback wave. Moreover, we also recorded with the same ECoGs but with untethered, wireless, recordings in the same animal, during social behaviors in the home cage. With these recordings, we hope to compare patterns of activation during the perception of social stimuli with patterns activated during performance of social behaviors.

Title: Parallel systems for social and spatial reasoning within the brain's apex network

Authors: *B. DEEN, W. FREIWALD;
Rockefeller Univ., New York, NY

Abstract: In the primate visual system, there is extensive evidence for domain-specificity: brain regions specifically involved in processing certain stimulus categories, such as faces or scenes. To what extent are higher-order brain regions, and cognitive processes, domain-specific? Here we consider areas within the default mode or apex network, argued to be anatomically positioned at the top of the cortical hierarchy, and implicated in a range of abstract cognitive processes, including social cognition, spatial navigation, and episodic recall. To precisely characterize functional organization in individual human brains, we scanned $N = 10$ participants using fMRI on a range of perceptual and cognitive tasks, across three scan sessions (7.5 hours per participant). Tasks involved visual perception, semantic judgment, and episodic simulation of close familiar people and places, and everyday objects. We find evidence for parallel subnetworks within the apex network that respond specifically during conditions involving familiar people and places, across visual, semantic, and episodic tasks. Person- and place-specific areas are identified across multiple zones of association cortex, including medial prefrontal cortex, medial parietal cortex, the superior frontal gyrus, and the temporal-parietal junction (FSL's improved linear model, $q < .01$). Within each zone, we observe a pattern of interdigitation between person- and place-specific areas. Across zones, regions with a given category preference are specifically functionally connected with one another in resting-state data, while regions with differing category preferences are not functionally connected. These two parallel, functionally specialized apex subnetworks were observed reliably across all participants.

These results demonstrate that category-specificity is not limited to perceptual systems, but is pervasive across brain regions positioned at the top of the cortical hierarchy. They suggest that our ability to reason about other people and places rely on parallel cognitive and neural mechanisms.

Title: Face mechanisms differ between gaze at live faces and gaze at webcam faces: Comparisons of eye-tracking, electroencephalography, neuroimaging, and cross-brain coherence between dyads

Authors: *N. ZHAO[1], X. ZHANG[2], J. A. NOAH[2], M. TIEDE[5], J. HIRSCH[2,3,4,6,5];
[1]Sch. of Psychology and Cognitive Sci., East China Normal Univ., Shanghai, China; [2]Dept. of Psychiatry, [3]Neurosci., [4]Comparative Med., Yale Sch. of Med., New Haven, CT; [5]Haskins Labs., New Haven, CT; [6]Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom

Abstract: A common experience secondary to the COVID-19 lockdown has been the reliance on web-cam platforms such as Zoom for conducting business and maintaining interpersonal relationships. Experience tells us that webcam faces and interactions are not the same as real face-to-face interactions, even though the faces and the people are the same. Why? We test the hypothesis that variations in visual sensing are related to interactive face processing and cross brain synchrony. A multimodal methodological approach was applied to investigate dyads in two conditions: face-to-face gaze and webcam gaze using functional near-infrared spectroscopy (fNIRS), with simultaneous electroencephalography (EEG) and eye-tracking. Stranger dyads (n=28 participants, 14 dyads) engaged in live mutual face-watching (real face and same-face on webcam) using a previously described[1] face-watching paradigm. Eye-tracking showed longer ($p < 0.001$) dwell times and reduced ($p<0.001$) horizontal positional variation for face-to-face relative to the webcam condition consistent with variations in visual sensing mechanisms. Additionally, the N170 event related potential showed a greater negative amplitude for real faces than for web faces consistent with an early advantage for the real face stimulus. Spectrum power in the theta band was also higher in the face-to-face condition consistent with oscillatory specificity for real-face processing. Neuroimaging findings for [face-to-face > gaze at webcam face] included bilateral and dorsal temporal regions, whereas activity for the [gaze at webcam face > face-to-face gaze] showed robust left activity in ventral regions of temporal, occipital, and parietal areas ($p<0.05$) consistent with regional mechanistic specificity for the real face condition. Inter-brain synchrony was also greater ($p = 0.05$) for the real-face dyadic condition for signals between angular gyrus, occipital/temporal gyrus, and somatosensory cortex consistent

with neural coupling effects specific to the real faces. Further, brain-to-brain synchrony for the somatosensory regions was positively correlated with visual sensing (dwell time) (r = 0.66) for face-to-face gaze and not for web cam gaze. Findings support the hypothesis that visual sensing mechanisms, neuro electrical oscillations, and visual face-processing pathways play an important role in live face-to-face interactions. Together, these converging lines of simultaneous multimodal evidence reveal early to late neurobiological processes that differentiate face watching pathways based on live face-to-face or web cam presentations.

Title: Simultaneous fNIRS-EEG reveals theta band differences spatially localized to the supramarginal gyrus during Face-to-face gaze at a human as compared to a robot-control

Authors: *M. KELLEY[1], J. A. NOAH[2], X. ZHANG[2], T. PARKER[1], J. HIRSCH[2,3,4,5,6];
[1]Interdepartmental Neurosci. Program, [2]Psychiatry, [3]Neurosci., [4]Comparative Med., Yale Sch. of Med., New Haven, CT; [5]Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom; [6]Haskins Labs., New Haven, CT

Abstract: While the neural and hemodynamic processing mechanisms of face-to-face interaction have previously been explored[1], the related temporal dynamics of these mechanisms are less well understood. Here, functional Near Infrared Spectroscopy (fNIRS) and electroencephalography (EEG) were acquired simultaneously to assess the temporal features of neural responses during eye-contact with another person and a robot control. **Methods.** Subjects (n=11) performed a 3-minute eye-contact task twice with two partners: a real human and a robot bust with eyes that blink and move but which otherwise lacks naturalistic features or behaviors. The task consisted of alternating 15-second (s) blocks of eye-contact with partner and of rest. Eye-contact was either allowed or prevented via a “smart glass” divider which separated participants from their

partner, and which had electronically controlled transparency or opacity. Eye-contact blocks were divided into 850ms EEG events with randomized no-eye-contact intertrial intervals of 200-400ms. Hemodynamic data were acquired via a 124-channel Shimadzu LABNIRS system and electromagnetic data were acquired in a modified 10-10 layout via a 32-channel g.USBamp system. **Data analysis and Results. fNIRS:** A general linear model (GLM) of task and rest blocks was convolved with the canonical hemodynamic response function to identify regions which differed between human and robot eye-contact. Past findings[1] of differences in a supramarginal gyrus and angular gyrus cluster (SMG/AG) were replicated (peak T=4.49, $p<0.05$). **EEG:** Data were filtered to 0.01-40 Hz, epoched to -100—850 ms, and decomposed via an independent component analysis. A normal mesh model boundary element method was used for component source localization and the GLM-defined SMG/AG cluster was used to constrain solutions. Components with <50% residual variance for the GLM-informed source were identified, clustered by scalp topography, and limited to one component per subject. Group time-frequency wavelet analysis of the SMG/AG component cluster was compared across partners. Significance was assessed via permutation testing. The SMG/AG cluster showed equivalent theta band oscillations (4-8hz) early in eye-contact epochs for both partners, but differences emerged later in the epoch (540ms-740ms). This preliminary data suggests that temporal differences in theta band activity in the SMG are involved in processing live face stimuli as social partners.

Title: The hippocampus represents abstract social place: encoding and decoding evidence in independent samples

Authors: *M. SCHAFER[1], P. KAMILAR-BRITT[1], V. SAHANI[1], S. J. MOELLER[2], V. GABBAY[3], Y. HURD[1], K. BACHI[1], D. SCHILLER[1];

Abstract: Background: Humans adeptly navigate complex social landscapes. **T**his capacity may depend upon social mapping: a hippocampal centered network may organize information

about social relationships into a multidimensional map, similar to that of physical space. In this framework, other people can be thought of as occupying abstract social places based on their locations along social dimensions, such as power and affiliation.
Methods: To test for such a brain representation, functional magnetic resonance imaging (fMRI) was collected in two samples of healthy individuals (n=27, 12 female and n=16, 6 female) while they completed a choose-your-own-adventure game where they interacted with fictional characters. Participants' relationships (i.e., decisions) with each character were modeled as sequences of locations in an abstract two-dimensional social space of power and affiliation. These locations were then compared to brain patterns.
Results: Hippocampal fMRI signals consistent with a social place representation were observed in a representational similarity regression with both region-of-interest (ROI) and whole-brain searchlight approaches, as well as an ROI-based decoding probability analysis. This effect was present in both samples, and was not explained by other measures of task behavior or other kinds of categorical or continuous task-based social information (e.g., character identity or familiarity), or by demographic variables (i.e., age and sex).
Conclusions: Our findings suggest that other people's social places are represented in the human hippocampus. Future work will ask how social place representations are combined into maps and used for flexible behavior - so-called "social navigation" - and how alterations in these representations may be implicated in disorders that feature both hippocampal and social dysfunction.

Title: Micu1 deficiency leads to cognitive impairment and anxiety-like behavior

Authors: S.-M. DENG, G.-J. HUANG;
Grad. Inst. of Biomed. Sci., Chung Gung Univ., Taoyuan, Taiwan

Abstract: The regulation of calcium by mitochondria is an essential event for maintaining cellular physiology. Studies have provided evidence that the mitochondrial calcium uniporter (MCU) regulates calcium uptake into mitochondria matrix. Mitochondrial calcium uptake

protein 1 (Micu1) has been demonstrated to play a critical role in regulation of MCU activity. Human patients carrying loss-of-function mutations in Micu1 suffer from muscle weakness, ataxia, and learning difficulties. Despite of numerous cell culture studies, there is limited information from knockout mice models. In this study, we used Cre-loxp system to generate Micu1 conditional KO mice, and various behavioral tests and electrophysiology will be accessed to measure behavioral phenotypes and long term potentiation (LTP). In order to understanding the morphology and functions of mitochondria, the electron microscopy imaging and mitochondrial oxygen consumption rate had been detected. Our pilot results showed mice without Micu1 in the brain exhibiting weaker motor function, higher level of anxiety, and poor performance in learning, which is in line with the symptoms of human patients. To answer the mechanism of phenotype alteration, we will use inducible knockout mice model and primary culture of neuron and glia cell, to investigate the role of Micu1 in both cell type-specific and time dependent manner. To better understating whether restoration of Micu1 expression can rescue the anxiety and learning behavior, we will inject AAV viral vector to overexpress Micu1 in the specific brain regions and measure mice behavior. This analysis shall give us a better understanding of how Micu1 influences the downstream expression profile and provides potential treatment of Micu1 deficiency.

Title: The striatal neurons contribute to specific behavioral updates in a classical conditioning task

Authors: *H. ALATRISTE-LEON, J. O. RAMÍREZ-JARQUÍN, F. TECUAPETLA;
Univ. Nacional Autonoma de Mexico, Mexico City, Mexico

Abstract: The striatum, the main input to the basal ganglia, is implicated in the control of behavioral flexibility, movements, and learning mediated by reinforces. The spiny projections neurons (SPNs) and cholinergic interneurons (ChIs) have been suggested to control the

behavior´s update of animals to new contingencies in instrumental conditioning, but little is known about how these neurons participate to adapt behaviors to changes in classical conditioning. Therefore, this study aims to evaluate the contribution of SPNs and ChIs activity on the behavioral flexibility of mice in a classical conditioning task. Preliminary results: We standardized a head-fixed task with four different auditory stimuli paired to four different outcomes (stim 1 to big, stim 2 to small, stim 3 to neutral, stim 4 to air puff), and after verifying the proper acquisition of the tones (monitoring anticipatory responses), we switch the tones-outcomes in a reverse mode. As the first experiment and to evaluate the contribution of striatal activity on the behavior update, we optogenetically inhibited the striatum, using AAV-Syn-Arch, during the switch of the tones. Later as a second experiment and to evaluate the ChIs contribution on the behavior update, we investigated the optogenetic inhibition of ChIs, using AAV-DIO-Arch in ChAT-Cre mice. Lastly, to investigate how the dynamic of striatal projection cells may read the cholinergic modulation, we are recording the striatal activity by expressing the genetically encoded calcium indicator (GCaMP6f) and monitoring the striatal activity by micro-endoscopes in the striatum of either D1-Cre or A2a-Cre mice. Our preliminary conclusions suggest that the SPNs and ChIs contribute to specific updates, in a classical conditioning task, depending on the values of the outcome's changes.

Title: Investigating amygdala striatal projections during positive and negative reinforcement regimes.

Authors: *E. DIAZ-HERNANDEZ[1], E. ILIAKIS[2], J. GALANAUGH[2], K. CHOI[3], M. V. FUCCILLO[4];

Abstract: The selection of current actions is under control of both positive and negative reinforcement. Alterations in the balance between these reinforcement systems can create conflicts and lead to compulsive, maladaptive behavioral responding. While dorsomedial striatal (DMS) neurons play a central role during action selection, it is unclear how this structure

differentially contributes to positive and negative reinforcement behavior. One DMS afferent population strongly related to emotional value is the amygdala which exhibits robust modulation to positive and negative stimuli. Here we examine amygdala-DMS circuits and their role during positive and negative reinforcement regimes. We start by mapping relevant circuits using two parallel approaches: (1) retro-cre AAV injected in DMS and AAV-Flex-Synaptophysin-mRuby injected into amygdala to assess how amygdala-DMS projections are distributed across striatum; (2) retrograde tracing using cholera toxin (CTB) in different DMS regions to assess how amygdalar afferents distributed by anterior-posterior striatal target. In order to determine the in vivo contributions of DMS-targeting amygdala populations, we designed an operant task that elicits positive and negative reinforcement within the same session. Using tone discrimination, the animal is directed to perform either positive operant reinforcement (lever press for chocolate) or negative reinforcement (lever press to avoid shock). Using in vivo electrophysiology single-unit activity and opto-tagging in freely moving mice, we recorded striatal-targeting amygdala neurons to identify how this population is differentially modulated by positive and negative reinforcement strategies. Preliminary anatomical results reveal a specific region where amygdala-DMS projections are concentrated while preliminary in vivo recordings exhibit divergent neural coding for amygdalar-DMS neurons depending on reinforcement type. This work will provide insight into potential circuit mechanisms that balance positive and negative reinforcement strategies.

Title: Melanocortin-4 receptor control of striatal-dependent action selection

Authors: *E. C. HEATON[1], G. TRINOSKEY-RICE[2], S. L. GOURLEY[3];
[1]Pediatrics, Neurosci. Program, [2]Pediatrics, [3]Pediatrics and Psychiatry, Emory Univ., Atlanta, GA

Abstract: Goal-directed action refers to behaviors that are dynamic, sensitive to unexpected events, and require the dorsomedial striatum (DMS). Meanwhile, habitual behaviors are reflexive and unchanging and rely on the dorsolateral striatum (DLS). Molecular factors underlying an organism's ability to flexibly shift between goal-directed and habitual behavior are incompletely understood. We recently discovered that striatal melanocortin-4 receptor (*Mc4r)* expression correlates with this behavioral flexibility in adult male and female mice. To identify functional consequences, we used viral-mediated gene silencing to reduce *Mc4r*. *Mc4r* knockdown in the DMS enhanced the ability of mice to select actions based on reward likelihood and value, while reduction in the DLS facilitated habit formation. Thus, MC4R *presence* serves as a brake on the functions of distinct striatal subregions in decision making. Changes in *Mc4r* expression modulates the activity of medium spiny neurons, leading to the hypothesis that chemogenetic manipulation of *Mc4r+* DMS neurons would impact expression of behavioral flexibility. Stimulation of *Mc4r+* DMS neurons via Gq-coupled Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) facilitated animals' ability to select actions based on reward likelihood. Meanwhile, inhibition via Gi-DREADDs rendered animals insensitive to changes in reward likelihood, promoting habits. These results reveal that striatal MC4R may be a key factor in sustaining *versus* "breaking" habits, and thus could serve as a target for treating maladaptive habits that contribute to neuropsychiatric disease.

Abstract: Value-based decision-making is at the core of nearly all motivated behaviors and requires the ability to associate outcomes with specific actions and make adaptive decisions about future behavioral action. At the core of value-based decision-making and reinforcement is the nucleus accumbens (NAc), which is integrally involved in learning, selecting, and executing goal-oriented behaviors. The NAc is a heterogeneous population primarily composed of D1 and D2 medium spiny projection (MSN) neurons that are thought to have opposing roles in behavior, in which D1 MSNs promote reward and D2 MSNs promote aversion. By expressing channelrhodopsin selectively in D1- and D2- populations (using D1-Cre and A2A-Cre mice) in the NAc core, we show that mice will nose poke for optical self-stimulation of both cell types, suggesting D2-MSN activity is not inherently aversive. While optogenetic approaches give some information about how cellular activation can modulate behavior, they eliminate the temporally specific neural activity patterns that encode information in behaving animals. To understand how real-time activity in these populations is linked to behavioral execution, we expressed the genetically encoded calcium indicator (GCaMP6f) within D1 and D2 MSNs coupled with in vivo fiber photometry to record from these cell populations in awake and behaving animals during pavlovian and operant conditioning tasks. Utilizing complex reinforcement schedules that allow dissociation of stimulus value, outcome, cue learning, and action, we show that D1 MSNs respond to the presence and intensity of unconditioned stimuli – regardless of value. Conversely, D2 MSNs respond to a mismatch between what is expected and what is received and thus encode errors in prediction in a value-independent fashion. To establish a causal link between the information encoded within these neuronal populations and behavioral output, we next expressed an inhibitory opsin (halorhodopsin) selectively in either D1- or D2-MSNs to inhibit these cells at specific time points during a fear conditioning task. We show that inhibition at select time points, either by inhibiting D2-MSN activity during the predictive cue or D1-MSN activity during the shock outcome, disrupts learning of the association. We thus provide foundational evidence for the discrete aspects of information that are encoded within these cellular populations.

Title: Dopamine release in the nucleus accumbens core signals valence-free perceived saliency

Authors: *M. KUTLU[1], J. E. ZACHRY[1], P. MELUGIN[1], S. CAJIGAS[1], M. CHEVEE[1], S. KELLY[1], L. TIAN[3], C. SICILIANO[1], E. S. CALIPARI[2];

Abstract: Significant work has aimed to define the precise information encoded by dopaminergic projections innervating the nucleus accumbens. Prevailing models are based on reward prediction error (RPE) where dopamine encodes associations between rewards and predictive cues and responds to perceived errors in predictions to update behavior. However, RPE cannot describe multiple phenomena to which dopamine is inextricably linked, such as behavior driven by aversive and neutral stimuli. We combined complex reinforcement tasks with direct, subsecond dopamine monitoring in the nucleus accumbens (NAc) of mice, machine learning, and computational modeling to describe behavior across multiple contingencies reinforced by differentially valanced outcomes. We show that dopamine release only conforms to RPE predictions in a subset of learning scenarios but fits valence-independent perceived saliency encoding across conditions. Together, we provide an extended, comprehensive framework for accumbal dopamine release in valence-independent behavioral control.

Title: The impact of oxytocin on dopamine signaling in the dorsal striatum of anesthetized rats

Authors: *D. P. DABERKOW[1], M. P. GAINER[1], D. E. GINDER[2];
[1]Eastern Washington Univ., Cheney, WA; [2]Washington State Univ., Pullman, WA

Abstract: Oxytocin (OXT) is involved in many aspects of brain function. Current research suggests that, due to the possible modulatory effect of OXT on learning and memory circuitry, OXT treatment for depression and addiction could be beneficial. Defining the neural mechanisms of OXT is crucial to understanding how OXT may be therapeutic for certain psychological disorders. Dopamine (DA), a neurotransmitter highly implicated in learning and memory, may be modulated by OXT. In general, OXT and DA receptors are located within the same brain regions. More specifically, there is overlap in the expression of OXT and DA receptors in the dorsal and ventral striatum. Furthermore, OXT fibers innervate DA neurons. The neuroanatomical association between the dopaminergic and oxytonergic systems provides a neurological mechanism by which OXT could potentially alter DA neurotransmission. METHODS: Male Sprague-Dawley rats were anesthetized, immobilized in a stereotaxic frame (Stoelting Co. Wood Dale, IL, USA), skin/fascia was cleared, and small holes drilled in the skull for placement of electrodes. A reference electrode (Ag/AgCl) was placed just below dura and a fast-scan cyclic voltammetry (FSCV) electrode was placed in the dorsal striatum (+1.0 AP, +2.0 ML, -5.0 DV). Subsequently, a twisted bipolar stimulating electrode (Plastics One, Roanoke, VA) with ~1 mm tip separation was placed just above the medial forebrain bundle (-4.6 AP, +1.4 ML, -7.0 DV). Constant current, biphasic stimulus pulses (60 Hz, 60 pulses, 300 µA) were applied (NL 800, Neurolog, Medical Systems, Great Neck, NY) and the stimulating electrode was incrementally lowered until a robust DA signal was evoked. Once clear and consistent DA signals were observed, intranasal OXT (1.0 µg/kg or an equivalent volume of saline for controls) was administered. RESULTS: Intranasal OXT increased DA release in the dorsal striatum, relative to controls (saline-treated rats). CONCLUSIONS: OXT modulates DA neurotransmission in the dorsal striatum. These results suggest OXT is potentially therapeutic for psychological disorders via, in part, the modulation of DA signaling. Title: The computational role of the basal ganglia in human cognition: A comparison of cognitive architectures through dynamic causal modeling

Authors: *H. HAKE;
Univ. of Washington, Seattle, WA

Abstract: Regulatory input from the basal ganglia (BG) to the prefrontal cortex (PFC) performs an important role in cognition. Theoretical models of this input, however, disagree on its computational properties, characterizing the majority of BG input as either direct (directly influencing PFC activity), or modulatory (indirectly influencing PFC activity through the gating of signals from other cortical areas). To determine the computational nature of these inputs in cognition, three alternate configurations of BG connectivity were tested using fMRI data from 200 individuals in the Human Connectome Project acquired during seven representative cognitive tasks and two resting state sessions. The structure of each model configuration (Direct, Modulatory, and Mixed (both Direct and Modulatory)) was based on a high-level cognitive architecture known as the Common Model of Cognition (CMC). The CMC seeks to explain abstract computations underlying cognition in terms of five interacting brain modules. Connectivity between these brain modules, specifically those containing the BG and the PFC, were modified to reflect these three models of BG connectivity. The Direct model had a direct, bidirectional connection between BG and PFC modules (basic CMC configuration). The Modulatory model lost this bidirectional connection, and instead contained modulatory connections from the BG to other cortical modules in this architecture. The Mixed model contained both direct and modulatory connections. Model configurations were then tested using Dynamical Causal Modeling, a mathematical modeling procedure that takes the structural and functional framework provided by cognitive architectures to measure if activity in certain brain regions is affecting another. Here, we show that for each of the seven cognitive tasks and the resting state, the Mixed model consistently outperformed Direct and Modulatory models. The models that performed second to the Mixed model depended on the specific cognitive task, suggesting an ability for the BG to flexibly adapt to various task demands. Taken together, the current data provide evidence for a likely set of core computations that the BG uses to differentially regulate cortical activity, and are present during task and task-free behavior.

Title: Distinct Roles of Dopamine D1 and D2 Receptor-Expressing Neurons in the Nucleus Accumbens for a Strategy Dependent Decision Making

Authors: *T. NISHIOKA[1], T. MACPHERSON[2], K. HAMAGUCHI[4], T. HIKIDA[3];
[1]Icahn Sch. of Med. at Mount Sinai, NEW YORK, NY; [2]Lab. for Advanced Brain Functions, Osaka Univ., Osaka, Japan; [3]Osaka Univ., Suita-Shi, Japan; [4]Kyoto Univ., Kyoto, Japan

Abstract: To optimize decision making, animals need to execute not only a strategy to choose a good option but sometimes also one to avoid a bad option. A psychological study indicates that positive and negative information is processed in a different manner in the brain. The nucleus accumbens (NAc) contains two different types of neurons, dopamine D1 and D2 receptor-expressing neurons which are implicated in reward-based decision making and aversive learning. However, little is known about the neural mechanisms by which D1 or D2 receptor-expressing neurons in the NAc contribute to the execution of the strategy to choose a good option or one to avoid a bad option under decision making. Here, we have developed two novel visual discrimination tasks for mice to assess the strategy to choose a good option and one to avoid a bad option. By chemogenetically suppressing the subpopulation of the NAc neurons, we have shown that dopamine D2 receptor-expressing neurons in the NAc selectively contribute to the strategy to avoid a bad option under reward-based decision making. Furthermore, our optogenetic and calcium imaging experiments indicate that dopamine D2 receptor-expressing neurons are activated by error choices and the activation following an error plays an important role in optimizing the strategy in the next trial. Our findings suggest that the activation of D2 receptor-expressing neurons by error choices through learning enables animals to execute the appropriate strategy.

Title: Oscillations regulate attractor dynamics within neural circuits

Authors: *A. LIBBY[1], T. BUSCHMAN[2];
[2]Princeton Neurosci. Inst. & Dept of Psychology, [1]Princeton Univ., Princeton, NJ

Abstract: Previous knowledge improves perceptual accuracy by overcoming sensory noise. This is thought to be due to attractor dynamics within sensory cortex that pull noisy stimuli into a sensible percept (Burak and Fiete 2012; Litwin-Kumar and Doiron 2012). However, when a neural representation falls into an attractor, it can become 'stuck', limiting the the network's ability to respond to changes in the environment. These two needs are in tension - strong attractor dynamics facilitate perception, but weak attractor dynamics allow the network to be sensitive to new sensory inputs. It is not clear how the brain balances (or switches) between having strong and weak attractors. Here, we propose oscillations may allow the brain to sample between these two dynamical regimes. To test this hypothesis, we embedded strong attractor dynamics within the excitatory connections of a recurrent neural network. These attractors facilitated 'perception' of noisy/weak sensory drive. However, once in an attractor, the network required extra sensory drive to escape the attractor. Attractors could be weakened by increasing inhibition (Wong and Wang 2006); however, this then weakened attractor dynamics. We found that oscillations in inhibition could balance between these two regimes. At the peak of oscillations (when inhibition is high), a weak sensory drive can move the network between attractors. In contrast, at the trough of oscillations (when inhibition is low), attractors are strong (facilitating perception), but transitions between attractors only occur for very large sensory inputs. In this way, oscillations allow the network to 'breathe' between a dynamical regime that emphasizes attractor dynamics and a regime that is sensitive to external inputs. In this way, the model captures previous experimental results that found sensory processing (Mathewson et al. 2011; Dugué, Marque, and VanRullen 2011), visual attention (Busch and VanRullen 2010; Buschman and Miller 2009), short-term memory (Siegel, Warden, and Miller 2009), and memory retrieval (Pfeiffer and Foster 2015) occur at specific phases of oscillations. In addition, our results provide a mechanistic reason for oscillations, suggesting they alter the dynamic landscape of recurrent networks, allowing them to sample between a strong attractor regime exploiting prior knowledge and a flat regime exploring new states.

Title: Neural oscillations in fronto-parietal network encode learning of new rules

Authors: *S. TAFAZOLI[1], C. I. JAHN[2], N. T. MARKOV[4], C. J. MACDOWELL[1], T. BUSCHMAN[3];

[2]Princeton Neurosci. Inst., [3]Princeton Neurosci. Inst. & Dept of Psychology, [1]Princeton Univ., Princeton, NJ; [4]Princeton Neurosci. Inst., Princeton Unviersity, Princeton, NJ

Abstract: To act intelligently in a situation, we must learn what rules to follow for that context. Then, as the situation changes, we must learn new rules. To understand the neural mechanisms of learning rules, we trained monkeys on a task that required them to learn a new 'rule' on each block of trials. On each trial, the monkeys chose between three colored squares (with the color randomly drawn from the full color wheel). The 'rule' for that block of trials guided the animals response -- their goal was to choose the square with the closest color to a 'target' color. Importantly, the target color was not instructed. Instead, the animals had to learn this new rule through trial and error. Once the animals learned the target color, it changed abruptly, requiring the animal to detect the change and learn a new rule. Consistent with animals using feedback to learn the rule, a Q-learning model predicted the monkeys' choices. Previous work has found that rule representations are distributed across multiple brain regions including prefrontal cortex (PFC) and posterior parietal cortex (PPC). To assess how this representation emerges during learning of a new rule, we used large-scale simultaneous recordings across the fronto-parietal network and found that oscillations in local field potentials (LFPs) in frontal and parietal areas change with learning. Gamma-band oscillations (35-55 Hz) were increased in PFC immediately after a change in rule, consistent with gamma oscillations increasing the bottom-up flow of sensory information when learning the rule. In addition, the power of alpha-band oscillations (10 Hz) was correlated with the animal's uncertainty about the current rule. Alpha oscillations have been associated with suppression of a rule, suggesting the current rule was inhibited when the animal was uncertain. Our results build on previous work showing oscillations support rule representations and argue that these representations can develop during learning.

Title: Perineuronal nets in the dorsomedial striatum contribute to behavioral dysfunction in mouse models of excessive repetitive behaviors

Authors: *B. A. BRIONES, M. N. PITCHER, W. T. FLEMING, A. LIBBY, E. J. DIETHORN, A. E. HAYE, C. J. MACDOWELL, A. D. ZYCH, R. C. WATERS, T. J. BUSCHMAN, I. B. WITTEN, E. GOULD;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Excessive repetitive behavior is a debilitating symptom of several neuropsychiatric disorders. Parvalbumin-positive (PV+) inhibitory interneurons in the dorsal striatum have been linked to repetitive behavior, and most of these cells are surrounded by perineuronal nets (PNNs), specialized extracellular matrix structures. We examined four mouse models of excessive repetitive behavior (BTBR, Cntnap2, Shank3, prenatal valproate treatment) and found a greater percentage of PV+ interneurons with PNNs in the dorsomedial striatum (DMS) compared to controls. In BTBR mice, we found that excessive repetitive behavior was associated with low numbers of dendritic spines on medium spiny neurons (targets of PV+ interneurons), and differences in neuronal oscillations as well as inhibitory postsynaptic potentials (IPSPs). Reduction of DMS PNNs to control levels normalized repetitive behavior and altered dendritic spine density and IPSPs. These findings suggest that cellular abnormalities in the DMS may contribute to maladaptive repetitive behaviors and that manipulating PNNs can restore typical structure and function.

Title: Low frequency spike-field coupling for error monitoring in medial frontal cortex: Empirical findings and biophysical modeling

Authors: *B. HERRERA[1], A. SAJAD[2], S. P. ERRINGTON[3], J. D. SCHALL[4,3], J. J. RIERA[1]; [1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Psychological Sci., [3]Psychology, Vanderbilt Univ., Nashville, TN; [4]Biol., York Univ., Toronto, ON, Canada

Abstract: The medial frontal theta rhythm has been linked to cognitive control and error monitoring (Cohen, *Trends Neurosci*, 2014). However, its mechanisms and functions remain uncertain. Here, we bring new insights combining computational simulations with neurophysiological data. First, we simulated 100 layer 5 pyramidal cells (L5PCs) receiving background Poisson-like spike trains on their apical dendrites. We found that low frequency oscillations in the membrane potentials corresponding to the theta and low-alpha range can inherently arise from such a random stimulation, even with these L5PCs completely disconnected. However, differences in phase make this oscillation unobservable within local field potentials (LFPs). Short (~10 ms) interruption of these inputs resulted in a phase-reset, creating broad frequency band spectral changes of the LFPs. Resetting was coincident with a transient elevated spike rate across all simulated neurons. Our previous work has reported similar spectral changes in the theta-alpha frequency band and increases in putative PCs spiking in neurophysiological data recorded from two monkeys performing a saccade stop-signal task. In this task, subjects were required to generate a saccade to a peripheral target, but to inhibit this planned saccade when a stop-signal appeared. Errors occurred when monkeys generated saccade despite the appearance of stop-signal. Motivated by the theoretical results, we quantified the strength of spike-field phase synchronization of 293 neurons recorded across 16 penetrations sampling neural activity across all layers of the Supplementary Eye Field (SEF) around the period in which a saccade was generated. Spike-field phase-synchronization, indexed by pairwise-consistency measure (Vinck et al., *J Comput Neurosci*, 2012) was calculated for the spiking activity of each neuron relative to its corresponding channel LFP. Overall, spike-field phase-synchronization of putative pyramidal neurons was highest for the theta and low-alpha bands (5-10 Hz) compared to other frequency bands. Furthermore, we observed a relative increase of this phase-synchronization on error compared to correct trials. Preliminary results found this relationship for neurons in all layers, while our simulations suggest the possibility of an enhanced input at the level of the L5PC basal dendrites when an error is made. With this, ongoing work aims to investigate whether increases in phase-synchronization may reflect further input to the deep cortical layers involved in error processing.

Title: Transient beta and gamma bursts in simulations and the mouse basolateral amygdala during the open field test

Authors: *S. CHO, J. CHOI;
Korea Inst. of Sci. and Tech. (KIST), Seoul, Korea, Republic of

Abstract: Neural oscillations reflect the phenomenon by which the individual neurons dynamically interconnect to rhythmically shift their overall activity as a neuronal ensemble. The spectral components of these oscillations have been traditionally characterized as increased power at specific frequency bands over sustained periods of time. Recent studies, however, suggest that such sustained oscillations can be an accumulation of temporally transient and spectrally specific burst events observed at a single trial level. In showing the physiological relevance of beta and gamma bursts in sensorimotor and cognitive systems of different species, multiple algorithms were used to distinguish temporally precise and possibly causal correspondence between neural activities and behaviors. Yet, no rigorous comparison has been made for these algorithms to address degrees to which the methodological differences result in disparate analysis outcomes.

We here examine five burst detection algorithms, namely bandpass filtering (BP), envelope-based (ENV), single-tapered spectrogram (STP), multitaper spectrogram (MTP), and continuous wavelet transform (CWT), and present their efficacy in simulation and experimental data.

For simulations, the synthetic neural signal was constructed by superimposing beta (25 Hz) and gamma (40 Hz) bursts onto aperiodic noise processes. We first tested burst detectability of each algorithm under the effect of Gaussian noise and burst duration in the simulated signals. Next, the temporal accuracy of individual burst detections was observed by quantifying how much these detections shift in time compared to the simulated bursts. The algorithmic performances did not differ much in detecting long, salient bursts bur rather showed distinctions for short and transient events, for which CWT reported best detectability and temporal accuracy. The statistical differences in algorithms were further tested on the mouse LFP data (Thy1-ChR2-YFP; n=5) acquired from the basolateral amygdala (BLA) during the open field test. The statistical dependency of burst durations and burst occurrence rates on locations and algorithms was evaluated. Although no statistical significance was found between locations, the algorithms showed significant differences in their parameterized burst durations and rates.

Our results therefore demonstrate the necessity of concerning the distinct advantages of each method in relation to the signal properties (e.g., waveforms, spectral characteristics) and encourage the hybrid use of multiple methods to maximize temporal precisions of burst detection, especially when cognition and behaviors have to be correlated.

Title: Phase-amplitude coupling of brain oscillations in verbal memory encoding

Authors: *A. V. MEDVEDEV;
Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Objective
Brain oscillations have been suggested to be involved in information transfer within and between neural networks by modulating neural excitability at different spatial and temporal scales. The interaction of oscillations across different time scales is revealed as cross-frequency coupling (CFC) and it represents a high-order structure in the functional organization of brain rhythms. There is growing evidence on the functional significance of CFC in various cognitive processes. In particular, phase-amplitude coupling (PAC) between gamma-band and low frequency oscillations have been implicated in working memory. To investigate the role of PAC in episodic memory, intracranial EEG (iEEG) records from patients with epilepsy during successful and unsuccessful verbal memory encoding (memorization of unrelated word lists) were analyzed in this study.
Methods
IEEG data were used from the open access repository (Restoring Active Memory, RAM). Time-frequency spectra in relation to each word presentation (1600 ms) were analyzed and 16 patients were selected for further analysis of PAC based on the availability of electrode locations within the four regions-of-interest (ROIs) of the temporal lobe (hippocampus, inferior, medial temporal and fusiform gyri). Modulation Index (MI; an amplitude-independent PAC measure proposed by Tort et al 2010) was then used to analyze the amplitude modulations of gamma-band frequencies in relation to the phase of low frequencies 4-16 Hz. The MI values were compared for subsequent successful vs. unsuccessful word retrieval.
Results
In each patient, several electrode sites showed significant increase in power of gamma-band activity during word encoding, and this increase was significantly larger for successfully recalled words ($p < 0.01$; the subsequent memory effect). For group analysis, the MI values were averaged across sites showing significant gamma response within each ROI and then across patients with the same ROI. The MI was significantly higher overall for successful encoding in the hippocampus, inferior and medial temporal gyri ($p < 0.01$). In addition, ROIs were characterized by regional specificity of coupling in terms of specific low and high frequencies showing the strongest association.

Conclusions
These results provide preliminary evidence that phase-amplitude coupling between gamma-band and low frequencies may play a functional role in memory encoding. It can be suggested that a more precise temporal structure of brain rhythmic processes results in a more efficient formation of transient neural assemblies which in turn determines the successful formation of a memory engram.

Title: Investigating implicit versus explicit motor sequence learning in an intra-subject EEG-study

Authors: *S. DYCK[1], C. KLAES[2];
[1]Ruhr-University Bochum, Bochum, Germany; [2]Neurosurg., Knappschaftskrankenhaus Bochum, Bochum, Germany

Abstract: Motor sequences play an essential part in our daily life since many everyday actions we perform have a sequential nature. Learning a motor sequence, for example a dance choreography, usually consists of two parts: Acquiring knowledge about the sequence elements and their temporal order (explicit component) and being able to combine these elements into a single, skilled behavior and to actually perform the sequence (implicit component). In this project, we investigate the neural oscillations that play a role in implicit and explicit motor sequence learning (MSL) using EEG. In our task design, participants concurrently learn an implicit and an explicit motor sequence of key presses in a modified version of the serial reaction time task (Nissen & Bullemer, 1987). The participants undergo five training sessions over the course of a week, while EEG recordings are performed at the first and last training session using a wet EEG with 64 electrodes. The two time points of measurement enable us to not only contrast implicit and explicit motor sequence learning in an intra-subject design, but to also investigate changes in neural oscillations over the course of learning. We will present our study design and preliminary data of 10 participants, including behavioral as well as EEG data. On a behavioral level, implicit and explicit sequence learning is reflected by significantly reduced reaction times, while implicit learning takes more time to be evident compared to explicit learning. A time-frequency analysis of the obtained EEG data shows that sequence learning is

related to alpha and beta suppression prior and during the key presses at motor-cortical electrodes.

Title: Combining journeys into expected outcomes: orbitofrontal-hippocampal interactions during spatial reversal learning

Authors: *J. RICEBERG[1], A. SRINIVAS[3], M. SHAPIRO[2];
[2]Neurosci., [1]Icahn Inst. of Med. at Mount Sinai & Albany Med. Col., New York, NY; [3]Albany Med. Col., Albany, NY

Abstract: To adapt to changing circumstances, we often recall similar situations and the consequences of past choices. Memory for recent events requires the hippocampus; using memory to adapt to changing circumstances requires the prefrontal cortex. Spatial discrimination learning in the plus maze is impaired by hippocampal inactivation, whereas OFC inactivation leaves such learning intact but impairs reversals of well-established contingencies. The mechanisms required for hippocampus-OFC interactions that support learning are unclear. As rats perform spatial reversals in the plus maze, both CA1 and OFC units fire differentially across maze locations and predict pending choices. To investigate functional interactions, we simultaneously recorded ensembles OFC and CA1 units as rats learned spatial reversals. Neuronal activity recorded in the start arms revealed striking interactive dynamics as rats learned a novel reversal: (1) OFC units were reliably phase locked to hippocampal theta oscillations. (2) Mixed pairs of CA1 and OFC neurons fired together reliably within single theta cycles. (3) Though CA1 population vectors (PVs) predicted changes in OFC activity, OFC PVs did not predict CA1 dynamics. (4) Locations decoded from PVs in the two structures followed different dynamics: CA1 ensembles stably represented distinct spatial journeys, whereas OFC ensembles developed more generalized representations of journeys to different goal locations that held identical rewards. These activity dynamics occurred only during new learning, not during stable

performance or familiar reversals. The results indicate frontotemporal interaction mechanisms for computing cognitive maps that guide decision-making.

Title: Vestibular and Eye-Movement Related Correlates in Rodent Nucleus Prepositus

Authors: *J. STOTT, M. A. VAN DER MEER;
Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The head direction (HD) system in rodents comprises a set of interconnected brain areas. While we know a great deal about the HD system in the cortex and thalamus, much less is known about its origins in the brainstem. Theories of how the HD system works assume that the core attractor network in the dorsal tegmental nucleus (DTN) and lateral mammilary nucleus (LMN) receives angular head velocity information (AHV) to update the HD signal. One of two major candidates to provide this signal to the DTN is the nucleus prepositus hypoglossi (NPH). However, based on anatomical and recording studies in the primate, NPH is thought of as an oculomotor nucleus. It remains unknown what information is carried by NPH in the rodent, and if it conveys an AHV signal to DTN required by current HD models. To evaluate the role of NPH in signaling AHV and/or eye-movement related signals, we recorded acutely from NPH neurons in male and female mice during passive (sinusoidal) rotation, under head-fixed conditions. In daily sessions, after the probe was lowered into NPH, the platform was manually rotated to generate a range of angular head velocities. Eye movements were recorded during the vestibular-ocular reflex (VOR). At the end of each recording, current was passed to mark the recording site. In our analyses, we asked two general questions. First, is coding of AHV and eye-movement related signals in NPH intermixed at the single cell level, or separate? Second, how does AHV tuning in NPH compare to that found in DTN? Greater than half of NPH cells showed significant modulation of activity just before the time of saccade onset. Also, a large majority of cells showed significant, linear tuning to the speed of the platform (AHV). These populations were largely overlapping. Among, AHV cells, tuning was almost entirely of the asymmetric type; that is, showing a linear increase or decrease in firing rate along the continuum of head velocities. This result stands in stark contrast to at least one previous report of AHV cells in the DTN of freely moving rats (Bassett & Taube, 2001), which showed a predominance of

symmetric (V-shaped) tuning. These findings raise interesting questions for models of the HD attractor. Purely vestibular tuning was rare in NPH; rather, most AHV cells showed some modulation by eye movements. How then, is estimated head orientation accurately updated, if eye movements influence NPH output? Additionally, how do we account for symmetric AHV tuning in DTN when the inputs from NPH are strictly asymmetric? Further experiments are in progress to record from pathway-defined NPH and supragenual nucleus neurons, and to characterize these same cells in freely moving animals with simultaneous eye tracking.

Title: HCN channels stabilize heterogeneous conductance-based continuous attractor networks

Authors: *D. MITTAL, R. NARAYANAN;
Indian Inst. of Sci., Bangalore, India

Abstract: Continuous attractor network (CAN) models lend a powerful theoretical framework that has provided deep insights about grid cells and head-direction cells. Most models employed for understanding CAN dynamics rely on homogeneous rate-based or artificially spiking neurons with repeating motifs of structured synaptic connectivity. However, this formulation precludes detailed analyses of the impact of neural circuit components and associated heterogeneities on CAN dynamics. To address this caveat, we built multiple populations of conductance-based, physiologically constrained, one-dimensional CAN models consisting of distinct excitatory (E) and inhibitory (I) cell layers, endowed with different heterogeneities. CAN models built with homogeneous E & I neurons were tunable and scalable to exhibit “activity bump” movement across the neural lattice, irrespective of the relative excitability of the neurons. Next, we employed independent stochastic search algorithms to generate biophysically heterogeneous and physiologically validated populations of E (n=449) & I (n=930) neurons. We found I-layer, but not E-layer, heterogeneities to impact attractor dynamics. Specifically, none of 1000 randomized networks built with I-layer heterogeneities manifested activity bump propagation, whereas all 100 randomized networks with E-layer heterogeneities exhibited stable propagation. To address

the impact of synaptic heterogeneities on CAN dynamics, we picked distinct homogeneous networks and randomly scaled all synaptic strengths across multiple trials. We found ~65% of these networks to be stable, with no interdependencies or low-dimensional manifolds within the parametric space of stable networks. Finally, motivated by the ability of intrinsic neuronal resonance to stabilize rate-based CAN networks, we asked if modulation of HCN channels altered network stability. Strikingly, the proportion of stable models exhibiting activity propagation increased with increase in HCN-channel density, varying from ~60% to ~85% of the population. As HCN channels also contribute to reduction in excitability, we performed excitability-matched controls with fast HCN channels that do not introduce resonance. Fast HCN channels did not stabilize CAN model dynamics over a wide range of conductance values, suggesting resonance as a critical requirement for stabilization of network dynamics. Together, our conductance-based CAN models demonstrated the critical role of inhibitory neuronal excitability on CAN dynamics, and suggest intrinsic neuronal resonance as an efficacious mechanism to stabilize perturbation introduced by synaptic heterogeneities.

Title: Characterizing the tuning properties of all major projections to a spatially tuned cortical area.

Authors: M. GIANATTI, ***A. GARVERT**, K. VERVAEKE;
Univ. of Oslo, Oslo, Norway

Abstract: Place cells likely contribute to spatial navigation and memory formation. However, while place cells were discovered in area CA1 of the hippocampus several decades ago, it remains unclear how networks generate spatially tuned cells. Many models assume that place cells receive input from similarly tuned cells. However, recordings from presynaptic neurons in the hippocampus have found neurons with a wide range of activity and spatial selectivity. An essential step towards addressing this question is to characterize the tuning properties of all major input pathways. However, in area CA1, this has not been done due to technical challenges. Recently, neurons with very similar spatial tuning properties as in area CA1 were discovered in

the retrosplenial cortex (RSC). Compared to the hippocampus, RSC has the benefit of being located at the brain's surface, which enables characterizing the tuning properties of all major input pathways with two-photon microscopy. To do this, we first determined the main input pathways to RSC using retrograde viral tracing methods. This identified the orbitofrontal cortex (OFC), the secondary motor cortex (M2), anterior cingulate cortex (ACC), posterior parietal cortex (PPC), secondary visual cortex (V2) and various thalamic nuclei as the major projections to RSC. Next, we functionally characterized these input pathways using two-photon microscopy in head-fixed mice that perform a foraging task on a linear track. We selectively expressed GCaMP6s in each of these identified areas and measured calcium signals from their axons in RSC. We quantified the tuning properties and spatial information of axonal signals using generalized linear-nonlinear models and Bayesian decoding. Surprisingly, we found that the tuning properties of all input pathways were similar to the spatial tuning found in RSC. This suggests that RSC is part of a widely distributed network of spatially tuned circuits from which it may inherit its spatial tuning.

Title: Tactile landmark encoding in the mouse retrosplenial cortex

Authors: *A. LANDE, K. VERVAEKE;
Univ. of Oslo, Oslo, Norway

Abstract: To orient ourselves, we use familiar landmarks such as buildings or mountains. However, landmark representations need to be embedded in a cognitive map of our environment to be useful for navigation. While decades of research have revealed how multiple connected brain regions can represent spatial maps, how neural circuits represent landmarks remains less clear. Work in humans and rodents have revealed that the retrosplenial cortex (RSC) is a key area for landmark computation. A recent report also found that RSC represents spatial maps, suggesting that this brain area may link landmarks to spatial maps. However, because sensory stimuli and motor outputs are difficult to quantify during natural behaviours, it remains unclear how RSC represent landmarks and how this interacts with its representation of space. To address these questions, we capitalize on the fact that mice, as nocturnal animals, often rely on tactile

stimuli for navigation. Therefore, we developed a whisker-based, tactile virtual reality system for head-fixed mice running on a treadmill. Rotation of the treadmill engaged the movement of an object across the whiskers in specific locations, with a speed that matched the running speed, thus mimicking the sensation of passing a gap. Head restriction enabled us to use high-speed cameras to detect whisker stimuli with great temporal precision allowing optimal control of sensorimotor variables. Furthermore, this enabled us to use two-photon imaging and genetically encoded Ca^{2+} indicators to densely sample neurons in RSC. We found that a population of excitatory neurons in RSC represent tactile stimuli along the track. Interestingly, when we omitted stimuli on random laps in well-trained mice, a subset of cells maintained their representation of the stimulus, suggesting a mnemonic function of landmark representation. Furthermore, a subset of touch-responsive cells became active before a touch happened, predicting the upcoming contact. These findings strengthen the idea that RSC serves a role in encoding the position of landmarks in familiar environments and can predict the location of known landmarks when they are absent.

Title: The psychedelic ibogaine disrupts cognitive maps and activity correlation structure in mouse retrosplenial cortex

Authors: *V. E. IVAN[1], D. T. CUESTA[1], D. CURIC[2], J. DAVIDSEN[2], A. J. GRUBER[1]; [1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Physics and Astronomy, Univ. of Calgary, Calgary, AB, Canada

Abstract: Psychedelic compounds strongly modulate mental function, but their effects on cellular-level information processing are poorly understood. We tested recent theories of psychedelic effects on neural signaling and dynamics using neural recordings in the retrosplenial cortex (RSC) of behaving mice. The representation of position encoded by ensembles of

individual RSC neurons was destabilized by the non-classic psychedelic ibogaine when mice had to infer position between tactile landmarks. This corresponded with increased neural activity rates, loss of correlation structure, and increased responses to cues. Ibogaine had surprisingly little effect on the size-frequency distribution of network activity events, suggesting that signal propagation within RSC was largely unaffected, and that disruption of correlation & encoding arise from corrupted inputs, such as a predictive coding of events. These data support proposals that psychedelics increase the entropy of neural signaling due to impaired expectation-based constraint of activity. Furthermore, the loss of expected position encoding between landmarks recapitulated effects of hippocampal impairment, suggesting that disruption of cognitive maps or other hippocampal processing may be a contributing mechanism of such discoordinated neocortical activity.

Title: Spatial modulation of primary visual cortex in freely behaving rats

Authors: *B. CARY[1], G. TURRIGIANO[2];
[1]Brandeis Univ. Grad. Neurosci. Program, Waltham, MA; [2]Dept of Biol., Brandeis Univ., Waltham, MA

Abstract: Vision plays a crucial role in helping animals navigate and actively engage with their environment. Recent work from multiple labs has found that neuronal activity in primary visual cortex (V1) is modulated by spatial location, but whether this modulation is primarily driven by spatial cues or more broadly by other salient aspects of an animal's interaction with the environment is unclear. Here we address this by analyzing chronic extracellular recordings from V1 of freely behaving Long Evans rats. In this naturalistic context, we find many neurons in V1 with strong spatial modulation of firing. By following single neurons continuously for many days we are able to evaluate the stability and complexity of this spatial modulation during free behavior. Ongoing work focuses on analyzing the relationship between firing fields and the complex behavioral repertoires exhibited by these freely behaving animals, to investigate how broader aspects of the environment influence V1 representations.

Title: Projections to the lateral mammillary and dorsal tegmental nuclei arise from a small but overlapping population of neurons in the supragenual nucleus.

Authors: *J. A. GRAHAM, M. MCGUIER, M. S. CHANG, A. C. GUNDLACH, J. S. TAUBE;
Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Previous studies have shown that the site of the putative ring attractor for generating and stabilizing the head direction (HD) signal is thought to arise within the connections between two brainstem nuclei - the dorsal tegmental nucleus (DTN) and the lateral mammillary nucleus (LMN). Models differ on exact mechanisms, but all models result in a stable activity packet that represents the current HD. The activity packet is moved around the ring by vestibular inputs to accurately reflect the current HD as an organism moves through space. Models agree that the turning mechanism requires cells that fire in response to only one direction of movement (e.g. clockwise or counterclockwise turns). The supragenual nucleus (SGN) is an attractive candidate for such a mechanism, providing inputs to both DTN and LMN that are strongly lateralized (e.g. SGN output projects to the contralateral DTN and ipsilateral LMN). In addition, lesions of SGN result in the 'bursting' effect noted when lesioning upstream vestibular nuclei that is not present when lesioning LMN or DTN. This finding suggests that the SGN may provide the bulk of vestibular information to the HD system. While the SGN projects to both DTN and LMN, it is not known whether distinct or overlapping populations within SGN project to these areas, which has implications for how the HD signal is generated. To address this issue, we injected two different retrograde labels into the DTN and LMN of Long-Evans rats(n=18) and determined whether cells in SGN were single or double-labelled; double labeling would indicate that the projections to LMN and DTN arise from the same population of SGN cells. Tracer filled both targets in 14/18 animals. Results showed that the SGN à DTN projection is markedly stronger than the SGN to LMN projection, filling most cells within the central body of the SGN while cells projecting to LMN tended to be smaller, sparser and located on the periphery of the nucleus. A portion of cells projecting to LMN were double-labelled indicating that that they also projected to DTN. In contrast, there was a large number of single-labelled cells arising from the projections to DTN. These results suggest that there is a large population of neurons in SGN with

distinct location and morphology characteristics that project only to DTN. A smaller, more peripheral population projects to both DTN and LMN.

Title: Mice need the cortical representation of proprioception in order to establish new visuospatial memories.

Authors: *O. RUTLER, S. PERSAUD, J. M. PARK, R. M. BRUNO, E. R. KANDEL, S. KOSMIDIS, *M. E. GOLDBERG;
Neurosci., Columbia Univ., New York, NY

Abstract: Light enters the brain via the retina, which then transmits a retinotopic map of visual space to higher centers. Because the eyes are constantly moving, an object in a given spatial location can appear at many different retinal locations. Therefore, the position of an object on a retinotopic map does not, by itself, describe the spatial position of the object. Instead, the brain must establish a spatially accurate map by transforming this retinotopic map into a stable map of space independent of eye and head position. Two great neuroscientists proposed different strategies for solving this problem. Helmholtz postulated that the brain uses a corollary discharge arising from the motor commands for eye and head movements to transform the retinotopic map, thereby making the transformed retinal location of an object in the world spatially accurate. This transformation can occur even before the movement. Sherrington postulated that the brain could measure the locations of the eyes in the orbit and the head on the shoulders, and calculate the position of the object in space, a calculation which must occur after the actual movement. Psychophysical evidence in humans (Poletteti et al.) suggests that a corollary discharge mechanism is dominant soon after the brief appearance of a remembered stimulus in the environment, but is later replaced by a proprioceptive mechanism for long-term spatial memory. There is a proprioceptive representation of eye position in Area 3a of monkey somatosensory

cortex (Wang et al.), which is necessary for long term spatial memory (Sun et al.). Here we asked if proprioception were also necessary for establishing a spatially accurate visual memory in the mouse. We trained 24 C57Bl/6 mice to find a marked platform in a Morris water maze. After 2 days of training, we put 4 large visual cues on the walls of the maze but removed the cue from the platform. The mice gradually learned to find the hidden platform as measured by swim path length and latency. We then made sham or aspiration lesions in the dysgranular zone of somatosensory cortex (S1DZ), the mouse equivalent of monkey Area 3a. The sham mice continued to improve their performance, but the lesioned mice did not. We then moved the platform to a different quadrant of the maze. The sham mice learned the new platform location, but not the lesioned mice. Both groups easily found a visibly marked platform in a new location. Air-righting and rotarod tests showed that both groups of mice had normal motor and vestibular function. These results suggest that proprioception is necessary for the establishment of long-term visual memory of a vanished target, but corollary discharge is adequate for on-line navigation to a visual target.

Title: Attentional alpha oscillations identified in rat postrhinal cortex and hippocampus

Authors: *V. ESTELA-PRO[1], S. G. TRETTEL[2], R. D. BURWELL[2];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Alpha rhythms (8-12 Hz) are the most prevalent oscillations in the primate brain, but their functional role remains controversial. Historically, alpha was thought of as a correlate of a “ground state” or “cortical idling” that occurs during the absence of sensory input (Haegens et al., 2011; Pfurtscheller et al., 1996). According to this view, alpha oscillations are a passive mechanism that emerge when the brain is disengaged, whereas during sensorimotor or cognitive challenges they lose amplitude and are replaced by other neural mechanisms. More recently,

however, alpha has been shown to be an active mechanism, becoming stronger when visual inputs are actively ignored, leading to a proposed top-down inhibitory role for alpha rhythms in attention (Klimesch et al., 1998; Worden et al., 2000; Jenson & Mazaheri, 2010; Jones et al., 2010; Sacchet et al., 2015; Sadaghiani & Kleinschmidt, 2016; Kizuk & Mathewson, 2017). Currently, oscillation bands described in the rodent brain include a very broad theta band of 4-12 Hz and do not include a distinct range of frequencies for the alpha band. In humans, theta is generally defined as 4-8 Hz and alpha is defined as 8-12 Hz (Uhlhaas & Singer, 2010). Here, we describe a phenomenon in the rodent brain recorded in the postrhinal cortex and the hippocampus that exhibits characteristics similar to alpha oscillations in the human brain. These oscillatory events are generally 2-5 second episodes of increased power in the 9-12 Hz frequency band, peaking at ~10 Hz. They are markedly different from Type 1 theta in that they occur only when the rat is nearly motionless, whereas Type 1 theta power positively correlates with running speed. They also differ from Type 2 theta, which has a lower frequency of 4-7 Hz. Behaviorally, these 10 Hz events occurred during three parts of a bi-conditional task trial. They were most robust immediately after stimulus onset and after object selection, but they also occurred between trials. The 10 Hz events emerged as rats moved from simple strategies in early trials to complex strategies in later trials. These data suggest the need to update the defined oscillation bands in the rodent brain to include this novel oscillation that is analogous to attentional alpha in the human brain.

Title: Pulvinar manipulation alters posterior parietal cortex activity during performance on a visuospatial attention task

Authors: *F.-C. YANG[1], R. D. BURWELL[1,2];
[1]Dept. of Cognitive, Linguistic, and Psychological Sci., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The posterior parietal cortex (PPC), which is important for visuospatial attention, is connected with the pulvinar (lateral posterior nucleus of thalamus in rats). In primates, the pulvinar differentially projects to two subdivisions of the PPC. One subdivision supports top-

down attention and the other supports bottom-up attention (Cabeza, 2008). We have shown that pulvinar and dorsal PPC activity correlates with multiple phases of a visuospatial attention (VSA) task, including onset of the visual stimuli, decision-making, task-relevant location, and behavioral outcome (Yang, Jacobson, & Burwell, 2017 ; Yang & Burwell, 2020). However, the rodent PPC can also be subdivided into dorsal and ventral subdivisions (dPPC and vPPC), and neuronal correlates in the dPPC and vPPC are consistent with roles in top-down and bottom-up attention, respectively (Yang, Dokovna, & Burwell, under revision). To further understand how the pulvinar modulates PPC activity, we optogenetically manipulated pulvinar activity while simultaneously recording neuronal activity in the pulvinar, dPPC, and vPPC in male Long Evans rats during performance on a visuospatial attention (VSA) task. Our VSA task was adapted from the five-choice serial reaction time task for a double-sided, bowtie shaped enclosure atop the Floor Projection Maze in which stimuli are back-projected to the floor of the maze (Jacobson, Ho, Kent, Yang & Burwell, 2014). In the VSA task, trials alternated from side to side. On each trial, rats were required to attend to three locations. In one of these locations, a target stimulus was randomly and briefly illuminated. An approach to the correct target location was followed by a liquid reward. For analysis, a trial was divided into behavioral epochs including stimulus onset, selection behavior, and reward. Trials were sorted by whether or not the pulvinar as inactivated. We recorded neuronal activity of six rats, and isolated 318 cells in the dPPC, 225 cells in the vPPC, and 474 cells in the pulvinar. Both pulvinar and PPC cells signaled stimulus onset and behavior consistent with the interpretation that the pulvinar and PPC are engaged in multiple aspects of visuospatial attention. Additionally, PPC ensembles were altered by pulvinar inactivation. Details will be presented.

Title: The Neural Correlates of Speech Errors

Authors: *A. MEDVEDEVA[1], K. FORSETH[2], O. WOOLNOUGH[3], P. ROLLO[4], N. TANDON[5];
[1]Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX; [2]UT Hlth. Sci. Ctr. In Houston, Houston, TX; [3]Vivian L Smith Dept. of Neurosurg., Univ. of Texas Hlth. Sci. Ctr. At Houston, Houston, TX; [4]UTHSC at Houston, Houston, TX; [5]Neurolog. Surgery, Univ. of Texas Med. Sch. at Houston, Houston, TX

Abstract: To investigate the neural correlates of error detection and correction, we recorded intracranial EEG during a tongue twisters task that reliable evokes overt speech errors in 17 focal epilepsy patients undergoing intracranial electrode implantation for seizure monitoring. Then we compared activity during errors vs during correct speech while patients read aloud and then recited each tongue twister from memory. As expected, phonological substitution errors were higher for stimuli with phonologically-similar compared to dissimilar onsets but only when the error was likely to form a word (similar word error condition), Bonferroni-corrected $t(16) = 2.04$, $p = .004$. Articulation during errors revealed potential error detection processes in frontal, parietal, and superior temporal regions, FDR-corrected $ps<.01$. The results suggest that a wide network contributes to planning speech and correcting and detecting errors to minimize errors in everyday speech.

Title: Neural fiber "conductivity" elucidates a mechanism of language lateralization

Authors: *K. MATSUO[1], N. YASUI-FURUKORI[2], K. SHIMODA[2], Y. KAJI[3], K. AKIYAMA[4];
[1]The Univ. of Electro-Communications, Tokyo, Japan; [2]Dept. of Psychiatry, [3]Dept. of Radiology, Dokkyo Med. Univ. Sch. of Med., Tochigi, Japan; [4]Dokkyo Med. Univ. Sch. of Med., Mibu, Japan

Abstract: Patients with mental illness often show a reduced left language lateralization. The mechanism may be that the neural “conductivity” would be reduced in the patients and the non-dominant hemisphere would become active to facilitate the real-time language processing. The supposed mechanism entails a rapidity hypothesis; a rapid communication between hemispheres would achieve a lateralization but a delayed one would effect a bilaterality. The corpus callosum (CC) would be responsible for this procedure. By contrast, the direction of the lateralization (usually, leftward) might be defined to the hemisphere with a faster language processing than the other, which would involve language fibers including the arcuate fasciculus (AF). If the rapidity hypothesis is correct, (1) people with a strong lateralization should have a higher “conductivity” in the CC than those with bilaterality, and (2) the stronger the left or right lateralization, the

higher the “conductivity” in the left or right AF, respectively. We investigated these by 73 healthy controls after obtaining the written informed consent. A 3-T MRI (Siemens Prisma) was used to conduct diffusion spectrum imaging [1] and compute the generalized fractional anisotropy (GFA) as the measure of “conductivity” (computed by [2]). AveLI [3-4] was applied as the lateralization index (LI) by task-fMRI with verb generation. Two types of masks were prepared: perisylvian language area (PSL) and area round Brodmann’s area 44 (area44) [5]. A regression analysis was performed using GFA volumes (transformed to the MNI space) with a regressor of either the LI or the absolute LI using SPM12 software. A regression analysis with the absolute LI by the PSL mask depicted a region in the CC around the anterior midbody. Moreover, a left superior temporal region around the AF was indicated by a positive regression using the LI by the PSL mask. The GFA in the CC was higher in people with a left lateralization (LI>0.2 by area44 mask; N=61) and those with a right lateralization (LI<-0.2; N=5) than those with a bilateral LI (N=7), whereas the GFA in the AF was higher in the order of left lateralization, bilateral, and right lateralization (no significance). The results were consistent with the rapidity hypothesis; the speed of neural communication plays a role in the language lateralization, which explains the reduced left lateralization in patients at least partly. Title: Spatiotemporal Dynamics of Visual Naming

Authors: *B. ERVIN[1,2], J. BUROKER[1], A. BYARS[1], L. ROZHKOV[1], J. L. LEACH[1], P. S. HORN[1], C. SCHOLLE[1], F. T. MANGANO[1], H. M. GREINER[1], K. D. HOLLAND[1], R. ARYA[1]; [1]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Objective: Spatiotemporal dynamics of visual naming were investigated in pediatric epilepsy patients undergoing stereo-electroencephalography (SEEG) monitoring.

Methods: Volumetric brain regions were linked to cognitive phases of visual naming by the Parcel-Activation-Resection-Symptom matching (PARS) approach, matching high-gamma (50-150 Hz) stereo-EEG power modulations (HGM) localized to neuroanatomic parcels during visual naming, with changes in neuropsychological metrics after resection or ablation of those parcels. Published clinical electrical stimulation observations were matched where resection data was sparse. Cortical parcels wherein at least half electrode contacts simultaneously showed significant HGM were aligned by temporal onset, to delineate spatiotemporal propagation of naming-related HGM.
Results: In 41 epilepsy patients, parcel-specific visual naming HGM showed sequential onset with extensive temporal overlap. Early activation was shown bilaterally in the occipital lobes, but HGM became increasingly left lateralized until vocalization, with propagation through limbic system. At response time, HGM was found in bilateral superior temporal, and right frontal activation was noted post-vocalization. Correlations between resected/ablated parcels, and post-surgical neuropsychological outcomes showed specific spatiotemporal groupings.
Conclusions: Functional roles of cortical parcels were inferred from changes in neuropsychological scores after resection/ablation and published clinical electrical stimulation observations. Convergence of this data with spatiotemporal propagation of HGM during visual naming supports a cognitive model with six subcomponents of visual naming having overlapping temporal profiles: Visual Decoding, Semantic Association, Lexical Access, Phonemic Representations and Pre-articulation, Vocalization, and Monitoring.
Significance: Cerebral substrates assisting in visual naming are bilaterally distributed. Relative hemispheric contribution varies with sub-task-specific cognitive demands. The PARS approach can be extended to study other cognitive and functional brain networks.

Title: Text arousal mediates developmental language and salience network activity during reading

Authors: *A. N. BURGESS[1,2], K. S. ABOUD[2,3], L. E. CUTTING[2,3];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Vanderbilt Univ., Nashville, TN; [3]Vanderbilt Kennedy Ctr., Nashville, TN

Abstract: Emotional content is a critical yet understudied metric of literacy texts. Compared to emotionally neutral passages, texts with overall high arousal tend to activate affect- and linguistic-related regions. However, less is known about how phrase-by-phrase arousal impacts neuronal processing or how this relationship may be pertinent for children learning to focus on and comprehend passages. We hypothesized that more intense passage phrases would correspond with increased activation in the reading and language network (RLN) and the salience network. To investigate these associations, we examined a cohort of third-grade children (N = 35) while they read two passages during a functional magnetic resonance imaging (fMRI) session. Phrases were presented in grammatical units one at a time, and maximum arousal per phrase was calculated based on word-level ratings from the Warriner et al. (2013) affective norms. Using a psycho-physiological interaction analysis, we modeled how phrase-level arousal impacted the BOLD response during passage reading. Children's behavioral reading comprehension (RC) proficiency was measured using the Gates-MacGinitie Reading Test one year following fMRI data collection. During passage reading, we see expected activation of the RLN and disengagement of the default mode network. Higher arousal phrases were associated with increased activity in a critical RLN region, the left fusiform gyrus, but also decreased activity in affect processing brain regions, such as the anterior cingulate cortex and the ventromedial prefrontal cortex. Additionally, children who had increased activity in the posterior superior temporal sulcus, mediating phonological processing, during high arousal phrases had better RC scores the following year. These findings suggest that as children process more intense text, they upregulate linguistic processing and downregulate affect processing - contrary to adults. This study highlights the importance of emotion processing during text reading in childhood and how arousal may impact passage comprehension and intervention.

Title: Network models evaluating semantic cognition theories show white matter tracts differentially mediate language production processes

Authors: *S. Y. PARCHURE[1,2], J. D. MEDAGLIA[4,3], D. Y. HARVEY[3], H. STOLL[4], A. KELKAR[4], J. P. ZIMMERMAN[3], D. S. BASSETT[2,3], R. H. HAMILTON[3];
[1]Perelman Sch. of Med., [2]Bioengineering, [3]Neurol., Univ. of Pennsylvania, Philadelphia, PA; [4]Drexel Univ., Philadelphia, PA

Abstract: Semantic cognition is critical to language production and comprehension. Patients with semantic impairment due to neural disease have language disabilities that profoundly disrupt daily living. However, the anatomical basis of semantic cognition is as yet poorly understood, with proposed theories implicating left-lateralized regions in the peri-sylvian fissure to a broader network comprising nearly the entire brain. To evaluate the various models of semantic cognition as predictors of language production performance, we used a network neuroscience approach along with behavioral tests. N=31 native English speaking healthy adults (Age= 25.6 +/- 6 yrs, 13 male) participated in the study. All subjects underwent Diffusion Spectrum Imaging (DSI) scans, with adjacency matrices computed from pairwise region to region streamlines among 234 brain regions reconstructed from tractography within each subject. Each participant completed 2 language tasks: Verb generation and Sentence completion. Networks corresponding to each language model were constructed for each subject: 1. Left inferior fronto-occipital fasciculus (IFOF), 2. Inferior longitudinal fasciculus (ILF), 3. Uncinate fasciculus (UF), 4. Peri-sylvian language network, and 5. Connections from language network to rest of brain. The mean of streamline edge weights, a measure of strength of anatomical network connections, was obtained for each modeled network. A stepwise linear mixed effects modeling approach using Ln(response times) as the behavioral outcome measure was used. For Verb generation, the IFOF ($p<0.001$) and ILF ($p=0.015$) significantly predicted responses. UF, Peri-sylvian language network, and edges from language network to rest of brain were not significant ($p>0.05$). For Sentence completion, models of UF ($p=0.0044$) and Peri-sylvian language network ($p<0.001$) were significant. ILF, IFOF, and edges from language network to rest of brain were not significant ($p>0.05$). This research represents a novel use of network neuroscience to evaluate theories of semantic cognition, identifying relationships between semantically demanding language tasks and specific tracts with connections across the brain. The results corroborate prior fMRI studies on the role of IFOF in semantic processing and retrieval, and the relevance of IFOF and ILF but not UF in Verb generation. Further, a double dissociation between networks predicting Verb generation (IFOF and ILF) and Sentence completion (UF and Peri-sylvian language network) was seen. This finding suggests a neurobiological basis of

differential recruitment of language network regions according to the specific semantic processing task.

Title: Intracranial recordings of reference to common objects

Authors: *E. MURPHY[1], K. FORSETH[1], O. WOOLNOUGH[1], P. S. ROLLO[1], Z. ROCCAFORTE[1], N. TANDON[1,2];
[1]Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [2]Mem. Hermann Hosp., Houston, TX

Abstract: We isolated the mapping of sentence representations onto successful versus unsuccessful lexical referents. We used intracranial electrocorticography with high spatio-temporal resolution to address this issue. Patients (n=56) were implanted with either penetrating depth or surface grid electrodes (n=13,298) for the evaluation of medically refractory epilepsy. They were asked to articulate the name of common objects in response to orthographic descriptions (average: 6.5 words, range: 3-12 words), presented in rapid serial visual presentation (500ms per word). The final word in each sentence was either referential to a lexical item, or non-referential ("A person at the circus who makes you [laugh/commute]") (84 trials per condition). We analyzed broadband gamma (70-150Hz) activity at each electrode to index cognitive engagement. We found robust responses in medial parietal cortex, para-hippocampal cortex and lateral prefrontal cortex for the encoding of semantically coherent referential expressions. We identified greater gamma activity at the onset of the final word in referential trials across left inferior frontal regions (150ms post-onset), medial parietal cortex (250ms), para-hippocampal gyrus (400ms) and ventromedial prefrontal cortex (730ms). We also found greater gamma power for non-referential trials in pSTG, marking the violation effect. Medial parietal regions mediate action encoding, which possibly explains these effects since non-referential items often involved impossible/failed actions. These regions are also part of the default network, which shows activity increases during endogenous attentional tasks, with representational search likely being greater for referential relations. We also contrasted non-referential trials that were semantically coherent and contained only weak violations of lexico-semantic or syntactic rules (e.g., "Something you beat with grass") with those containing strong

violations (e.g., “A glass made of Wednesday”). We found increased gamma activity in anterior inferior frontal gyrus, angular gyrus and posterior middle temporal gyrus for semantically coherent non-referential trials. This points to a role for these regions in constructing semantically legal structures. Insights into this referential network will contribute to rehabilitative solutions and neuro-prosthetic designs for individuals with reading deficits, and in particular patients with anomic aphasia and alexia.

Title: Auditory cortex influences subthalamic nucleus activity during reading aloud

Authors: *A. R. WEISS[1], A. KORZENIEWSKA[1], A. CHRABASZCZ[2], A. BUSH[3], J. A. FIEZ[2], N. E. CRONE[1], R. M. RICHARDSON[3];
[1]JHU Cognitive Neurophysiol. and BMI Lab, Dept. of Neurol., JHU Sch. of Med., Baltimore, MD; [2]Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA; [3]Brain Modulation Lab, Dept. of Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: Speech production requires successful information transfer within a basal ganglia-thalamo-cortical loop and can be disrupted in a number of neurological diseases that involve the basal ganglia (BG). Subthalamic nucleus (STN) activity is modulated during speech, and deep brain stimulation (DBS) of the STN can decrease both semantic and phonological fluency in patients with PD. The functional significance of this STN activity, these deficits, and their relation to activity in cortical speech areas are not well understood. Indeed, many prominent models of speech production exclude the STN, possibly due to the difficulty in acquiring empirical data. Here, we sought to better understand the role of STN in speech production by studying its electrophysiological interactions with cortical speech areas, which was possible because of a unique opportunity to directly assess basal ganglia neuronal activity during DBS surgery.
Intracranial local field potentials (LFP) were recorded in four patients while they read aloud words and non-words during the surgical implantation of DBS electrodes for PD. Depth electrodes were implanted in the STN (the locations of which were altered over the course of

surgery), and electrocorticography (ECoG) strips were implanted over primary motor cortex (M1), primary somatosensory cortex (S1), and superior temporal gyrus (STG). To estimate the strength of neural interactions between STN and different cortical areas, we used event-related causality (ERC), a method based on the concept of Granger causality, to study task-related propagation of neural population activity indexed by high gamma (70-150Hz) power in local field potentials and ECoG. We aligned trials to spoken response onset prior to analyzing high gamma event-related activity and ERC.
During reading aloud, we observed sustained and reciprocal neural interactions between ventral sensorimotor cortex and STN. Moreover, we observed a directionally specific influence of posterior STG on STN, prior to speech onset. The strength of this influence was affected by the lexical status of the utterance, with increased propagation during word vs. non-word reading. The difference in network interactions manifested as significantly shorter reading latencies during word trials than during non-word trials.
These results indicate that the basal ganglia receive neural information from auditory cortex, suggesting a potential role for the STN in state feedback control of speech. Models of speech production that include basal ganglia may help explain and mitigate speech deficits from DBS and help develop treatments for speech impairments associated with movement disorders.

Title: The neurocognition of social communication

Authors: *E. VALLES-CAPETILLO[1], M. GIORDANO[2];
[2]Plasticidad cerebral, [1]Inst. De Neurobiología, UNAM Inst. De Neurobiologia, Queretaro, Mexico

Abstract: Social communication is fundamental for successful social interactions, one of the most difficult communication forms is verbal irony[1]. Verbal irony is a statement that transmits the opposite meaning to its literal counterpart[2]. If social cues are nor interpreted correctly, the iirony can be interpreted as literal, white lie[3]; or unrelated. Mentalizing and holistic perceptual

processing have been associated with an adequate comprehension of verbal irony[4]. The brain areas that have been associated with verbal irony comprehension are the dmPFC and rmPFC, IFG, and STG[6], these results are based on 12 studies, many of them in Japanese. The purpose of the present study was to evaluate the cognitive and neural correlates of ironic comprehension in a Spanish speaking sample. Method: We created 14 contexts per condition (i.e. ironic, deceitful, literal and unrelated), and 14 statements. The linguistic proprieties, that allow us to distinguish between conditions, are comprehensibility, relevance, appropriateness, sincerity, and emotional valence. They were evaluated by 120 adults (mean age = 22). Then, 30 adults (15 M, age mean = 22) classified the intention of the statements according to the context. Individual differences in reading speed were controlled by recording the stimuli with one female and a male voice. Forty-eight adults (mean age: 26) participated in the MRI study. All were Spanish native speakers and right-handed. During the first session participants completed 18 tests that evaluated different processes associated with mentalizing, social abilities, executive functions, verbal abilities, and perceptual style; during a second session we acquired the functional brain images using magnetic resonance (MRI). Preprocessing of MRI data was performed with the fmriprep pipeline[7]. The data analysis was performed using FSL 5.0.9[8]. Results: The accuracy on the verbal irony task correlated with verbal abilities (rho = 0.60**), and mentalization (rho = 0.40*). Latency for verbal irony classification correlated with mentalization reaction time (rho = 0.40**), and inhibitory control (rho = -0.40**). During verbal irony, we observed increased BOLD signal bilaterally in the pSTG, in the RH in the orbital MPFC, SFG, frontal pole, and MFG; and in the LH in the aSTG. Conclusions: The contexts and statements had the desired qualities in that they were well understood by the participants. The psychometric tests showed an association between mentalizing and verbal irony detection, and social abilities. The fMRI study showed that irony recruited areas involved in mentalizing and semantic integration of social contexts. p { margin-bottom: 0.1in; line-height: 115% }

Title: A unifying computational account of temporal processing in natural speech across cortex

Authors: *V. VO[1], S. JAIN[2], N. M. BECKAGE[1], H.-Y. CHIEN[4], C. OBINWA[3], A. G. HUTH[2]; [1]Emerging Technologies Research, Intel Labs, Intel Corp., Hillsboro, OR; [2]Neuroscience,

Computer Sci., [3]Electrical Engin., The Univ. of Texas At Austin, Austin, TX; [4]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: To understand natural speech, it has been proposed that human cortex processes temporal information through a hierarchy of representations, from short-timescale regions like auditory cortex (AC) to longer timescales in prefrontal cortex (PFC) and precuneus (PrCu). Existing computational accounts of this phenomenon cannot directly model responses to natural stimuli, and collapse data across subjects and brain regions, limiting their predictive power and resolution. Here we propose an account that predicts responses to ecologically valid stimuli and implicitly captures the hierarchy, while providing all benefits of single-subject, single-voxel predictions. Interpreting the estimated models reveals a diversity in voxel function across cortex, tied to each region's timescale. We first built a multi-timescale recurrent neural network (MT-RNN) trained as a self-supervised language model, where each unit integrates temporal information at a fixed rate. We then extracted stimulus features from each MT-RNN unit to build multi-timescale encoding models (MT-EMs). MT-EMs were trained on fMRI data from 7 subjects listening to 5 hours of narrative English stories using ridge regression. MT-EMs significantly predicted brain responses on held-out data in much of the temporal lobe, PrCu and PFC, and captured known timescale differences across regions. Next we simulated experimental manipulations from prior fMRI studies of temporal context effects [Lerner 2011; Yeshurun 2017; Chien 2020]. These in silico experiments tested timescale properties of both MT-RNN itself and voxels in cortex using MT-EMs. In all tests, MT-RNN units exhibited effects in accordance with their assigned timescale. And despite only learning to predict BOLD responses in a passive listening task, MT-EMs could successfully replicate effects across cortex in nearly every test. While AC was sensitive to word-level manipulations and integrated information quickly, PrCu and PFC integrated information slowly and were sensitive to long-timescale manipulations. Lastly, we probed MT-RNN to infer what linguistic information was encoded in different units. We found that short-timescale units capture token-level information like part-of-speech or entity type, while longer timescales capture discourse-level information like narrative topic. Combined with the implied computational isomorphism between MT-RNN and cortical processing, these results provide new evidence that different timescale regions in the brain may preferentially process different linguistic features. This is the first unified, predictive account of temporal context effects in cortex during speech perception.

Title: Neuronal cascades shape whole-brain functional dynamics at rest

Authors: *G. RABUFFO[1], J. FOUSEK[2], C. BERNARD[3], V. K. JIRSA[4];
[1]Inst. De Neurosciences Des Systèmes - Aix-Marseille, Marseille, France; [2]Inst. de Neurosciences des Systèmes - Aix-Marseille Univ., Marseille, France; [3]INSERM U1106, Marseille, France; [4]Inst. De Neurosciences Des Systemes UMR1106, Marseille, France

Abstract: At rest, mammalian brains display remarkable spatiotemporal complexity, switching between different brain states at an infra-slow timescale (~tens of seconds). While the phenomenology of the resting state dynamics is valuable in distinguishing healthy and pathological brains [1], little is known about its underlying mechanisms. Using full-brain network modeling [2], we show that neuronal cascades spontaneously emerge at an infra-slow timescale when neuronal populations are coupled via a detailed structural connectome. Neuronal cascades occur under conditions of near-criticality and are characterized by epochs of increased deviations from baseline firing rate activity. The ignition and subsequent propagation of cascades depend upon the brain state and connectivity of each region. The largest cascades produce bursts of Blood-Oxygen-Level-Dependent (BOLD) co-fluctuations at pairs of regions across the brain, which explain most of the functional connectivity [3] and shape resting state dynamics. We experimentally confirm these theoretical predictions. We demonstrate the existence and stability of intermittent epochs of functional connectivity comprising BOLD co-activation bursts in mice. We then provide evidence for the leading role of the neuronal cascades in humans with simultaneous EEG/fMRI recordings. These results show that neuronal cascades are a major determinant of spontaneous fluctuations in brain dynamics at rest.

Title: Combined spatial and connective efficiency organizes the topology of mouse brain regions

Authors: *N. R. SMITH[1], A. BORZOU[4], S. N. MILLER[2], J. KASPER[3], S. AMEEN[4], J. M. SCHWARZ[4], J. D. HOMMEL[3];

Abstract: The mammalian brain is a complex set of highly interconnected, yet anatomically and functionally distinct, regions. Together, these brain regions are organized into a functional neural network, but it remains unclear what factors drive this organization. One possible factor driving the spatial orientation of discrete brain regions is the structural connectivity of the network which promotes efficient function, where a network is efficient if regions that are well-connected are placed closer together. The Allen Mouse Brain Connectivity Atlas provides a high-resolution structural connectivity map of mouse brain regions derived from a series of viral tracing experiments. With these data, we explored our hypothesis that regions which are highly interconnected are located proximal to each other resulting in an efficient spatial organization that is related to the network connectivity. To test this hypothesis, we composed a model of the mouse brain by first simplifying complex brain region geometry to spheres while maintaining original structure volume. Then, using accompanying axonal projection strength data from the Atlas, we defined the spatial-connective efficiency for the placement of brain regions in 3D space as the strength of axonal projections between each region divided by the distance between regions. With this parameter defined, we formed a weighted sphere packing problem using Atlas-derived connectivity and brain region volume data. We utilized the CVXPY convex optimization library for Python to model a solution for the maximal spatial-connective efficiency, and therefore the optimal theoretical placement, of the 26 wild-type mouse brain regions which compose the hypothalamus. We validated these results by implementing a Monte Carlo simulation to this weighted sphere packing problem and compared both solutions to the true mouse brain. We found that the mouse hypothalamus' true configuration correlates significantly with the theoretical configuration that optimizes for spatial-connective efficiency via both convex optimization and Monte Carlo simulation. This correlation intensified when we slightly adjusted the hypothalamus' true configuration to account for our non-overlapping, spherical model. These results suggest that the brain's spatial organization is partly driven by the efficiency of the network connectivity, which may have significant impact in understanding the processes governing early brain development.

Title: Network topology determines neuronal phase-of-firing codes

Authors: *M. R. PRATYUSH, C. ASSISI;
Biol., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: Neuronal networks encode information as spatiotemporal patterns of activity. In a spatiotemporal coding scheme, often referred to as a phase-of-firing code, inputs to a group of neurons are encoded by the phase at which they spike with respect to a common oscillation. In earlier studies , the phase code was implemented using a disconnected group of neurons, each unrestrained by the activity of the other, and capable of firing at any phase of the common oscillation. In contrast, in neuronal networks, the topology of the network must necessarily limit the space of possible responses. It is known that several regions of the brain encode sensory information using a phase-of-firing code, with recurrent network connections and a common oscillation. We ask, how does the structure of the network influence this phase code?
To address this question we simulated a neuronal network with balanced excitatory and inhibitory inputs to each neuron. When we stimulated this network with a uniform input, different groups of neurons were transiently synchronized. We show that the topology of the inhibitory sub-network determines the identity of neurons that form transiently synchronized groups. The order in which these transiently synchronous groups fired was stable to perturbations and periodic. Further, we found, for a given network, a profusion of periodic solutions are possible. In fact, using a small network with 81 neurons, nearly 10^9 periodic solutions were possible. Different initial conditions led the network to one of several such possibilities. How does one reliably access one out of these 10^9 possibilities? We show that heterogeneous inputs to subsets of neurons, coupled with an oscillatory drive, can lead the system to a particular stable periodic orbit. The phase at which these groups fired depended on the amplitude of inputs each received. Further, the dynamics of the network could be switched between different periodic orbits using transient heterogeneous perturbations.
Our study highlights general principles governing the dynamics of balanced networks driven by a common oscillation. Several regions of the brain show characteristic global oscillations, such as the hippocampal theta and gamma rhythms, and oscillations in the mammalian and insect olfactory networks. In addition, certain behaviours like sniffing in rodents or antennal flicking in insects induce a periodic time-dependent stimulus, resulting in imposed ‘extrinsic’ oscillations that drive the neuronal networks involved in sensory processing. The general principles elucidated in this study can potentially help in understanding the role of oscillations in the functioning of these systems.

Title: Paradoxical disinhibition of pyramidal neurons following parvalbumin optogenetic activation

Authors: *E. GIRAUD[1], M. LYNN[2], J.-C. BEIQUE[2], J.-P. THIVIERGE[1];
[1]Sch. of Psychology, [2]Cell. and Mol. Med., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The ability of brain regions to regulate information processing depends intimately on how distinct cell types are functionally organized into networks. In the prefrontal cortex (PFC), an elaborate repertoire of activity arises from the interaction of single excitatory (E) and inhibitory (I) neurons through their network connectivity. It remains unclear, however, how each neuronal subtype contributes to the population activity of the surrounding network. To examine the contribution of different neuronal subtypes to cortical dynamics, we employed in vitro recordings of PFC circuits and computational modeling with a diversity of cell types. We recorded and stimulated spiking activity in acute slices of PFC by combining electrophysiological and optogenetic methods on high-density multi-electrode arrays containing 4,096 closely spaced electrodes. To parse out the contribution of distinct cell types, we developed a spike sorting technique to distinguish putative regular-spiking excitatory neurons from fast-spiking inhibitory interneurons. Our sorting algorithm was validated using a targeted combination of viral and optogenetic strategies to activate parvalbumin (PV) interneurons. When probing different subsamples of cortical ensembles, we found that optogenetically activating PV neurons led to a counter-intuitive increase in excitatory pyramidal (PYR) activity and a decrease in overall inhibition. To gain a mechanistic understanding of these findings, we developed a theoretical framework based on linear response theory that encompassed somatostatin (SOM), parvalbumin and pyramidal cell populations. With this framework, we derived analytically the steady-state response of neuronal subtypes under targeted perturbations. We found that global inhibition stemming from PV and SOM neurons decreased when PV neurons were externally driven. This resulted in a disinhibition of pyramidal neurons, thus leading to an increase in their activity. We confirmed these analytical findings in a leaky integrate-and-fire model with PV, SOM, and PYR subtypes connected in a realistic circuit. In this model, pyramidal neuron disinhibition allowed for gain modulation of excitatory activity. Together, these results provide insights on how E and I cells can affect overall network activity through complex connectivity motifs. Moreover, they reveal that a complex mapping between the various cell-type ensembles within cortex underlie network responses, and that such responses could generate counter-intuitive network interactions.

Title: Multi-stable attractor dynamics in cortical layer 1: theory and in vivo voltage imaging experiments

Authors: *Y. QI[1], H. TIAN[1], V. J. PAROT[2], D. J. WONG-CAMPOS[1], X. LI[1], P. PARK[1], S. BEGUM[1], A. PREECHA[1], A. E. COHEN[1];

Abstract: Cortical layer 1 (L1) comprises a sparse population of purely inhibitory interneurons. Recent work has suggested that L1 interneurons integrate sensory and neuromodulatory inputs and exert a dis-inhibitory effect on underlying cortical pyramidal cells by inhibiting deeper-layer interneurons. These results have led to the hypothesis that L1 might play a role in attentional gating of sensory processing. However, the circuit mechanisms by which L1 integrates sensory and modulatory information remain unclear. Many L1 interneurons have axons that extend laterally and synapse reciprocally onto each other, forming a network of lateral mutual inhibition. We used numerical simulations to investigate the spatiotemporal excitability of the L1 network. We used an adaptive exponential integrate-and-fire neuron model, which captured realistic firing properties but was simple enough to enable large-scale network simulations. We positioned the cells at realistic densities and used distance-dependent synaptic strengths calibrated from patch clamp measurements in brain slice. We then simulated the effect of different spatial and temporal patterns of conductance-based stimuli. A simple two-cell network exhibited winner-take-all dynamics under tonic stimulation. This circuit motif appeared functionally equivalent to a flip-flop circuit in digital logic, a resettable short-term memory. In larger networks, gradually increasing strength of tonic network-wide excitation led initially to gradually increasing firing rate, followed by an abrupt transition to a sparse winner-takes all pattern in which a small percentage of the cells fired tonically while the rest were silent. The identities of the winner neurons could be biased by small excitatory inputs timed to match the onset of the global excitatory stimulus. We propose that this circuit mechanism might be an underlying mechanism of attentional fixation triggered by strong arousal. Experiments using all-optical electrophysiology (optogenetics combined with calcium or voltage imaging) are underway to compare these simulation results to circuit dynamics *in vivo*.

Title: Stimulation-mediated reverse engineering of silent neural networks

Authors: *X. REN, I. BOK, S. BHATT, E. MASTERSON, J. PHILLIPS, A. D. VAREBERG, A. HAI;
Univ. of Wisconsin Madison, Madison, WI

Abstract: Reconstructing connectivity of neuronal networks from single cell activity is essential to understanding brain function, but the challenge of deciphering connections from populations of silent neurons has been largely unmet. Most studies rely primarily on active units to derive connectivity, and largely exclude non-firing or minimally active neurons. However, numerous groups present evidence that more than half of the neurons in the brain are “silent”, firing at very low frequencies and having highly specialized receptive fields. In this work we demonstrate a supervised learning method to analyze the use of stimulation for determining connectivity between postsynaptic neurons and heterogenous populations of both silent and active presynaptic neurons in a leaky integrate and fire (LIF) neuron model. We generated spike trains for populations of neurons (size ranging between 200 and 2000 cells) recorded during stimulus response. 66% of the spike trains corresponded to “silent” neurons (firing at 1 spike/min, or 0.017 Hz) and the rest corresponded to responsive neurons (firing at 20 Hz). We show that repetitive stimulation epochs can evoke activity that is sufficient for determining the synaptic weights of the entire neuronal population. For the realistic neuronal population that includes silent neurons, the algorithm fails to predict the weights without stimulation (RMSE = 3.59 ± 0.42 for inferred vs. real synaptic weights, Pearson correlation $r = 0.44$, $p < 0.01$). When the population was sufficiently stimulated, the algorithm was able to derive weights with high accuracy (RMSE is 0.35 ± 0.06, Pearson correlation $r = 0.97$, $p \sim 0$, 15 stimulations, 100 iterations). We use these findings to further characterize the performance of our algorithm for determining weights from excitatory, inhibitory and unconnected neurons within the population, and compare the ability of the method to predict spike trains for increasingly larger population sizes. The testable weight predictions about the number and protocol of the required stimulations

is expected to enhance future efforts for deriving neuronal connectivity and drive new experiments to better understand brain function.

Title: Spiking neural networks show input-dependent sloppiness in synaptic architectures

Authors: *T. JABRI, J. N. MACLEAN;
Dept. of Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: Local circuitry in the mammalian neocortex is characterized by statistical regularities of synaptic connectivity. However, the dynamical consequences of these regularities remain unclear. All complex systems can be defined by 'sloppy' dimensions, meaning that their behavior is unmodified by large changes to specific parameter combinations, and 'stiff' dimensions which are the opposite. In the case of the neocortex, sloppiness in synaptic architectures would be crucial to allow for naturalistic spiking dynamics to be maintained in response to a diversity of input patterns, changes in connections through learning and neuromodulation. Using simulations on spiking neural networks operating in a naturalistic spiking regime, we determine the stiff and sloppy parameters of synaptic architectures and the impact of three classes of input (brief, continuous, and cyclical) on model sloppiness. Large-scale algorithmically-generated connectivity parameter values revealed that specific combinations of excitatory and inhibitory connectivity are stiff and that all other architectural details are sloppy. Moreover, while the extent of viable synaptic architectures capable of producing sustained naturalistic spiking diminished with the brevity of input, the stiff dimensions are comparable across input classes. We also find that experimentally estimated connectivity probabilities are similarly stiff and sloppy when compared to the architectures that we identified algorithmically. This suggests that simple statistical descriptions of spiking dynamics are a sufficient and parsimonious description of network behavior when examining structure-function relationships at the mesoscopic scale. This study provides evidence highlighting the importance of the interrelationship of excitatory and inhibitory connectivity to establishing stable spiking dynamics in the neocortex.

Title: Personalized cortical circuit modelling implicates synaptic dynamics in functional variation across individuals

Authors: *R. COOPER[1], M. DEMIRTAS[5], J. B. BURT[1], A. M. HOWELL[2], J. JI[1], A. ANTICEVIC[3], J. D. MURRAY[4];
[2]Neurosci., [3]Psychiatry, [4]Dept. of Psychiatry, [1]Yale Univ., New Haven, CT; [5]Univ. Pompeu Fabra, Barcelona, Spain

Abstract: Popular for its ability to non-invasively image the macroscopic anatomical and functional connections in the brain, functional magnetic resonance imaging (fMRI) of the human cortex has revealed promising results concerning the reliability and stability of individual-level cortical connectomics. However, the synapse-level mechanisms underlying inter-individual variability are not well-understood, such as the respective roles of long-range white-matter structural connectivity vs. cortical physiological dynamics. One approach to bridging these mechanistic gaps is using biophysically-based neural circuit models of large-scale brain dynamics which can be quantitatively fit to empirical neuroimaging data. In this study we have utilized a circuit model with neurobiologically interpretable parameters to model functional connectivity (FC) at the individual level in healthy subjects, finding that such a model is able to capture differences between subjects.
We selected 879 subjects from the Human Connectome Project, from which we generated parcellated, resting-state FC matrices. We employ a cortical circuit model developed by Demirtas et al. whose free parameters represent synapse-level activity, allowing the macroscopic inter-individual variations apparent in fMRI scans to be understood in terms of the underlying cellular architecture. A key advantage of this model lies in its assumption that local circuit properties are heterogeneous across the cortex, following a large-scale gradient related to cortical hierarchy and indexed by the T1w/T2w structural MRI measure. Using this low-dimensional circuit model, we generate simulated FC matrices which are optimized to maximally fit the respective empirical data for the left hemisphere of the cortex at the level of individual subjects as well as the group average.

Our circuit model, with hierarchical heterogeneity in local circuit properties, is sensitive to subject-level differences in FC. Allowing a hierarchical, heterogeneous distribution of weight parameters across the cortex substantially improves the model's ability to fit empirical FC data by specifically adding to the model the flexibility to capture leading components of inter-individual variation. Further, model parameters related to cortical physiological dynamics explain the majority of variation across subjects, while subject-level structural connectivity failed to significantly capture variation. Thus, our model supports the notion that microcircuit properties related to cortical physiology and dynamics contribute to neural variability across individuals in healthy populations.

Title: Noradrenergic neuromodulation of spatiotemporal dynamics in a large-scale model of mouse cortex

Authors: *Q. GU[1], **D. LI**[1], B. FULCHER[3], V. ZERBI[4], J. D. MURRAY[2];
[2]Dept. of Psychiatry, [1]Yale Univ., New Haven, CT; [3]Univ. of Sydney, Camperdown, Australia; [4]Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland

Abstract: The locus coeruleus (LC) is a small brainstem nucleus whose projections throughout the brain mediate neuromodulation by norepinephrine (NE). It remains poorly understood how this key neuromodulatory system regulates local brain dynamics and reshapes functional network interactions. A recent experimental study (Zerbi et al., 2019, *Neuron*) showed, through fMRI in mice, that chemogenetic activation of LC increases BOLD functional connectivity across cortex. We analyzed the data from that study and further report significantly increased variance and reduced autocorrelation of cortical BOLD signals after LC activation. To investigate the neural microcircuit mechanisms capable of generating these spatiotemporal dynamic changes, we developed a nonlinear biophysical mean-field dynamical circuit model of the mouse cortex. Interestingly, the reduction in BOLD autocorrelation could not be captured with previously-developed linearized models in which neural activity fluctuates about a single fixed point. This motivated us to examine the bistable regime of excitatory-inhibitory local circuits in which activity stochastically transitions between a bursty up and a quiescent down state. Based on

neurophysiology, we implemented LC-NE modulation via increased excitatory neuronal gain, and found that this reproduces all the key experimental observations, when in a down-state-dominating regime. When the neuronal gain increases further, up states dominate, which produces a U/inverted-U-shaped modulation curve, a well-known phenomenon in LC studies linked to cognitive enhancement. At the large-scale network level, gain modulation reshapes the effective dimensionality of cortex-wide neural activity patterns. Finally, we tested gain modulation of stimulus representation and propagation in the large-scale model, by applying a pulse input to somatosensory areas and testing stimulus decoding accuracy using activities of the non-stimulated areas. We found that increasing gain improves distributed stimulus representation, inline with the improvement in perception due to the LC-NE modulation. Together, we propose a circuit mechanism for the functional role of LC-NE system in reshaping local and large-scale cortical dynamics. The model, which links from neuronal effects of neuromodulation to local and large-scale cortical dynamics, also provides a platform to flexibly investigate various dynamical and cognitive phenomena at both local and long-range scales *in silico*.

Abstract: p { margin-bottom: 0.1in; direction: ltr; line-height: 120%; text-align: left; orphans: 2; widows: 2 }a:link { color: #0563c1 } The NEURON simulation software package (neuron.yale.edu) is the leading *in silico* system for building and testing computational models of neurons and neural networks. We combined the previously offline NEURON simulation program with real-time, dynamic clamp system (Cybercyte DC1, Cytocybernetics, NY) allowing comprehensive NEURON cell models to be directly interfaced with living cells during

electrophysiological recording experiments. In Synthetic Cell mode, the action potential (AP) from the NEURON model is used to voltage clamp a cell expressing a cloned ion channel. The experimentally-obtained cloned channel current is scaled appropriately then put into the dynamic clamp NEURON model and summed with the model currents. In this mode, the effects of cloned ion channel currents on NEURON model APs can be studied. We used the Akemann and Knopfel (2006) NEURON model of a Purkinje neuron to voltage clamp HEK cells stably expressing Kv11.1 (hERG). Members of the EAG family of potassium channels (eag, erg, elk) have been shown to modulate neuronal AP firing (Bauer and Schwarz, 2018). Adding the relatively slowly gating hERG current to the Purkinje neuron model decreased the frequency of AP firing and slightly depolarized resting membrane potential. For the Purkinje model, baseline resting membrane potential (RMP) was -60.9±0.4 mV with an AP firing frequency of 10.0±1.6 Hz (n=6). Addition of hERG current (21.0±1.8 pA tail current at +30 mV) reduced AP firing (1.6±1.6 Hz) and slightly hyperpolarized RMP to -62.4±0.3 mV (n=5). Decreasing HERG tail current to 10.7±0.7 pA resulted in an AP firing frequency of 7.4±1.9 Hz and RMP of -61.0±0.6 mV (n=5). Our results show that combining NEURON simulations with real-time dynamic clamp system expands the capabilities of electrophysiology research. Applications include delineating the role of ion channel mutations underlying neurological disorders on neuronal function and in drug discovery to identify drugs targeting expressed ion channels using neuronal activity of the NEURON model as the read-out.

Abstract: At chemical synapses, synaptic vesicles release their acidic contents into the synaptic cleft leading to the expectation that the cleft should acidify during neurotransmission. However, fluorescent pH probes targeted to the cleft of conventional glutamatergic synapses in both fruit flies and mice reveal cleft alkalinization, rather than acidification. To understand why, we created a reaction-diffusion scheme where we modeled pH dynamics at the *Drosophila* neuromuscular junction as glutamate, adenosine triphosphate (ATP) and protons (H^+) are released into the cleft. With bicarbonate and phosphate buffering systems as well as plasma membrane calcium-ATPase (PMCA) activity incorporated into the model, we predict substantial cleft acidification at release sites following neurotransmitter release for fractions of a milliseconds. Thereafter, the cleft rapidly alkalinizes and remains alkaline for over 100 milliseconds, as the PMCA removes H^+ from the cleft in exchange for calcium ions from adjacent pre and postsynaptic compartments. Thus, recapitulating the empirical data. The magnitude and time course of alkalinization is observed to be influenced by the small volume of the cleft. In addition, we observe that phosphate, but not bicarbonate buffering is effective at ameliorating the magnitude and time course of the acidic spike. Yet, both buffering systems are effective at ameliorating cleft alkalinization.

Title: A systematic, data-driven analysis reveals cortical neuron-type morphologies for dense recordings using simulation-based machine learning

Authors: V. HAYNES, *S. CROOK, Y. ZHOU;
Arizona State Univ., Tempe, AZ

Abstract: Advancements in multi-channel recordings of single-unit activity (SUA) *in vivo* present an opportunity to examine how neurons should be grouped based on spatially varying extracellular action potentials (EAPs). Previous methods for grouping units based on EAPs from sparse recordings inherited the limitations of single-channel recordings due to the restriction to

the time domain. This predominantly resulted in binary classifications of putative excitatory and inhibitory types in the literature. However, recent studies using high-density electrodes suggest that some morphological properties of cortical neurons could be inferred from multi-channel recordings. Jia et al. (2019) used novel measures of EAP spatial variations with unsupervised learning to show that propagation velocity of EAPs across channels can differentiate two types of excitatory cells. Buccino et al. (2018) combined computational models of morphologically realistic neurons that simulate EAPs and deep learning techniques to show that dense electrode arrays can be used to differentiate more neuron-types in principle. Here, we improve on these results using a more systematic, data-driven approach that characterizes spatial and multi-timescale dynamic patterns in dense recordings, determines which morphological properties are observable from spatiotemporal EAPs, and develops a useful classification scheme for plausible neuron-types recorded *in vivo*.

We address the problem of grouping neurons based on spatiotemporal EAPs using automated feature engineering and computational modeling to uncover reliable morphological types given fundamental biophysical constraints for recordings of SUA. Our systematic, data-driven pipeline leverages an unsupervised method for extracting patterns spanning channels and timescales while also differentially representing individual units. We simulate a pool of units from diverse cortical neuron-type models at many spatial locations. This allows discovery of multiple unique spatial templates where combinations of these templates are reflected in unit representations that are predictive of variations in dendritic features of the underlying neuron-types. We characterize plausible latent morphologies based on the unit representations across all neuron-types and the spatial templates. Finally, we demonstrate how our approach addresses inference of neuron-types and their gross morphologies by comparing experimental and simulated units in the same latent morphological space.

Title: Quantum mechanics/ molecular mechanics analysis, synthesis and biological evaluation of epalrestat based mutual-prodrugs for diabetic neuropathy

Authors: *S. CHOUDHARY, O. SILAKARI;
Pharmaceut. Sci. & Drug Res., Punjabi Univ., PATIALA, India

Abstract: In the current study, a quantum mechanics/molecular mechanics (QM/MM) based biotransformation study was performed on synthetically feasible mutual-prodrugs of epalrestat which have been identified from an in-house database developed by us. These prodrugs were submitted to quantum polarized ligand docking (QPLD) with the CES1 enzyme followed by MM-GBSA calculation. Electronic aspects of transition state of these prodrugs were also considered to study the catalytic process through density functional theory (DFT). ADMET analysis of these prodrugs was then carried out to assess the drug-likeness. On the basis of in-silico results, the best five prodrugs were synthesized and further evaluated for their neuroprotective potential in high-fat diet-streptozotocin (HFD-STZ) induced diabetes in the rat model. Clinically relevant molecular manifestations of diabetic neuropathy including aldose reductase (ALR2) activity and oxidative stress markers such as reduced glutathione (GSH), catalase (CAT), and thiobarbituric acid reactive substances (TBARS) were determined in blood plasma as well as tissues of the brain and kidneys. The histopathological examination of these organs was also carried out to see the improvement in structural deformities caused due to neuropathy. Finally, in-vivo pharmacokinetic study was performed for the best two prodrugs to assess the improvement in biopharmaceutical attributes of parent drugs. Overall, EP-G-MFA and EP-MFA have significantly reduced the hyperglycemia-induced ALR2 activity, levels of oxidative stress markers, and manifested about a two-fold increase in the biological half-life (T1/2) of parent drugs. The overall findings of this study suggest that methyl ferulate conjugated prodrugs of epalrestat may be considered as potential protective agents in diabetic neuropathy.

Title: Improved spatial registration method for highly multiplexed gigapixel immunohistological image datasets in brain mapping studies

Authors: J. JAHANIPOUR[1], B. ROYSAM[2], A. SEDLOCK[1], *D. MARIC[1];
[1]NINDS/NIH, Bethesda, MD; [2]Electrical & Computer Engin., Univ. of Houston, Houston, TX

Abstract: Mapping brain tissue cytoarchitecture using multiplexed immunohistochemical (MP-IHC) techniques has recently gained increasing interest in the neuroscience imaging field. The major challenge in mining high content MP-IHC information from brain tissue slice preparations is the need to screen myriad of biomarkers of interest using iterative immunostaining and multispectral fluorescence microscopy imaging of same tissue samples processed in multiple sequential rounds to cumulatively acquire highly enriched (>50-plex) biomarker image datasets. The challenge with this type of technique is to spatially register the acquired image channels in each round of staining/imaging to precisely correct for microscope stage alignment, stitching artifacts, and tissue deformations. Transitioning from relatively small megapixel scale image datasets to extremely large gigapixel scale image datasets, such those generated from scans of human brain tissues, poses an extra challenge of image alignment due to the extreme size of the images that can be in the order of multi-gigapixels per channel. Traditional methods, such as feature-based registration, are adequate to estimate a robust affine transformation in small-scale images, but they fail to accurately estimate a robust transformation in large-scale images. To address this challenge on large-scale images, we developed a fully automatic pipeline to align each MP-IHC staining/imaging round to each subsequent round with sub-pixel accuracy using a common reference channel (nuclei or high contrast brightfield) in each imaging round. First, we use phase correlation method in Fourier domain to estimate the global shift between images due to stage alignment imprecision to correct for differences in tissue slide mounting onto the scanning microscope stage prior to each round of imaging. Next, we use an optical flow approach to estimate the pixel-to-pixel movement between images caused by tissue deformation due to tissue processing. The proposed method provides global, parallel, robust, parameter-free registration for large-scale multi-round epifluorescence images irrespective of image size, which is the current limitation of existing traditional image registration methods.

Title: Network simulations with popular programming languages that outperform or match C language

Authors: *C. FIETKIEWICZ, T. MUENZBERG;
Hobart and William Smith Colleges, Geneva, NY

Abstract: MOTIVATION
Many computational neuroscientists write simulation software using common programming

languages. However, performance differences between programming languages are generally not well known.
METHODS
A test model comprised a network of canonical Hodgkin-Huxley neurons (Hodgkin and Huxley 1952) with voltage-gated sodium and potassium conductances and monosynaptic connections. One neuron received an intracellular stimulus in order to generate network activity. Performance was evaluated based on the length of run times for the overall simulation.
Five programming languages were tested: C, Java, Julia, JavaScript, and Python. Python was also evaluated with a performance enhancing compiler known as Numba. C is the de facto performance standard, while the other languages are popular due to various reasons, including ease of use and a large user base.
Each language can be categorized as either compiled or interpreted. Compiled languages included C, Java, Julia, and the Python/Numba combination. Interpreted languages included Javascript and standard Python (without the Numba performance enhancer).
RESULTS
Run times were calculated in two ways: (i) the gross difference between start and stop times, similar to a stopwatch, and (ii) precise measurement of exact CPU usage via profiling software. Java and Julia exhibited the shortest run times. C was at least 15% slower, even with full compiler optimization. This contradicts a common assumption that C is necessarily as fast as any general purpose language. Python with Numba was at least 20% slower, as compared to Java and Julia.
Interpreted languages have poorer performance because instruction interpretations require additional translation at the time of execution. We included them because of their popularity. As expected, the interpreted languages were much slower. Javascript was approximately 200% slower, meaning that the run time for Javascript was 3 times as large as the run time for Java or Julia. However, Python without Numba was practically incomparable with run times on the order of 10,000 times as large as those of Java and Julia.
CONCLUSIONS
The compiled languages performed well, as expected. However, Java and Julia outperformed C. This counters a common assumption that C automatically provides the highest possible performance. Though Python with Numba was the slowest of the compiled languages, desirable features of Python may be an acceptable tradeoff for some. Javascript was expectedly slower, which should be considered in developing web-based simulators. Python without Numba, however, yielded incomparably low performance, and modelers should be aware of this deficiency.

Title: End-to-end neocortical cell type classification from current-clamp electrophysiology recordings using convolutional neural network

Authors: *R. WANG[1], S. HAN[1], M. GAJOWA[2], C. LIU[3];
[1]Dept. of Electrical Engin. and Computer Sci., [2]Dept. of Mol. and Cell Biol., [3]Dept. of Electrical Engin. and Computer Sci. and Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Neuronal type classification problem has been present in neuroscience since Ramón y Cajal's presentation of the neuron doctrine that highlighted the ample diversity of neurons. Today, we classify neurons by genetic makeup, anatomy, and physiology, enabling cell type-specific studies on the role of particular neurons. However, subtle differences in both neuronal type definitions and classification pipelines make comparing and reproducing experimental outcomes based on cell types challenging. Leveraging the ground truth data published in the Allen Institute Cell Types Database, which contains anatomical and morphological descriptions, genetic types, and electrophysiology features of neurons in the mouse neocortex, we constructed a robust and efficient convolutional neural network that successfully classifies neurons according to their genetic label or broad type (excitatory or inhibitory) solely using current-clamp electrophysiology recordings. Previous solution to this cell type classification consisted of dimensionality reduction juxtaposed with clustering using calculated action potential features. This technique resulted in a reported accuracy of 84.13±0.81% for classification among the five primary neuron types: excitatory pyramidal (Pyr), parvalbumin (PV), somatostatin (SST), 5HT3a, and vasoactive intestinal peptide (VIP) cells (Ghaderi et al., Front. Neurosci., 2018). In comparison, our single pipeline method is fast and streamlined while simultaneously achieving competitive test set accuracies with a single current-clamp trace as the input. The 95% confidence intervals for the test set accuracies of the presented deep learning architecture are 96.35±0.30% for correct differentiation between excitatory cells and inhibitory interneurons; and 88.52±0.26% for successful classification among Pyr cells, SST, PV, VIP, and neuron-derived neurotrophic factor (Ndnf) interneurons. After training, this end-to-end convolutional neural network-based classification method does not require any specific knowledge or human intervention for quick identification of the cell type with high accuracy.

Title: Gui-driven clustering of group-level intracranial EEG data in RAVE

Authors: *J. MAGNOTTI[1], X. ZHANG[1], Z. WANG[2], Y. ZHANG[1], M. BEAUCHAMP[1]; [1]Univ. of Pennsylvania, Philadelphia, PA; [2]Rice Univ., Houston, TX

Abstract: Intracranial electroencephalography (iEEG) is a popular technique that encompasses the use of surface and depth electrodes to directly record activity of small population of neurons from the human brain. We have developed RAVE ("R" Analysis and Visualization of iEEG), a freely available, GUI-driven software package purpose-built for iEEG data that takes as input raw iEEG data and outputs publication-ready graphs and analyses of both single- and multi-subject data. Because iEEG electrode placement is guided by clinical utility, a critical step in an iEEG analysis is determining which electrodes relate to the phenomenon under study. To address this problem, we developed a RAVE module implementing single-subject and group-level clustering for iEEG data. Critically, this module follows the RAVE software philosophy: keep the users close to the data; rigorous statistical methods; play well with others. Cluster centroids are visualized as time series and cluster membership shown on the subject's cortical surface or brain volume using the built-in 3dViewer. For group data, the module automatically handles inter-subject alignment using surface-based (for surface electrodes) or volume-based (for depth electrodes) alignment tools. We graphically display not only the primary clustering results, but also cluster diagnostics, centroid plots, and distance plots to provide information to the user about the relevant trade-offs of particular clustering solution. We have initially implemented k-means (or medians) clustering alongside hierarchical clustering (with user-selectable distance and linkage methods). The modular, open-source nature of RAVE allows for easy expansion of our existing solution, allowing for outside contributions and extensions to more sophisticated algorithms. The module allows users to input/output data to/from the module using open data standards—the module is fully functional even if the data were not pre-processed using RAVE, and it outputs data and figures that can be edited in other software. For more details, see: https://openwetware.org/wiki/RAVE

Title: A Novel Graphical User Interface for Large Scale MEA Recordings Provides Insight into the Evolution of Epileptiform Activity and Tracks Seizures over Space and Time

Authors: *R. PARRISH, A. MAHADEVAN;
Xenon Pharmaceuticals, Burnaby, BC, Canada

Abstract: High definition multi-electrode array (MEA) has enabled *in vitro* and *ex vivo* neuronal measurements at high spatial resolution to record local field potentials, action potentials, and

network activity with relative ease. Whilst we have advanced recording systems with over 4000 electrodes, with capabilities to record data at over 20K Hz, it still presents computational challenges to handle, process, extract and view information from these large recordings. It can be quite challenging and frustrating for researchers to extract and view even a single channel that has more than a billion points, let alone process a group of channels. We will present a computational method, and an open source toolkit built on Python, rendered on a web browser using Plotly's Dash for extracting, viewing, and creating interactive visualization. In addition to extracting and viewing small chunks of the high frequency data or entire traces of low frequency (down sampled) data, it provides a framework to collect user input, to analyze channel groups, generate raster plots, view quick summary measures for local field potential activity, detect and isolate noise channels and generate plots and visualization in both time and frequency domain. We also present a seizure detection method using sliding convolution windows, which can be used to detect the onset of seizures in a group of channels, start and end time, rate of seizure speed, and distance of seizure spread across the region of interest. We will demonstrate the utility of this toolkit, using datasets collected from the 3Brain BioCAM duplex system. The recording has 4096 channels, sampled at 20K Hz, over a duration of 1 hour. For the current analysis, we demonstrate the toolkit and methods with a low frequency dataset (0 to 2048 Hz) over a small group (100 to 300) of channels. Using this toolkit, we will present data demonstrating a novel finding relevant to the transition from tonic-clonic seizures to status epilepticus from slices bathed in low Mg^{2+} artificial cerebrospinal fluid. Furthermore, we will present data demonstrating how tracking rates of seizures and the speed of seizure spread can help one gain mechanistic insight into the epileptic phenotype. In summary, with advances in HD MEA recording systems with high spatial and time resolution, limited tools are available for researchers to process these big data sets. We will demonstrate a user-friendly toolkit to analyze HD MEA data and demonstrate the utility of this new graphic user interface with novel biological findings.

Title: Vesselvio: a novel and open-source application for vasculature dataset analysis and visualization

Authors: *J. R. BUMGARNER, R. J. NELSON;
Neurosci., West Virginia Univ., Morgantown, WV

Abstract: Vascular networks are essential for the delivery and clearance of nutrients, waste, and trafficking immune cells to and from tissue. These networks are highly organized, and their structure often can indicate and dictate states of health and disease. Quantitative analysis of these networks can improve the characterization of disease states and may inform future therapeutic strategies. Numerous advancements in imaging technologies and open-source segmentation software have led to the generation of large-scale and high resolution cerebrovasculature datasets. However, these advances have not been met with open-source and easily accessed analysis software packages. We have developed VesselVio, an open-source application for the analysis and visualization of vasculature datasets. Novel branch point filtering and radius analysis techniques are implemented and tested against ground truth datasets. The utility and compatibility of VesselVio is demonstrated via the analysis of female and male mouse 3D inferior colliculus segmentations and 2D human retinal fundus images.

Title: Sparc connectivity knowledge base: discovering autonomic knowledge

Authors: *T. GILLESPIE[1], M. SURLES-ZEIGLER[1], J. MENKE[2], D. P. NICKERSON[3], B. OZYURT[1], B. DE BONO[3], M. E. MARTONE[1];
[1]Neurosciences, [2]Ctr. for Res. in Biol. Systems, UCSD, La Jolla, CA; [3]Auckland Bioengineering Inst., The Univ. of Auckland, Auckland, New Zealand

Abstract: The Stimulating Peripheral Activity to Relieve Conditions (SPARC) program is a NIH-funded consortium whose overarching goal is to improve the understanding of how the

autonomic nervous system (ANS) interacts with end organs and the central nervous system. A major objective of SPARC is to use this knowledge to develop the next generation of neuromodulator devices as effective therapies for diseases of the nervous system. To assist in that effort, the SPARC Data and Resource Center (DRC) is fielding an infrastructure for sharing data and tools for mapping the ANS. A centerpiece of this infrastructure is the SPARC Connectivity Knowledge base (SCKB) and associated visual map of ANS circuitry. The SCKB contains knowledge about CNS-ANS-end organ circuitry derived from SPARC data and scientific literature, in a form that supports reasoning. All connections are annotated with the SPARC vocabularies to ensure anatomical structures are used consistently. The SCKB currently contains two levels of semantic connectivity knowledge: circuit and individual connections. A circuit represents a detailed model of ANS connectivity associated with a particular organ, e.g., bladder or functional circuits, e.g., defensive breathing. These circuits are created through interviews with SPARC investigators, anatomical experts and the scientific literature. They contain detailed representations of neuron populations giving rise to ANS connections, including mappings of the locations of cell bodies, dendrites, axon segments and synaptic endings involved in a particular circuit. Circuits are modeled using ApiNATOMY, a knowledge model and tool suite specifically created to represent biological connectivity. These detailed circuits are supplemented with more general knowledge on connectivity between CNS nuclei, ANS ganglia, nerves, and end organs derived from the scientific literature. To facilitate extracting this knowledge from the literature and maintaining relevance over time, we developed a Natural Language Processing (NLP) pipeline, which extracts connectivity relationships between unique anatomical structures within a sentence from the scientific literature. The SCKB is being used to create a queryable visual atlas of ANS circuitry through the SPARC portal using a familiar street-map interface. Connectivity knowledge obtained from the SCKB is routed via hand-drawn anatomical features to provide highly flexible and explorable “flatmaps” linked to relevant SPARC data and knowledge. The SCKB provides a central location to populate, discover, and query ANS connectivity knowledge over multiple scales for SPARC and the neuroscience community at large.

Title: An Automated Respiratory Data Pipeline for Waveform Characteristic Analysis

Authors: *S. LUSK[1], C. S. WARD[1], A. CHANG[3], A. TWITCHELL-HEYNE[1], G. ALLEN[3], R. RAY[2];
[2]Deparment of Neurosci., [1]Baylor Col. of Med., Houston, TX; [3]Rice Univ., Houston, TX

Abstract: Whole body barometric flow through plethysmography is used to study respiratory output in mouse and rat genetic and disease models. Turn-key commercial and custom systems are both used to gather multiple data streams including respiratory-pressure waveforms, O_2 and CO_2 measurements, and other data points for a reasonable estimation of tidal volume and key metabolic parameters. These experiments typically produce large amounts of data for analysis that are time consuming and difficult to organize. For analysis, the investigator may use cumbersome hand annotation subject to observer bias or several software products may be combined to manage raw data, statistical analysis, and graphing. Commercial software is prohibitively expensive or bundled with turn-key systems that limits options for those using bespoke respiratory measurement systems. To address these deficiencies, we developed a software pipeline for processing raw respiratory recordings and associated meta-data (experimental design, age, weight, temperature, etc.) into operative respiratory outcomes, publication-worthy graphs, and robust statistical analyses. This pipeline consists of three modules. The first module is a Python based graphical user interface (GUI) for uploading all relevant data files and allows the user to define and label both independent and dependent variables relevant to the experimental design, statistical analysis, and graphical outputs. In the second module (Breathcaller) the data are processed with a Python program to segment the respiratory waveform based on user defined thresholds for movement artifacts and unique features. Breathcaller quantifies respiratory cycle components and demarks unique features including sighs, apneas, expiratory reflexes, and user defined entities. The module also allows for browsing the raw signals with markup of annotated breaths to facilitate validation of breath detection, and to permit manual annotations of features if desired. The third module (SG-Runner) is an R-based program that accepts the Breathcaller output along with configuration files from the GUI to graph the desired variables while performing a linear mixed effects statistical model analysis of the data with appropriate post-hoc tests. Following graph generation, statistically significant differences in respiratory variables are automatically highlighted in the graphs. The open-source program offers a facile and highly customizable platform for automated handling and analysis of animal respiratory and metabolic data that sets the stage for high-throughput studies and machine learning approaches on large data sets.

Title: The ΔF/F's are too small! A computational method for removing light contamination in two-photon calcium imaging

Authors: *B. LAU[1], G. ZIPURSKY[3], J. GAUTHIER[2];
[2]Biol., [1]Swarthmore Col., Swarthmore, PA; [3]New York Univ., New York, NY

Abstract: Two-photon (2P) imaging of calcium indicators has enabled major advances in systems neuroscience. Many applications of this technique rely on accurate estimates of ΔF/F, the change in fluorescence ascribed to each neuron. One potential source of error in ΔF/F measurements is from contamination by background light, which increases the denominator (resting fluorescence) without affecting the numerator (deviations from rest). To test whether current cell finding techniques are susceptible to background light contamination, we applied them to a simulation where ground truth was known (Song et al. 2021, J Neurosci Methods). Surprisingly, two popular methods greatly underestimated the true ΔF/F (CaImAn, median 0.02 of true ΔF/F; Suite2P, median 0.27). Moreover, the degree of underestimation varied widely across cells (CaImAn quartile range 0.0082-0.031; Suite2P 0.21-0.32). Underestimation could introduce unexpected errors into spike inference algorithms or analyses that try to explain variance. Inconsistent errors across cells might also obscure activity patterns, such as functional cell classes that could otherwise be identified by the amplitude of their transients.
To obtain more accurate measurements of ΔF/F, we developed a technique to remove background contamination using a post-hoc computational analysis. We constructed an estimator of cell brightness at rest (ΔF/F denominator) using a simple model of 2P fluorescence. When applied to simulated data, our method estimated ΔF/F nearly perfectly on average (median 1.10) and with a tighter distribution of ratios (quartile range 0.90-1.12). When applied to real data, where ground truth is not available, our method found much higher values of ΔF/F than popular methods (median ratio 7.9, quartile range 6.9-8.9), consistent with improved background compensation.
More accurate and consistent estimates of ΔF/F could improve spike inference and other analyses that rely on absolute ΔF/F values. This might allow for detection of new subclasses of neurons, or improve identification of special kinds of calcium events, such as complex spikes in Purkinje cells or CA1 pyramidal cells. More generally, correcting published ΔF/F values has the potential to alter scientific conclusions.

Title: Core principles for the implementation of the Neurodata Without Borders data standard

Authors: *M. L. REIMER[1], L. BANGALORE[2], A. M. TAN[3], S. G. WAXMAN[4];
[1]Neurol., Dept. of Neurol. and Ctr. for Neurosci. and Regeneration Research, Yale Univ. Sch. of Medicine, New Haven, CT 06510, USA; Rehabil. Res. Center, Veterans Affairs Connecticut Healthcare Syst., West Haven, CT; [2]Dept. of Neurol. and Ctr. for Neurosci. and Regeneration Research, Yale Univ. Sch. of Med., West Haven, CT; [3]Neurol., Yale University/VA Connecticut Healthcare Syst., West Haven, CT; [4]Neurol., Yale University, Neurosci. and Regeneration Res. Ctr., West Haven, CT

Abstract: The Neurodata Without Borders data standard (NWB) unifies diverse modalities of neurophysiology data. It defines how to structure and store data and is streamlined for research settings. Integrating NWB with a database unleashes its full potential to promote collaboration, standardize analyses, capitalize on historical data, and ensure data integrity.
To demonstrate the benefits of this computational innovation--which allows the incorporation of big data analytical principles into a standard laboratory setting--we implemented the NWB standard to streamline database operations with DataJoint in Jupyter notebooks, a user-friendly open document format. Specifically, we illustrated this process by converting open-field animal behavioral data into the NWB data standard. This permitted rapid application of data query filtering techniques within the DataJoint pipeline and Jupyter notebooks. Taken together, our previous report provided ample evidence that support the powerful utility of applying data standardization and warehousing principles to laboratory behavioral data.
Here, we present an extension of this prior work demonstrating the advantages of implementing the NWB and DataJoint pipeline within microscopic imaging protocols, e.g., z-stack 3D optical images collected from histological tissue samples. Additionally, we highlight the next generation of Jupyter notebooks, “Jupyter Labs”. As invaluable pedagogical tools, we will continue to use simple programming examples in this presentation.
Databases leveraging the NWB data structure are the foundation of analytical systems used by academic leaders including the Allen Institute and the International Brain Laboratory. The joint use of NWB with DataJoint transforms traditional laboratory datasets and workflows. Our Jupyter examples will showcase the analytical and collaborative advantages of adopting these technologies. Finally, this workflow can be tailored to other modalities by researchers interested in evaluating and implementing an NWB-based data storage and analysis pipeline.

Title: Coldcuts: an open source r package to draw brain segmentations

Authors: *G. A. D'AGOSTINO, S. R. LANGLEY;
Lee Kong Chiang Sch. of Medicine, Nanyang Technological Univ., Singapore, Singapore

Abstract: The generation of large datasets from the brain, such as imaging or transcriptomics, requires the use of analytical pipelines which run entirely on open source programming languages such as R and its environments. However, there are few options to relate the results of these pipelines back to the original structural context of the brain without going through third party software, and these options are often limited in scope. Moreover, copyright-free precise representations of brain structures are useful for didactic purposes and can be hard to find. We present coldcuts, an R software package to quickly render a previously generated brain segmentation as ordered sets of polygons that can be easily plotted in 2 dimensions using any plotting library. coldcuts accepts a variety of compressed inputs such as NIfTI, NRRD or RAW binary formats, slices the voxel array along the 3 anatomical planes and automatically draws polygons for every slice with high precision. Structure search and maximum projections are supported, as well as the integration with any dataset for which a structural correspondence can be drawn easily, such as large scale brain transcriptomic studies. As an example we present complete drawings for several human, ape, mouse and Drosophila melanogaster brain segmentations, together with functions to plot transcriptomic datasets such as GTEx and Brainspan. Additionally, 3D representations of every segmentations are supported, both in an interactive and static format.

Title: Eeg and deep learning - which features to feature? using a gated recurrent network to predict future feature performance

Authors: *J. SLATER[1], J. HOFER[2], B. VIERCK[2];
[1]Stratus, Irving, TX; [2]Positronic AI, Chesterfield, MO

Abstract: Deep learning models for EEG frequently utilize features generated from the data instead of, or in addition to, the raw data itself. Which features to use and how many can be a major stumbling block in model design. To solve this problem, we used a Gated Recurrent Unit (GRU) model run for a small number of epochs to screen features for subsequent inclusion in a multi-feature model - either a Long Short-Term Memory Unit (LSTM) or Convolutional Neural Network (CNN) model. Both models are designed to solve the short-term memory issues of standard recurrent neural networks (RNNs) when evaluating lengthy times series. The "gates" within these models can learn which data in a numeric sequence is important to keep or throw away. The key difference between a GRU and LSTM is that a GRU contains 2 gates (*reset* and *update*) while an LSTM contains three (*input*, *output* and *forget*). A GRU model is less complex and computationally faster than an equivalent LSTM. GRUs perform well with smaller data sets but are usually outperformed by LSTMs especially if there are critical relationships in the time series related to long sequences with long-distance relationships. Two publicly available EEG datasets were utilized - the first containing subjects with mild traumatic brain injury (mTBI) and controls, and a second including subjects diagnosed with Parkinson's disease and controls. For each dataset, multiple features were generated from the EEG data, including a power spectral decomposition (PSD), Lyapunov exponent (LYA), Higuchi Fractal Dimension, and Lempel Ziv Complexity for each electrode, as well as interhemispheric coherence (IC) between matching electrode pairs. A GRU model was constructed for each feature, run for a limited number of epochs, then the average classification accuracy was calculated as a measure of model performance. The generated features were then used, singly and in combination as inputs to each of two different model types - CNN and LSTM. 75% of the files were used for training with 25% withheld for model validation. The primary outcome measure was the maximum validation accuracy achieved. PSD + IC using a CNN model achieved an 82.6% accuracy for the Parkinson's feature set, and PSD + IC + LYA using a LSTM model achieved a 75.4% accuracy for the mTBI data set. Features with the highest average accuracy scores from the GRU model consistently added to the performance of the subsequent multi-feature model - both CNN and LSTM. Some of features with lower average GRU accuracy scores were still later determined to add value to the multi-feature models. This study validates the use of a GRU model as an initial screening tool for feature selection.

Title: Nwb widgets, a python library for interactive visualizations of nwb data

Authors: *B. DICHTER[1], L. TAUFFER[1], C. BAKER[1], S. SHARDA[1], M. MCCORMICK[2], O. RUEBEL[3];
[1]CatalystNeuro, Benicia, CA; [2]Kitware Inc, Clifton Park, NY; [3]Computat. Res. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: Neurodata Without Borders (NWB) is emerging as a field standard for exchanging cellular neurophysiology data, providing a structure to share their data in a way that maximizes reusability. In order to facilitate exploration of published NWB data, we have developed an interactive data visualization library, NWB Widgets, to provide informative, efficient, and intuitive visualizations of NWB datasets. NWB Widgets parses the NWB file to provide automatic visualizations of any type of data. Data objects in NWB files are assigned “neurodata types” that indicate what type of data they are (e.g. voltage trace, spike times, body position tracking etc.). NWB Widgets defines a library of visualizations, and maps these visualizations to corresponding neurodata types. This allows it to provide a set of common visualizations for each neurodata instance (e.g. voltage traces are shown as traces over time, spike times are shown as a raster plot, and body position is shown as X vs Y). If no visualizations are available for a particular neurodata type, NWB Widgets searches back through the inheritance tree and uses visualizations from the first parent type with visualizations defined. This approach allows us to efficiently cover the entire space of neurodata types, as well as automatically cover any types in neurodata extensions that subclass core types. NWB Widgets can also be easily extended to create a custom visualization for an existing or new neurodata type. NWB Widgets uses ipywidgets for interactivity. These components let you navigate through the data by setting parameters like time windows, channels selections, and unit selections. The plots are then

rendered using Plotly or matplotlib. The data visualizations are organized in an accordion structure and rendered on-the-fly, only when (or if) they come into view. This allows us to define many visualizations without increasing the code runtime. When a visualization is rendered, it only reads the data in the window of interest from the NWB file. This allows us to visualize data from very large files (as long as the view window is not very large). Our goal is for NWB Widgets to facilitate data exploration and reuse across a variety of platforms. Using the "ros3" HDF5 driver, NWB Widgets can stream data directly from any public s3 bucket, such as those in the DANDI Archive. This is particularly fast if run in DANDI Hub, a free jupyter hub that is configured to work well with the DANDI Archive. The code is open source, and other projects may import and use its components. NWB Explorer imports NWB Widgets, and utilizes the defined visualizations to enable data exploration on their platform.

Title: Breasi-crispr: an efficient genome editing method to interrogate protein localization and protein-protein interactions in the embryonic mouse cortex

Authors: N. K. TIWARI[1], B. L. MEYERINK[1,3], P. KC[1], C. M. KITTOCK[1,3], A. KLEIN[3], C. EVANS[2], **L.-J. PILAZ**[1,4];

Abstract: Since the introduction of CRISPR/Cas 9-based genome editing, many advancements have been made to improve the technology's efficiency and specificity and broaden its applications. One such method is "Efficient additions with ssDNA inserts-CRISPR" or Easi-CRISPR. This technique is highly efficacious at generating knock-in or point-mutant mouse models using ssDNA as a template for homology directed repair (HDR). Here, we combine Easi-CRISPR with in utero electroporation in embryonic mouse brains. Together, this method is called Breasi-CRISPR (Brain Easi-CRISPR). Breasi-CRISPR enables knock-in of both short and long epitope tag sequences in genes of interest with high efficiency. It allows for tagging of endogenous proteins in a vast number of embryonic brain cells. Using Breasi-CRISPR, we were

able to detect epitope tagged proteins with both low and high expression levels, such as: ACTIN LMNB1, EMERIN, FMRP, NOTCH1, FXR1, ZBTB7A and RPL22 by immunohistochemistry as soon as one day after electroporation at embryonic day 13 (E13). Co-electroporating CRISPR reagents with an EGFP reporter at this timepoint, we observed efficient gene editing in up to 50% of the EGFP+ cells two and five days after electroporation, and in more than 30% of all the cells located in the electroporated region. This high efficiency gene editing enabled the visualization of tagged proteins by Western Blotting in lysates from individual cortices 2 days after electroporation. With pooled brain lysates from individual litters, we had success performing co-immunoprecipitation (co-IP) experiments with endogenously tagged proteins to test for protein-protein interactions. Moreover, we performed co-IP mass-spectrometry analyses of the Breasi-CRISPR tagged autism-related protein FMRP to discover its interactome in the embryonic cortex. This analysis uncovered interactions between FMRP, ribosomes, and the spliceosome as well as proteins involved with complement activation, histones and intermediate filaments. Finally we demonstrate that Breasi-CRISPR enabled the tagging of endogenous proteins with EGFP in 20% of all the electroporated cells expressing a tdTomato reporter, allowing live-imaging of endogenous proteins in organotypic brain slices as soon as 2 days after electroporation. Together, these data show Breasi-CRISPR is a powerful tool with many applications that will help elucidate the role of pertinent proteins at early timepoints in neurodevelopment.

Title: Exon junction complex factor, Rbm8a, is requiredfor cortical interneuron development

Authors: *Y. MAO[1], C. MCSWEENEY[2], F. DONG[2], M. CHEN[3], N. CROWLEY[2], J. MOTT[2]; [2]Biol., [1]Penn State Univ., University Park, PA; [3]Penn State Univ., STATE COLLEGE, PA

Abstract: The formation of the nervous system requires a balance between proliferation, differentiation and migration of neural progenitors. Mutations in genes regulating development impede neurogenesis and lead to neuropsychiatric diseases, such as autism spectrum disorders (ASDs) and schizophrenia (SZ). Recently, mutations in nonsense mediated mRNA decay (NMD)

genes have been associated with ASDs, intellectual disability (ID), and SZ. Here, we seek to examine the role of exon junction complex (EJC) gene, *Rbm8a*, in the development of the nervous system. We selectively knocked out RBM8a in neural stem cells, and the resulting mice exhibited microcephaly, early postnatal lethality, and altered distribution of excitatory neurons in the neocortex. Moreover, *Rbm8a* haploinsufficiency in the central nervous system results in a decrease in cell proliferation in the ganglionic eminences (GE). A significant decrease in parvalbumin (PV)+ and neuropeptide Y (NPY)+ interneurons in the cortex, and abnormal distribution of interneurons are observed. Consistently, neurons in the cortex of knockout (KO) mice show a significant decrease in GABA frequency. To further examine the role of Rbm8a in interneuron differentiation, conditional KO (cKO) of *Rbm8a* in Nkx2.1 interneuron progenitor cells affects Nkx2.1 progenitor proliferation and alters interneuron distributions. Taken together, these data indicate the critical role of Rbm8a in interneuron development, and establish that perturbation of this gene leads to profound developmental deficits.

Title: Identification of human astrocyte progenitors and their association to glioblastoma subtypes

Authors: *S. VAN GULDEN, C.-Y. PENG, A. K. LINDEN, J. A. KESSLER; Northwestern Univ., Chicago, IL

Abstract: Understanding human astrocyte lineage cells and their involvement in brain malignancies has been limited due to inaccessibility of human brain tissue. Here we present an approach for generating astrocyte progenitors and astrocytes using human pluripotent stem cells (hPSCs), as a model for studying the developmental diversity of astrocytes and how it correlates with glioblastoma (GBM) subtypes. Using a combination of biochemical, molecular, and single cell transcriptomic techniques, we characterized the hPSCs-derived astrocytes at two developmental time points and demonstrated that cells generated follow normal developmental progression along the astroglial lineage. Due to the heterogeneous nature of our culture at the astrocyte precursor stage, we used a combination of surface markers to isolate and characterize four different progenitor populations that arise during astrocyte differentiation. Transcriptional

analysis revealed a correlation between gene expression profiles in hPSC-derived astrocyte progenitor populations with proneural and mesenchymal GBM subtypes. Additional characterization of these progenitor populations revealed genes associated with Notch signaling and TGF-β signaling pathways. These findings suggest that hPSC-derived astrocyte progenitors and astrocytes share developmental mechanisms replicated by the cell types found in GBM tumors. Therefore, understanding how the generation of glioma subtypes is linked to the developmental processes that regulate neural and glial diversification has important implications for the understanding and treatment of this disease.

Title: Lineage Commitment Of Daughter Cells Generated From Single Pallial NG2- and GFAP-expressing Progenitors

Authors: *A. OJALVO-SANZ, R. SÁNCHEZ-GONZÁLEZ, L. LÓPEZ-MASCARAQUE; Cajal Inst., Madrid, Spain

Abstract: Neural Progenitor Cells (NPCs) are generated from a pool of neuroepithelial cells that begin to transition into Radial Glial Cells (RGC). These cells, in partially overlapped waves, first producing several self-amplifying symmetric divisions and then RGCs divide asymmetrically generating either neurons, astrocytes, NG2-glia or oligodendrocytes. Few embryonic cortical progenitors appear to be lineage-multipotent, suggesting the existence of progenitors committed to one specific lineage. Other studies reveal a different spatio-temporal pattern related to the progenitor cell potential, reinforcing the idea that **NPCs constitute a heterogeneous population**. In addition, the NG2-glia is another remarkable cell type that serves as a progenitor. Then, it is known how NPCs produce the diverse cell progeny, although many unknowns about lineage relationships and progenitor heterogeneity remain unravelled. To address this, we looked at the derived-cell progeny of single GFAP- or NG2-expressing progenitors targeted with stable

and heritable labelling. To target single NG2- or GFAP-progenitors within the pallial SVZ we used either **UbC-(NG2-PB)-StarTrack** or **UbC-(GFAP-PB)-StarTrack**, respectively. After *in utero* electroporation of those StarTrack strategies, at different mouse embryonic stages (E12, E14, E16) and neonatal (P0), we performed a clonal analysis of their derived-cell progeny at P30. Our findings provide fundamental aspects of the fate and lineage cell potential of GFAP- or NG2-expressing progenitors during development.

Title: Sibling Cell Relationships of Single Subpallial Progenitor Cells Using the UbCStarTrack

Authors: *R. SÁNCHEZ-GONZÁLEZ, A. OJALVO-SANZ, S. BARRIOLA, L. LÓPEZ-MASCARAQUE;
cajal insitutute, madrid, Spain

Abstract: Over the last decades a growing number of evidences pointed out on the heterogeneity of neural progenitor cells (NPCs). Neural development requires a perfect balance between proliferation and differentiation of NPCs to give rise a functional adult nervous system. In our research, we are focused on the heterogeneity of NPCs, to unravel the diversity of the different neural lineages. NPCs give rise to distinct neural cell types at different embryonic and adult stages increasing the cell diversity in the brain. Using a multi-color genetic lineage tracing system, UbC-StarTrack, we targeted specific progenitor cells to analyze the cell type and location of their adult cell-derived progeny as well as their lineage relationships. To this end, we designed different StarTrack strategies to permanently label the individual progenitor cells and their progeny accordingly with the identity of the NPCs (Sánchez-Gonzalez et al 2020a). At this regard, we performed a new PiggyBac transposase under the expression of Gsh-2 promoter (called UbC-(Gsh-2-hyPB)-StarTrack) to specifically target progenitor cells located in the ventral areas of the ventricular surface of early mouse embryo. The derived-cell progeny of those subpallial progenitors produce different neural types (astrocytes, oligondrocytes, NG2 and even neurons), displaying diverse clonal patterns in relation to both their ontogenic origin and cell identity.Our findings provide fundamental aspects of the progenitor potential, cell fate and the clonal relationships of their derived-cell progeny that might help to gain new insights into their behavior, complexity and functionality.

Title: Response to codon biased transcripts changes in a defined neural lineage.

Authors: *R. STEWART, S. ALLEN, D. FOX;
Duke Univ., Durham, NC

Abstract: Codon bias occurs when certain codons appear more frequently than their synonymous counterparts. This phenomenon occurs throughout all forms of life and has been shown to be important in determining protein expression at the steps of both transcription and translation. Although the impact of codon bias has not been thoroughly studied during animal development and in different tissues, we are beginning to understand how cellular response to codon biased transcripts intersects with cell identity and proliferative state. We have undertaken one of the first studies of cell and tissue-specific differences in codon bias in the model organism *Drosophila* and have uncovered some of the first evidence that tissues in the same animal respond differently to codon usage. Specifically, in cell types within the developing *Drosophila* brain, we find robust protein expression from reporters enriched in rarely used codons, whereas most other tissues in the fly do not express such reporters. Within the brain itself, neural stem cells are unable to express proteins encoded by rare-codon enriched genes, while differentiated neurons can. Cell identity appears tied to ability to express transcripts enriched in rare codons, as experimentally blocking neuronal differentiation drastically reduces expression of a rare-codon enriched reporter. To uncover molecular regulators that enable neurons to specifically express rare-codon enriched reporters, we have initiated a reverse genetic screen. This screen used RNAi and the UAS-GAL4 system to knock down such potential regulators enriched in neuroblasts or neurons. We assessed the role of each gene in enabling translation of rare-codon enriched transcripts by measuring expression of our rare-codon enriched reporter. Results of the screen will be presented at the poster. Using our *Drosophila* model, we may ultimately identify new regulatory mechanism during neuronal development and function: cellular response to codon bias.

Title: Loss of Ezh2 within the medial ganglionic eminence alters lineage commitment in cortical interneuron progenitors

Authors: *C. RHODES, M. SOHN, D. ASOKUMAR, Y. ZHANG, R. DALE, T. PETROS; NIH, Bethesda, MD

Abstract: GABAergic interneurons are a heterogenous cell population and their dysfunction is associated with numerous brain disorders. Interneurons are born in the ganglionic eminences (MGE, LGE and CGE), with distinct subtypes arising from different GE domains. Despite substantial evidence suggesting that initial interneuron subtypes are specified within these neurogenic niches, only a handful of fate-determining genes have been identified. One possible explanation is that progenitors contain epigenetic signatures directing cells towards a particular interneuron fate that are not yet apparent in the transcriptome. Ample evidence indicates that epigenetic mechanisms induce heritable changes in gene expression and are critical in mediating cell fate and differentiation in a variety of tissues. Yet we lack a comprehensive understanding of how epigenetic states influence interneuron cell fate in normal development and disease models.To explore the relationship between interneuron cell fate and epigenetic mechanisms in neural progenitors, we performed single cell RNA (scRNA-Seq) and single cell assay for transposase-accessible chromatin (scATAC-Seq) sequencing to determine the transcriptome and chromatin accessibility in the embryonic MGE, LGE, CGE and cortex. This allows us to screen for candidate enhancers and other non-coding regions regulating expression of specific interneuron subtypes. We detected distinct genes and corresponding chromatin profiles that are restricted to specific progenitor zones and interneuron lineages. By examining ATAC peaks in lineage-specific genes across cell types, we detected putative enhancers associated with specific GEs and potentially distinct interneuron subtypes. To expand on these initial observations, we generated a conditional knockout of *Enhancer of zeste homolog 2* (*Ezh2*) in MGE progenitors. Ezh2 regulates histone methylation and acts as a transcriptional repressor; thus loss of Ezh2 likely disrupts chromatin architecture and gene expression. These Ezh2 cKO mice displayed a significant decrease in PV+ interneurons in multiple brain regions. We are currently performing scRNAseq and scATACseq on the MGE of Ezh2 cKO to assess how the transcriptome and chromatin landscape is altered in these mice. These insights increase our understanding of how epigenetic modifications regulate interneuron fate and could open new avenues for understanding how disease-associated genes or genomic loci could perturb interneuron fate and maturation.

Dept. of Psychology, Stanford, CA

Abstract: Dopamine (DA) neurons in the ventral tier of the substantia nigra pars compacta (SNc) degenerate prominently in Parkinson's disease, while those in the dorsal tier are relatively spared. Defining the molecular, functional, and developmental characteristics of each SNc tier is crucial to understand their distinct susceptibility. We demonstrate that *Sox6* expression defines a ventral and a dorsal tier in the SNc. The *Sox6+* ventral tier includes an *Aldh1a1+* population and is enriched in gene pathways that underpin vulnerability. This dorso-ventral division extends beyond vulnerability - *Sox6+* neurons project to the dorsal striatum and show activity correlated with acceleration. *Sox6-* neurons project to the ventral striatum and respond to rewards. Moreover, we show that this adult division is partially encoded early in development. Overall, our work demonstrates a dual origin of the SNc that results in DA neuron cohorts with distinct molecular profiles, projections, and functions.

Title: Quantifying radial glial clone morphology and dynamics in the developing zebrafish brain

Authors: L. B. DOSTER[1], N. L. BROCKWAY[1], Z. T. COOK[2], *T. A. WEISSMAN[1];
[1]Biol., Lewis & Clark Col., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: During neurogenesis, individual mitotic radial glial cells produce postmitotic daughter neurons, forming small clones of related cells. These radial glial clones serve as a fundamental unit for neural proliferation during brain development; however, little is known about the functional relationship among clonally related cells. Sister cells can ultimately function in the same neural circuit and be involved in cortical organization (Yu et al., 2009; Li et al, 2012; Ohtsuki et al., 2012). Further, clonally related cells can undergo coordinated cell death during neurogenesis (Brockway et al., 2019). To better understand the functional role of clones, we have developed quantitative criteria to classify and measure radial clones in the developing zebrafish hindbrain. Using Brainbow expression to color-code and track radial clones in vivo, we applied semi-automated techniques to measure four main aspects of radial clones: 1) the number and size of cells within each clone; 2) spatial orientation; 3) the color associations among cells within a clone; and 4) the temporal dynamics of radial clones. Using these measures, we compared clones quantitatively across different conditions. These tools help to track clones and measure clonal dynamics during neural development; ultimately we aim to understand how radial clone organization contributes to brain function.

Title: Similarities and differences of reprogrammed neurons via direct conversion and human induced pluripotent stem cells in modeling DYT1 dystonia

Authors: *B. DING;
Univ. of Louisiana At Lafayette, Lafayette, LA

Abstract: DYT1 dystonia is a hereditary neurological movement disease. It is caused by a heterozygous deletion in *TOR1A* gene, resulting in the loss of one glutamate residues in the carboxy-terminal region of TOR1A protein (ΔE). Although ΔE has been shown to be a loss-of-function mutation, the mechanisms underlying ΔE leads to changes in the nervous system to cause dystonia remain poorly understood. While rodent models provide insights into disease mechanisms, significant species-dependent differences exist because animals with the identical heterozygous mutation fail to show pathology. Excitingly, reprogramming of human neurons from adult fibroblasts overcomes the limitation of inaccessibility to patient neurons and provides an unprecedented approach in deciphering the molecular pathogenesis underlying neurological diseases. In this study, DYT1 neurons have been generated via two strategies: (1) direct conversion from patient fibroblasts using lentiviral delivery of transcription factors, and (2) induced pluripotent stem cells (iPSCs)-based induction and differentiation. Using different combinations of reprogramming factors, different neuronal subtypes could be generated, including generic neurons (GNs), motor neurons (MNs), and cholinergic interneurons (ChINs). Directly converted MNs (diMNs) and iPSC-derived MNs (iMNs) have been systematically examined and compared in modeling DYT1 dystonia. Diseased neurons generated by both approaches showed similar phenotypes in impaired neurodevelopment, abnormal nuclear morphology, disrupted nucleocytoplasmic transport and dysregulation of nuclear lamin B1. Interestingly, diMNs showed more severe deficits than iMNs. Thus, diMNs are excellent materials for pathogenesis study based on immunocytochemistry. Compare to diMNs, iMNs possess unique advantages, such as much higher purity and yield, and the shorter culture time to reach the mature stage (3 weks vs 6 weeks). Generation of large amount of highly pure neurons via iPSC-based approach makes it possible to biochemically identify dysregulated factors in diseased neurons.

Title: Bipolar disorder iPSC-derived neural progenitor cells display aberrant store-operated calcium entry and neurodevelopment

Authors: *T. HEWITT[1], B. ALURAL[1], J. WANG[2], M. TILAK[1], N. JONES[1], S. D. SHERIDAN[2], R. H. PERLIS[2], J. LALONDE[1];

Abstract: Bipolar disorder (BD) is a chronic and disabling condition characterized by alternating episodes of severe depression and mania. The large majority of cellular research conducted about BD focuses on phenotypes present at the mature neuron stage, even though some manifestations of BD may occur earlier in development. This begs the question of whether it can be considered a neurodevelopmental disease. Although deviations in neuron development are suspected to contribute to the pathophysiology of BD, the precise molecular underpinnings remain unknown. In cells, calcium plays a central role in development via signaling cascades. As such, calcium accumulates in the endoplasmic reticulum (ER) from where it can be rapidly released in response to a second messenger. Calcium levels are, therefore, tightly regulated through store-operated calcium entry (SOCE)—a mechanism that promotes calcium influx through ORAI channels when the ER is depleted. Recently, we found striking evidence of aberrant SOCE activity in BD patient-derived induced pluripotent stem cells (iPSCs) differentiated into neural progenitor cells (NPCs) in comparison to iPSC-NPCs derived from healthy control individuals. Additionally, an RNA-sequencing experiment using this model uncovered upregulated neurodevelopmental processes in the BD-derived NPCs. This led us to hypothesize that calcium dynamics and neurodevelopment were aberrant in the BD-derived progenitors and neurons. To begin testing this, the sharp decrease in SOCE between BD patient-derived and control iPSC-NPCs was found to correlate with reduced STIM/Orai puncta formation. Probing the premature differentiation phenotype, we sought to compare the progenitors' capacity to self-renew and differentiate as neurons. To do this, we employed an EdU proliferation assay and a neurosphere formation assay. These led to the discoveries that BD-derived NPCs exhibited slower rates of proliferation, and faster rates of neurite outgrowth and migration. Finally, to model these processes in a 3D context, we generated 50-day old cerebral organoids from healthy- and BD-derived iPSCs. Using immunocytochemistry for radial glia markers PAX6 and pVimentin (dividing radial glia), we found that BD-derived organoids displayed smaller and thinner subventricular zones. As these zones are the sites of neurogenesis in developing and mature brains, this decreased area suggests a reduced progenitor cell pool due to premature differentiation. Together, our findings suggest that both SOCE and development are dysregulated in BD-derived NPCs, which implicates neurodevelopment in the pathophysiology of BD.

Title: Establishment of a Spatially Separated Microfluidic Culture System to Study the Regeneration of Axons from Human iPSC-Derived Sensory Neurons in the Context of Diabetic Peripheral Neuropathy

Authors: *M. JAMES, A. VENKATESAN, M. POLYDEFKIS, M. FARAH;
Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Diabetic peripheral neuropathy (DPN) is the most common complication of diabetes and is estimated to affect over 50% of the almost 35 million people diagnosed with diabetes in the United States. One important aspect of this disease that is not yet well understood is why nerves from people with diabetes mellitus 2 (DM2) regenerate more slowly than control patients, especially within the epidermal layer. We believe the neuronal origin of the axon, and more importantly, the target environment has a large effect on the regenerative capacity of sensory axons. I.e., that sensory axons from diabetic patient neurons will regenerate more slowly than controls, and that no matter the sensory axon origin, axons will regenerate more slowly in the epidermal environment of a diabetic patient than that of a control patient. To study this pathogenesis, we are creating a spatially separated co-culture system of sensory neurons and target tissue (skin) in microfluidic devices. We have established a system for culturing sensory neurons within these devices and for studying the regenerative capacity of those cells. Human induced pluripotent stem cell (iPSC)-derived sensory neurons were cultured in cell body compartments of microfluidic devices and allowed to extend axons into the axonal compartments. We have successfully matured and cultured these neurons in microfluidic devices and observed long axons, ~ 3mm, in un-injured axonal compartments. We have confirmed the generation of mature sensory neurons by staining for Islet 1 (ISL1) and POU domain, class 4, transcription factor 1 (POU4F1) also known as brain-specific homeobox/POU domain protein 3A (BRN3A). To quantify the efficiency of differentiation within the devices, we calculated the percent positive cells for both ISL1 (95%) and Brn3A (87%) within the cell body compartment, which confirmed our ability to reliably differentiate these cells within microfluidic devices at a high efficiency. Once the sensory neurons reached maturity, axotomies were performed in some of the axonal compartments by vigorous vacuum aspiration to severe the axons at the entrance to

the compartment, which allows us to track axonal regrowth and regeneration. Axons reliably regrew into the axonal compartment, and they continued to grow for at least 7 days post-axotomy. With this work, we have successfully been able to create a system for reliably studying distal axon growth and regeneration in human iPSC derived sensory neurons. This system also creates the opportunity for future spatially separated sensory neuron co-culture experiments for the study of DPN and other sensory neuropathies.

Title: Deciphering stress-related sympathetic neuropathology in familial dysautonomia using induced pluripotent stem cell-based disease modeling

Authors: *H. WU[1], W. YU[1], H. LIU[1], F. LEFCORT[2], N. ZELTNER[1];
[1]Univ. of Georgia, Athens, GA; [2]Montana State Univ., Bozeman, MT

Abstract: Familial dysautonomia (FD) is a neurodevelopmental and neurodegenerative disorder that mainly affects the peripheral nervous system, especially the sympathetic nervous system (SNS). One of the most devastating symptoms in patients with FD is the dysautonomic crisis, a severe dysregulation and dysfunction of the SNS triggered by stress. Interestingly, brain function which is the main stress responding center is minimally impacted in FD. This highlights the importance of the SNS in FD pathology. To date, the role of SNS dysfunction in FD, specifically, the pathological mechanism in sympathetic neurons (symNs) that leads to developmental defects, degeneration and FD crisis, remains unclear. A challenge of that is the lack of a accessible human model system comprised of symNs. Here, we adopt the human pluripotent stem cell (hPSC)-based disease modeling to investigate the defects in FD patient, healthy control and isogenic control-derived symNs. We show in early stages of differentiation, FD iPSCs display inefficient neural crest (NC) specification. When differentiating into sympathetic neuroblasts, FD NCs have a lower survival rate, yet remaining progenitor cells still generate symNs. These results reveal early developmental defects of SNS in FD. Using microelectrode array and calcium imaging, we found that FD symNs are spontaneously hyperactive. Accordingly, FD symNs drive higher cardiomyocyte beating in a co-culture system. We further confirmed symN hyperactivity using primary symN from mice lacking ELP1, the main gene mutation in FD. To understand the molecular cause of hyperactivity, we show that

ELP1 rescue does not rescue hyperactivity, suggesting the complexity of FD mechanisms in human. In addition, we found decreased intracellular norepinephrine (NE) levels in FD symNs, suggesting impaired autoregulatory function. Indeed, FD symNs expressed less norepinephrine transporter (NET), a NE reuptake transporter, and displayed decreased NE reuptake ability. Treating control symNs with NET inhibitor increased their activity, which supports our hypothesis. Furthermore, a clinically tested FD drug dexmedetomidine significantly suppressed FD symN hyperactivity, showing that symN pathology is a key feature in FD. Finally, we performed a mini drug screen and showed that our hPSC-based platform can be used for future FD drug discovery. Together, our studies show that symN hyperactivity caused by ill-controlled neurotransmitter release may contribute to FD pathology in patients. Our *in vitro* system allows the examination of molecular mechanisms underlying symN defects in FD and shows that hPSC-symN is a competent tool for studying SNS diseases.

Title: Ipsc-astrocytes derived from patients with Alzheimer's disease show altered Ca^{2+} signalling and ability to degrade tau protein.

Authors: V. BREZOVAKOVA, S. JADHAV, D. CIZKOVA, *E. SYKOVA;
The Inst. of Neuroimmunology of SAS, Bratislava, Slovakia

Abstract: Astrocytic tau pathology has been described in many neurodegenerative diseases including Alzheimer's disease (AD). Growing evidence points to major structural and functional differences between human and rodent astrocytes, thus prompting the research on human glial cells. Induced pluripotent stem cells (iPSC) represent a valuable tool to model and study human cells in health and disease. We generated human astrocytes from iPSCs derived from patients with sporadic AD (sAD), familial AD (fAD), and non-demented controls (NDC). Upon *in vitro* differentiation, all clones gained astrocyte-specific morphological and proteomic features without considerable inter-clonal differences. Since reactive astrocytes contribute to the dysfunction of Ca^{2+}signalling in AD, we analyzed the Ca^{2+} activity of individual clones upon

glutamate stimulation. We found that sAD astrocytes exhibited Ca^{2+} overload accompanied by hyperphosphorylation of protein kinase C- alpha/beta II when compared to healthy astrocytes. Moreover, sAD astrocyte secretome altered Ca^{2+} influx in neurons derived from non-demented control iPSCs (iNeurons). Astrocytes actively participate in amyloid-beta metabolism, however, their involvement in tau processing is yet to be elucidated. We investigated the secretome of astrocytes for their potential to metabolize tau protein *in vitro*. We show that tau induces the secretion of astrocytic gelatinases, specifically metalloproteinase 9 and 2 (MMP-9, MMP-2). Both MMP -9 and MMP -2 were responsible for the degradation of monomeric and aggregated tau species *in vitro*. Moreover, we found that the degrading capacity of astrocyte conditioned media (ACM) from NDC and sAD was significantly higher than that from fAD ACM. The degrading capacity of ACM also correlated with the levels of pERK1/2, a kinase involved in MMP secretion. ACM-degraded tau was less toxic when added to iNeurons than "native tau" *in vitro*. Our study unveils a mechanism by which astrocytes can modulate tau pathology. The activity of metalloproteinases secreted by astrocytes contributes to neuroprotection via attenuation of tau toxicity on neurons.

Title: Protein Kinase A inhibition modulates endogenous levels of dipeptide repeat proteins in C9orf72 ALS/FTD patient iPSC-derived neurons

Authors: *S. SALOMONSSON[1,2], N. V. LICATA[3], K. M. WILSON[1,2], M. PANCHER[4], V. ADAMI[4], A. M. ISAACS[1,2], A. PROVENZANI[3];

Abstract: Introduction
A well-characterised feature of Amyotrophic Lateral Sclerosis (ALS) and Frontotemporal Dementia (FTD) associated with C9orf72 mutation is non-canonical repeat associated non-AUG (RAN) translation of a G_4C_2 repeat expansion, producing disruptive dipeptide repeat proteins (DPRs) in the patient brain. The mechanisms by which DPRs are produced and escape

degradation are not well understood, particularly in terms of endogenous levels in patient-derived neurons. We investigate novel small molecule modulators of DPR levels through a primary screen and validate the hits using independent patient iPSC-derived motor neuron lines.

Methods

N=3 independent patient iPSC lines were used. Differentiation of mature spinal cord motor neurons was induced through a 2D dual SMAD inhibition protocol. iPSC-derived motor neurons (iPSC-MNs) were treated with small molecules identified in a primary high throughput screen of RAN translation modifiers, which screened a library of compounds using a cell model expressing a (G_4C_2)x58-GFP reporter construct and an AUG-driven RFP control. Endogenous poly-GP and poly-GA levels in iPSC-MNs were quantified through MSD immunoassay.

Results

Four hits from the primary screen were carried forward to testing in patient iPSC-MNs. Two of the small molecules targeted the cyclic AMP pathway, whereof one inhibited Protein Kinase A (PKA) activity and stood out as significantly effective in reducing DPR levels in patient iPSC-MNs, although there were donor-dependent response differences to treatment. Donor-dependent differences in baseline DPR levels were observed, which did not correlate with repeat length.

Conclusion

We found a role for PKA activity in modulation of endogenous DPR levels, which is a novel investigative avenue in the search for specific therapeutic targets for C9orf72-associated ALS/FTD. The patient iPSC-MN lines responded differently to treatment, which may be due to differences in DPR turnover rates or RAN translation machinery, highlighting the importance of utilising patient-derived cell lines from several independent genetic backgrounds when investigating therapeutic targets for genetic diseases.

Sch., Boston, MA; [10]The Collaborative Ctr. for X-linked Dystonia-Parkinsonism, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: X-linked Dystonia-Parkinsonism (XDP) is an inherited adult-onset movement disorder affecting predominantly male of Filipino descent. At molecular level, a disease-specific SINE-VNTR-Alu (SVA) retrotransposon insertion occurs within intron 32 of *TAF1*, core member of the TFIID complex mediating the RNA pol II promoter initiation. Histopathological analyses unveiled a progressive differential degeneration in the adult neostriatum of XDP patients. However, whether and how a partial loss of *TAF1* function and/or an SVA-driven pathological gain of function contribute to XDP is yet unknown. While all XDP males are usually affected, females are obligate heterozygous carriers not manifesting the full syndrome. Because of X-chromosome inactivation (XCI), females transcriptionally silence the majority of genes on one X chromosome, including *TAF1*. Understanding how XDP manifests in female carriers can reveal key features about XDP pathophysiology. Here, we analyze female wild-type and carrier-derived induced pluripotent stem cells (iPSCs) as well as postmortem brain tissues to identify intrinsic properties of *TAF1* expression that may underlie differential degeneration in XDP. We characterized iPSCs from female carrier individuals, identifying a set of isogenic lines where one clonal iPSC line expresses the wild-type X and two other clonal iPSC lines express the XDP haplotype. We found that *TAF1 is* decreased in female wild-type iPSCs, XDP carrier iPSCs, and several regions of the female post-mortem brain, compared to males. However, in the striatum, *TAF1* is not sex-differentially expressed, perhaps indicating a regional sensitivity to *TAF1* expression. Also, in the caudate nucleus, *TAF1* expression decreases after 15 years of age, implying cell-type, age and sex specific mechanisms regulating its expression, and highlighting the importance of disease-relevant cellular models. To recapitulate the mature and complex XDP cellular system, we developed a novel protocol to differentiate female carrier and male control, XDP, and SVA-deleted XDP iPSCs into striatal organoids. Through an extensive phenotypical and molecular characterization, we found that striatal organoids are mainly composed of medium spiny neurons (MSNs) and striatal interneurons, exhibiting a functional network activity up to at least 1 year. Our striatal organoid model can serve as a valuable 3D cellular model of XDP,

recapitulating key molecular features of the disease. This will contribute to elucidate mechanisms modulating the transcriptional dysregulation in XDP, shedding light upon novel insights of XDP etiology.

Title: Som-specific knockout of the ASD candidate gene PTEN results in elevated fear and anxiety and disrupts local circuitry in the central amygdala

Authors: *T. W. HOLFORD, M. BOLTON;
Max Planck Florida Inst., Jupiter, FL

Abstract: Autism spectrum disorder (ASD) is a complex disorder with large individual variability, where every case has differences in the type and severity of symptoms. Despite the recent increase in diagnoses, scientists have advanced considerably less in their understanding of the mechanisms of ASD because few individual genes that are implicated in ASD are mutated in much more than 1% of patients. One proposed mechanism is that the dysfunction of GABAergic interneurons may play a role in the development and progression of the disorder by interrupting the excitatory and inhibitory balance of neural networks. In our research, we elucidate the role of one class of interneurons in ASD by knocking out a high-risk gene (phosphatase and tensin homologue on chromosome ten, or PTEN) selectively in somatostatin- expressing (SOM+) interneurons. We found that mice with a SOM+ conditional knockout of PTEN had elevated levels of anxiety and fear recall, suggesting a disruption of amygdala function. We then investigated potential dysfunction at the cellular and circuit levels using confocal microscopy, electrophysiology, and 2P local circuit mapping. We found that SOM+ cells lacking PTEN were overgrown morphologically, with larger cell bodies and larger, more complex dendritic arbors. Additionally, SOM+ cells in the central amygdala (CeA) lacking PTEN had elevated levels of excitatory drive from the basolateral amygdala (BLA) as well as a drastic disruption of lateral inhibition within the CeA, seen by decreased connection probability and reduced inhibitory post

synaptic currents. Given what is known about central amygdala circuitry, these deficits in CeA SOM+ neuron activity conceivably underlie the fear and anxiety-related phenotype observed in mice with a conditional SOM+ PTEN knockout.

Title: Different neurexin isoforms uniquely contribute to temporal aspects of the behavioral response to food deprivation

Authors: *B. L. BASTIEN, M. P. HART;
Genet., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Structural and functional properties of neural circuits underlie behavior, and perturbations in either can lead to abnormal, dysfunctional, or sometimes debilitating behavioral changes. The conserved synaptic adhesion molecules neurexins impact structure and function of circuits and are associated with autism spectrum and schizophrenia, disorders characterized by distinct behavioral phenotypes. Neurexins impact synaptic function and some behaviors, but significant gaps remain in our understanding of the molecular mechanisms that connect neurexins to behavior. We analyzed the *C. elegans* behavioral response to food deprivation in order to test the role of genes, including neurexin, in a conserved behavior with an experimentally defined neuronal circuit. Using the "WorMotel" platform and unbiased computer vision image analysis, we analyzed activity levels of hundreds of hermaphrodite *C. elegans* while fed or food deprived. While control worms significantly increase locomotor activity when food deprived (sustained >8 hours), worms lacking *nrx-1* (the singular neurexin in *C. elegans*) have a significantly reduced response to food deprivation (on food, there is no difference in locomotor activity levels between control and *nrx-1* worms). Loss of *nrx-1* also disrupted responsiveness to octopamine, a key neuromodulator in the food deprivation response circuit that increases locomotor activity. *nrx-1* has two major isoforms: the long α and short γ (lacking extracellular domains). Using isoform-specific mutation alleles and isoform-specific transgenic expression in neurons, we found initial response to food deprivation (hour 1) and octopamine require the short isoform, while sustained response to food deprivation (beyond hour 1) required only the long isoform, which was not required for response to octopamine. Loss of *nlg-1*, the singular neuroligin in *C. elegans* and the canonical postsynaptic binding partners of *nrx-1*, had

no impact on the food deprivation response. Loss of *nlg-1* in *nrx-1* mutants (*nlg-1*; *nrx-1* double mutants) eliminated the *nrx-1* phenotype in long-isoform dependent sustained responses to food deprivation, but not short isoform (which is unable to bind *nlg-1)* dependent initial responses or octopamine responsiveness. This demonstrates a novel role for *nrx-1* isoforms and a non-synergistic interaction with *nlg-1* in controlling temporal aspects of a single behavior at the molecular and potentially circuit level. Our work uncovers novel molecular complexity for the role of *nrx-1* in circuits and behavior, emphasizing the utility of using behavioral readouts for understanding gene function in neurons, circuits, and behaviors in parallel.

Title: Counteracting epigenetic mechanisms in human neuronal morphogenesis and maturation

Authors: *F. RITCHIE[1], J. VACHARASIN[1], A. CULVER[1], S. LIZARRAGA[1], S. CHEON[1], A. BAGNELL[1], M. MCCORD[1], C. PAPENDORP[2], E. CHUKWURAH[1], A. SMITH[1], M. COWEN[1], P. GHATE[1], S. DAVIS[1], J. LIU[2];

Abstract: Autism Spectrum Disorders (ASD) are highly heritable neurodevelopmental disorders characterized by social and verbal impairments as well as repetitive behaviors. Large human genetic studies showed that genes encoding chromatin and transcriptional regulatory proteins are among the most commonly mutated genes in ASD. Absent, Small, or Homeotic 1-like (ASH1L) is a histone methyltransferase that has previously been identified as a major genetic risk factor for ASD. ASH1L methylates Histone H3 on Lysine 36 (H3K36), which mainly coincides with transcriptional activation. ASH1L is proposed to counteract the activity of Polycomb Repressor Complex 2 (PRC2) by preventing the tri-methylation of Histone H3 on Lysine 27 (H3K27me3). We identify an overrepresentation of genes associated with neuronal projection development or morphogenesis that are highly correlated with ASH1L in the developing human cerebral cortex. Hence, this suggests that ASH1L could have a role in regulating neuronal morphogenesis. We find that knockdown of ASH1L in human stem cell-derived neurons alters different parameters of neuronal morphogenesis. Specifically, we report that ASH1L-depleted neurons have decreased neurite outgrowth, but have increased cell soma size and growth cone areas.

Additionally, we show that deficits in ASH1L lead to an increased percentage of DCX-positive neurons compared to control cultures. DCX is a marker of immature cortical neurons suggesting that ASH1L knockdown potentially leads to delayed maturation. We further find that ASH1L phenotypes are rescued by inhibition of the catalytic activity of PRC2. Taken together, these results indicate that the counteracting activities of ASH1L vs. PRC2, are important for the control of neuronal morphogenesis and maturation in human experimental systems.

Title: Transcriptomic profiling and bioinformatic analysis reveals modulation of mTOR-associated genes following glycine type 1 transport (GlyT1) inhibition in BALB/c mice

Authors: A. C. RUCKER[1], S. E. JONES[1], S. I. DEUTSCH[2], *J. A. BURKET[1];
[1]Mol. Biol. and Chem., Christopher Newport Univ., Newport News, VA; [2]Psychiatry and Behavioral Sci., Eastern Virginia Med. Sch., Norfolk, VA

Abstract: Mechanistic Target of Rapamycin (mTOR) has been implicated in several monogenetic forms of autism spectrum disorder (ASD). The NMDA receptor (NMDAR), a regulator of mTOR complex 1 (mTORC1), has emerged as a viable pharmacotherapeutic target in ASD. VU0410120 (VU120), a highly selective glycine (GlyT1) transporter inhibitor, improved social and cognitive behaviors in BALB/c mice, a model of impaired sociability. Transcriptomic and bioinformatic analyses of archived microarray data were conducted to determine strain differences and prosocial effects of VU120 in BALB/c and Swiss Webster (SW) mice. Frontocortical RNA was subjected to transcriptome profiling using the Affymetrix microarray. Briefly, global prosocial responses of individual mice were ranked and assigned to prosocial response categories. In vehicle- and VU120-treated groups of BALB/c mice, samples designated with the highest and lowest total ratings of social behaviors were used for microarray analysis; SW mice were chosen for comparison (n=4/group). Gene expression was studied using Affymetrix Transcriptome Analysis Console (TAC), Cytoscape, DAVID, and KEGG software. Principal component analysis identified clustering of vehicle-treated BALB/c mice irrespective of high or low sociability; BALB/c mice non-responsive to VU120 treatment clustered with vehicle-treated BALB/c mice. Importantly, a separate cluster for BALB/c mice responsive to treatment was observed independent of vehicle-treated groups and in closer proximity to the

vehicle-treated SW mice. Subsequent targeted analyses of 103 protein coding genes involved in regulation of mTOR signaling pathway were explored. Between strain comparisons of differentially expressed genes showed significant fold changes of mTOR-associated genes (PPKAA2, DEPTOR, APC, CAD, PPP2R2A) in BALB/c mice relative to SW (-1.20 < or > 1.20, $p \leq 0.05$; FDR $p \leq 0.05$). Comparisons were made between BALB/c mice that displayed increases in sociability following VU120 treatment (responders) to BALB/c mice that did not respond to treatment (non-responders). BALB/c responders showed significant differences in expression of regulators of mTOR (IRS1, PIK3CG, PIK3C2B, RAC1, PPP2R2A, RPS6KB2, EPM2A, DDIT4). Gene ontology analysis revealed significant fold enrichment for biological processes with upregulation in BALB/c non-responders compared to responders related to negative regulation of TOR signaling ($p = 0.013$), semaphorin signaling ($p = 0.006$), neuronal migration ($p = 0.004$) and neuronal development ($p = 0.021$). Overall, these data encourage exploration of a therapeutic role for NMDAR activation in regulation of the mTOR signaling pathway.

Title: Neurons from PACS1 syndrome have altered expression of transcripts involved in axon outgrowth and impaired neural network activity

Authors: *L. RYLAARSDAM[1], A. D. GUEMEZ-GAMBOA[2];
[2]Physiol., [1]Northwestern Univ., Chicago, IL

Abstract: PACS1 syndrome is a neurodevelopmental disorder characterized by intellectual disability, autism spectrum disorder (ASD), epilepsy, distinct craniofacial abnormalities, and global developmental delays. PACS1 syndrome results from a recurrent *de novo* missense p.R203W variant in phosphofurin acidic cluster sorting protein 1 (PACS1). Almost nothing is known about how this variant in PACS1 affects the developing nervous system and very few therapeutic options are available for patients. In order to begin to address the impact of the R203W variant on different cell types in the developing brain, I performed single-cell RNA sequencing on cerebral organoids generated from patient and control-derived stem cells. I found a total of 199 unique differentially expressed genes (DEGs) between $PACS1^{+/R203W}$ and control organoids. DAVID Bioinformatics Resources analysis of DEGs and Weighted Gene Co-

expression Network Analysis (WGCNA) of the neuronal cells suggest that PACS1$^{+/R203W}$ neurons have increased expression of genes involved in axon outgrowth and guidance. These processes are critical for proper neural network formation in the developing brain and alterations could have serious consequences for the individual. To test if the electrical properties of neural networks are impaired in PACS1 syndrome, I cultured iPSC-derived neurons on multielectrode arrays. While PACS1$^{+/R203W}$ neurons had the same burst duration for individual electrode bursts, network burst duration was strikingly longer. PACS1$^{+/R203W}$ neurons also exhibited decreased synchrony with a lower percentage of spikes happening inside bursts. Future studies will be focused on determining the mechanism behind these electrophysiological impairments. This work is some of the first to look at the impact of the PACS1 syndrome variant on the developing brain and shows promising avenues of study for determining disease mechanisms in order to develop therapies.

Title: Elevated temperature alters the excitation to inhibition (E-I) balance to alleviate cognitive deficits in the Scn2a autism mouse model.

Authors: *Y. AWASTHI[1], Y. SHEN[2], *M. W. ANTOINE[2];
[1]NIH, Bethesda, MD; [2]NIH, ROCKVILLE, MD

Abstract: In most mammals (humans included) core body temperature is regulated to a setpoint value between 36.1 and 37.8°C, with an average fluctuation from the target of 0.5°C during a 24-hour day. Despite mechanistic safeguards, major temperature deviations (1-3 °C) from the setpoint occur in the body and in turn the brain. In children, these increases in brain temperature are generally well-tolerated. However, for unknown reasons, large fluctuations in brain temperature in some cases result in deleterious outcomes such as seizures, whereas for select autistic children beneficial effects including improved cognition can occur. Here, we describe a neural mechanism for circuit-level adaptive regulation of cortical activity during large fluctuations in brain temperature. Our study reveals temperature-induced alterations in the excitation to inhibition (E-I) balance that stabilize activity in the cortex. We show that in the Sodium Voltage-Gated Channel Alpha Subunit 2 (*Scn2a*) mouse model for autism with

intellectual disability, these temperature-induced circuit-level alterations can be beneficial by normalizing circuit function and improving higher-level cognition.

Abstract: The vast majority (80-90%) of autism spectrum disorder (ASD) patients suffer from the idiopathic form of this neurodevelopmental disorder. Tractable models that can be directly correlated to patient phenotypes are essential for moving toward a precision medicine approach to treating ASD, a highly heterogeneous disorder. To address this, our research group has longitudinally phenotyped a cohort of developmentally delayed toddlers who go on to develop ASD as well as typically developing controls. These data include social communication and language assessments, neuroimaging data, eye tracking, and leukocyte transcriptomics. From a subset of these subjects, we generated induced pluripotent stem cell-derived neural progenitor cells (NPCs) and performed single cell RNA sequencing to better understand the processes associated with idiopathic ASD in early prenatal development.
Preliminary results showed a shift in neural progenitor subtype distribution between ASD and typicals. ASD NPCs showed a reduction of SB100+ and Neurod1+ NPCs, with an increase in VCAM1+, LGASL1+ and RBFOX3+ NPCs. ASD-specific transcriptional signatures were associated with IGF1 and retinoic acid signaling. Here we characterize unique properties of NPCs in ASD and their correlations with neuroimaging and behavior data in subjects from a deeply phenotyped cohort, including pilot data exploring sex differences in ASD.

Title: Loss of Tsc1 from striatal direct pathway neurons impairs endocannabinoid-LTD and enhances motor routine learning

Authors: *K. R. CORDING[1], K. N. BENTHALL[2], A. H. C. W. AGOPYAN-MIU[2], C. D. WONG[2], E. Y. CHEN[2], H. S. BATEUP[2,1,3];

Abstract: Autism spectrum disorder (ASD) is characterized by social and communication deficits, as well as the presence of restricted and repetitive behaviors (RRBs). Over one hundred genes have been associated with ASD risk, including genes that cause syndromic disorders, which are associated with a constellation of neurological, psychiatric and medical conditions. One such disorder is Tuberous Sclerosis Complex (TSC), caused by mutations in either *TSC1* or *TSC2*, in which roughly half of patients meet the clinical criteria for an ASD diagnosis and most have epilepsy. While epilepsy in TSC likely arises from altered excitability in forebrain circuits, the brain regions and cell types important for ASD-related behaviors are less well understood. We hypothesized that alterations in striatal circuits, which mediate motor learning, action selection, and habit formation, might contribute to the RRBs observed in TSC patients with ASD. Striatal function depends on the coordinated activity of two subpopulations of GABAergic cells: direct pathway spiny projection neurons (dSPNs) and indirect pathway spiny projection neurons (iSPNs). dSPNs and iSPNs are distinct in their projection targets, and at the simplest level, bulk activation of dSPNs increases locomotor behavior and action selection while stimulation of iSPNs inhibits movement. To determine how developmental loss of Tsc1 affects striatal synapses and whether this is sufficient to alter striatal-dependent motor behaviors, we generated mice in which *Tsc1* was selectively deleted from either dSPNs or iSPNs. We find that motor routine learning in the accelerating rotarod task is enhanced in mice with *Tsc1* deletion restricted to dorsal striatal dSPNs, but not iSPNs, which also occurs in mice with global haploinsufficiency of *Tsc2*. Further, using whole-cell patch clamp electrophysiology we find that loss of Tsc1 causes a non-cell autonomous enhancement of cortical inputs onto dSPNs but not iSPNs, which is associated with loss of endocannabinoid-mediated synaptic long-term depression (eCB-LTD). Utilizing translating ribosome affinity purification (TRAP), we find

reduced ribosome engagement of multiple mRNAs encoding proteins required for eCB-LTD in Tsc1 KO dSPNs, which provides a potential molecular basis for the eCB-LTD deficit observed in these cells. Together, these findings demonstrate that increased cortical drive of dSPNs resulting from Tsc1 loss is sufficient to enhance the learning of a fixed motor routine, which may have implications for the emergence of restricted, repetitive patterns of behavior in TSC.

Title: Aberrant DJ-1 expression underlies L-type calcium channel hypoactivity in tuberous sclerosis complex and Alzheimer’s disease

Authors: *F. NIERE[1], L. P. CACHEAUX[1], A. UNERI[1], S. NAMJOSHI[1], C. REYNOLDSON[1], J. PENARANDA[1], C. J. MCARDLE[1], X. WANG[1], W. C. TAYLOR[1], S. CRAFT[2], T. MA[2], C. D. KEENE[3], K. F. RAAB-GRAHAM[1];
[1]Physiol. and Pharmacol., [2]Gerontology and Geriatric Med., Wake Forest Sch. of Med., Winston Salem, NC; [3]Pathology, Univ. of Washington Sch. of Med., Seattle, WA

Abstract: L-type voltage-dependent Ca2+ channels (L-VDCC) integrate synaptic signals to facilitate a plethora of cellular mechanisms. L-VDCC dysfunction is implicated in several neurological and psychiatric diseases. Despite their importance, signals upstream of L-VDCC activity that regulate their channel density, however, are poorly defined. In disease models with overactive mammalian target of rapamycin complex 1 (mTORC1) signaling (or mTORopathies), including tuberous sclerosis (TS) and Alzheimer’s disease (AD), we report a novel mechanism downstream of mTORC1 signaling that results in a deficit in dendritic L-VDCC activity. Deficits in L-VDCC activity are associated with increased expression of the mTORC1-regulated RNA-binding protein DJ-1. DJ-1 binds the mRNA coding the auxiliary Ca2+ channel subunit α2δ2

responsible for shuttling L-VDCC to the membrane and represses its expression. Moreover, this novel DJ-1/α2δ2/L-VDCC pathway is disrupted in human AD and preclinical models of AD and TS. Our discovery that DJ-1 directs L-VDCC activity and L-VDCC-associated protein α2δ2 at the synapse suggests that DJ-1/α2δ2/L-VDCC is a common, fundamental pathway disrupted in TS and AD that can be targeted in clinical mTORopathies.

Title: Procedural learning abnormalities in individuals with ASD and their biological parents

Authors: *M. B. TROST[1], S. E. KELLY[1,2], L. M. SCHMITT[3,4], E. K. BOJANEK[1,2], K. E. UNRUH[1,2], J. A. SWEENEY[3], M. W. MOSCONI[1,2];
[1]Life Span Institute, Univ. of Kansas, Lawerence, KS; [2]Kansas Ctr. for Autism Res. and Training (KCART), Univ. of Kansas, Lawrence, KS; [3]Dept. of Psychiatry and Behavioral Neuroscience, Univ. of Cincinnati Col. of Med., Cincinnati, OH; [4]Div. of Developmental and Behavioral Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Sensorimotor impairments and deficits in procedural learning have been found in individuals with autism spectrum disorder (ASD) and their unaffected first-degree relatives (Mosconi et al., 2010). This suggests that procedural learning deficits may be familial in ASD, though no known studies have directly assessed the extent to which procedural learning impairments are associated between individuals with ASD (probands) and their parents (ASD parents) or may vary in relation to separate familial traits associated with ASD. Forty-four probands, 105 of their unaffected biological parents (ASD parents), 27 typically developing (TD) controls, and 47 TD parent controls matched on age, sex, and nonverbal IQ completed an oculomotor test of procedural learning. During testing, peripheral targets alternated between two fixed locations (+/- 6 degrees from center) at set intervals (1500 ms). Saccade latency, change in

latency over trials (rate of learning), and variability of latencies across trials were examined. Parents completed the Broad Autism Phenotype Questionnaire (BAP-Q) to assess subclinical traits associated with ASD. Parents were separated into BAP+ or BAP- groups using previously published cutoff scores (Sasson et al., 2013). No differences in saccade latencies, rate of learning, or variability of saccade latencies were seen for proband or ASD parents compared to control groups. Subgroup analyses indicated that probands whose parents did not show any BAP features (BAP-) showed increased variability of rightward saccade latencies relative to probands with at least one parent showing BAP features (BAP+) and TD controls (Group x direction interaction: F=3.92; p=.03). BAP+ parents showed faster leftward saccade latencies compared to BAP- parents and parent controls (β=-.02; p=.01). Rate of learning was inter-correlated among probands and their parents (h^2= 0.735, p=0.003). Together this suggests that procedural learning abnormalities in ASD may represent an important intermediate phenotype associated with familial risk. Our finding that probands with BAP- parents show increased rightward saccade latency variability during procedural learning is consistent with prior data implicating atypical functioning of left hemisphere striatal chronometric systems (D'Cruz et al., 2009), and further suggests these alterations represent familial trait liabilities independent of subclinical core traits. Findings that rate of learning was correlated among proband subgroups and their parents suggest that procedural learning impairments in ASD are familial and may serve as useful intermediate phenotypes for tracking familial mechanisms of ASD.

Title: Structure of corticostriatal tracts in middle-aged and older adults with autism spectrum disorder

Authors: *M. CORDOVA[1], J. HAU[2], A. SCHADLER[2], M. WILKINSON[1], K. ALEMU[2], A. BAKER[2], C. CHAABAN[2], E. CHURCHILL[2], I. FISHMAN[2], R.-A. MÜLLER[2], R. A. CARPER[2];
[1]Joint Doctoral Program in Clin. Psychology, San Diego State University/UC San Deigo, San Diego, CA; [2]Psychology, San Diego State Univ., San Diego, CA

Abstract: Individuals with autism spectrum disorder (ASD) show atypical white matter (WM) structure through childhood and young adulthood, but little is known about WM differences in middle-aged and older populations with ASD. In typical aging, fractional anisotropy (FA) decreases while mean diffusivity (MD) increases. WM changes in the striatum, a critical relay center, have been implicated in the cognitive decline observed during typical aging. Behavioral activation, inhibition, attention, and reward sensitivity depend on the striatum, and younger persons with ASD show altered FA and MD. Therefore, understanding differences in corticostriatal WM among middle-aged and older ASD/typical control (TC) populations is important. We hypothesized that 1) aging adults with ASD would show decreased FA and increased MD compared to TC and 2) greater age would be associated with decreased FA and increased MD for both groups. Participants aged 40-70 years were recruited with and without ASD. Diagnosis was confirmed by an expert clinician and TC participants had no family/personal history of ASD. Diffusion weighted MRI data were collected on a 3T scanner with one of two protocols (b = 1500 or 1000 s/mm^2) and processed using FSL and TractSeg. Diffusivity measures were extracted for 14 striatal (ST) tracts (7 left [L], 7 right [R]) and harmonized (for protocol) using ComBat. Groups were matched on gender, age, non-verbal IQ, handedness, brain volume, and head motion. Regressions were used to test the effects of age and diagnostic group on ST-tracts while controlling for motion and protocol. 58 participants with and without ASD (ASD n = 27, TC, n = 31) were included in analyses. Significant group differences in MD (ASD>TC) were observed after FDR correction in the R ST-postcentral, L and R ST-parietal, and L and R ST-occipital tracts. Greater age was significantly associated with greater MD in the R ST-postcentral, and the L and R ST-occipital tracts. No significant differences were observed for FA. Diagnosis and age effects were observed for MD across several ST-tracts that connect to cortical regions associated with attention, somatosensory, and visual networks; all of which send critical inputs for cognitive function to the striatum and show differences in aging and ASD. Results are consistent with a recent study indicating that MD is more sensitive to aging than FA. Although much attention has been paid to frontal-cortex and ST-frontal WM in typical aging and younger persons with ASD, our results highlight posterior ST-tract differences in middle-aged and older ASD. Future work will explore the relationship between ST-tracts, associated cortical regions, and neurocognitive measures.

Title: Neural responses to audiovisual speech in infants at increased likelihood for autism and links with language: An ERP pilot study

Authors: *K. DUNHAM[1,2], B. KECELI-KAYSILI[3], A. J. GOLDEN[3], P. SANTAPURAM[3], J. MARKFELD[2], J. I. FELDMAN[2,4], T. WOYNAROSKI[4,5,6,1];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Hearing & Speech Sci., Vanderbilt Univ., Nashville, TN; [3]Vanderbilt Univ. Med. Cener, Nashville, TN; [4]Frist Ctr. for Autism and Innovation, Nashville, TN; [5]Vanderbilt Univ. Med. Ctr., Nashville, TN; [6]Vanderbilt Kennedy Ctr., Nashville, TN

Abstract: Speech is inherently a multisensory process, wherein synchronized visual cues from the moving mouth complement the dynamic acoustic stream. Past research has shown that typically developing (TD) infants tune in to multisensory speech, looking to the mouth of their communication partners during the first year of life, presumably to access audiovisual cues that facilitate speech processing and language learning. This study aims to determine: (a) if visual cues increase efficiency of speech processing as indexed by event-related potentials (ERPs) in infants at general population-level likelihood for autism (infant siblings of TD children; Sibs-TD), (b) if infants at increased familial likelihood for autism (infant siblings of children with autism; Sibs-AUT) display a lesser boost in speech processing efficiency with access to multisensory versus unisensory cues compared to Sibs-TD, and (c) if individual differences in speech processing efficiency covary with language ability. Forty 12-18 month old infants (20 Sibs-AUT; 20 Sibs-TD matched on sex and chronological age) are being recruited. Participants view videos of a female speaking syllables in audiovisual (auditory speech + synchronous visual mouth movements) and auditory only (auditory speech + still image of the face) conditions. Data are collected using NetStation and a 128-channel Geodesic sensor net (Net Amps 400 amplifier, Hydrocel GSN 128 EEG cap, EGI Systems Inc.). The raw EEG signal is sampled at 1000 Hz and referenced to vertex (Cz). The amplitude of the P2 component (defined a priori as occurring between 160 ms and 340 ms) as measured at Cz is extracted from the average ERP of each participant. Parents also complete the MacArthur-Bates Communicative Development Inventories to report on their child's emerging vocabulary. Preliminary results for data processed to date (5 Sibs-TD; 5 Sibs-AUT) suggest that, on average, Sibs-TD display a *decreased* P2 amplitude in response to audiovisual versus auditory only speech, while Sibs-AUT display reduced differentiation of audiovisual versus auditory only speech as indexed by the P2 amplitude compared to Sibs-TD. Preliminary results also indicate moderate associations between the degree of P2 amplitude suppression and receptive and expressive language across groups. These findings suggest that differential processing of audiovisual speech may emerge early in life and that infants at increased likelihood for autism appear to show reduced differentiation of multisensory versus unisensory speech that may be clinically useful for explaining individual differences in language ability, as well as broader language delays or disorders.

Title: Disruptions of functional connectivity patterns in Chinese children with ASD - an EEG coherence study

Authors: *N. NOVITSKIY[1], X. GENG[1], A. MAGGU[2,1], J. C. Y. LAU[1,3], C. K. S. TO[4], P. C. M. WONG[1];
[1]Linguistics & Modern Languages, Brain and Mind Inst., The Chinese Univ. of Hong Kong, Hong Kong, China; [2]O-lab, Duke Psychology and Neurosci., Duke Univ., Durham, NC; [3]Roxelyn and Richard Pepper Dept. of Communication Sci. and Disorders, Northwestern Univ., Evanston, IL; [4]Unit of Human Communication, Develop. and Information Sci., The Univ. of Hong Kong, Hong Kong, China

Abstract: Autism spectrum disorder (ASD) pathophysiology involves disruptions in the brain's oscillatory rhythms that can be captured by electroencephalogram (EEG). Recent EEG studies have shown that coherence patterns of EEG signal can be used to classify subjects into ASD and non-ASD groups. This study aimed to validate whether functional connectivity at rest measured by EEG phase coherence can distinguish children with ASD from typical developing controls in Chinese population. A group of 44 children with ASD and 30 age and gender controlled children (age range: 5 - 12 years) were recruited and recorded in the study. The ASD diagnosis was obtained from a qualified clinician and ASD subjects also met Autism Diagnostic Observation Schedule (ADOS-2) classification criteria. EEG was recorded continuously with a 64-channel Neuroscan system (Compumedics, Australia) at 1000 Hz sampling rate while the subject was at rest with eyes opened. Two bipolar channels registered horizontal and vertical eye-movements. The EEG pre-processing steps included re-referencing to the average mastoid, band-pass filtering in 1-90 Hz range, regressing out the eye-movement artifact, Laplacian transform to minimize the volume conduction effects, epoching into 3-second intervals with 50% overlap, rejection of the high-amplitude epochs and pooling the electrodes into 10 clusters. Phase coherence between the clusters was calculated from the complex FFT spectra of individual epochs in four frequency bands: delta (0.5-4 Hz), theta (4-8 Hz), alpha (8-12 Hz), beta (12-30 Hz). Coherence was compared between the control and ASD groups with a mass-univariate t-test with Bonferroni correction for the multiple comparisons across the cluster pairs and frequency bands. The phase

coherence was significantly reduced in ASD patients in comparison to the controls in 21, 15, 22 and 3 cluster pairs in delta, theta, alpha and beta bands correspondingly. The most affected connections were posterior frontal-occipital pathway for the delta band, right parietal-occipital connection for the theta band, anterior frontal-left parietal for the alpha band and left temporal-left parietal for the beta band. In sum, ASD is associated with reduced connectivity measured by EEG in four frequency bands. The alpha and delta band connectivity was affected stronger than theta and beta bands. The most affected areas were located anterior in the alpha and delta bands and posterior in the theta and beta bands. Our findings extend previously reported disruptions in the resting-state EEG connectivity in children with ASD to Chinese population.

Title: Personalized Cerebellar Connectomic Signatures in Autism Spectrum Disorder

Authors: *F. D'OLEIRE UQUILLAS[1], E. BUEICHEKÚ[2], J. SEIDLITZ[3], K. STEELE[1], B. LI[1], R. GESUE[1], M. LATIF[1], T. FASULO[1], M. TROTTER[1], J. YAO[1], J. VERPEUT[4], H.-J. BOELE[1], J. SEPULCRE[2], S. S.-H. WANG[1], J. GOMEZ[1];

Sch., Boston, MA; [3]Children's Hosp. of Philadelphia, Univ. of Pennsylvania, Philadelphia, PA; [4]Dept. of Psychology, Arizona State Univ., Tempe, AZ

Abstract: Cerebellar injury at birth is the largest non-genetic risk factor for Autism Spectrum Disorder (ASD). Although brain regions develop in synchrony over childhood, the detailed connectomic intersections between cerebellar-subcortical-neocortical circuits and ASD remain poorly understood. Using within-subject measures of regional morphological covariation, we

estimated ASD-related alterations along the cerebellar-thalamic-neocortical pathway across childhood.
Methods: T1w MRI data from 69 children from the Autism Brain Imaging Data Exchange (94% males, 40% controls, median age 8±2 years, mean ± SD; range 5 to 17 years old) were used to compute individualized structural covariance networks. Local/intra-region (cerebellar-cerebellar, thalamic-thalamic connections) and distributed/inter-region (cerebellar-thalamic, thalamic-neocortical connections) graph-metrics of topological structural integrity (nodal degree, participation coefficient, edge-betweenness, global efficiency, small-worldness) were used as variables in general linear models to test for age x group interactions, corrected for multiple comparisons (false discovery rate $q<0.05$).
Results: At the local level, we found age by group effects in the nodal degree of cerebellar dentate nuclei ($p=0.015$), and thalamic medial ventral reuniens (mvR) nuclei ($p=0.02$). At the distributed level, we found effects in the participation coefficient of cerebellar dentate nuclei ($p=0.014$), medial geniculate (MGN) ($p=0.001$) and mvR ($p=0.001$) thalamic nuclei. Alterations in edge-betweenness were found from thalamic mediodorsal- lateral nuclei to inferior prefrontal gyri ($p=0.018$), ventral anterior nuclei to orbitofrontal cortex ($p=0.010$), central medial nuclei to parieto-occipital cortex ($p<0.0001$), and ventral anterior magnocellular nuclei to lateral occipital cortex ($p=0.043$).
Conclusions: The coordinated structural development of the cerebellar-thalamic-neocortical pathway is atypical in ASD children. A compromised nexus between cerebellum and neocortex is characterized by topological alterations in cerebellar dentate nuclei, MGN and mvR thalamic nuclei at both local and distributed levels. This investigation builds groundwork for studies that can evaluate the cerebellum as an important bellwether and site for intervention in ASD.

Title: Effects of visual and proprioceptive inputs on postural stability in individuals with autism spectrum disorder (ASD)

Authors: *D. SHIRLEY[1], B. KARMAKAR[1], Z. WANG[1], R. SHAFER[2], W. MCKINNEY[2], M. MOSCONI[2];
[1]Univ. of Florida, Gainesville, FL, FL; [2]Univ. of Kansas, Lawrence, KS

Abstract: Sensorimotor impairments are prevalent in autism spectrum disorder (ASD), though the degrees to which disruptions of individual sensory modalities affect motor control and execution in patients are not well understood. Previous studies have suggested that individuals with ASD show increased postural sway when visual information is occluded or proprioceptive illusion is introduced. The current study aimed to evaluate the interactive effect of both visual and proprioceptive inputs on postural stability and complexity in individuals with ASD. Forty-one individuals with ASD (ages 10-35 years) and 18 typically developing (TD) controls completed static stances on a force platform. Lightweight tendon vibrators (TVs) were attached to each of the Achilles tendons of participants' ankle joints. They vibrated at a frequency of 80 Hz when turned on, creating a transient proprioceptive illusion of lengthening of tendons and leaning forward. Participants completed four testing conditions: TVs turned on or off (TVon vs. TVoff) and with or without lights (LTon vs. LToff) in the room. Postural sway variability was quantified using the center of pressure (COP) trajectory length and COP standard deviation in the anterior-posterior (COP_{AP}) and mediolateral (COP_{ML}) directions. Postural sway complexity was quantified using the mutual information of COP_{AP} and COP_{ML} and detrended fluctuation analysis (DFA) of each COP time series. Individuals with ASD showed increased COP length and COP standard deviation in both directions relative to TD controls. Female individuals with ASD showed COP length and COP_{ML} standard deviation reductions relative to male patients, but this sex difference was not identified in TDs. COP length and COP_{AP} standard deviation and DFA in both directions increased significantly in TDs during TVon conditions. DFA in the ML direction also increased in TDs during LTon trials relative to LToff stances. Neither sensory manipulation (TVoff, LToff) showed an impact on COP or DFA measures in individuals with ASD. Our results suggest that while postural control in TDs is affected by degradation of proprioceptive or visual feedback, alterations of these sensory inputs did not disrupt postural stability in ASD indicating these sensory feedback mechanisms show minimal contributions to postural control in patients. Our study also is the first to identify sex differences during gross motor tasks involving multiple sensory interferences in ASD suggesting studies investigating ASD-specific sex differences in sensorimotor functioning are needed to clarify key neurodevelopmental processes that may vary across male and female patients.

Title: Abnormal alpha power spectra, modulation, and connectivity in low-functioning individuals with autism with intact exogenous attention

Authors: *K. SUNG;
Counseling Special Educ. and Neurosci. Div., Emirates Col. For Advanced Educ., Abu Dhabi, United Arab Emirates

Abstract: Some studies have shown that individuals with autism have attenuated resting-state EEG alpha (8 - 13 Hz) power and less modulation due to sensory stimulation. However, such findings were inconsistent across studies and limited to high-functioning autism (HFA), which may not represent the entire autism population. In this study, I recorded 256-channel EEG of adults with low-functioning autism (LFA; n=6) performing an exogenous cueing task after training, along with adults with HFA (n=6) and those typically developed (TD; n=6). In the experiment, participants used a computer mouse to identify a target that spatially coincides within a rectangular cue (valid cue; 80% of trials) or not (invalid cue; 20%). I adapted independent component and wavelet analyses to examine the time course of the alpha power change along the sequence of stimulus windows: blank baseline (500ms), fixation (500ms), cue (600ms), and target (500ms). The response time (RT) and visually evoked potential (VEP) were also examined. The results showed that all participants responded faster for the valid cue than the invalid cue condition, although the overall RTs were slower in the LFA than the HFA and TD groups. The permutation test of VEPs of the two cue conditions also showed a significant difference in all groups, demonstrating intact exogenous attention in these measures. However, participant groups showed quite different patterns of alpha oscillation over Oz and Fz. In TD, the alpha power peaked in the blank baseline and gradually decreased along the course of the stimulus presentation. The HFA group showed a similar pattern of alpha power change as TD but had a reduced alpha power peak in the baseline. The LFA group showed much more attenuated alpha power than the HFA group and showed no alpha change across stimulus windows. The topographic map of all channels also confirmed these findings. The functional connectivity analysis revealed a strong frontal-occipital alpha (10 Hz) coherence in the TD and HFA groups but no such connectivity in the LFA group. Instead, the LFA group had robust local connectivity in the frontal and posterior areas. The theta (5 Hz) band activity also showed a similar pattern of connectivity. While exploratory, the results replicated the primary finding of our previous study

that alpha oscillation is critically impaired in LFA, demonstrating the importance of the inclusion of individuals with LFA in studies. Importantly, if the alpha oscillation reflects a control mechanism of cortical activities, as some have claimed, these results indicate that the cortical alpha activity could serve as an electrophysiological marker for severe cases of autism.

Title: Distinct Auditory ERPs in Autism with and without Disproportionate Megalencephaly

Authors: *P. DWYER[1], S. VUKUSIC[2], A. SILLAS[2], C. D. SARON[2], S. M. RIVERA[1];
[1]Psychology, [2]Ctr. for Mind and Brain, UC Davis, Davis, CA

Abstract: Introduction
Prior research suggests that autism spectrum development (ASD) with disproportionate megalencephaly (ASD-DM) is a meaningful neurophenotype differing behaviourally from ASD with normal brain size (ASD-N), with implications for development and cognitive abilities. This study explored the functional correlates of DM in early development by examining auditory ERPs in ASD-DM, ASD-N, and typical development (TD) with normal brain size (TD-N).
Methods
Included participants were 47 TD-N (40 male, M_{age} = 36.72mos, M_{DQ} = 104.71), 78 ASD-N (67 male, M_{age} = 38.35mos, M_{DQ} = 56.60), and 14 ASD-DM (12 male, M_{age} = 37.64mos, M_{DQ} = 56.83). Groups were selected not to differ in age and (ASD only) cognitive ability. DM was defined by total cerebral volume (structural MRI) to height ratios 1.5 SDs above TD mean. While watching a quiet video, participants heard, via headphones, brief complex 50-80 dB tones (~250 trials/intensity; ISI 1-2s). 61-channel EEG was sampled at 1 kHz, average-referenced, and processed using SOBI ICA. P1 values were mean amplitudes over fronto-central channels ±50 ms around the grand-average peak/intensity: 73-173 ms (50 dB), 59-159 ms (60 dB), 46-146 ms

(70 dB), and 45-145 ms (80 dB). N2 values were quantified as mean voltages over fronto-central channels between 201-350 ms. Amplitudes were entered into mixed ANOVA (group x hemisphere x intensity).

Results

There was a main effect of group on P1 amplitudes, $F = 3.10$, $p < .05$, driven by attenuated responses in ASD-DM relative to TD-N, $F = 9.83$, $p = .003$, as well as trending smaller responses in ASD-DM than ASD-N, $F = 3.46$, $p = .07$. ASD-N and TD-N did not differ, $F = 0.79$, $p = .37$. There were no P1 main effects or interactions involving hemisphere or intensity. There was also a trend towards an effect of group on N2 amplitudes, $F = 2.66$, $p = .07$. This was driven by attenuation of the N2 in ASD-DM, $F = 3.71$, $p = .06$, and ASD-N, $F = 3.74$, $p = .06$, relative to TD-N. N2 amplitudes in ASD-DM and ASD-N did not differ, $F = 0.60$, $p = .44$. An omnibus main effect of intensity, $F = 9.77$, $p < .0001$, was driven by larger N2 responses to 70 dB than 50 dB tones and to 80 dB than 50 or 60 dB tones.

Discussion

Across intensities, the P1 response appears selectively attenuated in ASD-DM, while ASD-N and TD-N show similar ERPs in the P1 time window. In contrast, in the later N2 window, ASD-DM and ASD-N both exhibit similar ERPs that trend towards attenuation compared to TD-N. Overall, these results suggest DM status in ASD is associated with appearance of atypicality in cortical auditory ERPs more quickly after stimulus onset. However, the neurophysiological basis of this observation is as yet unclear.

Title: Atypical cortical and subcortical brain activation associated with precision visuomotor control in autistic adults

Authors: *Z. WANG[1], S. COOMBES[1], D. VAILLANCOURT[1], D. SHIRLEY[1], G. VALCANTE[1], A.-M. ORLANDO[1], R. ROMERO[1], B. KARMAKAR[1], A. WAGLE SHUKLA[1], M. MOSCONI[2];
[1]Univ. of Florida, Gainesville, FL; [2]Univ. of Kansas, Lawrence, KS

Abstract: Although conceptualized as a childhood disability, autism spectrum disorder (ASD) has increasingly been recognized as a lifelong neurological condition that could significantly impact adult functioning and quality of life. A recent clinical study has identified a more than 25-fold increased risk of Parkinsonism from two independent cohorts of autistic adults, suggesting that neurological conditions may evolve and even become more prominent as affected individuals age. However, studies focused on neuromotor control in autistic adults are scant, and we do not yet know to what degrees autistic adults might be at risk of developing neurological symptoms and neurophysiological systems show abnormal levels of degeneration. Sixteen autistic adults ages 30-73 years and 19 age-, sex-, and IQ-matched non-autistic controls completed a visually guided precision grip task during fMRI. Participants pressed an MRI-compatible load cell with their thumb and forefinger while viewing two horizontal bars from a visual display inside the scanner. Participants pressed to move the lower force bar upwards to the height of the static target bar and maintained a constant grip force for 2 sec followed by a one sec rest. A total of 4 blocks (10 trials/ block) were administered and alternated with 10 sec rest. The target bar was set at 15% of individuals' maximum voluntary contraction (MVC). Grip force variability and peak force were examined. Whole brain, voxelwise analyses were conducted on the fMRI imaging data. Our results showed no group differences in MVC. Autistic adults showed both mean and peak force reductions relative to non-autistic controls. Increased BOLD signal was observed in well-established regions of the visuomotor network including motor and premotor cortex, inferior parietal lobule, extrastriate visual cortex, thalamus, putamen, and cerebellum. Autistic adults showed greater BOLD activation than controls in the left precentral (M1) and postcentral (S1) gyrus, bilateral inferior frontal gyrus (IFG), and right cerebellum lobule VIII (CBL.VIII). Increased age was associated with increased task-related activation in bilateral IFG and right CBL.VIII in ASD. In contrast, increased age was associated with activation reductions of the left M1, RIFG, and right CBL.VIII in non-autistic controls. In autistic adults, decreased activation of RIFG was associated with more severe clinical ratings of repetitive behaviors. Overall, these results provide new evidence that neuromotor alterations in autistic adults involve aberrant cortical and subcortical organization that may contribute to critical aging-related clinical issues in ASD.

Title: The transgenerational inheritance of circadian disturbances in a valproic-acid (VPA) model of Autism Spectrum Disorder

Authors: *S. FERRARO, N. DE ZAVALIA, N. QUTEISHAT, S. AMIR;
Concordia Univ., Montreal, QC, Canada

Abstract: Autism Spectrum Disorder (ASD) is a heterogenous group of disorders with similar and overlapping symptomology but differential clinical progression and severity. Disturbances within the circadian system are a prevalent pathological accompaniment of ASD but remain unaddressed in ASD individuals, presenting significant lifelong challenges. Over the past two decades the incidence of ASD diagnoses has continued to rise, leading to the suggestion that epigenetic mechanisms may underlie both the emergence of maladaptive behaviours seen in the disorder and the increased prevalence of ASD within the population. Previous research has documented that both the ASD-like behaviours and the neurobiological alterations resulting from *in utero* exposure to valproic acid (VPA), persist into the F3 generation. In this study we explored whether comorbid circadian disturbances previously described in the VPA-exposed F1 generation were also present in the F2 and F3 generations. We produced a patrilineal breeding scheme wherein 5-month-old Wistar males exposed to either saline (n = 6) or VPA (n = 6) *in utero* were mated with naïve females (n = 12) to produce the F2 generation. Males from the F2 generation were similarly mated to produce the F3 line and all animals underwent circadian locomotor analysis. We demonstrate that the emergence of disorganized circadian behaviour arising from altered photic-entrainment capacity is present in F2 and F3 VPA-exposed lineages. Moreover, we show a sexually dimorphic persistence of these behaviours wherein males, but not females, demonstrate a longer and more stable presentation of circadian rhythm disruption across all three generations. These findings demonstrate that deleterious comorbid disturbances in the circadian timing-system can also be transmitted through generations and emphasize the urgent need for novel therapies addressing ASD comorbidities.

Title: Peptide Lv augments intermediate conductance calcium-dependent potassium (IK_{Ca}) channels

Authors: *D. L. PHAM[1], G. Y.-P. KO[2];
[1]Vet. Integrative Biosci., [2]Vet Integrative Biosci., Texas A&M Univ., College Station, TX

Abstract: Peptide Lv is an endogenous secretory peptide (~40 amino acids) expressed in various organs and tissues including the neural retina, brain, and vascular endothelium. Peptide Lv is named for its ability to increase the mRNA and protein expression of L-type voltage-gated calcium channels (LTCCs) in cultured neurons and cardiomyocytes. Peptide Lv is upregulated in the neural retina and retinal microvascular endothelium in diabetic animals and patients with proliferative diabetic retinopathy. Although it is able to promote endothelial proliferation and pathological angiogenesis, the detailed mechanism of its angiogenic action is unclear. Endothelial potassium (K) channels are important for endothelial hyperpolarization and function since inhibition of endothelial K channels dampens the endothelial cell (EC) proliferation, an essential property for angiogenesis. The hypothesis is that the angiogenic action of peptide Lv is through endothelial K channels. We found the treatment with peptide Lv in cultured ECs increased the mRNA and protein levels of intermediate conductance calcium-dependent potassium (IK_{Ca}) channels. Interestingly, peptide Lv had no effect on other endothelial K channels such as ATP-sensitive potassium (K_{ATP}) and small conductance K_{Ca} channels. Whole-cell patch-clamp recordings on cultured ECs were performed to further examine the effects of peptide Lv on endothelial hyperpolarization and endothelial IK_{Ca}. Cultured ECs treated with peptide Lv was significantly hyperpolarized, and peptide Lv significantly enhanced IK_{Ca} current density. Blocking IK_{Ca} dampened peptide Lv-elicited EC proliferation. Thus, the angiogenic action of peptide Lv is in part through the augmentation of endothelial IK_{Ca}. This work is funded by NIHR21EY031813-01A1 to GK.

Title: Sumoylation of the kv4.2 ternary complex increases current amplitude and surface expression by blocking internalization

Authors: *M. WELCH[1], L.-A. R. JANSEN[2], D. J. BARO[3];
[1]Georgia State Univ., Hampton, GA; [2]Georgia State Univ., Atlanta, GA; [3]Dept Biol, Georgia State Univ. Dept. of Biol., Atlanta, GA

Abstract: A family of Kv4 -subunits mediate a transient A-type potassium current, IA. Kv4 channels exist as ternary complexes with potassium channel interacting protein (KChIP1-4) and dipeptidyl peptidase like protein (DPP6/10). Multiple ancillary proteins associate with Kv4 throughout its lifetime to regulate function and expression. How interactions within the Kv4 macromolecular complex are modulated is poorly understood. Small ubiquitin-like modifier (SUMO) is an 11kD peptide post-translationally added to lysine (K) residues to control protein-protein interactions. To test if Kv4 SUMOylation modulates ternary complex interactions, human embryonic kidney (HEK) cells were co-transfected with 3 plasmids encoding a Kv4.2 GFP fusion protein (Kv4.2g), KChIP2a and DPP10. SUMOylation was or was not increased by co-expressing plasmids encoding SUMO and the SUMO conjugating enzyme, Ubc9. Whole cell patch clamp recordings showed increasing SUMOylation in HEK cells expressing Kv4.2g ternary complexes produced a significant 35% increase in IA maximal conductance (Gmax) (t test $p<0.05$), and cell surface biotinylation experiments revealed a significant 30% increase in Kv4.2g surface expression (t test $p<0.05$). A biotin internalization assay showed increasing Kv4.2g ternary complex SUMOylation significantly reduced channel internalization by 65% (t test $p<0.05$). Experiments were repeated using a mutant Kv4.2g construct where a previously identified SUMOylation site, K579, was mutated to arginine (R). Overexpressing SUMO and Ubc9 with Kv4.2g K579R +KChIP2a +DPP10 no longer produced the significant increase in IA Gmax (t test $p=0.98$) or surface expression (t test $p=0.53$), or the significant decrease in internalization (t test $p=0.34$). Ternary complex internalization depends upon the levels of endocytosis and subsequent recycling. Blocking endocytosis with Pitstop2 significantly increased IA Gmax by 57% (One Way ANOVA, Tukey's post hoc $F(3,38)=7.7$, $p<0.05$). Including SUMO peptide in the patch pipette significantly increased IA Gmax by 56% (Tukey's $p<0.05$). No further significant increase was observed when SUMO was co-applied with Pitstop2 (Tukey's $p=0.83$). Pitstop2 mimicked and occluded the effect of SUMO. Surprisingly, the association of Kv4.2g with the major adaptor for clathrin-dependent endocytosis, AP2, was not affected by overexpressing SUMO and Ubc9 (t test $p=0.66$). These data suggest that the effect of SUMOylation is downstream of endocytosis. Future experiments will test if SUMO affects Kv4.2g recycling. In sum, we show SUMOylation of Kv4.2g K579 increases IA Gmax mediated by the ternary complex by reducing internalization.

Title: SPHKAP anchors type-I PKA at neuronal somatic ER-PM junctions formed by Kv2.1 channels

Authors: *N. C. VIERRA[1], D. VAN DER LIST[1], M. KIRMIZ[2], J. S. TRIMMER[1];
[1]Physiol. & Membrane Biol., Univ. of California, Davis, Davis, CA; [2]Mol. and Cell. Physiol., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The voltage-gated K^+ (Kv) channel Kv2.1 is present in dense clusters on the plasma membrane (PM) of the somata, proximal dendrites, and axon initial segments of most brain neurons. In addition to its significant role in controlling electrical excitability, Kv2.1 also serves a non-canonical structural function in tethering the PM to the endoplasmic reticulum (ER) to form ER-PM junctions. To identify specific neuronal functions linked to Kv2.1-associated ER-PM junctions, we have started to define their molecular composition by immunopurifying (IPing) Kv2.1 from mouse brain and analyzing the IPed complexes by protein mass spectrometry. This approach allowed us to show that Kv2.1-associated ER-PM junctions enable compartmentalized Ca^{2+} signaling in the neuronal soma by promoting the clustering of the voltage-gated L-type Ca^{2+} channel (LTCC) Cav1.2 at ER-PM junctions (Vierra et al., eLife e49953, 2019). We have now identified cAMP-dependent protein kinase A (PKA)-related signaling proteins that also associate with Kv2.1 at ER-PM junctions. PKA regulates critical neuronal functions, including transcription, synaptic plasticity, and electrical activity. Spatiotemporal specificity of PKA substrate phosphorylation is determined by its binding to A-kinase anchoring proteins (AKAPs) that target PKA to spatially restricted signaling microdomains. Prominent in our Kv2.1 IP experiments was an AKAP called SPHKAP. Immunolabeling of brain sections from mice and rats of both sexes and cultured rat hippocampal neurons revealed co-clustering of SPHKAP with Kv2.1 and PKA-RIα, suggesting a unique role for PKA-RI at somatic ER-PM junctions. We also determined that SPHKAP clustering was sensitive to Kv2 channel-mediated ER-PM junction formation, as mice lacking Kv2 channels showed reduced somatic SPHKAP cluster size. In neurons, activation of certain PKA-associated signaling pathways is initiated by Ca^{2+} and PKA crosstalk enabled by AKAPs that place PKA near LTCCs. To test whether SPHKAP enables Ca^{2+}/PKA crosstalk at somatic ER-PM junctions, we performed shRNA-mediated knockdown of SPHKAP in cultured rat hippocampal neurons. We found that SPHKAP knockdown significantly reduced the amount of PKA molecules in close proximity to somatic Cav1.2 channels, impaired depolarization-evoked Ca^{2+} influx, and decreased LTCC-dependent activation of CREB and c-Fos, two transcription factors involved in learning and memory. Together, these data reveal that SPHKAP is targeted to somatic ER-PM junctions formed by Kv2.1 channels and promotes PKA-dependent regulation of somatic Ca^{2+} signals that are coupled to depolarization-dependent gene expression.

Title: Modulating Hippocampal Glutamate Release with Kv2-Mediated Endoplasmic Reticulum/Plasma Membrane Junctions

Authors: *L. C. PANZERA[1], I. CHO[1], A. N. LEEK[2], M. M. TAMKUN[2], M. B. HOPPA[1]; [1]Dartmouth Col., Hanover, NH; [2]Colorado State Univ., Fort Collins, CO

Abstract: Endoplasmic reticulum/plasma membrane (ER/PM) junctions act as subcellular hubs important for mediating calcium homeostasis, protein localization and lipid exchange. Although a number of ER proteins can interact with lipids on the PM, specific proteinaceous PM anchors that form stable ER junctions have remained elusive. The voltage-gated potassium channel Kv2.1 is the first PM protein found to engineer ER/PM junctions through interaction and recruitment of the transmembrane ER protein VAMP-associated protein (VAP). While Kv2.1 has a canonical conducting role in shaping electrical activity in the somatodendritic compartment, a non-conducting population of Kv2.1 channels form ER/PM junctions occupying ~10% of the neuronal soma. These sites are involved in trafficking, vesicle fusion, and the delivery of membrane proteins to the PM in addition to being sites of neuron-glia contact. Here, we present data in cultured hippocampal neurons that loss of Kv2.1 decreases the ability of the somatic ER to fill with calcium during electrical stimulation. More importantly, and in contrast to Kv2.1 dogma, we go on to demonstrate that Kv2.1 is enriched in synaptic terminals where it exclusively engages in a non-conducting role, significantly altering both ER calcium handling and synaptic function. Using noninvasive optical indicators, we reveal that genetic knockdown of Kv2.1 impairs stimulation-evoked calcium uptake into the ER and decreases synaptic vesicle exocytosis. Further, localization of Kv2.1 as well as VAP recruitment to terminals were found to be important for maintaining the unique role of these ER/PM junctions with regards to several aspects of synaptic physiology.

Title: Cav2.3 is required for A-type K^+ current regulation of spontaneous synaptic input in hippocampal dendrites

Authors: *J. G. MURPHY[1], J. J. GUTZMANN[1], L. LIN[1], J. HU[1], R. S. PETRALIA[2], Y.-X. WANG[2], D. A. HOFFMAN[1];

Abstract: The transient voltage-gated K^+ current (I_A) mediated by Kv4.2 in CA1 hippocampal pyramidal neurons regulates dendritic excitability, synaptic plasticity, and learning. We report that the voltage-gated Ca^{2+} channel Cav2.3 forms an ion channel complex with Kv4.2 and promotes I_A in CA1 pyramidal neurons. We found that Ca^{2+} binding auxiliary subunits of the Kv4.x family, known as K^+ channel interacting proteins (KChIPs), mediate Cav2.3 Ca^{2+} influx-mediated stabilization of Kv4.2 plasma membrane localization. We characterized the Cav2.3-Kv4.2 complex using immunofluorescence colocalization, coimmunoprecipitation, electron microscopy, FRAP, and FRET. Functionally, Cav2.3 Ca^{2+}-entry was found to promote whole-cell I_A due to an increase in Kv4.2 surface expression in heterologous cells and hippocampal neurons. Pharmacological block of Cav2.3 in neurons reduced whole-cell I_A which was less effective in Cav2.3 knockout (KO) mouse neurons. We also found reduced whole-cell I_A and an impaired proximal-distal dendritic I_A gradient in Cav2.3 KO neurons. Furthermore, reduced dendritic I_A in Cav2.3 KOs was found to occlude I_A-mediated regulation of excitatory synaptic currents and spine Ca^{2+} transients. These results reveal an intermolecular Cav2.3-Kv4.2 complex impacting basal synaptic function in CA1 hippocampal neurons.

Title: Transient ultrasound stimulation has lasting effects on neuronal excitability and whole-cell potassium currents.

Authors: *B. CLENNELL, T. G. J. STEWARD, B. W. DRINKWATER, D. J. WHITCOMB; Univ. of Bristol, Bristol, United Kingdom

Abstract: Background: Transcranial ultrasound stimulation can acutely modulate brain activity, but the lasting effects on neurons are unknown. We have previously shown that brief ultrasound stimulation resulted in the enhancement of intrinsic excitability of cultured cortical rat neurons, and this effect lasted for at least 8 hours (Clennell et al. 2021. Brain Stimul. 14(2):217-225). We subsequently investigated the effect on whole-cell sodium and potassium currents.
Objective: To assess the effect of transient ultrasound stimulation on neuronal excitability and whole-cell ion currents.
Methods: Primary rat cortical neurons were stimulated with a 40 second, 200kHz pulsed ultrasound stimulation or sham-stimulation. Intrinsic excitability was investigated through whole-cell patch-clamp recording by evoking action potentials (APs) in response to somatic current injection. Whole-cell sodium and potassium currents were recorded in response to sequential voltage steps in the presence of relevant ion channel blockers. Recordings were taken at set timepoints following ultrasound stimulation: 0-2 hours, 6-8 hours, 12-14 hours and 24-26 hours.
Results: In the 0-2 hour window, neurons stimulated with ultrasound displayed an increase in the mean frequency of evoked APs of 32% above control cell levels ($p = 0.023$). After 6-8 hours this increase was measured as 44% ($p = 0.0043$). By 12-14 hours this effect was eliminated and remained absent 24-26 hours post-stimulation. These changes to AP firing rates occurred in conjunction with statistically significant differences in AP kinetics that were similarly eliminated by 24-hours. We did not find any significant differences in the magnitude or kinetics of whole-cell sodium currents at any timepoint. Conversely, we did observe statistically significant increases in whole-cell potassium currents at 0-2hr ($\Delta I_{peak} = 24\%$, $p = 0.004$), 6-8hr ($\Delta I_{peak} = 20\%$, $p = 0.001$) and 12-14hr ($\Delta I_{peak} = 25\%$, $p < 0.001$) hours post-stimulation, which may explain the observed enhancement of AP repolarisation rates. Similar to the observed effects on excitability and AP kinetics, these changes were absent by 24-hours.
Conclusion: Stimulating neurons with 40 seconds of ultrasound enhances their excitability for up to 8 hours in conjunction with modifications to action potential kinetics. In addition, ultrasound induces sustained increases in whole-cell potassium currents suggesting changes to voltage-gated potassium channel function that may underpin the observed modifications to AP firing**.** These results can inform the application of transcranial ultrasound in experimental and therapeutic settings.

Title: Optical voltage recordings reveal multiple gradients in action potential repolarization in the proximal axon

Authors: *N. A. K. HANEMAAIJER[1,2], J. D. ELBERSE[1], M. H. P. KOLE[1,2];
[1]Dept. of Axonal Signaling, Netherlands Inst. for Neurosci. (NIN), Royal Netherlands Acad. of Arts and Sci. (KNAW), Amsterdam, Netherlands; [2]Cell Biology, Neurobio. and Biophysics, Dept. of Biology, Fac. of Sci., Utrecht Univ., Utrecht, Netherlands

Abstract: The axon initial segment (AIS) is a unique region of the proximal axon where the action potential (AP) is initiated to propagate forward into the axon and backward into the soma and dendrites. Within the AIS, the speed of AP repolarization is critical for the voltage-gated sodium channels to recover from inactivation, thereby determining the temporal dynamics for the next AP. Axons contain a large variety of potassium channels shaping repolarization, of which voltage-gated potassium channels (K_V, specifically K_V1) and large-conducting calcium- and voltage-dependent potassium (BK_{Ca}) channels directly mediate AP repolarization in the AIS. To better understand the detailed temporal and spatial properties of AP repolarization and the contribution of these channels, we used voltage-sensitive dye imaging to optically record the AP from the first 90 µm of rat L5 pyramidal axons in acute slices, which allowed us to compare the AP shape from regions within the same axon, including the myelinated internode. By optimizing holographic illumination, we restricted excitation light to the region of interest, which minimized light scattering from other neurites and maximized signal accuracy, enabling voltage-calibrated optical recordings at 50 µs and ~3 µm, temporal and spatial resolution, respectively. The results showed that the AP characteristics highly differed between axonal domains, with AP half-width being progressively narrower towards the distal AIS and within the internode in comparison to the proximal AIS (~350 µs vs ~720 µs, respectively, $n > 30$, $p < 0.001$). Next, we pharmacologically investigated which potassium channels contribute to setting the AP width in each axonal domain. Blocking K_V channels with 4-AP revealed an increase in the AP width in all regions of the axon. The effect of 4-AP became more pronounced with distance from the soma, with the width being increased to ~140% in the proximal AIS and to ~250% in the myelinated internode, consistent with the known expression of K_V channels. In contrast, application of Iberiotoxin, a blocker of BK channels, specifically increased the AP half-width in the proximal AIS to ~125% but not in other axonal domains. We are complementing these experimental approaches with computational simulations in COMSOL, studying the concerted action of

different ion channels at the nanoscale level. To summarize, using holographic voltage imaging, we show that distinct mechanisms control the AP repolarization in the forward and backward direction.

Title: Kv3.1 enables sub-millisecond spikes in upper vocal-motor neurons

Authors: *B. ZEMEL[1], A. NEVUE[2], P. V. LOVELL[3], C. V. MELLO[3], H. P. VON GERSDORFF[4];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]OHSU, Portland, OR; [3]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR; [4]Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The speed and accuracy of muscle control and coordination for execution of fine motor skills depend on the spiking activity of upper motor neurons. In mammals, there is robust evidence that specific subclasses of these neurons contain unique excitable features that may enable the temporal precision required for fast, complex behaviors. Zebra finches provide an excellent model system for testing how a unique population of upper motor neurons provide the temporal precision required for a rapid, precise behavior. Their songs consist of motifs containing syllables with complex acoustic structure on a sub-second time scale. This behavior is controlled by pallial nuclei that form microcircuits considered analogous to those in the layered mammalian neocortex. Specifically, the vocal-motor projection neurons of the robust nucleus of the arcopallium (RAPNs) provide direct input to brainstem vocal and respiratory neurons, and are spatially separated from the upper-motor neurons of the dorsal intermediate arcopallium (AIdPNs), a region implicated in the control of somatic motor functions such as wing flapping and hopping. RA and AId have similar molecular profiles, suggesting that RA may have evolved as a specialization of AId, which is consistent with the motor theory of vocal learning origin. Here we provide strong evidence linking the expression of the Kv3.1 channel to the narrow spike

waveform produced by RAPNs. In whole cell current clamp recordings performed in brain slices from adult male finches, RAPNs exhibit fast spiking action potentials (APs) with narrower, sub-millisecond half-widths and larger maximum repolarization rates than in AIdPNs. We also show that the AP waveform in RAPNs is more sensitive to pharmacological compounds targeting Kv3.x channels than in AIdPNs. These electrophysiological findings are complemented by *in situ* hybridization data indicating that Kv3.1 is the primary transcript encoding TEA-hypersensitive channels in finch RA. We suggest that Kv3.1 regulates the intrinsic excitability of RAPNs on a sub-millisecond time scale and propose that this property allows a subclass of upper motor neurons to operate as highly specialized control units for the production of rapid and precise movements in the zebra finch. This specialization of RAPNs closely resemble those of Betz cells identified in mammals that have wide-caliber myelinated axons, fast action potential (AP) conduction velocities and ultra-narrow AP half-widths (<500μs). Thus, our findings in the finch may be of general interest in understanding the regulation of excitability in specialized cortical motor circuits in vertebrates.

Title: A molecular basis for membrane-mediated inhaled anesthesia.

Authors: *S. HANSEN[1], M. A. PAVEL[2], R. LERNER[3];
[1]The Scripps Res. Inst., Jupiter, FL; [2]Scripps Res. Inst., Jupiter, FL; [3]Scripps Res. Inst., La Jolla, CA

Abstract: For 150 years anesthetics were thought to act on the plasma membrane, but a plausible site within the membrane had never been found. Here we show that inhaled anesthetics (chloroform and isoflurane) activate Twik-related potassium channel subtype 1 (TREK-1) through a two-step membrane-mediated mechanism. The membrane mediated site is located within clusters of ganglioside (GM1) containing lipids (see figure A). The clusters are ordered, cholesterol dependent, and bind palmitoylated proteins (i.e., proteins with a saturated 16 carbon lipid covalently attached). The anesthetics dislodge palmitoylated proteins including phospholipase D2 (PLD2). Once free from GM1 lipids, PLD2 translocates to PIP_2 containing

lipids where it encounters its substrate PC and activates TREK-1 (see figure B). General anesthetics chloroform, isoflurane, diethyl ether, xenon, and propofol all activate PLD2 in a live cell assay. The distance PLD2 travels during activation is less than 50 nm and imaged by two color super resolution microscopy of fluorescently labeled lipids and proteins. The short distance traveled allows for very fast activation of PLD2 and the channel. A catalytically dead PLD2 robustly blocks anesthetic TREK-1 currents in cell patch-clamp. Localization of PLD2 renders a TRAAK channel anesthetic sensitive, a channel that is otherwise insensitive. In the whole brain of flies, anesthesia perturbs GM1 clusters and PLD^{null} flies resist anesthesia. Our results establish a membrane-mediated target of inhaled anesthesia and suggest PA helps set thresholds of anesthetic sensitivity *in vivo*. Anesthetic induced movement of proteins between GM1 and PIP_2 clusters establishes a potent and dynamic layer of nanoscopic lipid signaling. And the disruption of lipid order by high concentration of anesthetic suggests a chaotropic effect contributes to the membrane-mediated mechanism of inhaled anesthesia.

Title: A data-driven approach for identifying gene expression-electrophysiological property relationships

Authors: *A. NIGAM, S. L. HILL, S. TRIPATHY;
Krembil Ctr. for Neuroinformatics, CAMH, Univ. of Toronto, Toronto, ON, Canada

Abstract: As the influence of genes on gene expression is extensively studied with next generation sequencing technologies, the effects of gene expression on neuronal electrophysiological properties remains poorly understood. With the help of in silico approaches, we can study a large sample size of cells at a given time, infer what is happening at the cellular and molecular level, and predict future directions for experimental work. Here, to study the relationship between gene expression patterns and electrophysiological properties in silico, we developed an analysis approach to assess these relationships using large patch-seq datasets.
We looked at all the genes and ten electrophysiological properties and filtered for gene-ephys pairs that are expressed in at least 5 cells or more in our inhibitory cell datasets (Gouwens *et al*., 2020; Scala *et al*., 2020). Next, we applied linear mixed models where we looked at the influence of gene expression on an electrophysiological property at different cell type resolutions in the patch-seq dataset from mouse visual cortex and mouse motor cortex. These different cell type resolution models (Class, Subclass, and Cluster) correspond to the taxonomic classification of these neurons. The linear mixed models are then applied on each gene and electrophysiological property combination. Further, we looked into the significant gene-ephys combinations to observe which resolution is the best to study gene expression and electrophysiological property. We concluded that the gene expression - electrophysiology property relationships at the class level are the best to study. Specifically, we found multiple significant gene expression - electrophysiology property pairs from the mouse visual cortex dataset that belonged to either voltage gated ion channel genes or genes already known to be associated with epilepsy. Moreover, we have been focusing on exploring the associations between the 40 potassium voltage gated ion channel genes (Ranjan *et al*., 2019) and electrophysiological properties at the subclass and cluster levels. Such gene expression - electrophysiology property associations will further increase our understanding of the mechanisms of the neurological diseases they are implicated in.
Eventually, our goal is to better understand how these genes correlated with ephys differences might intersect with genes previously linked with epilepsy in humans, with the goal of better understanding and interpreting genetic variants associated with epilepsy. Our next goal is to check whether the gene expression - electrophysiology property associations can be replicated in mouse and human excitatory cells datasets.

Title: A dendritic mechanism for retrieval-dependent memory consolidation

Authors: *E. GERON, W. GAN;
NYU, New York, NY

Abstract: Retrieval-dependent processing of a new memory improves its long-term retention. Although the positive effect of retrieval on memory strength was recognized at the beginning of the 20th century, its underlying neuronal mechanisms remain unclear. To study this, we trained mice with a modified fear conditioning paradigm, where a presentation of a reminder tone, shortly after tone-shock pairing, improved long-term memory retention. We next constructed a platform with which mice were conditioned while their brains were imaged via two-photon microscopy. We found that reminders induced a substantial increase in Ca^{2+} spike generation in apical dendrites of layer 5 pyramidal neurons (L5 PNs) of the primary motor cortex. The potency of reminders to evoke Ca^{2+} spikes was transient, occurring within less than 30 minutes after tone-shock pairing. Notably, different dendritic branches of individual L5 PNs exhibited Ca^{2+} spikes with different amplitudes. On branches with high Ca^{2+} spike amplitudes, spines were more likely to be activated before the spikes, and to undergo long-lasting weakening (depotentiation). In contrast, spines on branches with lower Ca^{2+} spike amplitudes tended to be activated after Ca^{2+} spike generation, and only spines with high activity during spiking underwent weakening. In addition, optogenetic inhibition of CaMKII, shortly after reminder-induced spikes, disrupted spine weakening, spike transience, and conditioned freezing. These results reveal that early reminders trigger the generation of dendritic spikes to cause branch-specific synaptic plasticity to support retrieval-dependent improvement of memory retention.

Title: Integrating neuron-glia knowledge and computational modeling to understand cortical synaptic plasticity

Authors: T. MANNINEN[1], A. SAUDARGIENE[2], ***M.-L. LINNE**[1];
[1]Fac. of Med. and Hlth. Technol., Tampere Univ., Tampere, Finland; [2]Neurosci. Inst., Lithuanian Univ. of Hlth. Sci., Kaunas, Lithuania

Abstract: Synaptic plasticity is expressed in the brain in diverse forms across multiple timescales. In the neuron-centric view, changes in neuronal activity and synaptic plasticity depend solely on the intrinsic properties of neurons and the information transmitted. However, non-neuronal glial cells, particularly astrocytes, have recently been shown to dynamically modulate synaptic transmission and plasticity. Several biochemical and biophysical mechanisms of astrocytes have been proposed to be involved in synaptic transmission and plasticity and the mechanisms involved seem to depend on the developmental stage of an animal, brain area, and neural circuitry. We are interested in studying different forms of synaptic plasticity in cortical synapses during postnatal development. We use our previously developed computational model for spike-timing-dependent long-term depression (t-LTD) at layer 4 to layer 2/3 synapse in somatosensory cortex as the base of our work (Manninen et al., 2020). The study involved using a multitude of data from molecular, biochemical, and electrophysiological experiments in rodent somatosensory cortex during postnatal development. The model links presynaptic, postsynaptic, and astrocytic mechanisms to the time window of t-LTD induction. In our model, postsynaptically released endocannabinoids increase astrocytic calcium signaling which in turn induces exocytosis of glutamate. Glutamate exocytosis from an astrocyte can further activate presynaptic N-methyl-D-aspartate receptors coupled with calcineurin signaling and influence synaptic properties dynamically. In the present study, we performed computational sensitivity analysis for the key model variables with an aim to extend the model to express different plasticity forms of cortical synapses in addition to t-LTD. Our results contribute to better understanding of synaptic plasticity mechanisms during postnatal development in health and disease. The novelty of our work is that we incorporate not only the neuronal mechanisms but also several astrocytic mechanisms responsible for synaptic plasticity.

Title: Thalamic inputs to cortical layer 5 neurons strengthen within a subcellular critical period

Authors: *C. E. YAEGER, D. VARDALAKI, N. J. BROWN, M. T. HARNETT;
McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: On the cellular level, neural plasticity is a function of pre and post-synaptic properties, such as the pattern of presynaptic innervation, postsynaptic receptor content and integration, and their convergent activity. During postnatal development, plasticity occurs in functional cascades, where specific synapses are plastic during defined windows of time. To achieve precise synaptic changes, do single neurons maintain distinct plasticity rules for functionally-specific inputs? Here we show that the apical oblique dendrites of layer 5b neurons in primary visual cortex have a developmentally restricted window of plasticity for feedforward thalamic input. We find that within layer 5b neurons, the oblique dendritic compartment is the sole recipient of input from the dorsolateral geniculate nucleus of the thalamus. In adult cortex, synapses on oblique dendrites integrate inputs linearly with minimal calcium influx and lack the capacity for NMDA-dependent potentiation, unlike neighboring basal dendrites. However, oblique dendrites can sustain NMDA-dependent nonlinearities, calcium spikes, and plasticity during early postnatal development (P14-21). The transition to adult properties is apparent by postnatal day 28 and requires vision. Plasticity during this developmental time window results in the robust recruitment of AMPA receptors, and by adulthood, oblique dendrites have a higher AMPA/NMDA ratio compared to basal dendrites. Early visual experience therefore changes the postsynaptic landscape in oblique dendrites, resulting in a decreased propensity for synaptic potentiation, while basal dendrites remain plastic into adulthood. The presence of strong, linear thalamic input to the apical obliques early in development may contribute to the stability of feedforward representations while experience-dependent plasticity is ongoing in other dendritic compartments.

Title: The contribution of different postsynaptic Ca^{2+} sources and Ca^{2+}-permeable AMPA receptors to timing-dependent LTP elicited by two distinct low repeat STDP paradigms at SC-CA1 synapses

Authors: *B. KHODAIE[1,2], E. CEPEDA-PRADO[1], E. EDELMANN[1,2,3], V. LESSMANN[1,2,3]; [1]Inst. of Physiology, Otto-von-Guericke Univ., Magdeburg, Germany; [2]OVGU ESF-funded Intl. Grad. Sch. ABINEP, Magdeburg, Germany; [3]Ctr. for Behavioral Brain Sci. (CBBS), Magdeburg, Germany

Abstract: STDP is a cellular model for learning that employs low frequency repeats of coincident action potential (AP) firing in pre- and postsynaptic neurons to induce timing-dependent LTP (t-LTP). Recent evidence showed that t-LTP at SC-CA1 synapses is equally robust as high-frequency stimulation induced conventional LTP. While conventional SC-CA1 LTP depends on postsynaptic Ca^{2+} rise through NMDA receptors and L-type VGCCs, the contribution of intracellular and extracellular Ca^{2+} sources to t-LTP is not well understood. We set out to decipher the origin of postsynaptic Ca^{2+} that triggers induction of SC-CA1 t-LTP elicited by physiologically relevant low repeat STDP stimulation. We performed whole cell patch clamp recordings in acute hippocampal slices from 4 weeks old male C57Bl6 mice and used either a canonical (1EPSP/1AP) or a burst (1EPSP/4APs) STDP protocol, which was repeated just 6 times at 0.5 Hz, to induce t-LTP in CA1 pyramidal cells. The importance of postsynaptic Ca^{2+} signaling for t-LTP was initially tested with application of the Ca^{2+} chelator BAPTA (10 mM) via the patch pipette, which blocked t-LTP induced by both protocols. Bath application of APV (50 µM) and Nifedipine (25 µM) were used to test the role of NMDAR and L-type VGCCs. Contribution of mGluR signaling was tested by co-application of the mGluR1 antagonist YM298198 (1 µM), and the mGluR5 antagonist MPEP (10 µM). Contribution of GluA2-lacking calcium-permeable AMPARs (cp-AMPARs) was tested by the bath applied inhibitors NASPM (100 µM) or IEM-1460 (100 µM). To test the role of ER Ca^{2+}stores, we used bath application of 2-APB (100 µM) to inhibit IP3 receptors, and intracellular ryanodine (100 µM) to block ryanodine receptors (RyRs). Our results show that t-LTP induction by the 2 protocols (6x 1:1 and 6x 1:4) recruited different induction mechanisms. Interestingly, both protocols depended on activity of cp-AMPARs, whereas only the canonical 6x 1:1 protocol depended on Ca^{2+} entry via NMDARs and L-type VGCCs. While group I mGluRs (mGluR1 and mGluR5) contributed to t-LTP induction with the burst protocol, the canonical 6x 1:1 protocol induced t-LTP did not involve group I mGluRs. However, activation of IP3 and RyR receptor sensitive internal Ca^{2+} stores was necessary to allow t-LTP with either of the 2 protocols. Thus, while our study reveals distinct mechanisms for the initial postsynaptic Ca^{2+} rise required for the 2 low repeat t-LTP protocols, both paradigms critically depend on sustained Ca^{2+} release from the ER and Ca^{2+} influx through cp-AMPARs during test stimulation after the induction paradigm. Title: Local excitatory control of CA1 interneurons shows diverse plasticity rules in the awake, behaving mouse

Authors: *P. PAUDEL, K. BAUGH, S. MCKENZIE;
Neurosciences, Univ. of New Mexico, Albuquerque, NM

Abstract: Memories are believed to be stored in the pattern of synaptic connectivity between neurons. Coincident neural activity between connected cells is known to change synaptic strength, but the rules for how activity affects connectivity *in vivo* are largely unknown. Area CA1 of the hippocampus has been the focus of most *in vivo* electrophysiological investigations of hippocampal function, but excitatory neurons in this region primarily influence each other indirectly through inhibitory interneurons. Therefore, we tested the spike-timing dependent plasticity rules governing the excitatory synaptic strength onto local inhibitory cells. The red-shifted opsin ChrimsonR was expressed under the parvalbumin (PV) promoter to target fast-spiking interneurons, and Channelrhodopsin 2 (ChR2) was expressed under the CaMKIIα promoter to target primarily pyramidal cells. To induce plasticity, red (635 nm) and blue (473 nm) light were synchronously pulsed at 8 Hz to drive rhythmic coincident activity in pyramidal and PV+ interneurons. The effects of plasticity were assessed by measuring dose response curves to red and blue light delivered before and after pairing. Bidirectional changes in excitability were observed in both pyramidal cells and interneurons, in response to blue and red light. Even in sessions where plasticity was observed, simultaneously recorded units could show stable responses. In a second experiment, units were detected online and cross correlations between spike trains were calculated in real time to identify putatively connected pairs. After a baseline recording, firing of the presynaptic pyramidal cell was used to trigger 10 ms of red light to activate ChrimsonR in PV+ interneurons. In a subset of putatively connected pairs, this protocol strongly increased the correlation in firing between the pre- and post-synaptic cell pairs. The increase in coupling strength correlated with the efficacy of the closed-loop protocol in driving short-time scale spike-spike correlations, as expected from a Hebbian learning rule. Together, these findings show the potential for heterogeneous plasticity rules at the excitatory to inhibitory

synapse in area CA1 of the hippocampus. Future experiments will explore the consequences of this plasticity on neural coding and memory.

Title: Effect of switches in brain states on calcium-based plasticity rules: a computational study for sleep-dependent memory consolidation.

Authors: *K. JACQUERIE, C. MINNE, G. DRION;
Electrical Engin. and Computer Sci., Univ. of Liege, Liege, Belgium

Abstract: Sleep contributes to memory through a mechanism called sleep-dependent memory consolidation. Little is known about its underlying physiological and functional mechanisms, but it involves global and long-lasting switches in neuronal population activity, called the wake-sleep pattern. At the network level, neuronal populations show transitions from active states to oscillatory states. Zooming in at the cellular level, neurons switch from *tonic firing to bursting*. In parallel, memory and learning rely on functional changes in neuronal connectivity through a process called *synaptic plasticity*. The main goal of this project is to investigate how these transient switches in brain rhythmic activity, or brain states, affect synaptic plasticity and learning. To this end, we exploit recent advances in the mathematical modeling of cellular-induced fast and localized switches in brain states [Drion, 2018; Jacquerie, 2021]. These models make the *generation of brain state switches independent from synaptic weights* between neurons and thus compatible with synaptic plasticity. We investigate the interaction between switches in brain states and learning using an associative memory task, which quantifies the ability of neurons coding for concomitant events to strongly connect together. To do so, we embed a neuron conductance-based model with a *calcium-dependent plasticity rule* in which internal calcium concentration governs the direction and the amplitude of the synaptic changes [Shouval, 2002; Graupner and Brunel, 2016], where internal calcium dynamics are regulated by the activation of NMDA receptors and voltage-gated calcium channels. This rule is parametrized to fit experimental data guaranteeing the correct behavior in wake state [Sjostrom, 2001]. The synaptic plasticity rule is shown to fail to reproduce sleep-dependent memory consolidation theories such as synaptic homeostasis hypothesis [Tononi, 2020] or active systems consolidation

[Born, 2012] for any parameter values. Indeed, regardless of the connection strengths established during the day, they all converge to a fixe point during the night, which resets the circuit connectivity during sleep without showing any down-selection or reinforcement. Adding the effect of neuromodulators on calcium-dependent plasticity rule solves this problem by modifying calcium signal transduction pathways, hence the synaptic rule properties. The proposed model makes it therefore possible to track the evolution of synaptic wiring during sleep-wake switches, as well as to study sleep related mechanisms that can affect plasticity rules.

Title: Are synaptic plasticity rules compatible with sleep-dependent memory consolidation?

Authors: *C. MINNE[1], K. JACQUERIE[2], G. DRION[3];
[1]Univ. of Liège, Fraiture, Belgium; [3]Electrical Engin. and Computer Sci., [2]Univ. of Liege, Liege, Belgium

Abstract: Among all essential functions of sleep, research has highlighted its preponderant role in memory formation and consolidation. At the cellular level, *synaptic plasticity*, the ability of neurons to modify their connections, is the cellular mechanism responsible for learning and memory. Therefore, sleep and synaptic plasticity are two linked concepts in the context of memory consolidation.
A large amount of experimental and modeling work has extracted mechanisms of synaptic plasticity, such as e.g. *spike-timing-dependent plasticity*, that occur during wakefulness [Bi and Poo, 1998]. But are they compatible with memory consolidation during sleep [Tononi, 2020; Born, 2016]?
Here, we tackle this question by focusing on the behavior of *phenomenological* models of plasticity, *i.e.* mathematical models based on spike-timing, during sleep. To this end, we build a 3-cell circuit composed of conductance-based models capable of reproducing faithfully the neuronal activity switches observed during the sleep-wake cycle [Drion, 2018; Jacquerie, 2021]. Plasticity is taking place between a pre- and a postsynaptic cell and implemented using well-known plasticity rules from the literature: the pair-based [Abbott, 2000] and triplet [Pfister, 2006] models. We show that those rules, which are successful in reproducing experimental observation in waking state, are no longer compatible with memory consolidation after a sleeping period. Interestingly, the outcome is not determined by the synaptic plasticity rule itself but rather by the choice of saturation bounds applied to the synaptic connection. We show that

modeling the effect of neuromodulators on the learning rule during the sleep-wake cycle, for instance by switching to synaptic depression only during sleep [Gonzalez-Rueda, 2018], permits to reconcile classical synaptic plasticity rules with sleep-dependent memory consolidation.

Title: Interplay between hevin, SPARC, and MDGAs: modulators of neurexin-neuroligin transsynaptic bridges

Authors: *S. FAN, M. MACHIUS, G. RUDENKO;
Dept. of Pharmacol. and Toxicology, The Univ. of Texas Med. Br., Galveston, TX

Abstract: Hevin (also known as SPARCL1) promotes synapse formation and stabilizes neurexin-neuroligin trans-synaptic bridges *in vivo*. Hevin is secreted predominantly by astrocytes, and its synaptogenic effects are antagonized by related protein, SPARC, which shares ~65% sequence identity in the two major domains (the FS-EC tandem). A third protein, the membrane-tethered MDGA, blocks neurexin-neuroligin trans-synaptic bridges. What's more, heparan sulfate (HS), a glycan modification on neurexins promotes neurexin binding to neuroligin, adding an additional dimension to the diversity and regulation of neurexin-neuroligin interactions. The exact molecular underpinnings of this interaction network that regulates neurexin-neuroligin trans-synaptic bridges is largely unknown. Here, we show that hevin and SPARC both bind neurexin and neuroligin, and they can compete with each other. Our 2.3 Å hevin FS-EC crystal structure reveals both profound similarities and profound differences with the SPARC counterpart. We show that hevin and SPARC FS domains are structurally conserved, and they both house nanomolar affinity binding sites for neurexin and neuroligin. In contrast, the hevin and SPARC EC domains are structurally very divergent, and they both essentially don't interact with neuroligin. SPARC's antagonist action compared to hevin likely is rooted in the absence of a long N-terminal region that is found in hevin but not SPARC. Intriguingly, we also show that the hevin FS domain competes with MDGA for an overlapping binding site on neuroligin; this shared site may be in the vicinity of a putative HS binding site on neuroligin. Furthermore, the hevin EC domain binds the extracellular matrix protein, collagen (like SPARC), which may provide an avenue to tether neurexin-neuroligin trans-synaptic bridges to

the extracellular matrix surrounding synapses. Collectively, our data provide mechanistic insight into a portfolio of molecules, both secreted and membrane-tethered, that cooperate together to regulate neurexin-neuroligin trans-synaptic bridges, impacting synapse formation and ultimately shaping neural circuits.

Title: Extracellular kinases: The role of Vertebrate Lonesome Kinase (VLK) in Eph-ecting the synaptic recruitment of NMDA receptors.

Authors: *P. CHANDER[1], H. R. WASHBURN[1], S. D. KOLLURU[1], T. J. PRICE[2], M. B. DALVA[1];
[1]Thomas Jefferson Univ., Philadelphia, PA; [2]Sch. of Behavioral and Brain Sci., UTD, Richardson, TX

Abstract: While protein function modification by intracellular phosphorylation is one of the more widely appreciated mechanisms mediating protein-protein interactions, the function of extracellular phosphorylation and their cognate protein kinases have remained obscure. One important event that requires extracellular phosphorylation is the direct interaction between the receptor tyrosine kinase EphB2 and the GluN1 subunit of the NMDAR. The EphB family of receptor tyrosine kinases are essential for spine synapse formation and synaptic localization of the NMDAR. However, little is known about the kinases that mediate phosphorylation of extracellular domains. Recent studies from the Dixon and Whitman labs have identified two protein kinases families the mediate most extracellular phosphorylation. Of these, the Vertebrate Lonesome kinase (VLK; PKDCC) is a putative tyrosine kinase with six family members. We have begun to examine the function of these kinases focusing on the tyrosine kinase VLK, an essential gene, with knockouts dying at birth from respiratory failure. Other notable phenotypes are cleft palate, polydactyly and defects in axon guidance, phenotypes that overlap with some of those found in knockouts of EphBs and their ligands the ephrin-Bs. To further characterize VLK function, we examined the subcellular localization and regulation of VLK in neurons. Since VLK is secreted in platelets, we asked if ephrin-B2 activation of EphB2 might result in VLK release into the media from neurons. Ephrin-B induces VLK secretion from cortical neurons.

Moreover, ephrin-B activation results in increased transcriptional activation of VLK. To begin to examine the mechanism for VLK release, we fractionated the brain. Remarkably, in both vesicle and synaptosome fractions, VLK co-fractioned with synaptic vesicle markers. To determine if VLK is localized in the cellular secretory pathway, we expressed a VLK-mCherry fusion construct in cortical neurons. VLK was distributed as discrete puncta through the axons. Live cell imaging revealed that VLK puncta underwent active bidirectional transport in axons of neurons and colocalized with pre-synaptic protein Synaptophysin 1 (SYP1). We are currently examining whether stable VLK puncta are associated with postsynaptic markers. Overall, data suggest that VLK is regulated by EphB signaling and may be associated with presynaptic sites.

Abstract: Synapse formation and function is regulated by several families of transsynaptic adhesion proteins that span the synaptic cleft, guide synaptic development, and regulate mature synaptic function. Of these families, the EphB family of receptor tyrosine kinases are required for spine synapse formation and the synaptic localization of the N-methyl-D-aspartate receptor (NMDAR). Normal brain function requires that NMDARs are properly localized to synaptic sites, and synaptic NMDARs are required for the induction of structural and synaptic plasticity. At the mature synapse, EphB2 binding the membrane bound ligands, the ephrin-Bs, to the ligand binding domain (LBD) of EphB2 drives a direct extracellular interaction between the EphB2 receptor and NMDAR. The direct extracellular EphB-NMDAR interaction requires post-translational modification of the extracellular domain of EphB2. Unbiased mass spectrometry data showed that a specific tyrosine reside, Y504, in the fibronectin type III (FN3) repeat domain of the extracellular region of EphB2 undergoes ephrin-B2 ligand-dependent phosphorylation.

Furthermore, functional analysis of EphB2 phosphorylation mutants indicated that Y504 is necessary and sufficient for the EphB-NMDAR interaction. Protein phosphorylation is a nearly universal mechanism used by cells to regulate intracellular and extracellular processes. The majority of phosphoproteins are intracellular; however, mass-spec and other approaches have shown recently that numerous extracellular proteins are phosphorylated. Here, we explore the possible mechanisms of EphB2 Y504 phosphorylation. We identify a secreted extracellular tyrosine kinase, vertebrate lonesome kinase (VLK), that is capable of phosphorylating EphB2 at Y504 and induces EphB2 interaction with the NMDA receptor. Additionally, loss of VLK results in a loss of the Eph-NMDA receptor interaction. Our findings also show that VLK fractionates with synaptic vesicles and colocalizes with synaptic vesicle markers, suggesting a mechanism of pre-synaptic secretion into the synaptic cleft. Together, these studies impact our understanding of the role and importance of extracellular protein-protein interactions in synaptic development and function.

Title: Vertebrate Lonesome Kinase phosphorylates EphB2 receptors on an extracellular residue to drive NMDA-dependent pain

Authors: *H. ELAHI[1], S. N. HASSLER[2], M. KUME[1], S. SHIERS[1], M. B. DALVA[3], T. J. PRICE[1];
[1]Univ. of Texas at Dallas, Richardson, TX; [2]Univ. of Houston, Houston, TX; [3]Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: EphB/ephrinB signaling plays a key role in synaptic function and is linked to several neuropathological conditions, including neuropathic pain. The EphB2 receptor tyrosine kinase is known to interact with *N*-Methyl-D-aspartate glutamate receptors (NMDAR), resulting in increased surface retention of NMDARs at the synapse and an enhancement of postsynaptic currents. As changes in NMDAR signaling have been heavily implicated in the development of both acute and chronic pain, targeting this receptor interaction may produce clinically relevant therapeutics. We have recently demonstrated that the phosphorylation of a tyrosine residue

(Y504) on the extracellular domain of the EphB2 receptor is necessary and sufficient to induce its interaction with NMDARs and cause mechanical pain hypersensitivity. The kinase responsible for this phosphorylation is unknown. We hypothesized that Vertebrate Lonesome Kinase (VLK) may be the key effector. Since the phosphorylation site of interest is located on the extracellular face of the EphB2 receptor, a secreted tyrosine kinase like VLK is an ideal candidate. Our results provide strong support for our hypothesis that VLK drives pain via extracellular phosphorylation of EphBs. We show that intrathecal injection of VLK resulted in long-lasting mechanical hypersensitivity in mice. Additionally, the effects observed for VLK were dependent on kinase activity and entirely dependent upon NMDARs because they were blocked by APV. We also show evidence of VLK protein and mRNA expression in dorsal root ganglion and spinal cord neurons of both mice and humans. Our results provide evidence for the involvement of VLK in pain behaviors and spinal cord NMDAR signaling, and identify a completely unique extracellular kinase target for the alleviation of pain.

Title: Biochemical Regulation of RhoA Activity and Signaling in Cortical Neurons via DISC1

Authors: *K. BJORNSON[1], B. A. KERMATH[1], A. SAWA[2], M. CAHILL[1];
[1]Comparative Biosci., The Univ. of Wisconsin-Madison, Madison, WI; [2]Dept. of Psychiatry, Johns Hopkins Univ., Baltimore, MD

Abstract: Structural plasticity of dendritic spines, the sites of most excitatory connections in the brain, is critical for many forms of synaptic plasticity, and ultimately, learning and memory. Long term potentiation (LTP) and long-term depression (LTD) are associated with spine head enlargement and shrinkage, respectively. Structural plasticity is largely mediated by intracellular signaling pathways that cause the reorganization of the actin cytoskeleton in dendritic spines. Small GTPases are potent regulators of synaptic structural plasticity via their direct and indirect influences on actin. Small GTPases are active when bound to GTP and inactive when GDP bound. The direct activation of small GTPases is accomplished by guanine nucleotide exchange factors (GEFs). RhoA activation is known to have a destabilizing effect on the actin cytoskeleton with associated alterations in dendritic spine stability. However, the specific biochemical

mechanisms that control RhoA activity in neurons remain largely uncharacterized. PDZ-RhoGEF is a RhoA-specific guanine nucleotide exchange factor whose expression is restricted to the central nervous system, with levels highest in the neocortex. Further, among RhoA-specific GEFs, PDZ-RhoGEF shows an unusually potent ability to activate RhoA. Nevertheless, owing to a scarcity of studies, minimal is known about the regulation and function of PDZ-RhoGEF in the brain. Here we show that PDZ-RhoGEF destabilizes dendritic spines in cortical neurons and causes cortical-dependent cognitive impairment. We found that PDZ-RhoGEF activity and cellular localization in vitro is controlled by its interaction with the DISC1 scaffolding-like protein, such that DISC1 inhibits PDZ-RhoGEF-mediated RhoA activity. Ongoing studies are examining the functional consequences of the interaction between PDZ-RhoGEF and DISC1 in dendritic spines and in cortical neurons in vivo. Taken together, these findings identify PDZ-RhoGEF as a potent regulator of synaptic stability and cognition, and highlight a previously unrecognized involvement for DISC1 in controlling RhoA activity via PDZ-RhoGEF.

Title: Biophysical modeling of actin-mediated structural plasticity

Authors: *M. BONILLA-QUINTANA, P. RANGAMANI;
UCSD, La Jolla, CA

Abstract: Memories are thought to be encoded in the connections between neurons (synapses) which are plastic, increasing or decreasing their strength depending on their activity. The postsynaptic part of most excitatory synapses are located in small protrusions from the dendrites, called dendritic spines, which undergo structural plasticity where a long-lasting synaptic strength increase (long term potentiation, LTP) or decrease (long term depression, LTD) correlates with an increase or decrease in the size of these spines, respectively. Changes in spine size are possible due to a reconfiguration of its cytoskeleton, composed primarily of actin filaments, triggered by a signaling cascade upon LTP/LTD induction. Although many studies have investigated parts of this process, it is challenging to have a full picture due to the small size of the spines, its high concentration of actin, and the diversity of proteins. Therefore, we propose a biophysical 3D model to investigate the dynamics of actin upon LTP/LTD and the resulting changes in the spine size and shape. Similar to previous models describing cell motility, our

model aims to determine the mechanisms underlying the spine reconfiguration. We use partial differential equations to describe the evolution actin, cofilin, and Arp2/3 concentrations, confined to a time-evolving domain representing the spine membrane with Helfrich potential energy. We focus on cofilin and Arp2/3 from all the possible actin-binding proteins (ABPs) because of their principal role in severing and branching actin filaments, respectively. The model allows the study of heterogeneous protein distribution inside the spine, which results in asymmetric and more realistic spine shapes. We show that the timing and location of the interaction between these proteins are crucial to generate long-lasting changes in the spine shape and size. Our model can reproduce the changes upon LTP and LTD by only altering the protein concentrations. Moreover, it can inform about spine abnormalities due to alterations in ABPs characteristic in diseases such as Alzheimer's Disease.

Abstract: We investigate supervised learning in a perceptron-like neural network architecture in which synaptic transmission is governed by nonlinear functions relating the post- synaptic currents to pre-synaptic neural activities. These nonlinearities are shaped by learning rules for binary classification, and can implement curved decision boundaries that are more flexible than hyperplanes. We show that such systems can achieve a larger capacity than the standard perceptron, even if all synaptic nonlinearities are constrained to be monotonically increasing. We discuss both offline optimization schemes and more biologically plausible online learning rules for finding useful decision boundaries, as well as the convergence properties of the proposed learning algorithms.

Abstract: In Parkinson's disease (PD), oxidative stress contributes to the underlying pathology. Oxidative stress activates c-Abl, a normally auto-inhibited nonreceptor tyrosine kinase, which causes the death of dopamine (DA) neurons in the substantia nigra pars compacta. Activated c-Abl kinase phosphorylates and inhibits parkin ubiquitin function, which leads to accumulation of toxic parkin substrates that contribute to α-synuclein (α-syn) induced neurodegeneration. α-Synuclein misfolding and aggregation play a significant role in progressive neurodegeneration in PD. Genetic inhibition of c-Abl kinase attenuates neurodegeneration in PD models. Thus, modulating the c-Abl-Parkin pathway could be a potential diseasing modifying strategy to prevent or halt the progression of PD. To date, several symptomatic drugs for PD have been developed, but none of them are disease-modifying. K0706, also known as vodobatinib, is a potent orally bioavailable, brain-penetrating small molecule inhibitor of c-Abl. The purpose of this study was to investigate the neuroprotective efficacy of K0706 in the α-syn preformed fibril (PFF) model of PD. K0706 treatment prevents the reduction in dopamine neurons, dopamine levels and the increase in phospho-S129 α-syn and phospho-Y39 α-syn as well as the accompanying behavioral deficits. We also observed a dose-dependent neuroprotective effect of K0706 in this α-syn PFF model of PD. These results suggest that the c-Abl inhibitor, K0706 may be beneficial as a disease modifying therapy in PD. K0706/vodobatinib is currently being evaluated in phase 2 clinical trial, ProSeek, in patients with early stage Parkinson's Disease.

Cell Engin., Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: c- Abl activation contributes to the pathology of Parkinson's disease (PD). Mitochondrial dysfunction results in oxidative stress, which leads to c-Abl activation, a molecular sensor of oxidative stress. c-Abl phosphorylates α-synuclein (α-syn) at Y39 leads to misfolding of α-syn. Previously, we have shown that Parkin inactivation by c-Abl causes accumulation of pathogenic parkin substrates, PARIS and AIMP2, and subsequently leads to parthanatos-mediated neuronal death. Current therapies focus on reducing the symptoms of the disease, but none of the existing drugs are disease-modifying therapies. Target engagement therapeutic approaches will be beneficial in halting or preventing the progression of PD. Current limitations with small molecule inhibitors are due to poor brain penetration, lack of efficacy, and other adverse effects. In the present study, we evaluated, IkT-148009, a highly potent c-Abl inhibitor, a small-molecule drug designed and engineered to target c-Abl kinase specifically. The primary aim of this current study was to evaluate target engagement of IKT-148009 in the α-syn preformed fibril (PFF) model and the conditional TetP-hA53T α-syn transgenic PD mouse model. The results demonstrate significant inhibition of activated c-Abl in the α-syn PFF and the TetP-hA53T α-syn transgenic PD mouse models, which prevents c-Abl-Parkin mediated demise of dopaminergic neurons. This study provides evidence for the clinical use of, IkT-148009, in the treatment of PD.

Title: A brain-penetrant stearoyl-CoA desaturase inhibitor reverses α-synuclein toxicity in synucleinopathy models in vitro and in Parkinson's disease-like mice

Authors: *C. CHUNG[1], S. NUBER[2], D. TARDIFF[1], P. BECHADE[2], T. MCCAFFERY[2], J. CHOI[1], B. CHANG[1,3], W. RAJA[1], E. NEVE[1], C. BURKE[1], X. JIANG[1], P. XU[1], V. KHURANA[1], U. DETTMER[2], K. RHODES[1,4], D. SELKOE[2], R. SCANNEVIN[1,5];

Abstract: Increasing evidence has shown that Parkinson's disease (PD) impairs midbrain dopaminergic, cortical and other neuronal subtypes in large part due to the build-up of lipid- and vesicle-rich α-synuclein (αSyn) cytotoxic inclusions. We previously identified stearoyl-CoA desaturase (SCD) as a potential therapeutic target for synucleinopathies. A brain-penetrant SCD inhibitor, YTX-7739, was developed and has entered Phase I clinical trials. Here, we report the efficacy of YTX-7739 in reversing pathological αSyn phenotypes in various *in vitro* and *in vivo* model systems. In cell-based assays, YTX-7739 decreased αSyn-mediated neuronal death, reversed the abnormal membrane interaction of amplified E46K (3K) αSyn, and reversed pathological phenotypes in A53T and αSyn triplication patient-derived neurospheres, including dysregulated fatty acid profiles and pS129 αSyn accumulation. In 3K PD-like mice, YTX-7739 readily crossed the blood-brain barrier, decreased unsaturated fatty acids, and prevented the motor behavior deficits and their progressive decline. YTX-7739 administration and decreasing SCD activity through deletion of one copy of the SCD1 gene restored the physiological αSyn tetramer to monomer ratio, dopaminergic integrity, and neuronal survival in 3K αSyn mice. YTX-7739 efficiently reduced pS129+ and PK-resistant in both human wild-type αSyn and mutant 3K mice. Together, these data provide further validation of SCD as a therapeutic target, and YTX-7739 as a clinical candidate, for treating human α-synucleinopathies.

Title: Gene therapy with VMAT2 reduces age-dependent neuromelanin accumulation and prevents Parkinson's Disease-like motor symptoms in neuromelanin-producing rats

Authors: J. COMPTE, M. GONZÁLEZ-SEPULVEDA, A. NICOLAU, T. CUADROS, J. ROMERO-GIMÉNEZ, A. PARENT, A. LAGUNA, *M. VILA;
Vall d'Hebron Res. Inst., Barcelona, Spain

Abstract: Background: In Parkinson's disease (PD), there is a preferential degeneration of neurons that contain the pigment neuromelanin, especially dopaminergic neurons of the substantia nigra (SN), the loss of which leads to classical motor PD symptoms. We recently developed the first rodent model of human-like neuromelanin production based on the viral vector-mediated nigral expression of melanin-producing enzyme tyrosinase (AAV-hTyr). This has revealed that neuromelanin can trigger PD pathology when accumulated above a specific pathogenic threshold. Because neuromelanin derives from the oxidation of free cytosolic dopamine, we hypothesized that enhancing dopamine vesicular encapsulation with vesicular monoamine transporter 2 (VMAT2) will decrease cytosolic dopamine that can convert to neuromelanin. This approach should slow down the intracellular buildup of neuromelanin that occurs with age and thus prevent, delay or attenuate PD pathology. **Material and methods**: Adult male Sprague-Dawley rats received single unilateral stereotaxic co-injections of AAV-hTyr and AAV-VMAT2 immediately above the SN. Control animals received equivalent amounts of either vehicle, AAV-hTyr or AAV-VMAT2, separately. At selected times post-injection animals were assessed for motor asymmetry and their brains processed for histological analyses. **Results:** VMAT2 overexpression in hTyr-expressing rats reduced intracellular neuromelanin to levels below its pathogenic threshold by lowering the production of dopamine-oxidized neuromelanin precursors. In these animals, reduction of neuromelanin levels was associated with a marked attenuation of Lewy body-like inclusions formation, nigrostriatal degeneration, extracellular neuromelanin accumulation, microglia/macrophage activation, astrocytic presence and PD-like motor deficits. **Conclusions:** Our results demonstrate the feasibility and therapeutic potential of modulating intracellular neuromelanin levels in vivo, thereby opening an unexplored window of potential strategies for PD treatment.

Title: CCR3 inhibition reduces recruitment of peripheral immune cells to the eye and brain in inflammatory disease models

Authors: *Y. LOPEZ, *Y. LOPEZ, S. CARYOTAKIS, S. REGE, J. MASUMI, L. AKRAPONGPISAK, A. TEICHERT, S. S. MINAMI, O. DHANDE;
Alkahest, San Carlos, CA

Abstract: Inflammation is a common thread through multiple age-related CNS diseases, appropriately termed inflammaging. One such example is age-related macular degeneration (AMD), the most common cause of irreversible blindness in people over 60 years old. AKST4290, a CCR3 inhibitor, is a promising oral drug for AMD treatment. This is evident in recently completed Phase 2a clinical studies, in which the majority of both treatment-naïve and refractory neovascular AMD (nAMD) subjects demonstrated stable or improved best-corrected visual acuity after 6 weeks of AKST4290 treatment. Preclinical studies using the sodium iodate ($NaIO_3$) induced oxidative stress model were subsequently conducted to examine whether the efficacy observed in nAMD patients was in part due to blocking CCR3-mediated retinal homing of damage-promoting immune cells from the periphery. This in turn could dampen local inflammation and may subsequently modify disease progression. This hypothesis was assessed in 2-month-old male C57BL/6 mice administered $NaIO_3$ and AKST4290 concurrently for 3 days. Flow cytometric analysis of RPE/choroid tissue, the primary site of AMD pathology, illustrates reduced $NaIO_3$-induced infiltration of myeloid, monocyte, neutrophil, and T cell populations with AKST4290. To further elucidate effects of AKST4290 on peripheral T cells, we assessed CCR3 inhibition in another inflammatory model, experimental autoimmune encephalomyelitis (EAE), which is known to have robust T cell infiltration in both the brain and eye. AKST4290 was dosed for 9 days after EAE induction along with a control group that received vehicle only. EAE elicited a significant increase in CD3+ cells in the cerebellum in comparison to control mice. In comparison, AKST4290 significantly reduced this T cell infiltration in the cerebellum. AKST4290 treatment trends towards reduced CD3+ T cells in the retina as well. Together, these data illustrate that CCR3 inhibition modulates immune cell infiltration in both the eye and brain. Furthermore, these data suggest a common mechanistic action of AKST4290 on T cells in inflammatory ophthalmic and neurological disease models.

Title: Anti-amnesic and neuroprotective effects of the selective butyrylcholinesterase inhibitor UW-MD-95 in a pharmacological mouse model of Alzheimer's disease

Authors: *T. MAURICE[1], A. CARLES[1], M. HOFFMANN[2], M. SCHEINER[2], L. CROUZIER[1], C. BERTRAND-GADAY[3], A. CHATONNET[3], M. DECKER[2];

Abstract: Alzheimer's disease (AD) is a devastating dementia characterized by extracellular amyloid-β (Aβ) protein aggregates and intracellular tau protein deposition. Clinically available drugs target acetylcholinesterase (AChE) and indirectly sustain cholinergic neuronal tonus. Butyrylcholinesterase (BChE) also controls ACh turnover and is involved in the formation of Aβ aggregates and maturation of senile plaques. We previously described new carbamate-based drugs, acting as highly potent pseudo-irreversible BChE inhibitors with high selectivity for BChE *vs* AChE and showing promising protective potentials in a pharmacological mouse model of AD [*Hoffman et al., J Med Chem 2019*]. We here characterized the neuroprotective activity of the most promising compound in the series, UW-MD-95, in mice treated intracerebroventricularly with oligomerized $A\beta_{25-35}$ peptide using behavioral, biochemical and immunohistochemical approaches. When injected once, in the 0.3-3 mg/kg dose-range, 30 min before the behavioral tests (spontaneous alternation in the Y-maze, object recognition or passive avoidance), UW-MD-95 showed symptomatic anti-amnesic effects in $A\beta_{25-35}$-treated mice. When injected once-a-day in the same dose-range, the drug prevented the appearance of $A\beta_{25-35}$-induced memory deficits. This effect was lost in BChE knockout mice but observed in their littermate controls. Moreover, the drug repeated treatment prevented $A\beta_{25-35}$-induced oxidative stress (assessed by increased lipid peroxidation or cytochrome c release), neuroinflammation (increased in IL-6 and TNFα levels or GFAP and Iba1 immunoreactivity) in the hippocampus and cortex, and apoptosis (increased Bax level). The novel dual-acting BChE inhibitor UW-MD-95 therefore appeared as a potent neuroprotective drug in the $A\beta_{25-35}$ model of AD, with potentially an impact on Aβ aggregation that could suggest a novel mechanism of neuroprotection.

Abstract: Palmitoylethanolamide prevents neurodevelopmental delay and early hippocampal damage after perinatal asphyxia.
Perinatal asphyxia (PA) is a clinical condition brought by a birth temporary oxygen deprivation. This health problem continues to be a morbidity factor in neurodevelopment. Palmitoylethanolamide (PEA) is a neuromodulator well known for its protective effects in neurodevelopmental disorders, such as autism, albeit not deeply studied regarding its particular effects following PA. Recent evidence from our laboratory revealed perinatal treatment with PEA (10 mg/kg) could attenuate cytoskeletal alterations in CA1 hippocampal neurons and improve behavioral outcomes 1 month after PA induction (Herrera et al., 2018). In order to extend these findings, we intended to elucidate whether PEA might exert protective effects earlier on neurodevelopment. Pups (N=75) were tested daily for several reflexes and signs that indicate the maturation of the nervous system. Vulnerability of CA1 neurons was analyzed with Electron Microscopy. Microtubule associated protein-2 (MAP-2) was assessed by Immunohistochemistry and Western Blot at P21. During the first 3 weeks of life, asphyctic rats displayed a significant delay in the appearance of air righting, auditory startle, sensory eyelid, placing and grasp reflexes. A late onset of gait, negative geotaxis and eye opening was also observed. In addition, a slower performance of negative geotaxis was encountered in PA rats from postnatal day 11 (P11) to postnatal day 14 (P14). At P21, ultrastructural signs of neurodegeneration and MAP-2 deficit were found on CA1 hippocampal region. PEA treatment could ameliorate hippocampal damage and reverse the delay in the appearance of gait and motor reflexes. Therefore, PEA appears as a promising neuroprotective agent for the developing injured

brain.

Title: The small molecule myeloid cell modulator TQS-168 normalizes the inflammatory phenotype of immune cells from ALS patients and extends survival in the SOD1 G93A ALS mouse model

Authors: *E. CHAVEZ JUAN, D. NESS, B. AJAMI, N. SCHWARTZ, J. HANNESTAD, S. KAKKAR, H. LANCERO;
Tranquis Therapeut., San Mateo, CA

Abstract: Background: Amyotrophic Lateral Sclerosis (ALS) is a rapidly progressing neurodegenerative disease that almost invariably leads to death. While the pathogenesis of ALS is not well understood, myeloid cell dysfunction and inflammation appear to contribute to its progression. To investigate this possibility, we developed TQS-168, a small molecule myeloid-cell modulator, and tested its effects on peripheral blood mononuclear cells from ALS patients, and in the SOD1 G93A model of ALS (a transgenic mouse that overexpresses a mutant form of human *SOD1*).Methods: Blood samples were obtained from ALS patients, PBMCs were isolated, and the ability of TQS-168 to regulate monocyte phenotype and cytokine release were determined ex vivo. SOD1 G93A mice and wildtype littermates were dosed with TQS-168 by oral gavage from the age of 70 days until death. Weight loss and survival were monitored by an experimenter blinded to the treatment condition. Cytokine levels were measured in plasma samples, and muscle fiber number and size were quantified in muscle tissue.Results: TQS-168 modulated monocyte phenotypes and cytokine production in PBMCs from patients with ALS. In the SOD1 G93A model, TQS-168 slowed weight loss and prolonged survival after symptom onset (defined as >3% decrease in body weight and the onset of motor symptoms). Plasma levels of multiple cytokines and monocyte subsets were regulated by TQS-168 in SOD1 G93A mice, and the correlation between changes in motor function and muscle morphometry was

determined.Conclusions: The small molecule TQS-168 regulates the inflammatory phenotype of myeloid cells in patients with ALS and slows disease progression in a mouse model of ALS. Modulation of cytokines by TQS-168 correlated with survival in SOD1 G93A mice. TQS-168 will enter clinical development to evaluate its potential as a treatment for ALS patients.

Abstract: Parkinson's disease (PD) is an incurable neurodegenerative disorder characterized by the progressive loss of dopaminergic neurons in the substantia nigra (SN). Impaired mitochondrial function and elevated levels of oxidized biomolecules in the midbrain of PD patients suggest an inability to mitigate oxidative stress may also be critical in disease pathogenesis. To explore this hypothesis further, we activated the Nuclear factor erythroid 2-related factor 2 (Nrf2) antioxidant response pathway in rodent glial cells and disease models, using two small-molecule inhibitors of its interaction with Kelch-like ECH-associated protein 1 (Keap1). In BV-2 cells and primary mouse microglia, pre-treatment with compound A or B suppressed inflammatory cytokine release following lipopolysaccharide (LPS) stimulation. Additionally, primary rat astrocytes exhibited upregulation of Nrf2-regulated antioxidant response element (ARE) genes and increased glutathione production in response to treatment with either compound. Intraperitoneal (IP) injection of compound B (50 mg/kg) in mice yielded upregulation of several ARE genes in brain tissue at 6 and 18 h time points, suggesting sufficient bioavailability for efficacy studies. Subsequent investigation of plasma and brain tissue 4 h after LPS injection (0.8 mg/kg) revealed modest suppression of inflammatory cytokine levels when

animals were injected with compound B prior to the LPS challenge. Moreover, the loss of SN dopaminergic neurons associated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) injection was significantly attenuated in mice that were treated with compound B. The treatment group also displayed diminished microglial activation throughout SN tissue in response to MPTP. In conclusion, our data strengthen the notion that enhancement of the Nrf2 signaling pathway may be beneficial in PD and other inflammatory disorders of the nervous system.

Title: Embelin Abrogates Amyloid beta Induced Neurotoxicity With Emphasis on Neuroinflammation, Neurochemistry and p38-MAPK

Authors: *R. ARORA[1], R. DESHMUKH[2];
[1]ISF Col. of Pharm. Moga Punjab India, Moga, India; [2]Pharmaceut. Sci., MRSPTU, Bathinda, India

Abstract: Embelin Abrogates Amyloid-β-Induced Neurotoxicity with Emphasis on Neuroinflammation, Neurochemistry and p38-MAPK Rimpi Arora*, and Rahul Deshmukh*1.Research Scholar, IKGPTU, Jalandhar, Punjab, India2.Neuropharmacology Division, Department of Pharmacology, I. S. F. College of Pharmacy, Moga- 142001, Punjab, India3.Department of Pharmaceutical Sciences & Technology, Maharaja Ranjit Singh Punjab Technical University, Bathinda-151001, Punjab, India
Abstract Background: Stress activated protein kinases such as p38 MAPK have been implicated in the pathogenesis of AD. Extracellular deposits of amyloid-β (Aβ) in neuronal synapse via p38MAPK have been considered as a major hallmark of Alzheimer's disease (AD). **Purpose:** Here in we have investigated the neuroprotective potential of embelin in Aβ-42 induced neurotoxicity in rats. **Material and Methods:** $A\beta_{1-42}$ oligomer was infused (3nmol/3µl) intracerebroventrically twice on day-1to induced Alzheimer's type dementia in rats. Spatial and

non-spatial memory was assessed at different time intervals and terminally biochemical, neurochemical and neuroinflammatory parameters were determined in rat hippocampal brain tissue. One week following $A\beta_{1-42}$ infused rats were treated with different doses of embelin (EMB) (2.5, 5 and 10mg/kg/p.o.) till 21st day. **Results:** $A\beta_{1-42}$ infusion upregulated p38 MAPK consequently significant deterioration in learning and memory while hippocampal tissue showed elevation in AChE activity, oxidative stress, and pro-inflammatory cytokine levels (TNF-α, IL-β etc.) and disturbed pattern of catecholamines and GABA/glutamate levels. On the other side, EMB significantly attenuated $A\beta_{1-42}$ induced cognitive deficits & other biochemical changes in rats. EMB treated rats showed improved learning and memory as well as able to reduce the burden of hippocampal oxidative stress and pro-inflammatory cytokines and restored catecholamines and GABA/glutamate balance in rats. **Conclusion and Implication:** The pro-cognitive effect of EMB may be due to its antioxidant and anti-inflammatory actions through p38MAPK downregulation. The observed results indicate the therapeutic potential of EMB in cognitive disorders. **Key words:** Alzheimer's disease; Embelin; Amyloid-β; Neuroprotection; Dementia; Cognitive deficit.

Title: Methamphetamine self-administration causes neuronal dysfunction in rat medial prefrontal cortex in a sex-specific and withdrawal time-dependent manner

Authors: *L. CHEN, S. L. CASSODAY, A. DONNER, N. CHOUDHURY, L. AL-HARTHI, X.-T. HU;
Rush Univ. Med. Ctr., Chicago, IL

Abstract: Methamphetamine (Meth) is a highly addictive and widely abused psychostimulant. There is no FDA-approved medicine for treating people with Meth use disorders (MUD). Although female and male Meth users are reportedly taking similar quantity of Meth, woman

users appear to suffer greater consequential dependence, and experience more frequent relapse during the abstinence. People with MUD also show sex difference in the severity of Meth-caused cognitive deficits/structural changes in the brain. The mechanism underlying such sex difference is unknown; and has rarely been studied. The medial prefrontal cortex (mPFC), one of the key regulators of cognition and addiction, is profoundly altered by Meth; but the mechanism by which Meth causes dysfunction of mPFC pyramidal neurons is not fully understood. To fill these knowledge gaps, we assessed drug-taking/drug-seeking behaviors and associated mPFC neuron activity in male and female adult rats after Meth self-administration (SA) followed by different withdrawal periods. Male and female F344 rats at age of 4-5 months old were trained to self-administer (SA) Meth (0.01mg/kg/infusion) for 1 week, and then 0.05mg/kg/infusion for another 2 weeks. A subset of rats was tested for drug-seeking behaviors on withdrawal day 2, 3, 9, 16, 23 and 30, respectively. Age-matched saline (SAL)-yoked rats were used as control. Brain slices containing the mPFC were prepared for whole-cell patch-clamp recording after 1-5 days (d, short-term) or 31-38d (long-term) withdrawal from the last Meth-SA. We found that both males and females showed similar drug-taking, total Meth intake and persisting drug-seeking behaviors during various withdrawal periods. Meanwhile, mPFC neuron firing was significantly decreased in Meth-SA male rats after a short-term withdrawal, but increased after a long-term withdrawal, compared to SAL-yoked controls. We also found that similar to the altered firing, evoked Ca^{2+} plateau potentials (indicating Ca^{2+} influx via voltage-gated Ca^{2+} channels) were also significantly decreased in these neurons from Meth-SA male rats after a short-term withdrawal, but increased in them after a long-term withdrawal, compared to SAL-yoked controls. In contrast, there was no significant change in firing or Ca^{2+} spikes of mPFC neurons from Meth-SA female rats, regardless of the withdrawal times. Collectively, our novel findings demonstrate that chronic Meth-induced mPFC neuron dysfunction is sex-specific and withdrawal time-dependent. They also suggest that a delayed response to Meth-induced mPFC neuronal dysfunction could drive females for longer period of Meth-SA that could cause more severe consequences.

Title: Tdp-43 expression in dementia-relevant circuits causes axonal degeneration and behavioral deficits in Drosophila

Authors: *R. KEATING GODFREY[1], R. T. BJORK[2], C. WILLIAMS[1], G. HALA'UFIA[3], H. B. COWELL[1], E. M. LEHMKUHL[1], E. ALSOP[4], K. VAN KEUREN-JENSEN[4], D. C. ZARNESCU[1];
[1]Mol. and Cell. Biol., [2]Grad. Interdisciplinary Program in Neurosci., [3]Sch. of Mind, Brain, and Behavior, Univ. of Arizona, Tucson, AZ; [4]TGen, Phoenix, AZ

Abstract: Trans active response (TAR) DNA-Binding protein 43 (TDP-43), an evolutionarily conserved RNA/DNA binding protein that regulates RNA processing, is known to form pathological, cytoplasmic inclusions in numerous neurodegenerative diseases. First identified in ubiquitin-positive inclusions in amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) and more recently in Alzheimer's disease (AD), TDP-43 appears to be a common molecular link among central nervous system neurodegenerative diseases. Given our success modeling TDP-43 proteinopathy in a fly model of ALS, we have developed a novel fly model of dementia by overexpressing human TDP-43 in the mushroom bodies (MBs) of the *Drosophila* brain. Insect MBs form an elaborate, associative network that overlaps in function and gene expression with neurons in the human hippocampus and frontal cortex, making it an appropriate brain structure to model human cognitive disease. We evaluate the effects of TDP-43 proteinopathy in MBs by measuring changes in TDP-43 localization in MB neurons, neurodegeneration in the MB axons, and behavior deficits in working memory and sleep. We find that TDP-43 is mislocalized from the nucleus to the cytoplasm and forms axonal inclusions. This results in both behavioral deficits and age-dependent axonal degeneration in MBs. Importantly, cognitive deficits in working memory and sleep appear prior to our ability to detect axonal degeneration, paralleling what is seen in human disease. Additionally, we sought to identify the molecular targets of TDP-43 in the MBs using RNA immunoprecipitations and RNAseq. These experiments identified several candidate targets of TDP-43 in mushroom bodies, including Dally-like protein (Dlp/GPC6), a translational target that we recently reported in *Drosophila* sALS models and patients. These findings suggest that TDP-43 overexpression in MBs causes FTD-relevant phenotypes that may help uncover novel mechanisms of disease. Future experiments are aimed at identifying additional FTD-relevant targets of TDP-43, including novel therapeutic strategies.

Title: Functional role of PLD1 signalosome in Frontotemporal dementia

Authors: *C. NATARAJAN[1], B. THOMPSON[2], B. KRISHNAN[1];
[1]Neurol., [2]UTMB, Galveston, TX

Abstract: Background: Phospholipase D (PLD), a lipolytic enzyme for membrane phospholipids, exists in two isoforms of mammalian phosphatidyl choline (PC) specific PLD; inducible PC-PLD1 and constitutive PC-PLD2. Elevated PLD activity is well documented in clinical studies involving Alzheimer's disease (AD). Our lab was the first to show that elevated PLD1 facilitates synaptic dysfunction and underlying memory deficits driven by amyloidogenic insults by Aß/tau. We observed preservation of memory in response to PLD1 specific small molecule inhibitor in transgenic mouse models and documented preservation of dendritic spines as an underlying basis. In this study, we explored a role for PLD1 in Frontotemporal Dementia in an attempt to explore its pathological role in tauopathy-driven dementia. **Methods:** We studied altered expression/activity of key F-actin signaling elements common to PLD1 signalosome in synaptosomal fractions of human post-mortem FTD brain regions. Synaptic deficits associated with elevated PLD1 expression in human FTD samples was studied by Fluorescence Analysis of Single Synapse Long Term Potentiation (FASS-LTP). Using immunofluorescence, we studied the association of PLD1 with tau, presynaptic, and post-synaptic receptors. **Results:** Elevated PLD1 expression in synaptosomal fractions of post-mortem FTD brain tissues was corroborated by synaptic deficits and association of PLD1 with postsynaptic density protein (PSD95). FASS-LTP assay indicated relatively lower long-term potentiation in synaptosomal fractions of FTD brains as compared to the control brains implying synaptic deficits in FTD subjects. **Conclusion**: In the light of these observations, we conclude elevated PLD1 expression is associated with toxicity of tau causing memory deficits in FTD patients. This PLD1-tau interaction alters PLD signaling partners such as mTOR (mammalian target of rapamycin), cofilin and phosphocofilin. This would implicate the actin-dependent remodeling of synapse to be a key step in the role of PLD1 signalosome in FTD. Delineating the effects of PLD1 signalosome in tauopathies such as FTD will hugely be beneficial in tau-targeting therapeutics for a multipronged approach in the treatment of neurodegenerative disorders.

Title: 1,3-butanediol ameliorates high-salt diet induced vascular dementia via mirna-histone acetylation

Authors: J. BEHERA, M. SINGH, ***N. TYAGI**;
Univ. of Louisville, Louisville, KY

Abstract: Progressive decline in cognitive function, and memory is on the rise and in fact parallels to that of the hypertension increase in aging humans. The mechanistic basis of high-salt diet (HSD) induced hypertension-associated memory impairment, and dementia pathology is not yet fully understood. Furthermore, it is also currently unknown whether ketone bodies are secreted by brain cells or whether it is responsible for the memory as well. Here, we examined the impact of ketone bodies or the precursor molecule (1,3-butanediol) supplementation on cognitive function through the histone acetylation in the hypertensive mice. To test the hypothesis, we employed adult female wild-type (WT) mice. The mice were fed with HSD (8%), and HSD mice were supplemented with 1,3-Butanediol (2%), and the HSD mice were supplemented with β-hydroxybutyrate (BHB, 0.2%) in the drinking water for 12 weeks. CODA noninvasive BP system (tail-cuff) testing revealed that 1,3-Butanediol or BHB reduced the systolic, and diastolic blood pressure significantly in the hypertensive mice. The results show that 1,3-Butanediol or BHB treatment of hypertensive mice reduced systemic level of the circulating miRNA-128-3p in comparison to the hypertensive mice. Further, the data analysis revealed higher behavioral proficiency, and more robust long-term, and short-term memory in HSD+BHB or HSD+ 1,3-Butanediol mice as compared to the hypertensive mice. This mechanistic study shows that HSD+ 1,3-Butanediol mice display an increased mitochondrial TFAM dependent upregulation of brain derived neurotropic factor (BDNF), and nuclear receptor subfamily 4A (Nr4a) in the mouse hippocampus most likely via an epigenetic activation of the H3K27ac acetylation at the promoters. Hippocampal overexpression of BDNF/Nr4a by Lentiviral BDNF/Nr4a administration rescued the hypertensive-memory impairment. In addition, the anti-miR-128-3p treatment restored the neuroprotective function and reduced the dementia pathology in the hypertensive mice. Taken together, our findings suggest that 1,3-Butanediol or BHB treatment increases the ketone bodies production, and that subsequently improves the cognitive function in the hypertensive mice. Title: Meta-analysis on the molecular mechanisms underlying nicotine modulation of HIV-associated dementia

Authors: *V. KRISHNAN[1], S. L. CHANG[1], M. VIGORITO[2], N. K. KOTA[1];
[1]Inst. of NeuroImmune Pharmacology, Dept. of Biol. Sci., [2]Inst. of NeuroImmune Pharmacology, Dept. of Psychology, Seton Hall Univ., South Orange, NJ

Abstract: HIV-Associated Dementia (HAD) is a significant comorbidity that many HIV patients face. Our study utilized the Ingenuity Pathway Analysis (IPA) license from QIAGEN to identify and analyze molecular profiles and pathways underlying nicotine's impact on HAD pathology. The Qiagen Knowledge Base (QKB) defines HAD as "Dementia associated with acquired immunodeficiency syndrome (disorder)." Although much remains unknown about HAD pathology, the curated research findings from the QKB shows 5 upregulated molecules that are associated with HAD+: CCL2 (Chemokine (C-C motif) ligand 2), L-glutamic acid, GLS (Glutaminase), POLG (DNA polymerase subunit gamma), and POLB (DNA polymerase subunit beta). The current study focused on these 5 HAD pathology molecules as the phenotype of interest. The Pathway Explorer tool of IPA was used to connect nicotine-associated molecules with the 5 HAD-associated molecules (HAD pathology molecules) by connecting 29 overlapping molecules (including transcription regulators, cytokines, kinases, and other enzymes/proteins). The Molecule-Activity-Predictor (MAP) tool predicted nicotine-induced activation of the HAD pathology molecules indicating the exacerbation of HAD. However, alternative pathways with more holistic representations of molecular relationships revealed the potential of nicotine as a neuroprotective treatment. It was found that concurrent with nicotine treatment the individual inactivation of several of the intermediary molecules in the holistic pathways caused the downregulation of the HAD pathology molecules. These findings predict that nicotine may have therapeutic properties for HAD when given alongside specific inhibitory drugs for one or more of the identified intermediary molecules.

Title: I Think, Therefore You Feel: Neuropsychological Correlates of Emotion Perception In Neurodegenerative Diseases

Authors: *S. YOKOYAMA[1], Y. CHEN[2], N. Y. XU[2], C. L. BROWN[2,1], A. Y. HUA[2,1], J. H. KRAMER[1], R. W. LEVENSON[2];

Abstract: When we accurately perceive others' emotions, we engage a variety of cognitive skills. Neurodegenerative diseases lead to deficits in cognitive functioning that could disrupt the ability to perceive others' emotions accurately. In the current study, we explored how cognitive skills (i.e., executive functions and word knowledge) relate to the ability to label and track others' emotions. We recruited 87 participants (59% male; aged 34 to 80), including 63 individuals with frontotemporal dementia and 24 healthy controls, who underwent neuropsychological testing. Three aspects of executive functioning were assessed: (a) working memory, (b) task-switching, and (c) inhibition, using digits backwards, trail making, and the Stroop Task, respectively. Word knowledge was assessed using the Peabody Picture Vocabulary Test. Additionally, participants completed two laboratory tasks assessing different facets of emotion perception: (a) an emotion labeling task that measures the ability to identify specific emotions (e.g., happy, sad) experienced by characters in films, and (b) an emotion tracking task that measures the ability to continuously track the emotional valence of a character in a film using a rating dial. Regression analyses of the three aspects of executive functioning revealed: (a) better working memory (digits backwards) was associated with better performance on both emotion perception tasks, (b) task switching (trails) was not associated with performance on either emotion perception task, and (c) better inhibition (Stroop) was associated with better emotion tracking, but not emotion labeling. In contrast, greater word knowledge was associated with better emotion labeling, but not emotion tracking. All results remained consistent after controlling for participants' age and sex. Findings suggest that the ability to inhibit focus from non-target cues (as measured by the Stroop Task) is important for accurately perceiving others' emotional valence. Conversely, greater word knowledge (as measured by the Peabody Picture Vocabulary Test) appears to be related to the ability to label others' emotions, perhaps reflecting the important role that semantic knowledge plays in emotion labeling.

Title: The granulin linker domain is necessary for proper folding, trafficking, and rescue of lysosome dysfunction: Implications for treatment of Frontotemporal Dementia and Alzheimer's disease.

Authors: *P. MERINO, J. ROOT, G. TAYLOR, L. TROIANO ARAU, T. KUKAR;
Dept. of Pharmacol. and Chem. Biol., Emory Univ., Atlanta, GA

Abstract: Decreased levels of progranulin (PGRN) cause frontotemporal dementia (FTD), neuronal ceroid lipofuscinosis (NCL) and are a risk factor for Alzheimer's disease and Parkinson's disease. PGRN is a glycoprotein composed of 7.5 tandem domains called granulins (GRNs). PGRN can be cleaved by proteases to release individual GRNs. Unfortunately, the precise function of PGRN and GRNs is unclear. Complete deficiency of PGRN/GRNs causes NCL, lysosomal dysfunction, lipofuscin accumulation, neuroinflammation, and ultimately neurodegeneration. Thus, we hypothesized that the primary function of PGRN is in the lysosome. In support of this idea, we and others find that PGRN is predominantly cleaved into GRNs by cathepsins in the lysosome. However, the lysosomal function of PGRN/GRNs is still unresolved. Moreover, there are conflicting reports whether GRNs are benign, beneficial, or detrimental to cellular health and function. To resolve these questions, we focused on understanding the folding and function of GRNs in the lysosome. In this project, we dissected the contribution of the intervening peptide linkers (L1-8) between each granulin domain (GRN 1-7) in human PGRN. We find that the peptide linkers play an important role in folding and structural stability of GRNs. Briefly, transient transfection of GRN2 followed by linker 3 (GRN2+L3) leads to the secretion of a well-folded protein. In contrast, GRN2 lacking linker 3 (GRN2-ΔL3) is expressed but secreted less efficiently and forms higher-order oligomers. Further, GRN2+L3 is internalized and trafficked to the lysosome when administered to cells in the media. In contrast, GRN2-ΔL3 does not traffic to the lysosome and is unable to rescue lysosomal dysfunction in PGRN-deficient cells. We investigated this phenomenon in more detail by making a series of GRN2 constructs with mutated linker sequences. Using this strategy, we aimed to determine if any additional peptide sequence can substitute for linker 3, or if specific amino acids are necessary for proper folding, trafficking, lysosome function, and cellular toxicity. Our data reveal that the presence of the linker is necessary for the folding of GRN2, and the specific sequence of linker 3 is important for the proper folding of the protein**.** Taken together, our results provide evidence that GRN linker sequences are necessary for protein folding and function. Most importantly, our data suggest GRNs themselves are the bioactive

component of PGRN and are sufficient to maintain lysosome function and homeostasis and are potential therapeutics to treat FTD caused by *GRN* mutations.

Title: Evaluating the role of PABPC4 as a potential novel modifier of TDP-43 pathology in FTLD-TDP

Authors: *U. SHETH[1,2], N. FINCH[1], M. BAKER[1], N. R. GRAFF-RADFORD[3], B. F. BOEVE[4], R. PETERSEN[4], D. S. KNOPMAN[4], K. A. JOSEPHS[4], B. E. OSARKSSON[3], R. RADEMAKERS[1], D. W. DICKSON[1,5], Y. ZHANG[1], L. PETRUCELLI[1,2], M. M. VAN BLITTERSWIJK[1,2], T. F. GENDRON[1,2];
[1]Neurosci., [2]Mayo Clin. Grad. Sch. of Biomed. Sci., [3]Neurol., Mayo Clin., Jacksonville, FL; [4]Neurol., Mayo Clin., Rochester, MN; [5]Pathology, Mayo Clin., Jacksonville, FL

Abstract: Frontotemporal dementia (FTD), the second most common form of dementia affecting people under the age of 65, is characterized by atrophy of the frontal and temporal lobes. Frontotemporal lobar degeneration (FTLD) is used to denote its pathological diagnosis. Approximately 50% of all FTLD and 95% of all Amyotrophic Lateral Sclerosis (ALS) cases are characterized by the abnormal cleavage, phosphorylation and aggregation of TDP-43, a DNA and RNA binding protein, highlighting pathological overlap between these diseases. Thus, reducing accumulation of toxic TDP-43 presents a promising therapeutic approach. Our exciting preliminary data show that polyadenylate-binding protein 4 (PABPC4) reduces accumulation of pathological TDP-43. Through transcriptomic studies, we discovered that higher levels of frontal cortex *PABPC4* mRNA correlate with greater survival in patients with FTLD. Further, we found a significant inverse correlation between frontal cortex *PABPC4* and phosphorylated TDP-43 (pTDP-43). It is thus noteworthy that PABPC4, a predominantly cytoplasmic protein involved in regulating mRNA stability, was reported to co-aggregate with TDP-43. To examine the effect of PABPC4 on pathological TDP-43, we knocked down or overexpressed PABPC4 in cultured cells overexpressing various TDP-43 species. We noted increased pTDP-43 when PABPC4 was knocked down and, conversely, decreased pTDP-43 when PABPC4 was overexpressed. These findings are congruent with the inverse relationship between *PABPC4* and pTDP-43

accumulation in the frontal cortex of FTLD cases. These early studies uncover PABPC4 as a potential suppressor of toxic TDP-43 accumulation. Studies are underway to define the mechanisms through which this occurs, uncovering the significance of this relationship in post-mortem human tissue, and the involvement of other proteins in the PABP family.

Abstract: Vascular dementia (VaD), the second most common cause of dementia worldwide, is a progressive neurodegenerative disorder that leads to cognitive decline. It is characterised by reduced cerebral blood flow to the brain (cerebral hypoperfusion), white matter hyperintensities and increased blood-brain barrier permeability. With age being a high-risk factor for VaD, coupled with a rapidly aging population, the number of VaD cases are on the rise. With a rapid step-wise decline in disease progression, the associated mortality is high, thus emphasising the

need to tackle the issue at the soonest. Further, current treatments for VaD patients are purely symptomatic. The unknown pathophysiology of VaD underpins the difficulty of targeting the root cause of the problem. While clinicopathological considerations have been made in the research of VaD, molecular mechanisms of the disease manifestation remain largely unexplored. Given the lifestyle-associated risk factors for VaD such as diabetes and hypertension, the environment seems to play a key role in modulation of gene expression. The gene-environment interaction, in the form of epigenetic alterations, could thus perhaps explain the underlying mechanistic changes observed in the pathophysiology of VaD. This study thus aims to investigate one such epigenetic alteration in a chronic cerebral hypoperfusion (CCH) mouse model - DNA methylation. A representative VaD mouse model was established using the bilateral common carotid artery stenosis (BCAS) method that involves surgically inserting micro-coils in C57BL/6 male mice. The coils were left in the mice for different timepoints of 7, 15 and 30 days respectively to study the temporal differences in the DNA methylation landscape. Additionally, as a nexus between the gene-environment interaction, intermittent fasting (IF), which involves time restricted feeding, was introduced as a prophylactic intervention. Hence, a parallel group of mice with the same timepoints were fasted for 16 hours every day for a period of 4 months before BCAS surgery was performed. At the end of the respective timepoints, the mice were sacrificed, and the DNA extracted from the cerebral cortex were sent for DNA methylation sequencing. This study, for the first time, shows that BCAS-induced CCH altered the DNA methylation landscape compared to the controls. Interestingly, with IF, the DNA methylation landscape was re-modelled and showed signs of reversal of the methylation status. IF ameliorated cognitive impairments induced under CCH and attenuated the neuropathological alterations as well. Therefore, IF shows promise in offering potential beneficial effects under CCH.

Title: Non-canonical role of PINK1 in modulating PKA function and dendrite outgrowth.

Authors: *S. K. SOMAN, R. K. DAGDA;
Pharmacol., Univ. of Nevada Reno, Reno, NV

Abstract: Background: Over more than 40 loss of function mutations in PTEN-induced Kinase 1 (PINK1) causes early-onset Parkinson's disease (PD) in humans. In the mitochondrion, full-length PINK1 is a serine-threonine kinase with a predominant role in enhancing mitophagy in oxidatively stressed neurons. However, emerging evidence suggests an extra-mitochondrial role of post-translationally processed, cleaved PINK1 (c-PINK1) in promoting neuronal development and plasticity. Like c-PINK1, Protein Kinase A (PKA) activity is vital for neuronal physiology, and *in vitro* and *in vivo* models of PD have shown that a deficiency in PKA function contributes to PD pathology. Our previous studies have shown that c-PINK1 and PKA interact to modulate neuronal plasticity by stabilizing dendritic networks through the extracellular release of Brain-Derived Neurotrophic Factor (BDNF). **Problem:** *The molecular mechanism(s) and spatio-temporal dynamics by which PINK1 promotes PKA-mediated dendrite outgrowth remains to be determined*. **Methods:** Primary Cortical Neurons (PCNs), prepared from 14 to 15-day C57BL/6 and PINK1-KO mouse embryos, were used as an experimental model. Kinetin (50µM) was used to activate endogenous PINK1 pharmacologically. Western blotting and ELISA were used to measure PKA subunit expression and phosphorylation patterns. Statistical analysis was performed with GraphPad Prism 5.0. Results are expressed as mean ±SEM from three independent experiments. The data analysis was performed by the experimentalist blind to experimental groups. One-way ANOVA with Bonferroni's post-hoc correction or Student's t-test were used as appropriate. **Results:** A significant reduction in the endogenous level and activation status of various subunits of the PKA holoenzyme was observed in PINK1-KO primary cortical neurons (PCN's) compared to WT-PCN's, suggesting that a loss of PINK1 function leads to reduced global neuroprotective PKA activity. In addition, in *vitro* PKA activity assays suggest that PINK1-mediated activation of PKA occurs within 8 hrs. and plateaus by 12 hours following treatment of PCNs with kinetin. Mechanistically, c-PINK1 enhances the autocatalytic-mediated activation of PKA and reduces the activation threshold by phosphorylating Type II regulatory subunits of PKA. To further elucidate the correlation between PINK1 activity and PKA function in dendrites, FRET-based PKA sensors were employed to analyze the spatio-temporal dynamics of PKA activation by PINK1 in dendrites of PCNs. **Conclusion:** Overall, our study demonstrates that PINK1 modulates PKA function and highlights the extra-mitochondrial and neuroprotective roles of PINK1 in neurons.

Title: Layer-specific enteric glial cell response and gut immune events during the neurodegenerative process in the mouse model of Parkinson's disease induced by 6-hydroxydopamine

Authors: *B. THOMASI[1], L. VALDETARO[1], L. S. HAYASHIDE[1], A. M. N. FERNANDES[1], A. MUSSAUER[1], M. L. SILVA[1], M. RICCIARDI[1], N. ROCHA[1], A. C. FARIA-MELIBEU[1], M. L. RIBEIRO[1], P. CAMPELLO-COSTA[1], V. MOURA-NETO[2], A. TAVARES-GOMES[1]; [1]Univ. Federal Fluminense, Niterói, Brazil; [2]Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Enteric glial cells (EGCs) constitute the majority of the neural population of the enteric nervous system and are found in all layers of the gastrointestinal tract (GIT). They are active in enteric functions such as immunomodulation, as evidenced by the regulation of the intestinal epithelial barrier (IEB). Both EGCs and IEB have been described as altered in Parkinson's disease (PD). Our previous results working with the mouse model of PD induced by 6-hydroxydopamine (6-OHDA) showed a colonic inflammatory response marked by increased IBA1 and GFAP immunoreactivity in the colonic mucosa. Our goal was to explore colonic histology, EGCs, and immune components in the GIT layers during the neurodegenerative process induced by 6-OHDA. C57Bl6 male mice were unilaterally injected with 6-OHDA in the striatum and another group of animals operated was used as controls. Animals were submitted to an indirect motility assay through feces water analysis. Colon tissue was extracted for different analyses at 48h, one week (1w), and two weeks (2w) post-lesion. Through H&E staining and immunofluorescence, we evaluated the myenteric ganglia. For biochemical analyses, the neuromuscular and mucosal layers were microdissected to Western blotting. 6-OHDA injected animals present less water percentage in their feces only at 1w and 2w post-lesion ($n=7$, $p\leq0.05$), pointing to dysmotility. At 48h post-lesion, GFAP and p-p38MAPK expression increased in the neuromuscular layer ($n=5$ and $n=3$, respectively, $p\leq0.05$) meanwhile no modifications in TNF-α, GDNF, and occludin expression in the mucosal layer. 1w post-induction, myenteric ganglia area ($n=3$, $p\leq0.05$) and neuromuscular GFAP content increased ($n=5$, $p\leq0.05$) as well as mucosal TNF-α ($n= 4$, $p\leq0.001$), GDNF ($n=6$, $p\leq0.05$), and occludin expression ($n=4$, $p\leq0.05$). Also, the intraganglionic glia presented an altered morphology with an ameboid profile and less S100β immunolabeling. 2w after model induction, ganglia area were still increased ($n=3$, $p\leq0.05$) with less S100β staining and occludin expression in the 6-OHDA group ($n=3$, $p\leq0.05$). At 48h time after neurodegeneration induction, we detected an increase in GFAP in the neuromuscular layer, suggesting that it may be a primary event for the upregulation of GDNF, TNF-α, and occludin in the intestinal mucosa. In addition, EG seems to elicit a plastic molecular response through time. EGCs are a complex and plastic cell type that regulates immune interactions in the gut, contributing to inflammatory responses. So, EG modulation may be an early enteric sign induced by parkinsonian neurodegeneration followed by inflammatory, dysmotility signs, and IEB structural plasticity.

Title: Death-associated protein kinase (DAPK1) and its role in a 6-OHDA mouse model of Parkinson's disease.

Authors: *M. SANTORO, A. T. ADAM, R. K. LAM, C. BACHMEIER, M. SHAMLOO; Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: Death-associated protein kinase (DAPK1) belongs to a large family of Ca^{2+}/calmoduline regulated serine/threonine kinases. Its cellular functions entail regulation of the cell cycle, autophagy, phagocytosis, and apoptosis. Mounting evidence suggests the involvement of DAPK1 in neurodegenerative diseases due to its dysregulated activity linked to Ca^{2+}/glutamate neurotoxicity and the initiation of pro-apoptotic cell pathways. In addition, a strong link between variants of DAPK1 and the incidence risk of Alzheimer's disease has been reported in several studies. To date, the role of DAPK1 in Parkinson's disease (PD) is poorly understood. In light of the pivotal roles of DAPK1 on cell survival and cell death, we hypothesize that dysregulation of DAPK1 activity in the aged brain contributes to the apoptotic cell demise of nigrostriatal dopaminergic neurons observed in PD patients. To answer our questions, we identified a lead molecule with selective inhibitory activity against DAPK1. Three analog compounds were synthesized and selected based on their IC_{50} for *in-vitro* screening. *In-vivo* experiments relied on male C57BL/6J mice aged 4 and 19 months. In addition, male mice C57BL/6J mice 12 weeks old were stereotaxically infused in the striatum with 2 µl of a 0.05 % solution of ascorbic acid containing 10 µgr of 6-OHDA per µl. We observed DAPK1 protein levels significantly down-regulated in the hippocampus of aged mice (55.6 % ± 24.9). Oppositely, protein levels of the inactive form of DAPK1 (phosphorylated on the serine 308) are increased against total DAPK1 (n=10 per group, $p < 0.05$). A similar trend was observed in the 6-OHDA treated mice with total protein levels of DAPK1 decreased. *In-vitro* assessment of toxicology and neuroprotective effects of our three novel DAPK1 inhibitors showed high tolerability of our analogs in human microglial cells and rat cortical neurons with a survival rate above 95 %. On the other hand, pretreatment of rat cortical neurons did not protect them against NMDA neurotoxicity. Furthermore, incubation of human microglia with our novel DAPK1

inhibitors does not impair phagocytosis. Our findings provide robust evidence for DAPK1 involvement in PD. Elucidation of autophagy and phagocytosis pathways using knocked-out DAPK1 mice will be conducted using an α-synuclein mouse model to elucidate the role of DAPK1 in amyloidosis and dopaminergic neuron vulnerability.

Title: Dopaminergic Neurons generated from iPSCs carrying mutations in either SNCA, GBA or LRRK2 recapitulate salient Parkinson’s disease phenotypes

Authors: *A. FATHI, S. DICKERSON, A. MUSKINSKY, M. MILLER, W. POON, J. LIU; Fujifilm Cell. Dynamics Inc., Madison, WI

Abstract: Human iPSC-derived dopaminergic neurons offer a developmentally and physiologically relevant *in-vitro* model of human midbrain dopaminergic neurons that innervate different regions in the CNS including the forebrain and striatum. Loss of dopaminergic neurons cause decreased dopamine levels in the CNS and result in neurodegenerative conditions including Parkinson’s disease (PD). Dopaminergic neurons decline with age and are selectively vulnerable to oxidative stress generated by dopamine oxidation that increases with age. The present study outlines the generation and characterization of iPSC derived dopaminergic neurons from two PD patients that inherited either the GBA (N370S) or LRRK2 (G2019S) mutation and genetically engineered SNCA A53T iPSCs. End stage dopaminergic neurons derived from healthy as well PD donors were assessed for GBA activity, neuronal MEA activity, and alpha-synuclein-mediated protein aggregation. These results recapitulated the many features of PD in a dish. Thus, this panel of human iPSC-derived dopaminergic neurons carrying disease-specific mutations can be used for various in vitro applications to uncover mechanistic insights of dopaminergic neuronal degeneration and identification of novel therapeutic targets.

Med., Baltimore, MD

Abstract: Intraneuronal accumulation of α-synuclein aggregates and the subsequent death of substantia nigra *pars compacta* (SNpc) dopamine (DA) neurons are hallmarks of Parkinson’s disease (PD). Microglial activation of the Nod-Like Receptor Protein-3 (NLRP3) inflammasome has been well-documented in various neurodegenerative diseases, including PD. We show here that loss of activity of the PD-associated E-3 ubiquitin ligase parkin in mouse and human DA neurons results in spontaneous neuronal NLRP3 inflammasome assembly, leading to DA neuron death. Parkin normally inhibits inflammasome priming by ubiquitinating and targeting NLRP3 for proteasomal degradation. Loss of parkin activity also contributes to assembly of active NLRP3 inflammasome complex via mitochondrial-derived reactive oxygen species (mitoROS) generation through the accumulation of another parkin ubiquitination substrate, ZNF746/PARIS.

Inhibition of neuronal NLRP3 inflammasome assembly prevents degeneration of DA neurons in familial and sporadic PD models. Strategies aimed at limiting neuronal NLRP3 inflammasome activation hold promise as a disease modifying therapy for PD.

Title: Phenotyping Parkinson's disease in patient-derived fibroblasts

Authors: *A. MCROBBIE-JOHNSON, E. CARRUTH, M. J. CORENBLUM, L. MADHAVAN;
Univ. of Arizona, Tucson, AZ

Abstract: Parkinson’s disease (PD) is a common age-related neurodegenerative disorder characterized by debilitating motor deficits and neurocognitive decline. It affects more than 10 million people worldwide, however, has no cure. A major roadblock impeding the development of effective therapeutics has been the inadequate understanding of PD etiopathology, coupled with its relatively late diagnosis at an advanced stage. Our previous work reported specific cellular and molecular alterations in skin fibroblasts of late-onset sporadic PD subjects, that distinguished them from fibroblasts of healthy controls (Teves et al. 2018). Based on these findings, the current work (1) further validates fibroblast features highly predictive of PD, and (2) assesses whether particular changes in the fibroblasts can track PD severity and progression. More specifically, we examined several fibroblast lines obtained from sporadic PD and healthy control individuals at <5 years from diagnosis (early-stage disease) and at post-mortem (end-stage disease). These fibroblast lines were subjected to a range of assays examining cell growth,

morphology, viability, redox status, mitochondrial and autophagic function. It was found that fibroblasts from early-stage PD patients were significantly smaller and rounder, and showed higher rates of proliferation, compared to age- and sex-matched control lines. This was associated with higher reactive oxygen species (ROS) levels (DCFDA assay), mitochondrial dysfunction (Seahorse Mito Stress test) and lower viability rates (MTT assay) in the PD fibroblasts. Additionally, PD cells displayed increased numbers of autophagic vesicles (electron microscopy), and greater autophagic flux as indicated by changes in the standard autophagy markers, LC3II and P62 (western blotting). Correlatively, a significantly higher expression of the PD-relevant protein alpha-synuclein (α-syn), a target of autophagy, was noted in the PD cells. Interestingly, preliminary data from the fibroblasts of the post-mortem cases indicated slower growth rates but further elevated levels of ROS, as well as highly reduced viability in the PD fibroblasts. In essence, these data suggest that patient-derived skin fibroblasts can not only serve as a useful system for diagnosing sporadic PD, but potentially also monitoring PD progression and severity.

Title: Cell-type specific alteration of excitability in the substantia nigra pars reticulata of parkinsonian mice

Authors: *L. DELGADO ZABALZA[1], M. GARRET[2], J. BAUFRETON[1], C. MIGUELEZ[3]; [1]Inst. of Neurodegenerative disorders, Univ. of Bordeaux, CNRS-UMR 5293, Bordeaux, France; [2]Inst. for Cognitive & Integrative Neurosci. Aquitaine, Univ. of Bordeaux, CNRS-UMR 5287, Bordeaux, France; [3]Pharmacol., Univ. of the Basque Country (UPV/EHU), Leioa, Vizcaya, Spain

Abstract: The *substantia nigra pars reticulata* (SNr) is the main output nucleus of the basal ganglia (BG), a subcortical network involved in motor, cognitive and associative functions. Recently, parvalbumin-expressing SNr subpopulation has been associated with motor functions; however the impact of dopamine depletion on the excitability of motor-related SNr-PV neurons is unknown. By combining immunohistochemical and electrophysiological *in vitro* approaches in

PVCre::Ai9T mice, we demonstrated that SNr-PV neurons exhibit different anatomical, molecular and electrophysiological profiles than non PV-expressing SNr neurons. Moreover, we revealed that only SNr-PV neurons lose their excitability in the unilateral 6-OHDA mouse model of PD, due to a reduction in background sodium currents in these neurons. Currently, we are using chemogenetic approaches to improve motor symptoms in parkinsonian mice and to demonstrate a causative relationship between SNr-PV excitability and motor function.

Title: S100b alters intrinsic firing and ca^{2+}activity of dopaminergic neurons: implications for parkinson's disease.

Authors: *E. A. BANCROFT[1], G. PANDEY[1,2], S. M. ZARATE[1], R. SRINIVASAN[1,2]; [1]Neurosci. & Exptl. Therapeut., Texas A&M Univ. Col. of Med., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Parkinson’s disease (PD) is associated with an abnormal increase in S100B within the midbrain and cerebrospinal fluid. In addition, overexpression of S100B in mice accelerates the loss of substantia nigra pars compacta (SNc) dopaminergic (DA) neurons, suggesting a role for this protein in PD pathogenesis. We found that in the mouse SNc, S100B-labeled astrocytic processes completely envelop the somata of tyrosine hydroxylase (TH) positive DA neurons. Based on this finding, we rationalized that abnormal increases in extracellularly secreted S100B by astrocytic processes in the SNc could alter DA neuron activity, thereby causing dysregulated midbrain function. To test this hypothesis, we measured the effect of bath perfused S100B peptide on the frequency and amplitude of spontaneous Ca^{2+} fluxes in identified TH+ and TH- midbrain neurons from 3-week old mouse primary midbrain cultures. Acute exposure to 50 pM S100B caused a 2-fold increase in Ca^{2+} flux frequency only in TH+ DA neurons. The L-type voltage-gated calcium channel (VGCC) inhibitor, diltiazem eliminated S100B-mediated increases in DA neuron calcium flux frequency, while the T-type specific VGCC blocker mibefradil failed to inhibit the stimulatory effect of S100B. We next asked if changes in intrinsic firing of DA neurons are upstream of the observed S100B-mediated changes in Ca^{2+} activity. We

performed whole cell electrophysiology in identified TH+ and TH- midbrain neurons to determine the effect of acute S100B application on recorded APs in aCSF containing AP5, NBQX, and Bicuculline. Interestingly, acute S100B application increased AP frequency in TH+ DA neurons alone. Because AP firing frequency is known to be regulated by activity of voltage-gated potassium channels (VGKCs), we also determined the effect of acute S100B application on Kv currents in midbrain neurons. Surprisingly, only TH+ DA neurons displayed an inhibition of Kv currents in the presence of 50 pM S100B, suggesting that S100B may inhibit activity of voltage-gated potassium channels (VGKCs) specifically expressed on DA neurons. Together, our results suggest that exposure to S100B pathologically alters intrinsic firing in midbrain neurons, thereby altering spontaneous Ca^{2+} activity. We propose that these changes are initiated via an extracellular interaction between S100B and VGKCs expressed in DA neurons. Our findings are relevant to understanding the complex mechanisms underlying DA neuron loss during PD.

Title: Ultrastructural plasticity of pallidothalamic terminals in the motor thalamus of <MPTP-treated parkinsonian monkeys: A 3D> quantitative analysis.

Authors: *G. J. MASILAMONI[1], H. KELLY[2], A. J. SWAIN[3], Y. SMITH[4];
[1]Yerkes Natl. Primate Res. Center, UDALL Cen, Atlanta, GA; [2]Yerkes Natl. Primate Ctr., Atlanta, GA; [3]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [4]Yerkes Res. Ctr., Udall Ctr. Excel. For Parkinson's Dis. and Dept. of Neurol., Atlanta, GA

Abstract: In the primate thalamus, the parvocellular ventral anterior nucleus (VApc) and the centromedian nucleus (CM) are under the control of tonic inhibitory inputs from large GABAergic terminals from the internal globus pallidus (GPi). In Parkinson’s disease and animal models of parkinsonism, the loss of nigrostriatal dopamine results in an increased inhibitory pallidothalamic outflow and complex changes in firing rates, firing patterns, and oscillatory firing properties of thalamocortical neurons (Kammermeier et al., 2016, J Neurophysiol 116:2869). Giving that the maintenance of tonic GABAergic synaptic transmission at high presynaptic firing rates is associated with specific ultrastructural features in terminals volume,

number and size of synapses and volume/number of mitochondria in the thalamus and other brain regions (Wanaverbecq et al., 2008, J Neurosci 28:11848; Barberis, 2020, Neuropharmacology 169:107643), we used a Single Block Facing/Scanning Electron Microscopy (SBF/SEM) high resolution 3D electron microscopic approach to compare the morphometry of single GPi terminals in the motor thalamus of 2 control and 2 MPTP-treated parkinsonian monkeys. Our findings demonstrate that pallidothalamic terminals in VApc and CM undergo major ultrastructural changes in parkinsonian monkeys: (1) increased volume terminal volume in both nuclei, (2) increased surface area of synapses in both nuclei, (3) increased number of synapses/GPi terminals in the CM, but not VApc, (4) increased total volume of mitochondria/terminals in both nuclei and increased number of mitochondria in CM. Our findings also show striking morphological differences in terminal volume, number/area of synapses and volume/number of mitochondria between GPi terminals in VApc and CM in control monkeys. In conclusion, results of this study demonstrate that GABAergic pallidothalamic terminals are endowed with a high level of structural plasticity that may contribute to the development and maintenance of the abnormal increase in pallidal outflow to the thalamus in the parkinsonian state. Furthermore, the evidence for ultrastructural differences between GPi terminals in VApc and CM suggests that morphologically distinct pallidothalamic terminals underlie specific physiological properties of pallidal inputs to VApc and CM in normal and diseased states.

Title: Pathogenic α-Synuclein inactivates translation repressor eIF4E-BP1 in Parkinson’s diseas

Authors: *M. KHAN[1], T. M. DAWSON[2], V. L. DAWSON[3];
[1]Johns Hopkins Med. Institutions, Baltimore, MD; [2]Inst. for Cell Engin., Johns Hopkins Univ. Inst. for Cell Engin., Baltimore, MD; [3]Inst. Cell Engin., Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Inhibition of cap-dependent translation by active eIF4E-BP1 (4E-BP1) serves as evolutionarily conserved survival mechanism under various stress conditions which include oxidative stress, immune stress and unfolded protein response. 4E-BP1 is a 5’-Cap dependent

translation inhibitor of mRNA transcripts. In recent years, neuroprotective roles of active 4E-BP1 have emerged in sporadic, autosomal recessive and dominant Parkinsonism. However, posttranslational status of 4E-BP1 is unknown in Parkinson's disease (PD) models and human PD brain. Here we report that 4E-BP1 is post-translationally phosphorylated and inactivated in both PD models and human PD brain. We applied novel proteomics approaches to explore the underlying molecular basis of 4E-BP1 inactivation and translation upregulation in α-Synuclein PFF (Pre-Formed Fibril) mice and cellular models. Our proteomics and Single Molecule Pulldown (SiMPull) data strongly suggest that α-Syn PFF directly interacts with TSC2 and destabilizes TSC1-TSC2 complex, which results in persistent mTORC1 activation and 4E-BP1 inactivation. We generated transgenic models to overexpress active 4E-BP1 in α-Syn toxic background. Overexpression of 4E-BP1 in α-Syn PFF treated neuron shows neuroprotection and block α-Syn pathology. Double transgenic α-Syn:4E-BP1 flies show dopamine neuron protection, rescue motor deficits and mitochondrial defects. Taken together, we provide novel molecular evidences of 4E-BP1 inactivation in Parkinson's disease and restoration of 4E-BP1 activity serves as a conserved protective mechanism against PD pathogenesis.

Abstract: Brain lipid dyshomeostasis has been proposed as an early pathological event that triggers the neurodegeneration of energy-demanding dopaminergic neurons in Parkinson's disease (PD). In line with this notion, several studies have reported the presence of lipid-enriched vesicles in the Lewy Bodies found in PD brain tissues and various experimental models of PD.

Moreover, several genetic risk factors for PD (for example, *PLA2G6*, *GBA*, and *SREBF1*) have known molecular functions in lipid homeostasis, suggesting a potential involvement of lipid dysregulation in PD pathogenesis. Intriguingly, the PD-linked protein Parkin has been reported to functionally interact with the fatty acid translocase CD36 and the major regulators of lipid metabolism, namely Sterol Regulatory Element Binding Proteins (SREBPs). However, Parkin modulation on brain lipid metabolism and its potential relevance in dopaminergic neuronal death remain elusive. In this study, we demonstrate by means of multiple experimental models that Parkin regulates SREBP2-Lipoprotein Lipase (LPL) pathway in neurons. We show that Parkin expression level positively correlates with neuronal LPL protein level and activity in human neuroblastoma cell line and a Parkin knockout (KO) mouse model. We identified SREBP2, an important transcription factor involved in lipid metabolism and cholesterol biosynthesis, as a potential mediator between Parkin and LPL. Supporting this, CRISPR-mediated KO of SREBP2 prevented Parkin effect on LPL expression. We further demonstrate that Parkin-SREBP2-LPL pathway regulates the intracellular deposition of lipid droplets (LDs), cellular organelles that are associated with neurodegeneration. Interestingly, this pathway is upregulated upon cellular exposure to PD-linked oxidative stress, which is known to induce accumulation of intracellular LDs. Finally, our data demonstrate that inhibition of either LPL or SREBP2 exacerbates cell deaths triggered by excessive oxidative stress. Taken together, our findings reveal a novel pathway implicating Parkin, SREBP2, and LPL in neuronal lipid homeostasis and LD formation in a PD-relevant context.

Title: Altered mitochondrial dynamics disrupts endoplasmic reticulum-mitochondria contacts in Huntington’s disease

Authors: *N. SAWANT, S. KUMAR, P. REDDY;
Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Huntington's disease (HD) is a fatal, progressive neurodegenerative disease, clinically characterized by chorea, seizures, cognitive decline, and emotional disturbances. Recent research suggests that abnormal interactions between mutant huntingtin (mHTT) and mitochondrial

fission protein - dynamin-related protein 1 (DRP1), induces free radical production and causes excessive mitochondrial fragmentation. Further, the excess fragmentation may also disrupt mitochondrial association with other cell organelles such as the endoplasmic reticulum (ER), as previously reported in other neurodegenerative diseases. These specialized contact sites with ER, known as mitochondria associated membranes (MAMs) are critical for maintaining calcium homeostasis, as mitochondria are major Ca2+ storage sites, therefore disrupted MAMs could be key in HD pathogenesis. **Experiment design:** Mutant HD STHdh$^{Q111/Q111}$ and wild type STHdh$^{Q7/Q7}$ cells were used for studying proteins such as IP3R3, GRP75, VDAC1 and Mfn2 involved in the ER-mitochondria interaction. The cells were treated with mitochondrial division inhibitor 1 (Mdivi1), an inhibitor of Drp1, to see if reduced mitochondrial fragmentation improves MAM contacts. **Methods:** Immunoblotting, immunofluorescence, immunoprecipitation, and co-localization (using pDsRed2-Mito and GFP-Sec61-β constructs for labelling mitochondria and ER respectively) techniques were used to study MAMs and associated proteins, along with mHTT. **Results:** The MAM contacts which were diminished in STHdh$^{Q111/Q111}$ cells, were significantly increased upon Mdivi1 treatment, along with increased IP3R3 and GRP75 interactions. Further, Mdivi1 increased IP3R3 and Mfn2 levels in both wild-type and mutant groups and mHTT localization was less nuclear after treatment. **Conclusion:** Taken together these findings suggest that Mdivi1 reduces excessive mitochondrial fragmentation, reduces mHTT toxicity in HD neurons, and restores the ER-mitochondrial contacts.

Title: Investigating androgen receptor dimerization as a novel mediator of toxicity in SBMA

Authors: *A. LISBERG[1], D. E. MERRY[2];
[1]Dept. Biochem. and Mol. Biol., [2]Dept Biochem & Molec Biol, Thomas Jefferson Univ., Philadelphia, PA

Abstract: Spinobulbar muscular atrophy (SBMA) is a progressive neuromuscular degenerative disease caused by a polyglutamine (polyQ) expansion in the androgen receptor (AR). This mutation causes misfolding and aggregation of the protein as well as cell dysfunction and death. While advances in the understanding of the molecular pathogenesis of SBMA have been made,

there is still no effective treatment for this disease. One pathogenic mechanism involves an AR interdomain interaction, deemed the N/C-interaction, that has been shown to be required for polyQ-expanded AR toxicity. This project seeks to understand the mechanism that underlies the role of the N/C interaction in SBMA to develop better therapeutics for this disease. Our initial experiments revealed that the AR N/C interaction is decreased by polyglutamine expansion, consistent with the known impact of the polyglutamine tract on adjacent AR protein structure. This result led us to hypothesize that different forms of the N/C interaction, which occur in either monomeric or dimeric AR, played different roles in SBMA pathogenesis. Using a biochemical assay to evaluate AR dimerization, we found that AR dimerization is increased upon polyglutamine expansion and is decreased upon N/C blockade, supporting the hypothesis that aberrant dimerization may play a role in the toxicity of polyQ-expanded AR. We next tested the hypothesis that AR dimerization, mediated by distinct amino acids within the DNA binding domain, is required for mutant AR aggregation and toxicity, and observed that blocking dimerization decreased nuclear inclusion formation. Investigation into the effect of blocking dimerization on polyQ-expanded AR toxicity in PC12 cells, mouse motor neurons, and iPSC lines is ongoing. Of note, we observed an increased cytoplasmic localization and decreased stabilization of dimerization-blocked AR that is not due to changes in AR nuclear export. Paired with quantitative differential interactome studies that have identified proteasomal components as interactors of interest, this finding suggests that enhanced AR degradation may play a role in the protection seen upon blocking AR dimerization. Further investigation into the role of proteasomal degradation is ongoing. Overall, this work seeks to provide further insight into the molecular mechanisms of SBMA pathogenesis and has identified AR dimerization as a novel mediator of toxicity in this disease.

Title: Morpholino-based TUBA4A knockdown in zebrafish recapitulates ALS-related abnormalities

Authors: *E. VAN SCHOOR[1,2], V. BERCIER[1,2], E. BRAEMS[1,2], P. VAN DAMME[1,3,2], D. R. THAL[2,4], L. VAN DEN BOSCH[1,2];
[1]Ctr. for Brain & Dis. Res., VIB, Leuven, Belgium; [2]KU Leuven, Leuven, Belgium; [3]Dept. of Neurol., [4]Dept. of Pathology, Univ. Hosp. Leuven, Leuven, Belgium

Abstract: Aim
Disease-associated variants of *TUBA4A* (alpha-tubulin 4A) have recently been identified in familial ALS patients. It was also shown that this mutated TUBA4A ineffectively forms tubulin dimers *in vitro* [1]. Interestingly, a downregulation of TUBA4A protein expression was suggested in familial as well as sporadic ALS patients [2]. To investigate whether a decreased TUBA4A protein expression could be a driving factor in ALS pathogenesis, we assessed if knockdown of TUBA4A expression in zebrafish could recapitulate an ALS-like phenotype.
Methods
We injected one- to two-cell stage zebrafish embryos from the AB strain with ATG morpholino's against the zebrafish TUBA4A (Tuba8l2). Western blotting was used to confirm the TUBA4A knockdown. To analyze axonal length, fish were fixed with 4% PFA and stained using an antibody against synaptic vesicle 2 (SV2). Motor behavior was assessed using the touch-evoked escape response (TEER). Finally, TUBA4A protein expression levels were assessed in post-mortem brain tissue of ALS patients.
Results
TUBA4A protein downregulation was indeed observed in post-mortem motor cortex of ALS patients. When we performed an ATG morpholino-based knockdown of zebrafish TUBA4A, this induced axonal branching defects at 48 hpf (hours post fertilization) as observed by SV2 immunohistochemistry. In addition, a decrease in maximal and average velocity as well as time and distance travelled was observed using the TEER assay. Both phenotypes were morpholino dose-dependent and could be rescued by the addition of wild-type *TUBA4A* mRNA, but not the ALS-related mutant A383T *TUBA4A* mRNA.
Conclusions
Knockdown of zebrafish TUBA4A using an ATG morpholino induces an axonal branching phenotype as well as motor behavior defects, reflecting a motor neuron disease-related phenotype. Addition of wild-type *TUBA4A* mRNA rescues this phenotype, further strengthening the causal relation with TUBA4A knockdown. Importantly, TUBA4A downregulation was observed in ALS post-mortem motor cortex tissue. Our data point towards an involvement of disturbances in the expression of TUBA4A in ALS disease pathogenesis.

Title: Molecular mapping of genetic modifiers in Tuberous Sclerosis (TSC) disease severity throughgenomic approaches

Authors: *A. HOWELL, D. ENRIQUEZ, C. LEGENDRE, P. SWAMINATHAN, H. FRY, S. KANESHAMOORTHY, W. LIANG, V. NARAYANAN, S. RANGASAMY;
Tgen, Phoenix, AZ

Abstract: Tuberous sclerosis complex (TSC) is an autosomal dominant neurogenetic disorder, in which affected individuals are heterozygous for a mutation in either the *TSC1* or *TSC2* gene, thereby causing constitutive activation of the mTOR signaling pathway. Phenotypic variability (PV) in TSC is well recognized, but its molecular basis is not understood. Variability in phenotype can be seen even within a single family (intrafamilial phenotypic variability [IPV]), where all affected individuals have the same TSC gene mutation. IPV clearly indicates that *TSC1* or *TSC2* mutation alone does not account for the observed phenotype and suggests a potential role for modifying factors. Mechanisms currently proposed for PV in monogenic disorders includes modifying effects of unlinked genes (**genetic modifiers**), epigenetic factors, mosaicism, allelic skewing of gene expression, and environmental or other stochastic factors. At the Center for Rare Childhood Disorders (C4RCD), we have assembled a cohort of 16 TSC-afflicted families that exhibit phenotypic variability between parent and child. Using whole exome and RNA sequencing, we aim to (1) identify aberrant gene expression, aberrant splicing, and mono-allelic expression in severe vs mildly afflicted patients (2) identify genetic modifiers in WES data that may be correlated with expression differences in severe vs mildly afflicted patients. Preliminary results using the R tool DESeq2 demonstrates that the differentially expressed gene set between severe and mild forms of TSC. Gene set enrichment analysis (GSEA) indicate that genes are associated with protein processing in endoplasmic reticulum and cell adhesion molecules. Previous research has shown that in human TSC-associated renal angiomyolipoma cells endoplasmic reticulum (ER) stress can develop due to mTORC1-driven protein translation, supporting our functional enrichment analysis. Additional linear regression models using Lasso will incorporate mutation type, mTOR pathway variants, and patient symptoms to predict differential gene expression, aberrant splicing, and mono-allelic expression (MAE) identified

through the detection of RNA outliers' pipeline (DROP). By understanding the molecular basis of PV, we aim to define a better genetic predicators of disease severity and new treatment for TSC.

Title: Tdp-43 is essential for oligodendrocyte myelination by regulating srebf2-mediated cholesterol metabolism

Authors: *S.-C. LING[1], W. HO[1], J.-C. CHANG[1], K. LIM[1], G. TUCKER-KELLOGG[1], A. CAZENAVE-GASSIOT[1], M. WENK[1], E. B. LEE[2], A. NGUYEN[2], S.-Y. NG[1], S. ONG[1], A. VIERA-ORTIZ[2];

Abstract: Cholesterol metabolism operates autonomously within the central nervous system (CNS), where the majority of cholesterol resides in myelin. We demonstrate that TDP-43, the pathological signature protein for amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), regulates cholesterol metabolism in oligodendrocytes. TDP-43 binds directly to mRNA of SREBF2, the master transcription regulator for cholesterol metabolism, and multiple mRNAs encoding proteins responsible for cholesterol biosynthesis and uptake, including *HMGCR*, *HMGCS1*, and *LDLR*. TDP-43 depletion leads to reduced SREBF2 and LDLR expression, and cholesterol levels *in vitro* and *in vivo*. TDP-43-mediated changes in cholesterol levels can be restored by reintroducing SREBF2 or LDLR. Additionally, cholesterol supplementation rescues demyelination caused by TDP-43 deletion. Furthermore, oligodendrocytes harboring TDP-43 pathology from FTD patients show reduced HMGCR and HMGCS1, and co-aggregation of LDLR and TDP-43. Collectively, our results indicate that TDP-43 plays a role in cholesterol homeostasis, and cholesterol dysmetabolism may be implicated in TDP-43 proteinopathies-related diseases.

Title: Effects of SOD1 aggregates on the electrophysiological properties of hESC-derived motor neurons

Authors: E. MOON[1], *G. AARON[2], A. O'NEIL[3];
[1]Neurosci. and Behavior Program, [2]Biol. Dept. and Neurosci. and Behavior Program, [3]Chem. Dept. and Neurosci. and Behavior Program, Wesleyan Univ., Middletown, CT

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease characterized by the dysfunction and death of motor neurons in the spinal cord, brain stem, and motor cortex. Approximately 10% of all ALS cases are familial (fALS) and have been linked to a variety of genetic mutations. About 20% of fALS cases are linked to a mutation in the *superoxide dismutase 1 (SOD1)* gene. Wild type SOD1 is an antioxidant protein responsible for capturing superoxide radicals and preventing oxidative damage. In individuals with SOD1-linked fALS, SOD1 mutations confer a toxic gain of function, resulting in abnormal protein aggregation. Interestingly, SOD1 aggregates are specifically toxic to motor neurons, causing previously healthy cells to die. Other types of neurons also incorporate SOD1 aggregates but show no signs of toxicity. Furthermore, research in both mouse and human pluripotent stem cell models of fALS have shown that motor neurons with SOD1 mutations have different electrical properties and firing patterns compared to wild type controls. Some findings suggest that motor neurons with SOD1 mutations are hyperexcitable while others suggest that cells are hypoexcitable. This apparent contradiction has led to the hypothesis that hyperexcitability may be an early, presymptomatic neuroprotective mechanism and that motor neurons transition into a phase of late hypoexcitability following disease onset and progression. The reasons for these changes in excitability are not fully understood, but work in both mice and humans has shown alterations in ion channel expression and properties as possible causes. Here, we use motor neurons differentiated from human embryonic stem cells with a GFP-Islet1 reporter and matured in culture for 21 days. Following maturation, we add H46R SOD1 aggregates to the culture medium for 72-120 hours. Using whole-cell patch clamp analysis, we show that hESC-derived motor neurons treated with SOD1 aggregates have a significantly depolarized resting membrane

potential and action potential threshold compared to healthy controls, potentially linking SOD1 aggregates to electrophysiological changes.

Title: Superoxide dismutase-1 aggregate strain type in human and transgenic mice amyotrophic lateral sclerosis

Authors: *T. BRANNSTROM[1], I. SIGFRIDSSON[1], E. STENVALL[1], K. FORSBERG[2], P. M. ANDERSEN[2], S. L. MARKLUND[1];
[1]Med. Biosci., [2]Clin. Neurosciences, Umeå Univ., Umeå, Sweden

Abstract: Mutations in SOD1 are a common known cause of ALS. Both ALS patients and transgenic mice develop aggregates of hSOD1 in motor neurons. By Binary Epitope Mapping it has been shown that in symptomatic mice two different types of aggregates (denoted A and B) can arise (Bergh et al. *Proc Natl Acad Sci U S A*, 2015, 112:4489-94). Inoculation of minute amounts of these into spinal cords of asymptomatic hSOD1 transgenic mice initiates spreading, exponentially growing templated hSOD1 aggregation concomitantly with premature fatal motor neuron disease (Ekhtiari Bindhendi et al. *J. Clin. Invest.* 2016:126:2249-53).Only for the hSOD1G127Gfs*7 truncation mutation (first described by Andersen et al, *Brain,* 1997, 120:1723-37) has it been possible to ascertain the strain type (A) in human tissue (Ekhtiari Bindhendi et al. *Acta Neuropathol.* 2018:136:939-953).Here we explored whether prion-competent mutant hSOD1 aggregates also exist in human ALS using a proximity detection kit and our set of anti-SOD1 antibodies. Using this setup we can show that the Strain type (A,B) is possible to specifically detect also in histologically processed tissues. Using the proximity detection kit it is possible to ascertain the cell type in which the specific strain type is occurring in. For the D90A human transgenic mice there is a difference in cellular spread between type A

and type B aggregates.Our results suggest that templated spread of hSOD1 aggregation might be cell type specific not only in hSOD1 transgenic models, but possibly also in human ALS.

Title: Novel Regulation of C9ORF72 Dipeptide Repeat Protein Synthesis by an Upstream Open Reading Frame, Initiation Factor DAP5, and Ribosome Stalling

Authors: *H. M. VAN 'T SPIJKER[1], E. STACKPOLE[1], S. ALMEIDA[1], O. KATSARA[2], B. LIU[1], K. SHEN[1], R. J. SCHNEIDER[2], F.-B. GAO[1], J. D. RICHTER[1];
[1]Univ. of Massachusetts Med. Sch., Worcester, MA; [2]Dept. of Microbiology, New York Univ. Sch. of Med., New York, NY

Abstract: Expansion of the G_4C_2(n) repeat in the *C9ORF72* intron is the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Each year 5,000 Americans are diagnosed with ALS and FTD is the most common form of dementia in people under 60 years old, and currently there are no cures. The expansion of the G_4C_2(n) repeat leads to loss of the C9ORF72 protein, the toxicity of accumulated repeat RNA, and toxicity of dipeptide repeats (DPRs) translated from the expansion. Using dynamic ribosome profiling on iPSCs from ALS patients, we identified three initiation sites in the intron upstream of G_4C_2. The initiation sites regulate production of DPRs in different reading frames, to produce poly-GA and poly-GP. We identified ribosomes on unspliced G_4C_2-containing RNA, indicating this is the substrate for translation of the repeat. G_4C_2 RNA translation is 5' cap-independent but inhibited by the initiation factor DAP5. DAP5 is an eIF4G homolog that lacks the eIF4E binding site and

it regulates translation of the G_4C_2(n) repeat. These results define novel translational mechanisms of expanded G_4C_2-containing RNA in ALS and FTD.

Title: Trametinib protects motor neurons from degeneration by enhancing autophagy in the SOD1 G93A amyotrophic lateral sclerosis model mice

Authors: *S.-Y. LEE, Y. CHUN, H. KIM, S. HAN;
Genuv Inc., Seoul, Korea, Republic of

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurological disease characterized by selective degeneration of motor neurons, that causes muscle paralysis and eventual death. To date, there is no clear therapeutics for improving the symptoms of ALS patients. Previously, we screened a MEK inhibitor, trametinib (SNR1611) from a FDA-approved drug library by its neurogenerative and neuroprotective effect. Here, we confirmed that oral administration of trametinib to SOD1-G93A transgenic mice increased motor performance and grip strength, and improved survival rate. Trametinib protected motor neuronal loss in the spinal cord. Trametinib also increased the level of autophagic markers (LC3, LAMP1 and cathepsin D), and significantly reduced the abnormal aggregation of p62 in spinal motor neurons. These clearly indicate that treatment of trametinib significantly improved the autophagy flux. A higher level of SOD1 protein was observed in cells expressing SOD1-G93A than in cells expressing SOD1-WT. Trametinib not only reduced the level of intracellular SOD1 but also prevented the formation of SOD1-postive aggregates which found only in cells expressing mutant SOD1. The combined data provides clear evidence that MEK inhibition might be a novel therapeutical approach for ALS by enhancing autophagy and eliminate disease-causing mutant proteins. Currently, trametinib is a repurposed drug candidate in the clinical trial (Phase I/IIa) for the indication of ALS in Korea (ClinicalTrials.gov identifier: NCT04326283).

Ctr., Los Angeles, CA; [6]Regenerative Med., Cedars-Sinai Med. Ctr., West Hollywood, CA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease that affects approximately 30,000 individuals within the US at a given time. ALS is characterized by progressive spinal and cortical motor neuron loss, with paralysis and death typically within 4 years of diagnosis. There is no cure, and current FDA-approved drugs only minimally slow progression. Transplanting supportive glial cells engineered to release glial cell line-derived neurotrophic factor (GDNF) is a promising treatment. Our group has generated and extensively characterized human fetal-derived neural progenitor cells (NPCs) lentivirally transfected to produce GDNF. These cells engraft in the spinal cord and slow the loss of choline acetyltransferase (ChAT)-positive motor neurons in the $SOD1^{G93A}$ rat model of ALS. We have recently completed a Phase 1/2a trial that showed the safety of delivering these cells to the spinal cords of ALS patients as a first in-human cell and gene therapy approach. While promising, use of fetal-derived NPCs is constrained by (i) the ethical concerns of human fetal tissue, (ii) scalability of the starting material and (iii) regulation of the GDNF release. To address these challenges, we have assessed human induced pluripotent stem cells (iPSC) as an alternative, renewable cell source that can differentiate to NPCs. In initial studies we generated iPSC-derived NPC lines lentivirally transduced to express GDNF (iNPC-GDNF). Single cell RNA-seq showed that while there was strong similarity and some overlap between iPSC-derived and fetal-derived NPCs, only a minority of the iNPCs clustered with the fetal-derived cells. To establish whether these cellular differences would be relevant for the functional effect of the cells iNPC-GDNF cells were transplanted unilaterally in the lumbar spinal cord of $SOD1^{G93A}$ rats that were then sacrificed at disease onset. While disease onset was not altered with cell transplants, hindlimb motor function was significantly improved in the treated limb compared to the non-treated side and to non-injected controls. Immunohistochemistry (IHC) for human specific cytoplasm (SC121) showed engraftment of iNPC-GDNF cells. Preliminary studies (n=3) to quantify ChAT+ motor neuron number and size indicate a protective effect on the treated side relative to

the non-treated side. Additionally, we have evaluated iNPC lines with a tetracycline-inducible GDNF construct. Inducible expression systems could tailor the GDNF dose to individual patients and provide the safety feature of turning off GDNF expression if required. These new iPSC-based NPC lines present a scalable and promising new regulatable cell and gene therapy for ALS.

Title: High-throughput screening (HTS) for identification of a tool compound targeting the interaction of SRSF1 with C9orf72 to prevent nuclear export in ALS and FTD

Authors: H. TRAN[1], D. J. BORROWS[3], H. WAN-PING[3], D. JONES[2], M. CHAMBERS[2], M. DA SILVA[1], G. HAUTBERGUE[3], T. RAMESH[3], **R. VAN DE BOSPOORT**[1], J. CONNELL[4]; [1]Charles River Labs., Leiden, Netherlands; [2]Charles River Labs., Saffron Walden, United Kingdom; [3]Sheffield Inst. for Translational Neurosci. (SiTRaN), Sheffield, United Kingdom; [4]Alzheimer's Res. UK, Cambridge, United Kingdom

Abstract: Hexanucleotide repeat expansions (HREs) in intron-1 of the *C9ORF72* gene are the most common known genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Thesemicrosatellite repeat sequences (GGGGCC, G_4C_2) contribute to neuronal injury via three non-mutually exclusive mechanisms. A growing body of evidence implicates toxic RNA and protein gain-of-functions due to abnormal nuclear export and repeat-associated non-AUG (RAN) translation of intron-retaining repeat transcripts into neurotoxic dipeptide repeat proteins (DPRs) as one of the main drivers of pathogenicity. Repeat RNA sequestration of SRSF1 triggers the nuclear export of repeat transcripts into the cytoplasm while its depletion inhibits the nuclear export of pathological *C9ORF72* transcripts and production of DPRs, thereby preventing neurotoxicity in reporter cells, patient-derived neurons and *Drosophila* models of C9ORF72-related disease (Hautbergue *et al*, 2017). Modulation of SRSF1 by morpholino mediated knockdown in a pure RAN translation zebrafish model further reduced DPR levels (unpublished Ramesh et. al.).
To identify tool compounds targeting the interaction of SRSF1 with C9orf72, an HTRF assay

was established in 1536-well format to detect proximity of tagged SRSF1 to tagged G_4C_2 RNA. This robust assay (S/B 10.1±0.1 and Z' 0.91±0.01) allowed for high throughput screening (HTS) of 50,000 compounds selected from our compound library collection for their significant structural diversity and CNS-differentiating physicochemical properties, lead-likeness and overall solubility profile. Following frequent hitter analysis (>4 pBSF) and structural alerts review (PAINS, BMS-Lilly), 503 compounds were selected based on their ability to inhibit TR-FRET signal. Preliminary clustering analysis showed good SAR.
Our data demonstrates the robustness of our HTRF assay for hit finding and shows how this in collaboration with academia accelerates identification of potential tool compounds. Our current efforts focus on further selection to <100 compounds with selectivity against counter assays, prior to future validation of their potency in inhibiting the SRSF1-dependent nuclear export of C9orf72-repeat transcripts and the production of DPRs in *in vitro* (reporter human cells, patient-derived neurons) and *in vivo* (zebrafish, mouse) models of C9ORF72-ALS/FTD at SITraN. The ADME profiles of promising compounds will also be conducted in the zebrafish and mouse models of disease.

Abstract: GGGGCC repeat expansion in *C9ORF72* is the most common genetic cause of both ALS and FTD. Toxic dipeptide repeat (DPR) proteins can be translated from both sense and antisense repeat RNAs, but it is unknown whether they can serve as biomarkers of target engagement in clinical trials testing therapies directed against the repeat RNA. We developed sensitive assays that reliably detect poly(GA) and poly(GR) in the cerebrospinal fluid (CSF) of *C9ORF72* patients, thus potentially serving as valid fluid-based diagnostic biomarkers. CSF poly(GA) and poly(GR) levels do not correlate with age at disease onset, disease duration, or score on the ALS Functional Rating Scale, and the average levels of these DPR proteins are similar in symptomatic and pre-symptomatic *C9ORF72* patients. However, in a human patient treated with antisense oligonucleotide (ASO) targeting *C9ORF72*, CSF poly(GA) and poly(GR) levels decreased significantly faster than poly(GP) levels. Thus, CSF poly(GA) and poly(GR) may serve as sensitive biomarkers for target engagement in *C9ORF72* patients, addressing a crucial need to determine the effectiveness of ASOs and other *C9ORF72*-directed therapies in planned clinical trials.

Title: Inhibiting elevated GCPII activity in aging mouse muscle reduces frailty

Authors: *T. R. JOE[1], C. TALLON[2], R. WISEMAN[3], A. G. THOMAS[4], B. S. SLUSHER[5]; [1]Cell Biol., [2]Neurol., [3]Pharmacol. and Mol. Sci., Johns Hopkins Univ., Baltimore, MD; [4]Johns Hopkins Drug Discovery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [5]Johns Hopkins Drug Discovery, Baltimore, MD

Abstract: Glutamate carboxypeptidase II (GCPII) is a neuropeptidase that catalyzes the conversion of N-acetyl-aspartyl-glutamate (NAAG) into N-acetyl-aspartate (NAA) and Glu. In the PNS, GCPII is expressed in Schwann cells and activated macrophages and is involved in regulating the synaptic pruning of neuromuscular junctions (NMJs) during normal development. Recently, we observed increased GCPII expression in the muscle of the $SOD1^{G93A}$ mouse model of amyotrophic lateral sclerosis (ALS) that was selectively associated with infiltrating activated macrophages. When using 2-(Phosphonomethyl)-pentanedioic acid (2-PMPA), a potent and selective inhibitor of GCPII, we observed a significant delay in muscle function loss and denervation in the ALS mouse. ALS and aging share similarities including the loss of motor neurons and degeneration of the skeletal muscle resulting in reduced synaptic inputs and fine motor skills, muscle weakness or wasting, and neuro-inflammation. Due to these similarities, we determined whether GCPII levels were altered in muscle of aged mice similarly to ALS mice. We collected gastrocnemius and soleus muscle tissue from 4-, 12-, and 20-month-old C57BL/6 mice and examined GCPII protein expression and enzymatic activity levels. We observed low expression of GCPII in 4- and 12-month-old mice gastrocnemius muscle and significantly increased expression in 20-month-old mice. Like in ALS, we observed co-localization of GCPII staining on infiltrating activated macrophages in aged gastrocnemius muscle. We then began treating 15-months-old mice, with daily 2-PMPA, for 5 months. Monthly frailty scoring was performed using an index that tracks a spectrum of aging-related characteristics. After 5 months of treatment, 2-PMPA treated mice had significantly reduced frailty index scores compared with vehicle-treated mice. Additionally, there was a significant delay in body weight loss and body temperature decline. These studies demonstrate that blockade of GCPII activity has potential therapeutic benefits for slowing aging-related frailty.

Title: Motor cortex with TDP-43 pathology display dysregulated metabolite and energy homeostasis

Authors: *B. HELMOLD[1], M. GAUTAM[1], A. GUNAY[1], N. CHANDEL[2,3], H. OZDINLER[1,4,5,6];
[1]Davee Dept. of Neurol. and Clin. Neurolog. Sci., [2]Dept. of Urology, Feinberg Sch. of Med., [3]Simpson Querrey Inst. for BioNanotechnology, [4]Robert H. Lurie Comprehensive Cancer Ctr., [5]Les Turner ALS Center, Feinberg Sch. of Med., [6]Chem. of Life Processes Inst., Northwestern Univ., Chicago, IL

Abstract: TDP-43 is a DNA/RNA binding protein that shuttles between nucleus and cytoplasm and is involved in key cellular functions. TDP-43 pathology is the most commonly detected proteinopathies observed in a broad spectrum of neurodegenerative diseases including amyotrophic lateral sclerosis (ALS). Mitochondria is at the center of energy production and generation of other metabolites required for cellular function. TDP-43 pathology impairs mitochondrial health and function, which results in the observation of mitochondrial defects in the upper motor neurons. To understand metabolite dysregulation in ALS motor cortex due to TDP-43 pathology, we performed metabolomic profiling of motor cortex isolated from prpTDP-43^{A315T} mouse model of ALS. Motor cortex of postnatal day 90 prpTDP-43^{A315T} and respective WT mice were dissected out and the metabolites were isolated followed by mass spectrometry profiling of metabolites. Careful analysis of metabolome revealed that several key metabolites such as NAD+, ATP, 2-hydroxyglutarate, glutathione disulfide, and phophoenol pyruvate were differentially regulated due to TDP-43 pathology. This analysis also revealed purine, arginine, glutamate, aspartate, methionine metabolism were among the key metabolite pathways differentially regulated. Proper balance of NAD+/NADH is critically important for ATP generation and metabolite alterations. Recently, a compound that can improve NAD+/NADH balance, namely nicotinamide mononucleotide (NMN), was shown to increase levels of NAD+, improve the health and function of mitochondria, and lead to increased survival in mouse models of mitochondrial disease. We treated corticospinal motor neurons with NMN *in vitro* and our results suggest that NMN improves health of diseased CSMN by improving NAD+/NADH balance. Thus, our study shows that in ALS motor cortex there is significant dysregulation of key metabolites and energy deficiency and maintaining NAD+/NADH ratio may help restore metabolite and energy homeostasis. Improving the health and function of mitochondria and energy production could potential prove to be a therapeutic strategy for ALS.

Amyotrophic lateral sclerosis (ALS) is a sporadic or genetic disease associated with peripheral loss of synaptic connectivity at neuromuscular junctions and central loss of motor neurons. The $SOD1^{G93A}$ mouse model has been widely used to study a familial form of ALS. C1q, the initiating molecule of the classical complement cascade, marks synapses in the central nervous system for glial elimination during normal development, while triggering aberrant synapse loss in neurodegenerative disorders. In ALS, C1q additionally tags the neuromuscular junction within the peripheral nervous system prior to its removal by macrophages. Despite data showing that embryonic knock out of C1q was not protective in a mutant SOD1 model, we hypothesized that excessive synaptic pruning initiated by C1q contributes to motor deficits in ALS and that pharmacologically inhibiting this process would be beneficial. We treated adult $SOD1^{G93A}$ mice with an anti-C1q blocking antibody from 7 to 16 weeks of age. Treatment resulted in reduction of C1q in plasma, spinal cord and muscle tissue, along with inhibition of downstream classical complement activation after 9 weeks of treatment. Treated mice showed significant improvement in the amplitude and reduced latency of compound muscle action potential, demonstrating increased synaptic connectivity at the neuromuscular junction upon C1q inhibition. Furthermore, anti-C1q treatment reduced Nf-L levels in CSF and plasma of $SOD1^{G93A}$ mice, marking the reduction in neuronal damage in this model. These data indicate that anti-C1q therapy preserves synapses of the neuromuscular junction and reduces neuronal damage in an ALS model. A Phase 2 study of ANX005 anti-C1q therapy in ALS patients is ongoing (clinical trials.gov NCT04569435).

Ctr., Los Angeles, CA; [5]Biostatistics, Massachusetts Gen. Hosp., Boston, MA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disease involving motor neuron loss that leads to paralysis and death within 3-5 years of diagnosis, with no effective treatments or cures. Dysfunctional astrocytes may contribute to motor neuron loss, while the growth factor glial cell line-derived neurotrophic factor (GDNF) provides motor neuron protection. Human fetal cortical-derived neural progenitor cells were expanded under cGMP and transduced with lentivirus encoding GDNF (CNS10-NPC-GDNF). Following transplantation, these cells differentiated into astrocytes, released GDNF and protected spinal

cord motor neurons in preclinical animal studies. CNS10-NPC-GDNF were then unilaterally transplanted into the lumbar spinal cord of 18 ALS subjects in a Phase 1/2a dose escalation study using a new minimally invasive surgical device with the primary outcome being safety at one year with secondary outcomes including muscle strength preservation in the treated versus non-treated leg. Muscle strength was protected in the treated leg over time, which reached significance in the low dose cohort at the 12-month time point. Asymptomatic benign neuromas at the dorsal root entry zone of some transplant sites were incidental post-mortem findings in some cases. 9 of 14 subjects who have died due to disease progression have been analyzed and have unilateral transplants releasing GDNF in the spinal cord. In a few of the transplant sites, cells were present in the ventral horn but in most cases cells were located in the dorsal regions of the cord. There was no positive or negative effect on the survival of motor neurons. This study reached the primary endpoint of safety and is the first combined gene and cell therapy approach for ALS to show both cell survival and growth factor release for at least 24 months.

Title: Normalization of C9ORF72 pathology in vivo by targeting Staufen 1

Authors: *D. R. SCOLES, S. PAUL, W. DANSITHONG, M. GANDELMAN, C. T. NELSON, K. P. FIGUEROA, S. M. PULST;
Neurol., Univ. of Utah, Salt Lake City, UT

Abstract: Expansion mutations in the *C9ORF72* G4C2 repeat are causative of both amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), two devastating diseases affecting a significant segment of the population. We have previously shown elevated mTOR and other autophagy-related proteins in fibroblast cells derived from patients with ALS/FTD and other neurodegenerative diseases, associated with overabundance of the RNA binding protein Staufen1 (STAU1). The objectives of this study are to determine if STAU1 functions mechanistically in

regulating mTOR expression and if targeting STAU1 could restore C9ORF72-related phenotypes *in vivo*. Previous studies had demonstrated that STAU1 interactions with 5'-UTRs of mRNAs enhance translation. We performed blot overlay assays demonstrating that STAU1 directly interacted with the 5'-UTR of mTOR. Following this, we established a reporter assay with the mTOR 5'-UTR upstream of luciferase, and consistent with increased translation, STAU1 overexpression increased the luciferase signal while the mRNA abundance remained constant. Next, to determine whether reducing STAU1 abundance could modify C9ORF72 phenotypes *in vivo*, we crossed C9ORF72-BAC mice with *Stau1* knockout mice (*C9ORF72/Stau1+/-)*. We found that in 16-week-old *C9ORF72/Stau1+/-* mice spinal cord neurodegeneration was attenuated, as indicated by restored levels of the neurotransmitter Chat, the pan-neuronal marker NeuN and the astrocyte reactivity marker Gfap. In addition, we observed that *Stau1* haploinsufficiency restored markers of defective autophagy, including mTOR, p-mTOR, p62 and LC3-II. Histological analysis of spinal cords revealed polyGA, a product of repeat associated non-AUG translation (RAN translation) that accompanies C4C2 repeat expansion in C9ORF72, showed the typical aggregates and increased immunoreactivity in both neurons and neuropil, features that were absent in mice haploinsufficient for *Stau1*. We conclude that Stau1 overabundance leads to abnormal autophagy and related toxic pathways associated with DPR proteinopathy that can be restored by targeting Stau1 expression. These data support STAU1 as a therapeutic target for C9ORF72-related FTD or ALS as well as other neurodegenerative diseases in which STAU1 is overabundant.

Title: GCPII inhibition prolongs survival and delays muscle mass and function loss in aged C57BL6/J mice

Authors: *C. TALLON[1], T. R. JOE[2], R. WISEMAN[3], A. G. THOMAS[4], B. S. SLUSHER[5]; [1]Neurol., [2]Cell Biol., [3]Pharmacol. and Mol. Sci., Johns Hopkins Univ., Baltimore, MD; [4]Johns Hopkins Drug Discovery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [5]Johns Hopkins Drug Discovery, Baltimore, MD

Abstract: Sarcopenia is the progressive loss of muscle mass and function and is a natural part of the aging process. Sarcopenia can contribute to frailty and increase the likelihood of falls and fractures in older adults. With our aging population, sarcopenia is predicted to have significant negative economic ramifications, and thus being able to slow the process would be beneficial. Although the precise mechanisms leading to sarcopenia is currently an area of active research, increased inflammation has been reported in both aging human and mouse muscle tissues and is thought to contribute towards sarcopenia. Our lab has observed elevated expression of the enzyme glutamate carboxypeptidase II (GCPII) in aged mouse muscle that is specifically associated with infiltrating activated macrophages. GCPII cleaves N-acetylaspartylglutamate (NAAG) into NAA and glutamate and its activity has been observed to regulate glutamatergic transmission and drive synaptic pruning at the neuromuscular junction (NMJ) during development. Our lab recently observed a significant delay of muscle function loss and NMJ denervation in an ALS mouse model using the potent GCPII inhibitor 2-(Phosphonomethyl)-pentanedioic acid (2-PMPA). To determine whether 2-PMPA treatment could delay muscle function loss in aged animals, we treated 15-month old C57BL6/J mice with 100mg/kg of 2-PMPA IP daily for 5 months and monitored monthly body weight, grip strength, compound muscle action potential (CMAP), open field behavior, end stage muscle weights and survival. Compared to vehicle treated mice, we observed a significant delay in body weight loss and grip strength after 1 and 4 months on 2-PMPA therapy. 2-PMPA treatment also delayed CMAP amplitude decline, with treated animals having 20% greater values after 4 months of treatment, but the effect did not reach significance. 2-PMPA-treated animals also exhibited elevated ambulation in the open field test after 4 months of treatment. After 5 months of treatment, gastrocnemius and bicep muscle weights were significantly higher in 2-PMPA treated animals than vehicle treated mice. Most noteworthy, 2-PMPA treatment significantly prolonged survival, with survival of 8% versus 58% of vehicle and 2PMPA-treated mice, respectively, after 5 months of treatment. These data support GCPII inhibition as a potential therapeutic strategy to delay muscle function loss related to aging and improve survival.

Title: Identification of neuronal autoantigens in patients with progressive multiple sclerosis

Authors: P. KABIRAJ, B. CLARKSON, R. JOHNSON, *C. HOWE;
Neurol., Mayo Clin., Rochester, MN

Abstract: Multiple sclerosis (MS) is one of the leading causes of neurological deficits in the US. While current therapeutic options for controlling the relapsing-remitting phase of the disease are effective and widely employed, most patients with MS still eventually enter a progressive phase that is marked by permanent, irreversible loss of neurologic function. At present, there are no drugs or therapeutic strategies available to halt this insidious process. It has long been known that CD8+ T cells predominate in active MS lesions and are associated with axon injury and disease progression. However, the pathogenic role of these cells is still poorly understood. Based on extensive animal model data we have proposed that anti-neuronal CD8+ T cells that specifically target demyelinated axons perpetrate the damage and loss of neural circuitry that underlies disease progression in MS. In order to identify the HLA class I antigens targeted by these CD8+ T cells we hypothesized that B cell responses facilitated by T cell help will result in the presence of serum autoantibodies directed against the same protein antigens recognized by the effector T cells. Using liquid-chromatography mass spectrometry (LCMS) and antibody-mediated identification of autoantigens (AMIDA), we have started to identify the repertoire of neuronal antigens recognized by the immune system in patients with progressive MS. We have generated induced pluripotent stem cell clones from 6 MS patients and 4 healthy controls and we have generated neural stem cells and induced neurons from this material. These patient-specific neurons were stimulated with IFNg for 72 hr to induce upregulation of MHC class I molecules, as we have previously described. Following lysis, MHC class I molecules were immunoprecipitated with the W6/32 clone to capture HLA-A, B, and C molecules. Bound peptides were eluted and analyzed via LCMS. In parallel, lysates from iPSC-derived neurons and from resected human brain tissue were adsorbed against human IVIg and then incubated with biotinylated immunoglobulin isolated from a pool of serum from 3 patients with MS or from control subjects. Following immunoprecipitation on Protein G HP SpinTrap columns, the bound proteins were eluted and analyzed by mass spectrometry. To date we have identified 5 unique peptides and we are now testing CD8+ T cell responses against these peptides presented by autologous protein antigen-fed dendritic cells.

Title: Role of PERK-B in INSTI-induced adverse effects in HAND

Authors: *S. GHURA, S. BOND, C. AKAY-ESPINOZA, K. L. JORDAN-SCIUTTO;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Combined antiretroviral therapies (ART) have increased the life expectancy of people living with HIV (PLWH), however about 50% of PLWH present with a spectrum of neurocognitive impairments termed HIV-associated neurocognitive disorder (HAND). Although the exact mechanisms remain unknown, clinical data indicate loss of gray and white matter in specific brain regions critical for learning and memory. These alterations are induced by several factors including HIV itself and ART. We have previously demonstrated that ART therapeutics, specifically integrase inhibitors (INSTIs), that are widely used as first-line therapeutics to control HIV infection, are neurotoxic and inhibit differentiation of oligodendrocytes. At the cellular level, HAND is often characterized by increased endoplasmic reticulum (ER) stress which leads to activation of the unfolded protein response (UPR). Acute UPR activation, a cytoprotective response, aims to alleviate ER stress, whereas chronic UPR activation can be maladaptive. Importantly, we have demonstrated that ART-induced neurotoxicity and detrimental effects on oligodendrocytes are mediated by UPR. A downstream event in UPR is the activation of ER stress sensor PKR-like ER kinase (PERK), which has been implicated in several neurodegenerative disorders, including HAND. Recent studies reported three non-synonymous SNPs of PERK occurs in 31% of the general population. These SNPs are genetically linked forming haplotype B (PERK-B) distinct from the more common haplotype (61%), PERK-A. PERK-B has a putative higher kinase activity, potentially predisposing individuals to neuronal dysfunction. Notably, PERK-B has been associated with an increased risk for progressive supranuclear palsy, a neurodegenerative disease. Data from our lab demonstrates that HAND patients who express PERK-B are associated with worse cognitive global deficit scores. However, our understanding of the role of PERK and effects of PERK haplotypes in mechanisms underpinning cellular dysfunction in HAND remains elusive. In the current study, we hypothesize that PERK plays a critical role in ART-mediated UPR in the context of HAND. More specifically, PERK-B augments INSTI-induced UPR activation in neurons and oligodendrocytes, contributing to HAND pathology. We have developed a novel mouse model that expresses PERK-B. *In vitro* and *in vivo* data from this model supports the role of PERK-B in HAND pathology. The novel mouse model will examine how the different haplotypes modulate cell-specific mechanisms underlying HAND pathology which could validate if PERK-B is a risk factor for worse cognitive impairment in patients with HAND.

Title: In vitro characterization of mitochondrial and metabolic activities in patients presenting with SLC6A1 mutations associated epileptic encephalopathy

Authors: *F. S. ROUSSEL, C. N. DENNYS, A. HARTLAUB, S. SINHA RAY, J. A. SIERRA-DELGADO, S. B. LIKHITE, A. BRADBURY, K. C. MEYER;
Ctr. For Gene Therapy, Res. Inst. Nationwide Children's Hosp., Columbus, OH

Abstract: Mutations in the SLC6A1 gene cause an epileptic encephalopathy, characterized by absence, atonic and myoclonic seizures. Patients also present with developmental delay, EEG abnormalities, language impairment and intellectual disability. Solute carrier family 6 member 1 (SLC6A1) encodes for the GABA transporter 1 (GAT-1) and is mainly expressed in the brain. The protein is responsible for the reuptake of GABA into presynaptic neurons and glia, clearing the extracellular space and modulating neurotransmission. Since little is known about the disease mechanisms and the cell types involved, the development of in vitro models to study the disease in the context of patient cell lines and for testing of new therapeutics is urgently needed. We have previously developed a rapid reprogramming method to convert patient skin fibroblasts into induced Neuronal Progenitors Cells (iNPC) that can further be differentiated into induced Astrocytes (iAs). Here we utilized this methodology in addition to a rapid chemical conversion method to produce neurons (iNs) from patient fibroblasts to investigate the impact of SLC6A1 mutations in both iNs and iAs. These cells were analyzed for GAT-1 levels, markers of neurological stress (elevated BIP, and dysfunctional mitochondria) as well as GABA production and secretion. Interestingly, we found that iNPCs, iAs, and iNs had unique metabolic requirements to survive in vitro, suggesting sensitivity to select nutrients. Morphological assessment of iNs showed normal neuronal morphology, however iAs had a distinct morphology indicative of activation. Co-culturing patient iAs with healthy mouse GFP+ neurons lead to reduced neuron survival. Next, we assessed the mitochondrial and metabolic profiles in patient iAs to determine if aberrant metabolism contributed to iAs disease mechanisms. Seahorse analysis indicated that cellular glycolysis and mitochondria activity do not differ significantly from healthy controls. Combined, this data suggests SLC6A1 iAs contribute to disease pathology in an unidentified mechanism. Further investigations to understand underlying disease cause and the role of iAs and iNs in the disease physiopathology will assist in the development for a novel treatment for patients with SLC6A1 mutations.

Title: Neurotoxicity associated with a novel anticancer drug, beta-lapachone (ARQ-501).

Authors: *H. XIA[1], A. BEHROUZI[1], H. RODRIGUES DE OLIVEIRA[2], J. C. FEHRENBACHER[1];
[1]Pharmacol. and Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Fac. of Hlth. Sci., Univ. of Brasilia, Brasilia, Brazil

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a major dose-limiting side effect of many efficacious anticancer drugs and there currently are limited therapeutics to alleviate the symptoms of CIPN. Despite this knowledge, many investigational drug studies still do not characterize the incidence of CIPN in preclinical or clinical studies. Our previous work identified that oxidative DNA damage within sensory neurons contributes to CIPN, therefore drugs that enhance the generation of reactive oxygen species (ROS) within sensory neurons may induce neurotoxicity. Recent studies have identified NAD(P)H:quinone oxidoreductase 1 (NQO1) as a potential drug target for the treatment of various cancer types. A class of investigational quinones, including beta-lapachone, are bioactivated by NQO1 and can thereby cause futile redox cycling between the quinone and hydroquinone species, generating high amounts of ROS. There are currently multiple clinical trials investigating the use of beta-lapachone as a therapeutic agent; however, the potential for neurotoxicity has not been assessed in this class of drugs. In this study, we aim to determine whether beta-lapachone induces neurotoxicity in sensory neurons.
Primary cultures derived from dorsal root ganglion (DRG) of male Sprague Dawley rats (150g) were used to assess NQO1 expression in sensory neurons and to determine whether beta-lapachone modulates sensory neuron function. Cultures (7d post-harvest) were treated with 0.3, 3, 10, or 30 µM beta-lapachone for 2 hours, after which normal media was replenished. Calcitonin gene-related peptide (CGRP) release was stimulated by capsaicin (30 nM) 24h after the initial beta-lapachone exposure. Sister wells were lysed for protein and immunoblotted for pH2AX, or PFA-fixed for immunofluorescence imaging. Neurite outgrowth analysis was performed on fixed cultures using the neurite outgrowth algorithm by ImageXpress (Molecular

Devices).
NQO1 is expressed in cultured small-diameter sensory neurons and in small- and large-diameter neuronal soma of DRG from male adult mice. Treatment of neuronal cultures with beta-lapachone diminished neuronal sensitivity and the total content of CGRP in a concentration-dependent manner. Treatment with beta-lapachone also altered the morphology of sensory neurons in culture, decreasing neurite length in a concentration-dependent manner.
Our data demonstrate that NQO1 is expressed in sensory neurons of the DRG and drugs that target NQO1 are likely to induce CIPN in patients.

Title: N-acetyl-l-cysteine improves cognitive performance via kynurenine pathway in mice lead poisoning during lactation

Authors: *D. RAMÍREZ ORTEGA[1], P. OVALLE RODRÍGUEZ[1], D. GONZÁLEZ ESQUIVEL[1], G. PÉREZ DE LA CRUZ[2], B. PINEDA[1], V. PÉREZ DE LA CRUZ[1];

Abstract: The immature brain is singularly sensitive to lead (Pb) neurotoxicity, compromising the cognitive and behavioral attributes which persist even later in adulthood. Several mechanisms have been implicated in the Pb cognitive impairment including calcium homeostasis, oxidative stress generation, changes in neurotransmitters levels and recently, we have demonstrated the kynurenine pathway (KP) participation, specifically, high levels of kynurenic acid (KYNA) were accompanied by cognitive impairment. KYNA is considered as a neuromodulator that has an important role in cognitive processes due to is an endogenous antagonist of NMDA and α7-nicotinic acetylcholine receptors, representing a good target to be modulated. In this line, it has been shown that N-acetylcysteine (NAC) affects the KP, diminishing kynurenine aminotransferase activity (KAT) and decreasing KYNA levels accompanied by an improvement in cognitive parameters. The aim of this work was to evaluate the effect of NAC on Pb poisoning during lactation in KYNA levels, KAT activity and cognitive parameters. Mice pups were exposed via their dams' drinking water (lead acetate 500ppm) from PND0 to PND23. NAC group received 300 mg/day through food. Pb-NAC group received Pb trough drinking water and were fed with NAC at the same time. Control group received normal

water. The long-term memory was evaluated through buried food probe at PND 60. KAT activity and KYNA levels were evaluated in brain by HPLC. As results, Pb group showed a significant increase in time looking for food, compared to controls. This increase was abolished when mice were treated with NAC at the same time as with Pb. KYNA levels increased in the presence of Pb, but co-treatment with NAC decreased them. KAT activity decreased in the NAC and Pb-NAC groups. These results suggest that NAC can be a good treatment to decrease KYNA levels in Pb poisoning where altered cognitive parameters can be improved.

Title: The effect of methotrexate treatment on neuroinflammation gene expression in pediatric cancer patients

Authors: G. SHEETS[1,2], R. MANDAL[3,2], B. MOORE[2], A. UMRIGAR[2], E. BEATON[1], M. STARK[4], M. NORMAN[2], P. PRASAD[4], J. ZABALETA[2], L. LI[2], C. HICKS[2], *F. TSIEN[2]; [1]Univ. of New Orleans, New Orleans, LA; [2]Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [3]Tulane Univ., New Orleans, LA; [4]Children's Hosp. New Orleans, New Orleans, LA

Abstract: Methotrexate, a structural analogue of folic acid, is one of the most effective and widely used drugs for treating various types of cancer, particularly leukemias and lymphomas. Methotrexate treatment in pediatric patients has been associated with the long-lasting development of detrimental neurological and psychosocial sequela following cancer survival. These deficits, termed late effects, persist after the methotrexate exposure and may include abnormal behavior such as unusual aggression, problems with executive functioning and processing speed as well as mental disorders like ADHD, depression, and anxiety. Our study includes a retrospective review of neurological and psychosocial evaluations from pediatric cancer survivors enrolled in the Late Effects Clinic at Children’s Hospital New Orleans, Louisiana (CHNOLA). We also use targeted RNA microarray and bioinformatic analysis of neuroinflammation genes in brain specimens obtained from deceased patients from the Pathology Department at CHNOLA. Results from the present study will provide information

regarding gene-environment interactions and thus reveal candidate risk genes and pathways contributing to neurocognitive and psychiatric late effects.

Title: A novel multimodal compound, AR1001 attenuates multimodal and cognitive dysfunction in a 3xTg mouse model of Alzheimer's disease

Authors: *S. KIM[1], H. KIM[2], B. KANG[3], S. KANG[4], J. JUNG[5];
[1]SNU Med. Library, SEONGNAM CITY, Korea, Republic of; [2]Aribio, Seongnanm, Korea, Korea, Republic of; [3]Aribio, Seongnam si, Korea, Republic of; [4]Aribio Ltd, Seongnam, Korea, Republic of; [5]Aribio Ltd, Seongnam si, Korea, Republic of

Abstract: Alzheimer's disease is a neurodegenerative disease characterized by the production of β-amyloid proteins and hyperphosphorylation of tau protein. Inflammation and apoptotic severity were highly correlated with earlier age at onset of Alzheimer's disease and were also associated with cognitive decline. This study aims to examine whether the AR1001 could modulate CREB, autophagy and Wnt signal, cognitive deficit and take neuroprotective effects in 3x Tg mouse model of Alzheimer's disease. AR1001 protected their cognitive impairment and improved their memory function by daily oral administration for 60 days consecutively. In addition, AR1001 alleviated the acute inflammation induced by oAβ. Using a QDoc-labeled aptamer and molecular beacon detected to whole brain, the endogenous long noncoding miRNA, the constitutive U6 miRNA, and miR-106b and miR-7 could be detected in the cytoplasm of a normal mouse brain, cultured hippocampal neurons, and an Alzheimer's disease model mouse brain, respectively. The fluorescence recovered by aptamer and molecular beacon correlated highly with the amount of miR-7 and miR-106b, as measured by confocal microscope. We propose novel CLARITY as a simple, fast, inexpensive, and sensitive method for miRNA detection, with a very low background, which could be applied to a variety of research or diagnostic purposes. By simultaneously achieving ∼50-fold signal amplification and offers a robust and versatile approach for detecting miRNAs in situ, including in thick tissues where high background undermines the performance of unamplified FISH. Furthermore, AR1001 played a role in the down-regulation of caspase-3/9 proteins, MMP2/9 and reduced the early apoptosis and oAβ deposits that normally followed APP processing in 3xTg AD mice. The results of this study

showed that the treatment of AR1001 had neuroprotective effects in oAβ-deposited 3x Tg AD mouse model.

Title: Ketamine-induced neurotoxicity mediated through endoplasmic reticulum stress

Authors: *N. RIGG[1], F. A. ABU-HIJLEH[1], V. PATEL[2], R. K. MISHRA[3];
[1]Psychiatry and Behavioural Neurosci., McMaster Univ. Neurosci. Grad. Program - Minds, Hamilton, ON, Canada; [2]Psychiatry and Behavioural Neurosci., McMaster Univ., Hamilton, ON, Canada; [3]Psychiatry and Behavioural Neurosci., McMaster Univ. Hsc-4N 78, Hamilton, ON, Canada

Abstract: Ketamine has traditionally been used as a dissociative anesthetic. However, there is growing concern over the increased use of ketamine in recreational and therapeutic settings due to potential toxic effects. Recent studies have demonstrated that ketamine is cytotoxic in several cell lines, such as fibroblasts, hepatocytes, uroepithelial cells, and hippocampal cells. Ketamine has been shown to cause disturbances in calcium signalling, increased reactive oxygen species (ROS) production, and mitochondrial dysfunction leading to apoptosis. However, it is not yet clear whether endoplasmic reticulum (ER) stress plays a role in ketamine neurotoxicity in striatal neurons. Disturbances to ER homeostasis, such as calcium dysregulation and ROS, can initiate ER-mediated cell death, which is characteristic of many neurodegenerative diseases. Thus, the purpose of this study was to determine whether ketamine is neurotoxic through an ER stress-dependent pathway and to elucidate the underlying mechanism. Mouse striatal cells were treated with ketamine (0.01mM, 0.1mM, 1mM) or DMEM for 12 to 72 hrs. Following treatment, intracellular calcium was measured, and changes in the expression of ER stress markers were evaluated using RT-qPCR. MTT results revealed that ketamine (1mM) was toxic to striatal cells, as demonstrated by a time-dependent decrease in cell viability after 24 hrs compared to controls. Ketamine reduced basal intracellular calcium levels in a dose-dependent manner at all times and induced a decreased response to KCl depolarization compared with control cells after 24 hrs.

Ketamine upregulated pro-apoptotic ER stress markers', which quickly favoured pro-apoptotic signalling over cell survival. Initial upregulation of glucose-regulated protein-78 (GRP78), the master regulator of ER stress, was observed, while prolonged exposure showed decreased expression. Increased expression of pro-apoptotic C/EBP homologous protein (CHOP) observed throughout the experiment demonstrates ER-stress-mediated apoptosis. Further, the expression of ER-resident neurotrophic factors (MANF and CDNF), which aid in cell survival during stress, decreased after 48 hrs of treatment. Taken together, our results propose that chronic ketamine exposure impairs calcium signalling, inducing severe ER stress and triggering a dynamic neuronal response resulting in ER stress-dependent apoptosis, which may be mediated through PERK- elF2a-ATF4 signalling. These results further support the need for caution when prescribing this drug.

Title: A mouse model of adrenomyeloneuropathy develops progressive CNS pathology

Authors: *C. KAYATEKIN, K. SINGH, K. KEEFE, R. CHIANG, M. HANUS, J. GANS, W. HUANG, D. KUMAR, J. ESCOBEDO, E. TEEPLE, Z. ZHAO, D. WANG, A. KLOSS, J. PROTO, T. GLADYSHEVA;

Abstract: Adrenoleukodystrophy, or ALD, is a rare neurometabolic disease that is caused by mutations in the *ABCD1* gene, which encodes for a transporter responsible for shuttling very long chain fatty acids (VLCFAs) into the peroxisome for degradation. It is a debilitating disorder, which has a spectrum of clinical presentations. The more severe form is a rapidly progressing demyelinating disease (cerebral ALD or CALD with a life expectancy of 2-4 years after onset), which often strikes in childhood and can be potentially halted by a successful hematopoietic stem cell transplant from donor without an *ABCD1* mutation. Another form, adrenomyeloneuropathy or AMN, is a slower progressing degeneration of the spinal cord. While an *ABCD1* knockout mouse model exists, it does not develop the pathological hallmarks of ALD. To identify disease phenotypes in this mouse model that can enable therapeutics development, we performed an extensive behavioral, biochemical, and single nuclei transcriptional analysis of the *ABCD1* knockout mouse. We found evidence of progressive accumulation of VLCFAs in the spinal cord, subtle changes in neuronal populations, and white matter pathology that advances with age. These findings support the hypothesis that the buildup of VLCFA in the CNS

contributes to dysfunction and disease, while providing endpoints for disease modifying investigational therapies to treat ALD.

Title: Nicotinamide Mononucleotide Protects Against Cisplatin-Induced Mitochondrial Dysfunction and Increases Survival of Cortical Neurons Derived From hiPSC

Authors: *M. RASHID, K.-H. YOO, A. OLIVEROS A, M.-H. JANG;
Mayo Clin., Rochester, MN

Abstract: Mitochondrial dysfunction is thought to play a critical role in a variety of neurological disorders. Chemotherapy-induced cognitive impairment (CICI) is often reported as a neurotoxic side effect of chemotherapy and no effective treatments currently available. Recently, we demonstrated that the NAD+ precursor nicotinamide mononucleotide (NMN) prevents cisplatin, a frontline platinum-based chemotherapy, from inducing impairments in human cortical neurons derived from iPSCs *in vitro*, as well as cognitive deficits in a mouse model of CICI *in vivo*. Despite this, NMN's potential to protect against cisplatin-induced mitochondrial dysfunction remains to be studied. Here we demonstrate that NMN prevents against cisplatin-induced

mitochondrial dysfunction in human cortical neurons derived from hiPSCs. Treatment with cisplatin significantly increased oxidative DNA damage and mitochondrial reactive oxygen species generation (mROS) in our cortical cultures. Furthermore, we found that cisplatin increased the colocalization of the mitochondrial marker TOMM20 with the lysosome marker LAMP1. Interestingly, we detected LAMP1 colocalization with the early and late endosome markers RAB4B and RAB7A, respectively. Additionally, there was colocalization of TOMM20 with LC3B (autophagosome marker). In parallel, cisplatin decreased intracellular ATP content and diminished cell viability. Additionally, cisplatin treatment impaired neuronal morphogenesis, and reduced the expression of the pre- and post- synaptic markers PSD95 and SYP in our hiPSCs derived cortical neurons. These changes were consistent with loss of mitochondrial membrane potential, and loss of cristae membrane and matrix swelling. Importantly, pretreatment with NMN prevented these adverse effects. Taken together, our results suggest that mitochondrial dysfunction and increased oxidative stress are involved in cisplatin chemotherapy-induced cognitive impairment. In support of our recent *in vivo* studies, NMN increased survival in human cortical neurons derived from hiPSCs, while concomitantly preventing cisplatin-induced mitochondrial dysfunction as evidenced by decreasing oxidative stress and preserving mitochondrial structure. Therapeutic agents, such as NMN, may be effective in mitigating cisplatin-induced deleterious effects on mitochondria.

Title: Tumor necrosis factor-α inhibition limits hematoma expansion following intracerebral hemorrhage in chronic nicotine-exposed rats.

Authors: *A. K. REHNI, S. CHO, A. P. RAVAL, M. A. PEREZ-PINZON, K. R. DAVE; Neurol., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Spontaneous intracerebral hemorrhage (sICH) is a serious form of hemorrhagic stroke that causes enormous mortality and morbidity worldwide. Tobacco use is an established risk factor of sICH and worsens sICH-outcome. We have shown that chronic nicotine-exposed rats of both sexes display an increased hematoma growth post-sICH. Chronic nicotine exposure increases the levels of tumor necrosis factor-α (TNF-α) in brain microvessels and increased levels of TNF-α receptors[1] are associated with increased risk of sICH. Therefore, we

hypothesized that chronic nicotine exposure-induced increase in TNF-α causes increased hematoma expansion. To test this hypothesis, we evaluated the effect of pharmacological inhibition of TNF-α on hematoma expansion following sICH in nicotine-exposed rats. Rats were treated with nicotine (4.5 mg / kg / day b.w.) using osmotic pumps for 2-3 weeks. Young rats of both sexes were randomized between different treatment groups. Saline (vehicle) or etanercept (TNF-α inhibitor) (6.24 mg/ kg b.w., i.p.) was administered 5 and 2 days prior to the onset of sICH. sICH was induced using intra striatal administration of collagenase in rats. sICH in females was induced during the diestrus stage of estrous cycle. After 24 hours, neurological scores were assessed. Isolated brains were sectioned to measure hematoma volume by a blinded investigator. The hematoma volume of male rats belonging to the TNF-α inhibitor treatment group (90±8 mm^3, n=8) was significantly lower ($p<0.05$) than the control group (135±16 mm^3, n=8). Moreover, the neurological score of male rats in TNF-α inhibitor treatment group (8.5 ± 0.6) was also significantly lower ($p<0.005$) than the control group (10.6 ± 0.3). The hematoma volume observed in the TNF-α inhibitor treated females (82±11 mm^3, n=8) was significantly lower ($p<0.05$) than the controls (127±11 mm^3, n=8). Further, neurological score noted in the TNF-α inhibitor treatment female group (7.9±0.5) was significantly lower ($p<0.001$) than the control group (10.4±0.3). Our results show that TNF-α inhibition limits hematoma growth in previously nicotine-exposed rats suffering from sICH. Therefore, we conclude that TNF-α activation may be involved in mediating chronic nicotine exposure-induced increase in hematoma expansion. This information will help us understand the pathophysiology of increased hematoma growth in sICH patients who are tobacco users and thus may contribute towards identification of future therapeutic strategies. Title: Chronic nicotine increases both blood-brain barrier permeability and inflammation in rats of both sexes

Authors: *S. CHO, A. K. REHNI, A. P. RAVAL, M. A. PEREZ-PINZON, K. R. DAVE; Neurol., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: As one of the leading causes of preventable death, tobacco use has been found in epidemiological studies to not only increase the risk of but also worsen outcomes following intracerebral hemorrhage (ICH) in both men and women. Previously, we showed that nicotine treatment increased hematoma volumes and neurological deficits after collagenase-induced ICH in both male and female rats. We hypothesize that chronic nicotine exposure causes greater hematoma growth in ICH by increasing blood-brain barrier (BBB) permeability through increased inflammation and decreased tight junction proteins. To test this hypothesis, young Sprague-Dawley rats of both sexes were subcutaneously implanted with an osmotic pump containing either nicotine (4.5 mg / kg / day) or saline (vehicle group). After two to three weeks, animals were perfused with saline, and microvessels were isolated from brain tissue. Brain tissue from female animals was collected during the diestrus stage to avoid hormonal fluctuation. Tight junction proteins were measured using Western blot and normalized to GAPDH. The rate of hydrogen peroxide production was measured using the Amplex Red hydrogen peroxide assay. We previously showed decreased levels of Claudin 3, Claudin 5, and occludin and increased BBB permeability in nicotine-treated rats compared to saline-treated rats in both males and females. In male animals, PECAM-1 levels were 79% ($p<0.05$, n=7 for both groups) lower in nicotine-treated rats than saline-treated rats. In female rats, ZO-1 and PECAM-1 levels were 51% ($p<0.05$, n=6 for saline, n=5 for nicotine) and 43% ($p<0.05$, n=7 for both groups) lower in nicotine-treated animals than saline-treated animals. In addition, TNFα levels were 102% ($p<0.05$) and 64% ($p<0.05$) higher in nicotine-treated rats than saline-treated rats in males (n=9 for saline, n=8 for nicotine) and females (n=6 for both groups), respectively. In male animals, the rate of H_2O_2 production was 51% ($p<0.05$) higher in nicotine-treated rats (n=8) than saline-treated rats (n=8). In female rats, the rate of H_2O_2 production was not statistically different in

nicotine-treated animals than saline-treated animals (n=10 for saline, n=9 for nicotine). Overall, our results show that chronic nicotine exposure increases BBB permeability by decreasing tight junction proteins and increasing inflammation in animals of both sexes. This observed increased BBB permeability and inflammation may be responsible for the increased ICH damage in nicotine-treated rats.

Title: Identification of the mechanism by which red cell microparticles limit hematoma growth following intracerebral hemorrhage

Authors: *S. SAMA[1], S. CHO[1], A. K. REHNI[1], W. JY[2], K. R. DAVE[1];
[1]Peritz Scheinberg Cerebral Vascular Dis. Res. Labs., Univ. of Miami Sch. of Medicine, 1420 NW 9th Ave, NRB/203E, Miami, FL; [2]The Wallace H Coulter Platelet Laboratory, Div. of Hematology/Oncology, Univ. of Miami Sch. of Medicine, 1600 NW 10th Ave, RMSB 7109, R36-A, Miami, FL

Abstract: There is no proven therapy for spontaneous intracerebral hemorrhage (sICH), the deadliest stroke sub-type. As hematoma volume correlates with mortality in survivors, limiting hematoma expansion appears to be an effective therapeutic strategy. However, hemostatic agents used today have thromboembolic and neurological complications that outweigh their benefits. In contrast, red cell-derived microparticles (RMPs) are novel universal hemostatic agents with an excellent safety profile[1] as based on earlier studies. We previously showed that RMPs possess potent hemostatic activity[2] and RMP treatment limits hematoma growth in a rat model of sICH. However, the mechanism of action of RMPs is not well understood. In the present study, we investigated how RMPs influence the intrinsic and extrinsic pathways of secondary hemostasis. To evaluate this, we examined clot formation in human plasma deficient in coagulation factors VII, VIII, IX, XI, and XII in the presence and absence of RMPs (2.8×10^8 particles/mL). Pooled human plasma from 53 donors and factor-deficient plasma were purchased from George King Bio-Medical and mixed to generate plasma that is 85%, 92.5% and 96.25% deficient in each of the five factors, and R-times (clotting times) were determined with thromboelastography. RMP concentration was based on earlier studies, and all experiments were performed in triplicate. We found that RMP treatment decreased R-times in 96.25% (21.2 min to 13.4 min) and 92.5% (17.5 min to 13.3 min) deficiency but not in 85% deficiency of factor VII. For factor VIII-deficient plasma, RMP reduced R-times in 92.5% (22.6 min to 17.7 min) but not in 96.25% or 85% deficiency. For factor IX-deficient plasma, RMP treatment reduced R-times in all three degrees of deficiency: in 96.25% (44.3 min to 27 min), 92.5% (27.8 min to 18.7 min), and 85% (25.3 min to 17 min). We observed a similar trend for factor XI-deficient plasma; RMP treatment reduced R-times in 96.25% (22.8 min to 17.9 min), 92.5% (18.1 min to 15.6 min) and 85% (16.9 min to 13.7 min) deficiency. We found that RMP treatment did not decrease R-times for factor XII in all three tested degrees of deficiency. Overall, we found that RMPs significantly ($p<0.05$, $n=3$ each) reduced R-times for plasma deficient in factors VII, VIII, IX, XI but not XII. We are in the process of evaluating the mechanism by which RMP affects primary hemostasis. Our results indicate that RMPs limit hematoma expansion in sICH by enhancing secondary hemostasis through both intrinsic and extrinsic pathways.

Title: Fibroblasts promote blood brain barrier repair and stroke recovery in a TIMP2 dependent manner

Authors: L. XU[1], ***Y. YAO**[2,1];
[1]Univ. of Georgia, Athens, GA; [2]Univ. of South Florida, Tampa, FL

Abstract: Recent studies identified Col1a1$^+$ fibroblast-like cells in large blood vessels in the CNS. To investigate the function of these cells, we generated mutants with reduced fibroblast-like cells (Col1a1-DTR) by crossing the Col1a1-Cre line with DTR mice, which contain a loxP-flanked STOP sequence before diphtheria toxin receptor. The Col1a1-DTR mutants failed to show obvious defects after diphtheria toxin injection, indicating a minimal role of Col1a1$^+$ fibroblast-like cells under homeostatic conditions. In an intracerebral hemorrhage (ICH) model, however, these mutants showed exacerbated blood-brain barrier (BBB) damage and aggravated brain injury with reduced fibroblast marker (Collagen-1 and PDGFRα) expression, highlighting a beneficial role of Col1a1$^+$ fibroblast-like cells in ICH. Echoed with this finding, fibroblast-conditioned medium (FM) significantly enhanced TEER and reduced FITC-Dextran leakage in an in vitro ICH model. Interestingly, FM up-regulated the expression of tight junction proteins (occludin, ZO-1, and claudin-5), which seal gaps between endothelial cells; but did not affect the expression of caveolin-1, a key protein in transcytosis, indicating a paracellular rather than transcellular mechanism. To investigate how exactly fibroblasts exert the beneficial role in ICH, we performed mass spectrometry analysis, and identified TIMP2 (a protein with known BBB-protecting function) in FM. Using both pharmacological and genetic approaches, we further demonstrated that ablating TIMP2 abolished the neuroprotective effect of FM. Together, these results suggest that Col1a1$^+$ fibroblast-like cells secrete TIMP2, which inhibits tight junction protein loss and paracellular leakage, promoting BBB repair and ICH recovery. These findings suggest that fibroblasts and TIMP2 may be targeted in the therapy of stroke.

Title: Renovascular hypertension induces subcortical white matter degeneration accompanied by disruption of the blood-brain barrier

Authors: *X. JIN[1,3,4], Y. OH[1,3], Y. CUI[5], J. CHOI[1,3,2], B. KIM[1,3,2];
[1]Dept. of Brain Sci., [2]Dept. of Neurol., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [3]Dept. of Biomed. Sci., Ajou Univ. Grad. Hospital, Jilin Province, China, yanji, China

Abstract: Chronic impairment of cerebral blood flow due to vascular risk factors may underlie subcortical white matter stroke. To observe pathological changes in the white matter that are expected in human patients, it is important to have adequate animal models. However, very few studies have successfully established optimal animal models that exhibit unequivocal and consistent- ischemic subcortical white matter lesions. We have recently observed distinct white matter pathologies in rats with renovascular hypertension (RVHT) induced by two-kidney, two-clip (2K2C) procedure. In this model, we detected marked reduction in myelin basic protein and axonal degeneration exclusively within the corpus callosum and cingulum. A substantial extent of mature oligodendrocyte (OL) loss was evident accompanied by increased number of immature OLs, reactive astrogliosis, and microglial activation. We also investigated white matter hyperintensities on T2-weighted magnetic resonance imaging and decreased fractional anisotropy value on Diffusion Tensor Imaging. Furthermore, deposition of fibrinogen and IgG extravasation in the subcortical white matter indicated increased permeability of BBB during pathological progression of the white matter damage, which was approximately consistent with increased Hypoxyprobe-1 (pimonidazole) immunoreactivity. Expression of aquaporin 4 (AQ4), a water channel located in astrocytic end feet was markedly increased, while pericytes did not exhibit any sign of degeneration. In addition, we observed decreased endothelial tight junction proteins ZO-1 and increased matrix metallopeptidase 9 (MMP9) expression. MMP9 immunoreactivity was increased in a variety of cell types, including microglia, oligodendrocytes, astrocytes. Since MMP9 has been mechanistically linked to BBB compromise, we hypothesized that MMP9 inhibition would have a beneficial effect in ischemic white matter injury by reducing BBB disruption and improving behavioral outcomes. Therefore, we are now testing this hypothesis by an intracerebroventricular injection of MMP9 inhibitors (BB94) in rats with RVHT.

Title: Characterization of the Blood Brain Barrier Disruption in the Photothrombotic Stroke Model

Authors: *R. Z. WEBER[1,2], L. GRÖNNERT[1], G. MULDERS[1,3], M. A. MAURER[1], C. TACKENBERG[1], M. E. SCHWAB[1], R. RUST[1];

Abstract: Cerebrovascular physiology is maintained by the blood brain barrier (BBB), a dynamically regulated interface separating the central nervous system (CNS) from the systemic circulation. BBB disruption is an important pathophysiological feature in the course of ischemic stroke which significantly contributes to the development of severe brain injury. In this study, we investigated and characterized the extent of BBB leakage in the acute phase of the photothrombotic stroke model, a popular permanent occlusion model to study long term recovery following ischemia in rodents. We observed enhanced BBB permeability over a time course of 3 weeks in peri-infarct and core regions of the ischemic cortex. BBB permeability slightly increased in the contralesional cortex, hippocampus and the cerebellum at different time points, and in regions where lesion-induced degeneration of pathways is prominent. Severe damage of tight and adherens junctions and loss of pericytes was observed within the peri-infarct region. Overall, the resulting features observed in this model closely simulate human stroke. Thus, it represents a suitable model to study BBB damage and therapeutic approaches interfering with this process.

Title: Structural changes at synapse due to Blood Brain Barrier leakage by recurrent vascular insult leads to memory defecits

Authors: *L. DIWAKAR, R. HUSSAIN, S. MAURYA, V. RAVINDRANATH;
Ctr. for Brain Research, Indian Inst. of Sci., Bengaluru, India

Abstract: Structural changes at synapse due to Blood Brain Barrier leakage by recurrent vascular insult leads to memory deficits. Authors: Latha Diwakar[1], Rehab Hussain[1], Shashank Kumar Maurya[1] and Vijayalakshmi Ravindranath[1], 1Centre for Brain Research, Indian Institute of Science, Bengaluru, India.Dementia is a concern worldwide as its incidence increases in aged population impacting social and economic factors. Many clinical studies have provided significant insights indicating the potential link of vascular dysfunction to dementia, particularly mixed dementia. Vascular dysfunction occurring as cerebral small vessel infract develops later to white matter hyperintensity (WMH), which has been linked to the onset of pathogenesis of vascular dementia. To understand the molecular drivers underlying the cognitive decline and disease progression, we developed a mouse model of vascular dementia. We implanted cannula into the lateral ventricles of C57 mice to produce repeated microinfarcts in brain using endothelin-1 (ET-1), a vasoconstrictor peptide. Recurrent vascular insults were given by 3-doses of ET-1 over 9 weeks and resulted in deficits in associative and spatial learning after 9 weeks of ET-1 injection. Further, there was prominent blood brain barrier (BBB) disruption after recurrent vascular insults observed as IgG deposition near the vessels. There was loss of pericytes coverage indicating changes in the integrity of BBB. To understand the consequence of BBB breach on structural changes of neurons, we performed Golgi staining and carefully analyzed apical and basal dendrites in CA1 region of hippocampus. We found significant loss in apical and basal dendrites corroborating memory deficits. This mouse model will be useful for understanding pathogenic mechanisms underlying vascular dementia.

Title: Neuroendocrine modulation alters cellular protection in the neurogliovascular unit

Authors: *C. HAYES[1], B. ASHMORE[1], A. VIJAYASANKAR[1], J. POSEY[1], N. ASHPOLE[2]; [1]Univ. of Mississippi, Oxford, MS; [2]Dept. of BioMolecular Sci., Univ. of Mississippi, University, MS

Abstract: Insulin-like growth factor-1 (IGF-1) is a neuroendocrine modulator with autocrine and paracrine functions. IGF-I peaks during puberty but declines throughout adulthood and advanced ages, coincidentally when neurodegenerative diseases are more prevalent. Two of the most prominent contributors to disorders associated with neurological aging are oxidative stress and glutamate-induced excitotoxicity. Previous evidence highlights that exogenous IGF-1 treatments in animal models of dementia, cognitive impairment, and stroke acts directly on neurons protecting and preserving neuronal function. Interestingly, the IGF-1 receptor (IGF-1R) is expressed on all cells in the brain. Therefore, the systemic reductions in circulating IGF-1 likely contribute to the viability and function of the entire neuro-glio-vascular unit. We recently reported that reduced IGF-1 leads to impaired glutamate handling in astrocytes, indirectly impacting neurons. We hypothesized that IGFR deficiency within each component of the neuro-glio-vascular unit increases susceptibility to glutamate-induced toxicity and oxidative stress. To test this, we used pharmacologic and genetic interventions to reduce IGF-1R in specific cell types and assessed cellular toxicity, reactive oxygen species (ROS) production, and mitochondrial dysfunction in response to glutamate toxicity. The results confirmed that neurons are highly susceptible to excitotoxicity, unlike astrocytes or endothelial cells, and the reduction of IGFR does not lead to overt toxicity. Although astrocytes and endothelial cells are highly resistant to glutamate-induced toxicity when IGFR is reduced, their production of ROS in the hours following insult increases. Mitochondrial dysfunction in astrocytes is also apparent at maximal respiration in the previously described treatment. Reduction of IGF-1R signaling in astrocytes also increased neurotoxicity in co-cultures of neurons, astrocytes, and endothelial cells, suggesting maintenance of astrocytic IGF-1R signaling is critical for neuroprotection. Overall, our findings indicate that the excitotoxic response of each major cell type of the neuro-glio-vascular unit is regulated by IGF-1. Although astrocytes and endothelial cells are resistant to excitotoxic death, the alterations in oxidative stress signaling when IGF-1 is inhibited may inherently affect the survival and function of nearby neurons. Further studies are warranted to understand the selective reduction of IGF-1R in *in vivo* models of the specific neuro-glio-vascular cell types to delineate the mechanisms and processes by which IGF-1 signaling protects neuronal health and viability.

Title: Antidiabetic drugs reduce tobacco smoke-promoted cerebrovascular damage after traumatic brain injury

Authors: *F. SIVANDZADE[1], F. ALQAHTANI[2], L. CUCULLO[1];
[1]Oakland Univ. William Beaumont Sch. of Med., Oakland Univ., Rochester, MI; [2]Pharmacol. and Toxicology, King Saud Univ., Riyadh, Saudi Arabia

Abstract: Traumatic Brain Injury (TBI) is among the main reasons for cerebrovascular and neurological damage. Premorbid conditions such as tobacco smoking (TS) can exacerbate post-TBI brain damage and impact recovery as a result of TS content of reactive oxygen species (ROS) and oxidative stress (OS) stimuli promoting vascular endothelial impairments. Additionally, due to common pathogenic modulators of BBB impairment between chronic TS and hyperglycemia (HG), antidiabetic drugs like metformin (MF) and rosiglitazone (RSG) were shown to reduce BBB damage promoted by the chronic TS exposure. This study evaluated antidiabetic drugs' therapeutic feasibility and effectiveness to prevent/reduce TS-promoted cerebrovascular damage after TBI and/or improve post-TBI recovery through an in vivo study. For this purpose, male C57BL/6J mice, age range 6-8 weeks, were exposed to TS for four weeks. RSG and MF were administered daily via intraperitoneal (IP) injections of dose levels of 10 or 20 mg/kg (RSG) and 100 or 200 mg/kg (MF) with dose volumes of 20 mL/kg. After four weeks, test animals were subjected to TBI by head weight drop so that a metal weight (30 g) was inserted into a pre-positioned vertical guide, whereas the weight free fell for a distance of 80 cm before reaching the target. Body weights of the mice were frequently measured and general activity (through open field test) of the mice were analyzed before, 1 hr, 24 hr and three days after TBI. Finally, mice were sacrificed to collect blood and brains samples for subsequent biochemical and molecular analysis. Western blotting and quantitative RT-PCR analyses were applied on homogenized brain tissues to assess the expression of Nrf2 (critical antioxidant transcription factor), its downstream effectors (HO-1, NQO-1) and tight junction proteins including ZO-1, Occludin, and Claudin-5. Levels of inflammatory markers including NF-kB,

PECAM-1, VCAM-1, IL-6, IL-10, and TNF-α were also evaluated. The results revealed that MF and RSG can effectively decrease the harmful effect of TS on body weight and OS generated in response to TS. RSG and MF also upregulated NRF2 expression and its downstream effectors NQO-1 and HO-1, decreased TS-induced endothelial inflammation and loss of barrier integrity. RSG and MF also decreased the TS-aggravated post-traumatic behavior in mice undergoing TBI. In conclusion**,** through the underlying linking mechanism, antidiabetic drugs could be repurposed to reduce BBB damage and subsequent severity of TBI outcomes caused by TS dysregulation of the cellular antioxidant response system.

Title: Evaluation of acute neurological changes, mortality, body weight and immunofluorescence to NeuN and GFAP in rats with lateral traumatic brain injury induced by a novel hydropneumatic device

Authors: *F. V. VILLALPANDO VARGAS[1], L. G. MEDINA-CEJA[2], E. GONZÁLEZ HERRERA[1], T. D. HERNÁNDEZ SÁNCHEZ[1];
[1]Univ. of Guadalajara, Guadalajara, Mexico; [2]Univ. of Guadalajara, Zapopan, Jalisco, Mexico, Mexico

Abstract: Sequelae of traumatic brain injury (TBI) are showed in 20 to 50 million people, which represent a high economic and social cost. The experimental models of TBI are the best tool for studying the mechanisms underlying injuries, within which the lateral fluid percussion (LPF) is the most widely used. However, the main disadvantage of LFP is the complexity and limitation in biomechanical control. We evaluated lesions induced with a novel hydropneumatic device of TBI produced by MexBio Research Innovations, S.A. de C.V., which is controlled electronically and programmable. To this aim, male Wistar rats (190-250 g, n=24) divided in sham (n=12) and TBI (n=12) groups were used. Animals were anesthetized using isoflurane (58.2 ± 6.9 s) to realize a circular craniotomy (5.0 mm diameter; epicenter in -4.5 AP and 2.5 ML mm, in relation with bregma). To induce TBI, animals were placed in this device on a heating pad during and after injury; the pressure level was adjusted to 2.1 ± 0.05 atm (peak pressure) with duration of 25 ms. Occurrence of immediate mortality was observed in 8.33%, post-impact behavioral seizures were not presented. The acute neurological changes were evaluated such as duration of apnea

(was not presented), hind limb reflex (239.5 ± 148.9 s) and self-righting reflex (278.5 ±122s). After rats righted themselves, they were re-anesthetized to suture scalp incision. Body weight was daily monitoring, Sham group at 2 (n=12) and 7 days (n=6) presented a weight loss of 5.2% and of 4%, respectively; in TBI group at 2 (n=12) and 7 days (n=6) after TBI was 8.7% and 6%, respectively. After 2 or 7 days of injury (n=6 per group, per date), animals were intracardially perfused with paraformaldehyde 4%, cryopreserved with sucrose 15% followed by 30% and frozen with 2-methylbutane embedded in dry ice. Coronal sections of 20 um were obtained in cryostat and immunofluorescence (IF) was performed with NeuN and GFAP antibodies. Photos of CA1, CA3, dental gyrus (DG) and primary motor cortex in both hemispheres were obtained (objective 20x, two sections per rat). In TBI group, the NeuN IF showed neuronal loss in CA1 and DG of injured ipsilateral hemisphere compared to their own contralateral and with both hemispheres of sham group; The GFAP IF showed a reactive astrocyte response in TBI group of all regions analyzed of injured ipsilateral hemisphere compared to their own contralateral and both hemispheres of sham group. In conclusion, this novel hydropneumatic device induced mild TBI with the parameters used (peak and duration pressure). However, it is imperative to induce an insult with different parameters in order to identify which are the favorable conditions to induce different severities of TBI.

Title: Brain-derived Neurotrophic Factor-Expressing Engineered Mesenchymal Stem Cells Restore Traumatic Brain Injury-Induced Tissue and Behavioral Deficit

Authors: *H.-J. KIM[1], B. CHOI[2], D. HONG[2], S. SUH[2], S. LEE[1];
[1]SL BiGen, Inc., Incheon, Korea, Republic of; [2]Dept. of Physiol., Hallym University, Col. of Med., Chuncheon, Kang Won Do, Korea, Republic of

Abstract: Traumatic brain injury (TBI) can cause serious damage of all races and ages, and in fact, it is estimated that 40-50 million people are affected worldwide each year. TBI causes not only primary damage but also secondary damage. Secondary damage is associated with molecular cascades including cellular excitatory toxicity, disruption of blood-brain barrier (BBB), ischemia, programmed cell death, and inflammation that appear after primary nerve

damage. Most scientific approaches focus on protection, repair, or regeneration in regenerative medicine, and stem cells has been studied in many disease and injury models using from a variety of sources and application at pre-clinical and clinical level. Brain-derived neurotrophic factor (BDNF) is one of the neurotrophic factors that play an important role in the differentiation, maturation, and survival of nerve cells. Here we show well-established BDNF-expressing engineered human mesenchymal stem cell (BDNF-eMSC) is an effective approach to treat TBI through intracerebroventricular (ICV) transplantation. For this, controlled cortical injury (CCI)-damaged 2-months old male rats were assessed for molecular, motor, and neurocognitive pathologies. Transplantation of BDNF-eMSCs successfully effects on neuronal cell death, innate brain inflammatory cell activation, motor and cognitive behavioral functions via dose-dependent manner. Thus, TBI-induced molecular, motor, learning and memory pathologies, which improve the transplantation of BDNF-eMSCs and represents toward for control of damage of TBI.

Title: Biomarkers following repetitive mild head injury

Authors: M. STEVENS[1], K. FUETES[1], N. BENS[2], C. MURPHY[1], I. MOSLEY[1], S.-F. LU[1], P. KULKARNI[2], N. G. SIMON[1], M. BROWNSTEIN[3], *C. F. FERRIS[2];

Abstract: Head injury is among the leading causes of disability and death in adults under 35 and over 65. There are 2.5 million emergency room visits annually for these injuries, with the vast majority diagnosed as “mild” with no specific treatment intervention. The number of mild head injuries is likely greater because many are unreported. There is increasing recognition that repeated mild head injury can result in long-term cognitive deficits and increase the risk for dementia later in life. In this pilot study, we assessed the effect of one or three mild head strikes on two proteins in plasma that are candidate biomarkers for blood-brain barrier (BBB) disruption, neurofilament light (NfL) and glial fibrillary acidic protein (GFAP), and on two markers of neuroinflammation, Iba1 and AQP4, in prefrontal cortex and midbrain by immunohistochemistry. The studies were approved by the Lehigh University IACUC (biomarkers) and the Northeastern University IACUC (immunochemistry). Mild concussion was

generated in adult rats anesthetized with isoflurane using a momentum exchange device with a pneumatic pressure drive, 50 g compactor at 7.4 m/s impact velocities. We have used this model to characterize the neuroradiological effects of a single and multiple mild head impact injuries in rats. The impact piston was directed to the top of the skull, midline, in the approximate area of Bregma. Animals are awake and moving within 5-7 min post-impact. There was no evidence of structural brain damage or contusion in any of the impacted rats based on MRI. The NfL and GFAP assays were conducted on samples taken 2, 4, 24, and 48 hrs after impact. The single impact injury had no effect on either marker. In the 3-hit animals, no change was detected in GFAP, while NfL levels were sharply elevated at 2 (100-fold) and 4 (60-fold) hrs post-strike in males. In females, NfL was elevated at 2 (40-fold) and 4 (8-fold) hrs after impact and remained elevated vs baseline for 48 hrs. Immunohistochemistry conducted 3 weeks after multiple head impacts showed elevated expression of Iba1 and AQP4, indicating sustained inflammation as a consequence of repetitive mild head injury. These data, while preliminary, suggest that repetitive mild head injuries result in BBB disruption and neuroinflammation that persists for weeks. While there is additional work needed to refine the blood biomarker assay as several studies have shown that plasma GFAP represents a marker for BBB disruption, the data suggest an approach that can help characterize the risks associated with repetitive mild head injury.

Title: Tbi on a chip: linking physical impact to neurodegeneration by differentiating primary and secondary injury mechanisms

Authors: *E. ROGERS[1], T. BEAUCLAIR[1], A. THYEN[2], L. PRACHT[1], R. SHI[1];
[1]Purdue, West Lafayette, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The rapidly increasing prevalence of post-traumatic brain injury (TBI) long-term neurological sequelae is an alarming trend with profound societal consequences. While clinical observations have confirmed a link between the development of neurodegenerative diseases (ND) and TBI, the underlying mechanisms remain elusive. Further, these complications are exacerbated by the initial, subclinical nature of mild-TBI (the most common) which can delay diagnosis past the prime window for intervention, after irreparable damage has been firmly established. In response, we have engineered a highly novel, primary neuronal culture-model to reproduce real-world physical trauma scenarios with unprecedented levels of interrogatory capabilities for mechanistic investigations into post-TBI neurodegeneration. Specifically, we can impart rapid acceleration injuries in clinically relevant g-force ranges to neuronal networks grown on multielectrode arrays with a novel pendulum-injury device, recapitulating TBI on a chip. We have coupled this high precision primary injury device with the post-impact monitoring of acrolein levels, a highly reactive aldehyde, established biomarker of post-TBI oxidative stress and neurodegeneration, and a likely convergence point between TBI and ND, to delineate impact-induced changes brought upon by secondary injuries.
Using immunocytochemical methods, we noted significant, force-dependent increases in acrolein (acrolein-lysine adducts) at 24hrs post-impact, indicative of post-impact neuronal degeneration. These changes were amplified by the following manipulations: exposure to higher g-forces (30-250 g, peak); the rapid (4-6 sec interval) application of multiple impacts (1, 3, 5 and 10x); and exposure to 40 mM EtOH for a 10 min duration immediately following impact. Further, we demonstrate the enhancement of injury-recovery as a function of increasing time intervals between repeated hits. In addition, conditioned media from maximumly-impacted cultures can cause intracellular acrolein elevation when introduced to non-impact, control networks, indicating acrolein's role as a diffusive-factor in post-TBI secondary injuries.
This model provides a unique level of cellular and temporal resolution not attainable with animal models. Further, it can separate primary and secondary injuries, while mechanistically untangling and evaluating relevant comorbidities. Combined with our available *in vivo* models, we expect to gain insight into the mechanisms underpinning TBI (acute and chronic) and its link to ND, helping to guide our translational laboratory endeavors and improving clinical diagnoses and treatments.

Title: Axonal injury following mild traumatic brain injury is exacerbated by repetitive insult and is linked to the delayed loss of NeuN expression without concomitant neuronal death in the mouse

Authors: *Y. OGINO[1], T. BERNAS[1], J. GREER[2,3], J. T. POVLISHOCK[1];

Abstract: Traumatic brain injury (TBI) is a major health care problem worldwide. Mild TBI (mTBI) is the least severe type of TBI but it, even though, affects brain structure and function and can lead to persistent abnormalities. Repetitive mTBI exacerbates the acute phase response to injury but its long-term implications remain poorly understood. We aimed to elucidate the long-term implications of repetitive mTBI, particularly in the context of the chronic-phase burden of traumatic axonal injury (TAI), a major player in TBI-related morbidity, and its implications for retrograde neuronal perturbation or death. Murine neocortical tissue was investigated at acute (24-hours postinjury, 24hpi) and chronic time points (28-days postinjury, 28dpi) after singular or repetitive mTBI given by central fluid percussion injury (cFPI). Neurons immunofluorescently labeled with multiple markers, NeuroTrace and NeuN for detecting neurons, p-c-Jun for detecting axotomized neurons and DRAQ5 for detecting nuclei, were quantitatively assessed using automated 3D-image analysis. Single mTBI produced axotomy in 10% of neurons at 24hpi and the percentage increased after repetitive injury. The fraction of p-c-Jun+ neurons decreased at 28dpi but without neuronal loss (NeuroTrace), suggesting their reorganization and/or repair following TAI. In contrast, NeuN+ neurons decreased with repetitive injury at 24hpi while the corresponding fraction of NeuroTrace+ neurons decreased over 28dpi. This observed loss of NeuN expression was linked exclusively to non-axotomized neurons at 24hpi then extended to the axotomized at 28dpi, revealing a delayed response of the axotomized neurons. Collectively, we demonstrate an increased burden of TAI after repetitive mTBI, which is most striking in the acute phase response to the injury. Our finding of widespread axotomy in large fields of intact neurons rejects the premise that repetitive mTBI elicits progressive neuronal death, rather emphasizing the importance of axotomy-mediated change.

Title: Multiparametric Characterization of Physiology and Behavior in a Minipig Model of Pediatric Concussion

Authors: *A. H. NETZLEY[1], N. ARNOLD[2], K. A. MUNOZ[3], A. C. COLBATH[3], T. R. BUSH[2], A. MEODED[5], A. A. BADACHHAPE[5], G. PELLED[1,4];

Abstract: Children and adolescents who experience mild traumatic brain injury (mTBI), or concussion, often suffer from persistent cognitive and neurological deficits that can have a lasting negative impact on an individual's quality of life. Due to biomechanical considerations of the head impact, large animal models may accurately reproduce the unique consequences of pediatric concussion and provide a platform to identify biomarkers and test new therapies. We have developed a closed-head impact procedure capable of inducing concussion in juvenile (4 months old) Yucatan miniature pigs. We built a custom-engineered impact device with which we can generate closed-head injury with reproducible and controllable impact velocity, acceleration, and dwell time to deliver an impact that is clinically considered as a concussion. We conducted a comprehensive battery of tests designed to characterize post-injury behavioral and physiological function throughout maturation and development. We utilize traditional behavioral tests, such as open field and novel object recognition, as well as state of the art physiological assessment tools and wearable sensor technologies for gait analysis and activity tracking with the goal of evaluating multiple aspects of post-concussive impairment and recovery. Our preliminary results suggest that concussed pigs exhibit symptoms similar to those reported for post-concussive syndrome in humans. Specifically, we have found that pigs with concussion are less active throughout the day: Fitbit results show 50% fewer steps taken per day. We have also found that during a 10-minute open-field test the concussed pigs traveled twice the distance compared to control pigs. During a three-choice discrimination task, concussed pigs show waning interest in retrieving a food-reward, performing 33% slower over consecutive trials, whereas control pigs become 24% faster over trials. Additionally, in an executive function test where pigs had to remember location and retrieve treats, concussed pigs exhibit deficits of 57% in the month after injury. These data suggest that our injury model is capable of producing post-concussive symptoms in minipigs and can be used as a platform to identify new biomarkers to report on injury and to test new therapeutic strategies.

Title: Acute Changes in Spine Phenotype and Dendritic Properties in the Porcine Cortex Following Impact

Authors: *B. HOFFE[1], H. TOMSON[2], R. BANTON[3], T. PIEHLER[3], O. PETEL[2], M. R. HOLAHAN[1];

Abstract: Dendritic spines are responsible for relaying excitatory input and regulating signalling between neurons and their morphology can give insight into synaptic function. Excitotoxicity brought on by brain injury results in synaptic dysfunction, as intracellular Ca^{2+} increases. This increase in intracellular Ca^{2+} over-activates various cellular kinases and proteases responsible for microtubule stabilization. Previous work in our lab has shown that after an impact, there is an increase in tensile strain within the depths of the porcine cingulate sulcus. Moreover, there was a marked decrease of the microtubule stabilizing protein MAP2 specifically within the apex of the sulcus. In our current work, we explored whether changes in spine morphology were associated with out impact model. The Golgi-Cox staining method was used to visualize dendritic spine morphology. Following impact, coronal slabs were placed into Golgi-Cox solution for 2 weeks. Cortical pyramidal neurons within the sulcus apex and arm were reconstructed. Preliminary data revealed a shift towards mushroom-type spines, compared to thin and stubby-type spines within the sulci of the brain after impact. These findings suggest a shift towards an excitatory synapse shortly after impact. Along with our previous findings of changes in MAP2 properties, the shift towards an excitatory synapse could implicate activation of kinases and proteases responsible for regulating MAP2 dynamics and altering spine morphology.

Title: Two-photon imaging of intra- and extracellular chloride in a porcine model of post-traumatic epilepsy

Authors: *K. P. LILLIS[1], B. A. COSTINE-BARTELL[2], L. F. MARTINEZ-RAMIREZ[2], K. P. NORMOYLE[3], K. J. STALEY[4];
[1]Harvard Med. School, MGH, Charlestown, MA; [2]Neurosurg., [3]Neurology, Div. of Child Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [4]Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Post-traumatic epilepsy (PTE) results from up to 20% of civilian closed head injuries. There are currently no prophylactic treatments available to prevent post-traumatic epileptogenesis and PTE is frequently medically intractable. We hypothesize that injury-induced release of MMPs, alters the extracellular matrix, which alters chloride in the extracellular space and in nearby neurons, decreases GABA-mediated inhibition and increases network excitability in the injured tissue. In this study, we directly imaged chloride in the extracellular matrix or in neuronal cytoplasm following TBI in 4-6 month old Yucatan minipigs. Pigs were chosen because their gyrencephalic brains, containing gray and white matter, closely approximate human anatomy and deformational and inertial responses to external force. 30d prior to imaging, two burr holes were placed in the skull and corresponding durotomy was performed for each burr hole. Each hemisphere was then injected intraparenchymally with AAV encoding for either the genetically encoded chloride sensor SuperClomeleon (SClm, IC group) under control of the neuron-specific hSyn promoter or a control red fluorescent protein (EC group). The durotomy was then sealed with a transparent, flexible PDMS window. After 30d, the burr holes were exposed and EC pigs were injected bilaterally, through the PDMS membrane, with the extracellular chloride-sensitive dye ABP-dextran. The chloride-sensitive fluorophore was then imaged in both hemispheres using a custom-built large animal two-photon fluorescence lifetime microscope. One hemisphere was then injured using a cortical impactor. Both hemispheres were imaged again with two-photon microscopy. The animal then underwent an MRI, including diffusion weighted imaging (DWI). Finally, chloride was imaged again at a time point >4h post-injury. Four hours post-injury there was a mean decrease in ABP fluorescence lifetime of 25%, corresponding to an extracellular chloride increase of approximately 30mM. Similarly, the SClm YFP/CFP emission ratio decreased by 30%, corresponding to an increase in intracellular chloride. MRI DWI analysis is ongoing, but preliminary results show a mean 12% decrease in diffusivity in a subset of the lesion compared to the contralateral (un-injured) control. Together these preliminary findings are consistent with a model wherein TBI induces changes in the ECM that lead to secondary increases in both extracellular and intraneuronal chloride. If these findings are confirmed, this may point to a previously unknown mechanism of cerebral edema as well as pathological changes in GABAergic inhibition that contribute to post-traumatic epileptogenesis.
